Complete repair of TOF is performed using a median sternotomy and cardiopulmonary bypass with bicaval venous cannulation. By a transatrial approach, the RV outflow tract can be examined through the tricuspid valve. Muscle bundles obstructing the RV outflow tract are divided or resected. The VSD is closed with a patch. Pulmonary valvotomy is performed, when indicated, via a vertical incision in the main pulmonary artery. When the pulmonary valve annulus or infundibulum is severely hypoplastic, a transannular outflow tract patch may be necessary to relieve the obstruction. When an anomalous coronary artery crosses the infundibulum, a transannular incision may be contraindicated. In these cases, and in patients with pulmonary atresia, placement of a conduit (cryopreserved homograft or bioprosthetic heterograft) between the right ventricle (via a separate ventriculotomy) and main pulmonary artery will be necessary. Patients who undergo construction of a transannular patch develop pulmonary insufficiency as a consequence. This is surprisingly well tolerated in most infants, as long as the tricuspid valve is competent.

As these patients grow older, some will develop RV failure due to chronic pulmonary insufficiency, and pulmonary valve replacement may be necessary. Currently, pulmonary valve replacement is indicated for symptomatic patients or those at risk of life-threatening arrhythmias. For asymptomatic patients, it is generally agreed that pulmonary valve replacement should be undertaken before irreversible RV dysfunction occurs. cMRI has evolved as a valuable diagnostic tool for evaluating RV size, function, anatomic detail, and other hemodynamic parameters. An RV size “cutoff” is debated, but recent recommendations suggest considering valve replacement before RV end-diastolic volume index exceeds approximately 160 mL/m².

Catheter-based pulmonary valve replacement is an option for some patients depending on the RV outflow tract anatomy.

D. Prognosis and Complications

The early mortality following repair of TOF is 1%-5%. The results are worse for patients with TOF and pulmonary atresia. Long-term complications include recurrent obstruction of the RV outflow tract and development of RV dysfunction due to chronic pulmonary insufficiency. Actuarial survival at 20 years is 90% with excellent functional status.

► Transposition of Great Arteries

A. General Considerations

TGA is a congenital cardiac anomaly in which the aorta arises from the right ventricle and the pulmonary artery originates from the left ventricle (Figure 19–28). TGA is divided into *dextro*-looped (d-TGA) and *levo*-looped (l-TGA). The looping refers to the right or left looping of the primitive heart tube during fetal development, which determines whether the atria and ventricles are concordant (right atrium attaches to the right ventricle and left atrium attaches to the left ventricle) or discordant. l-TGA is associated with atrioventricular (AV) discordance (right atrium attaches to the left ventricle and left atrium attaches to the right ventricle) and is also termed congenitally corrected TGA. l-TGA is a rare variant of TGA and is beyond the scope of this chapter, which focuses on d-TGA. The defect can be subdivided into d-TGA with intact ventricular septum (IVS) (55%-60%) and d-TGA with VSD (40%-45%), one-third of which are hemodynamically insignificant. Pulmonic stenosis, causing significant left ventricular outflow tract obstruction, occurs rarely with an IVS and in approximately 10% of d-TGA/VSD.

▲ **Figure 19–28.** Typical transposition of the great arteries. The aorta arises from the morphologic right ventricle and is anterior and slightly to the right of the pulmonary artery, which originates from the morphologic left ventricle. Inset at bottom illustrates the independent systemic and pulmonary circulations, which may be connected by a patent ductus arteriosus or atrial septal defect. Inset at top illustrates a common relationship of the two great arteries in typical transposition.

B. Clinical Findings

d-TGA is a relatively common cardiac anomaly and is the most common form of congenital heart disease presenting as cyanosis in the first week of life. The malformation

accounts for approximately 10% of all congenital cardiovascular malformations in infants. The degree of cyanosis depends on the amount of mixing between the pulmonary and systemic circulations. In d-TGA, oxygenated pulmonary venous blood is returned to the lungs, and desaturated systemic blood is returned to the body. Because the two circulations exist in parallel, some mixing between them must occur to allow oxygenated blood to reach the systemic circulation and the desaturated blood to reach the lungs. Mixing may occur at a number of levels, most commonly at the atrial level through an ASD or a patent foramen ovale (PFO). Generally, two levels of mixing are necessary to maintain adequate systemic oxygen delivery with a VSD or PDA serving as an additional site for cardiac mixing. In d-TGA, there can be no fixed shunt in one direction without an equal amount of blood passing in the other direction; otherwise, one circulation would eventually empty into the other. Therefore, the amount of desaturated blood reaching the lungs (effective pulmonary blood flow) must equal the amount of saturated blood reaching the aorta (effective systemic blood flow). Clinical characteristics are dependent on the degree of mixing and the amount of pulmonary blood flow. These factors relate to the specific anatomic subtype of d-TGA. Neonates with d-TGA/IVS (or small VSD) have mixing limited to the atrial level and PDA. The ASD may be restrictive, and the PDA generally will close over the first days to week of life. As the degree of mixing decreases, the patient becomes increasingly cyanotic and will eventually suffer cardiovascular collapse. Fortunately, the majority of these neonates will manifest cyanosis early in life, which is recognized by a nurse or physician within the first hour in 56% and in the first day in 92%. In d-TGA with a large VSD, there is additional opportunity for mixing and increased pulmonary blood flow. The neonate with d-TGA/VSD may manifest only mild cyanosis, which may be initially overlooked. However, generally within 2-6 weeks, signs and symptoms of congestive heart failure will emerge. Tachypnea and tachycardia become prominent, while cyanosis may remain mild. Auscultatory findings are consistent with congestive heart failure with increased pulmonary blood flow, including a pansystolic murmur, third heart sound, mid-diastolic rumble, gallop, and narrowly split second heart sound with an increased pulmonary component. Neonates with d-TGA and significant pulmonary stenosis present with severe cyanosis at birth. Lesser degrees of pulmonary stenosis will result in varying levels of cyanosis.

In cases of d-TGA, the electrocardiogram is normal at birth, demonstrating the typical pattern of RV dominance. Although the classic chest radiographic appearance of an egg-shaped heart with a narrow superior mediastinum may be seen, this finding is often obscured by an enlarged thymic shadow. The abnormal ventriculoarterial connection is clearly seen on echocardiography, which demonstrates that the posterior great vessel arising from the left ventricle is a

pulmonary artery that bifurcates soon after its origin. The anterior great vessel is the aorta and arises from the RV. Associated lesions, including VSD, left ventricular outflow tract obstruction, and coarctation, may also be diagnosed. Although used less frequently for diagnosis, cardiac catheterization may be helpful to improve cardiac mixing by means of balloon atrial septostomy.

C. Treatment

The infant with d-TGA and severe cyanosis requires prompt diagnosis and treatment to improve mixing and increase the arterial oxygen saturation. The first intervention to improve mixing in a cyanotic newborn suspected of having TGA is to insure ductal patency by beginning an infusion of prostaglandin E₁. In the presence of a restrictive ASD, a balloon atrial septostomy, a technique developed by William Rashkind in 1966, is performed. The procedure involves inserting a balloon-tipped catheter across the foramen ovale into the left atrium. Inflation and forcible withdrawal of the catheter tears the septum primum and enlarges the ASD. Mixing generally increases immediately, with a substantial increase in arterial oxygen saturation. Without intervention, d-TGA is universally fatal. Untreated, 30% of neonates will die in the first week of life, 50% by the first month, 70% within 6 months, and 90% by 1 year. The definitive surgical treatment of patients with d-TGA has changed dramatically with the advent of the arterial switch operation (ASO). The ASO, first successfully performed by Jatene in 1975, has become the optimal surgical procedure for infants with this condition. Current techniques have reduced the operative mortality to 2%-4%. The operative technique involves transection of both great vessels and direct reanastomosis to reestablish ventriculoarterial concordance. Additionally, the coronary arteries are removed from the anterior aorta and relocated to the posterior great vessel (neo-aorta). The extensive experience gained with this procedure has confirmed that any variant of coronary artery anatomy can be successfully repaired, although certain unusual forms impose a higher risk. Because many patients with d-TGA have an IVS, left ventricular pressure falls early in life as pulmonary vascular resistance decreases. In this situation, it is essential that the arterial repair be performed within the first 2-3 weeks of life, while the left ventricle is still able to meet systemic workloads. In patients presenting later, the left ventricle can be retrained with a preliminary pulmonary artery band and aortopulmonary shunt followed by the definitive arterial repair. Although patients with large VSDs do not require early repair because of their decreased left ventricular pressure, experience has indicated that even in this subgroup, the operation is best performed within the first month of life, before secondary complications such as pulmonary hypertension, congestive heart failure, or infection develop.

Patients with fixed left ventricular outflow tract obstruction are not candidates for the arterial repair because

correction would result in systemic ventricular outflow tract obstruction. Most of these patients also have large VSDs. Palliation early in life with systemic-to-pulmonary artery shunting is an option, with definitive repair postponed until somatic growth results in cyanosis as the shunt is outgrown. At that time, the Rastelli procedure is performed, in which left ventricular blood is redirected through the VSD to the anterior aorta by placement of an intraventricular patch. The pulmonary artery is ligated, and right ventricle-to-distal pulmonary artery continuity is reestablished with a valve-bearing conduit. An increasing number of experienced centers currently recommend early complete repair in the neonatal period using a Rastelli procedure. Early repair eliminates the interim morbidity and mortality associated with a systemic-to-pulmonary artery shunt and chronic cyanosis.

D. Prognosis

Current hospital survival for the ASO is 96.6%-97.2%. Generally, dTGA/IVS has had a lower mortality than d-TGA/VSD or d-TGA/VSD/PS. Hospital mortality for d-TGA/IVS is 2.2%, compared to 4.3% for d-TGA/VSD. Long-term survivals at 5-10 years and 15-20 years are 92.2%-97.9% and 91.6%-96%, respectively. The most common cause for reintervention is supravulvar pulmonary stenosis, occurring in 19.7%-30.3%. A recent study of 40 patients undergoing a Rastelli operation over a 20-year period revealed a hospital mortality of 0%, with Kaplan-Meier survival of 93% at 5, 10, and 20 years. Freedom from conduit replacement was 86% at 5 years and 59% at 20 years.

vessel arises from the heart, overriding the ventricular septum, and gives rise to the systemic, coronary, and pulmonary circulations. The Collett and Edwards classification of truncus arteriosus focuses on the origin of the pulmonary arteries from the common arterial trunk, as follows:

Type I: Common arterial trunk gives rise to a main pulmonary artery and the aorta.

Type II: Right and left pulmonary arteries arise directly from and in close proximity to the posterior wall of the truncus.

Type III: Right and left pulmonary arteries arise from more widely separated orifices on the posterior truncal wall.

Type IV: Branch pulmonary arteries are absent. Pulmonary blood flow is derived from aortopulmonary collaterals.

Persistent truncus arteriosus is the result of failed development of the aortopulmonary septum and subpulmonary infundibulum (conal septum). Normal septation leads to the development of both pulmonary and systemic outflow tracts, division of the semilunar valves, and formation of the aorta and pulmonary arteries. Failure of septation results in a VSD (absence of the infundibular septum), a single semilunar valve, and a single arterial trunk. Most cases are associated with a VSD with the superior margin of the defect formed by the truncal valve. The truncal valve leaflets are generally dysmorphic and their motion may be restricted. Leaflet number is highly variable, with about 65% tricuspid, 22% quadricuspid, 9% bicuspid, and rarely unicuspid or pentacuspid. As a result of these abnormally developed valve leaflets, a moderate or greater degree of truncal insufficiency is present in 20%-26% of patients. The pulmonary arteries are usually of normal size and most often arise from the left posterolateral aspect of the truncal artery, often in close proximity to the truncal valve and ostium of the left coronary artery.

Other cardiac anomalies are common and include an ASD (9%-20%), an interrupted aortic arch (10%-20%), and coronary ostial abnormalities (37%-49%) with the left coronary artery frequently noted to have a high origin, not uncommonly near the takeoff of the pulmonary arteries. Extracardiac anomalies are reported in approximately 28% of patients with truncus arteriosus. Described abnormalities include skeletal, genitourinary, gastrointestinal, and DiGeorge syndrome (11%).

► Truncus Arteriosus

A. General Considerations

Truncus arteriosus is a rare anomaly that accounts for 0.4%-4% of all cases of congenital heart disease. A single arterial

B. Clinical Findings

The anatomy of truncus arteriosus results in obligatory mixing of systemic and pulmonary venous blood at the level of the VSD and truncal valve, which produces arterial saturations of 85%-90%. The systemic arterial saturation depends

on the volume of pulmonary blood flow, which in turn is determined by the pulmonary vascular resistance (PVR). As the resistance begins to fall, excessive pulmonary circulation ensues and leads to pulmonary congestion and signs and symptoms of congestive heart failure. This nonrestrictive left-to-right shunt may cause early development of irreversible pulmonary vascular obstructive disease.

The presence of truncal valve abnormalities poses further hemodynamic burdens. Truncal valve regurgitation leads to ventricular dilation and low diastolic coronary perfusion pressures that can result in myocardial ischemia. Truncal valve stenosis promotes ventricular hypertrophy, increases the myocardial oxygen demand, and limits coronary and systemic perfusion, especially with the large volume of runoff into the pulmonary vascular bed.

Neonates with truncus arteriosus present with signs of congestive heart failure and collapsing peripheral pulses. Chest radiography shows marked cardiomegaly, pulmonary plethora, often with minimal thymus shadow, and a right aortic arch. The electrocardiogram most often depicts biventricular hypertrophy. Echocardiography is the diagnostic procedure of choice and can demonstrate the truncal vessel, the structure and function of the truncal valve, associated lesions such as interrupted aortic arch, and often the pulmonary arterial anatomy. Cardiac catheterization is not per-

formed unless the anatomy is unclear, further information is needed about the status of the truncal valve, or the status of the pulmonary vasculature is unclear (ie, infants older than 3 months at diagnosis).

C. Treatment

The natural history of patients born with truncus arteriosus is early demise. Approximately 40% of infants are dead within 1 month, 70% by 3 months, and 90% by 1 year. Early death is caused by congestive heart failure. Survivors may do well for a period of time until the development of pulmonary vascular obstructive disease and Eisenmenger syndrome. The ultimate treatment of truncus arteriosus is surgical correction in the neonatal period. Medical treatment is palliative and directed toward controlling congestive heart failure with fluid restriction, diuretics, and afterload reduction. Complete repair entails separating the pulmonary arteries from the truncus, repairing the resulting defect in the aorta, closing the VSD, and restoring continuity of the RV outflow tract with an extracardiac conduit (Figure 19–29). Severe truncal valve regurgitation requires truncal valve repair or replacement. An associated interrupted aortic arch is repaired by constructing a primary end-to-end anastomosis of the distal ascending aorta with proximal augmentation if necessary.

▲ **Figure 19–29.** Type 1 truncus arteriosus. **A:** The main pulmonary artery arises from the truncus arteriosus downstream to the truncal valve. A ventricular septal defect is present. **B:** The main pulmonary artery is incised from the truncus. The ventricular septal defect is closed with a patch. A valved conduit is sutured to the anterior wall of the right ventricle and the distal pulmonary artery.

D. Prognosis

The results of truncus arteriosus repair have improved greatly during the last two decades. Before the importance of early operation to avoid irreversible pulmonary vascular disease was appreciated, patients underwent repair at most institutions at an average age of 2-5 years with high mortality rates. Current hospital mortality for the neonatal repair of truncus arteriosus ranges between 4.3% and 17%, with the majority of deaths occurring in complex truncus arteriosus or in truncus arteriosus with associated severe truncal valve regurgitation. All patients will ultimately require reoperation for replacement of the right ventricle to pulmonary artery conduit with only 30%-42% being free from reoperation at 10 years. Thirty-year survival is approximately 75%-83%.

▶ **Total Anomalous Pulmonary Venous Connection**

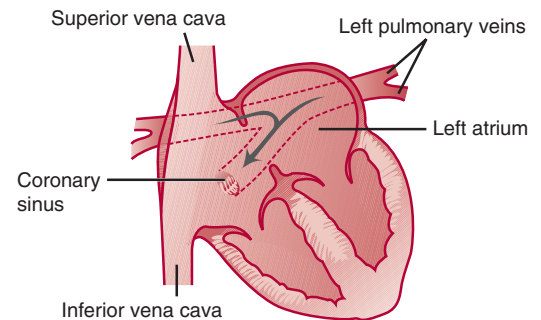

A. General Considerations

Total anomalous pulmonary venous connection (TAPVC) is a relatively uncommon congenital defect representing approximately 2% of all congenital heart anomalies. TAPVC encompasses a group of anomalies in which the pulmonary veins connect directly to the systemic venous circulation via persistent splanchnic connections. This abnormality results from failed transfer, in the normal developmental sequence, of pulmonary venous drainage from the splanchnic plexus to the left atrium. The most common classification system consists of four types: supracardiac (type 1), cardiac (type 2), infracardiac (type 3), and mixed (Figure 19-30). Partial anomalous pulmonary venous connection defines patients in whom some but not all venous drainage enters the left atrium, while the remaining veins connect to one or more persistent splanchnic veins.

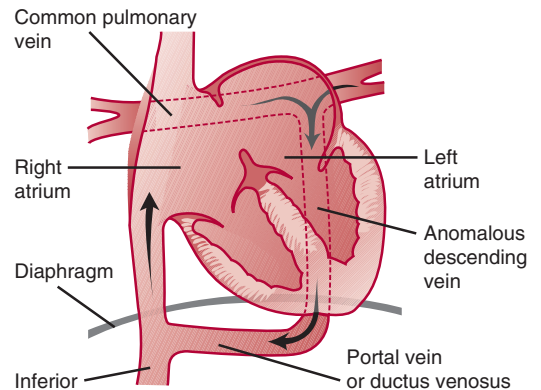

TAPVC can also be classified by the presence of obstruction. Impingement from surrounding structures or inadequate caliber of the draining pulmonary vein(s) can result in varying degrees of obstruction. Obstruction in supracardiac TAPVC can occur by compression of the ascending vertical

Type 1

Type 2

Type 3

▲ **Figure 19-30.** Common types of total anomalous pulmonary venous connection. Type 1: The pulmonary veins connect to a persistent left vertical vein, the innominate vein, and the right superior vena cava. Type 2: The pulmonary veins connect to the coronary sinus and the right atrium. Type 3: The pulmonary veins connect to an anomalous descending vein, a portal vein or persistent ductus venosus, and eventually enter the inferior vena cava.

vein between the left main stem bronchus and left pulmonary artery or by narrowing at the insertion of the vertical vein into the innominate vein. Obstruction is always present in the infracardiac type because the pulmonary venous blood must pass through the sinusoids of the liver. Obstruction is uncommon in the cardiac type.

Supracardiac occurs in approximately 45% of patients. The common pulmonary vein drains superiorly into the innominate vein, superior vena cava, or azygous vein via an ascending vertical vein. Cardiac TAPVC occurs in approximately 25% of patients. The pulmonary venous confluence drains into the coronary sinus or, on rare occasions, individual pulmonary veins will connect directly into the right atrium. Infracardiac TAPVC occurs in approximately 25% of patients. The pulmonary venous confluence drains into a descending vertical vein through the diaphragm into the portal vein or ductus venosus. Finally, a mixed type of TAPVC occurs in approximately 5% of patients and can involve any or all components of the previous three types.

B. Clinical Findings

TAPVC produces a mixing lesion because oxygenated blood from the pulmonary system drains back into the systemic venous circulation. The size of the ASD dictates the distribution of blood flow. Most patients with unobstructed TAPVC have few or no symptoms in infancy and present with signs and symptoms similar to an ASD. In the neonate with obstructed TAPVC, venous drainage from the pulmonary vasculature is impaired, leading to pulmonary venous hypertension and pulmonary edema. In severe cases, this increased pressure will lead to reflexive vasoconstriction of the pulmonary vasculature with pulmonary hypertension. Patients with obstruction present early in life with profound cyanosis from pulmonary edema.

The diagnosis can be made with echocardiographic identification of the anomalous connection of the pulmonary venous confluence to the systemic venous system. The ASD and other associated anomalies can be delineated. Cardiac catheterization is rarely necessary unless accurate measurement of PVR is needed.

The management of TAPVC is surgical repair. In patients with obstruction, medical management for stabilization may be employed but is often unsuccessful and should not delay surgical intervention.

C. Treatment

The principle of operative repair is to establish an unobstructed communication between the pulmonary venous confluence and the left atrium, interrupt the connections with the systemic venous circulation, and close the ASD. The specific repair is dependent on the type of anomalous connection.

1. **Supracardiac TAPVC** The repair of supracardiac TAPVC may be performed with moderate hypothermia (28-32°C) and bicaval cannulation or with a brief period of hypothermic (18°C) circulatory arrest. The optimal approach is to retract the ascending aorta to the left and the superior vena cava to the right to expose the pulmonary venous confluence. This approach provides excellent exposure without distortion of the heart or venous structures. The vertical vein can be identified and ligated (just prior to opening the confluence) outside the pericardium at the level of the innominate vein. A transverse incision is made in the pulmonary venous confluence, and a parallel incision is placed in the dome of the left atrium beginning at the base of the left atrial appendage. The common pulmonary vein is then anastomosed to the left atrium, taking care to construct an unrestrictive connection. A right atriotomy is made to close the ASD.
2. **Cardiac TAPVC** The repair of cardiac TAPVC can be performed with bicaval cannulation and moderate hypothermia with the use of a vent or a cardiotomy sucker to capture the pulmonary venous return. A right atriotomy is performed with identification of the ASD and the orifice of the coronary sinus. The roof of the coronary sinus is excised into the left atrium. A patch of pericardium or prosthetic material is then placed to close the enlarged ASD, effectively channeling the pulmonary venous and coronary sinus return into the left atrium. The conduction system travels in proximity to the coronary sinus, and care must be taken while suturing the patch in this area to avoid heart block.
3. **Infracardiac TAPVC** For infracardiac connections, a brief period of hypothermic circulatory arrest is often required. The heart is rotated superiorly. The descending vertical vein is identified by opening the posterior pericardium. The connection to the descending vertical vein is ligated at the level of the diaphragm. An incision is made along the length of the pulmonary venous confluence with a parallel incision on the posterior wall of the left atrium. The pulmonary venous confluence is then anastomosed to the left atrium, taking care not to narrow the connection. Tissue from the descending vertical vein can be used in the anastomosis. A right atriotomy is performed through which the ASD is closed.
4. **Recurrent pulmonary venous obstruction** The approach to recurrent pulmonary venous obstruction is dependent on the level of obstruction. Obstruction can develop at the anastomosis or within the individual pulmonary veins. The latter may initially present as an anastomotic constriction, as the true extent of obstruction is not always apparent at first. Isolated narrowing of the anastomosis between the common pulmonary

vein and left atrium often can be repaired with revision or patch augmentation of the anastomosis.

Obstruction of the individual pulmonary venous ostia is the greater challenge. Although the obstruction may initially appear to be limited to the ostium, progressive narrowing along the entire length of the vein into the hilum of the lung may occur with time. Repair of this lesion is technically challenging, and recurrent early obstruction is common. A new approach to recurrent pulmonary vein stenosis employs a “sutureless” technique utilizing in situ pericardium to create a neoatrium. The theory behind this repair is based on the concept that pulmonary venous obstruction results from inflammation induced locally by suture placement. Repair involves wide unroofing of the narrowed portion of each involved pulmonary vein from the left atrial anastomosis to the hilum. A wide flap of pericardium is then elevated with care taken to avoid disruption of posterior adhesions and injury to the phrenic nerve. This flap of pericardium is rotated over the unroofed pulmonary veins and sutured to the left atrial wall away from the venous ostia. A large neoatrium is then created into which pulmonary venous return can drain.

D. Prognosis

Early mortality in patients undergoing repair of TAPVC is associated with the initial degree of obstruction present. Early diagnosis and repair as well as optimal postoperative management, including aggressive treatment of pulmonary hypertension, have resulted in a dramatic reduction in operative risk. For patients surviving the perioperative period, the long-term survival and functional status are excellent.

Recurrent venous obstruction develops in 5%-17.5% of patients. Results following balloon angioplasty and/or stent insertion have been disappointing, and recurrent stenoses are the rule. Individual patch angioplasty of the ostia has also been utilized with poor long-term results. Lung transplantation has been considered in severe cases of extensive, bilateral disease. The mortality associated with reoperation for obstruction can be up to 59% when bilateral stenoses are present. The use of the sutureless technique for recurrent pulmonary vein obstruction has demonstrated improved survival and decreased recurrence.

► Tricuspid Atresia

A. General Considerations

Tricuspid atresia refers to single-ventricle hearts that lack a communication between the right atrium and right ventricle. The only outlet for the right atrium is the ASD. If present, aneurysmal tissue of the septum primum may prolapse into the left atrium. The left atrium is normal in morphology but is often dilated. A normal communication with a mitral valve between the left atrium and left ventricle is present. The right ventricle is diminutive in size without an inlet portion. It is connected to the left ventricle by a VSD surrounded completely by muscle. The anatomic subtypes of tricuspid atresia are based on the relationship of the great arteries. Type I defects (70%) have normally related great vessels, type II (30%) have transposed great arteries, and type III (rare) have congenitally corrected TGAs. These types are further subclassified by the degree of obstruction to pulmonary blood flow, which is present in 45%-75% of patients. Aortic valve (10%) and aortic arch (25%) obstruction may also be present. Patients with tricuspid atresia are at increased risk for Wolff–Parkinson–White syndrome due to congenital and surgically acquired pathways.

B. Clinical Findings

The clinical presentation depends on the relationship of the great vessels and degree of restriction at the level of the atrial and ventricular septum. Most infants present with some degree of cyanosis. Systemic output is usually unobstructed. Prostaglandins may be necessary to maintain ductal patency in infants with severe obstruction to pulmonary blood flow.

C. Treatment

The initial palliation for most patients is the placement of a modified Blalock-Taussig shunt to maintain adequate pulmonary blood flow. A more complex initial palliation with a Norwood procedure may be necessary in the case of transposed great vessels. The remainder of the palliation involves a hemi-Fontan and Fontan procedure (discussed in the section on Hypoplastic Left Heart Syndrome).

D. Prognosis

The overall survival for tricuspid atresia is similar to that reported for other single-ventricle lesions palliated with a

Fontan procedure. The survival is 83% at 1 year, 70% at 10 years, and 60% at 20 years.

► Hypoplastic Left Heart Syndrome

A. General Considerations

A variety of congenital cardiovascular malformations may result in a functional single-ventricle anatomy, most commonly tricuspid atresia, pulmonary atresia, unbalanced AVSD, and HLHS. The most common lesion is HLHS. Approximately 1000 infants with HLHS are born in the United States each year. It is the most common severe congenital heart defect, comprising 7%-9% of all anomalies diagnosed within the first year of life. All single-ventricle lesions share the common physiology of only a single ventricle capable of supporting cardiac output. HLHS refers to a constellation of congenital cardiac anomalies characterized by marked hypoplasia or absence of the left ventricle and severe hypoplasia of the ascending aorta. The systemic circulation is dependent on the right ventricle via a PDA, and there is obligatory mixing of pulmonary and systemic venous blood in the right atrium. There is associated aortic valve stenosis or atresia and mitral valve stenosis or atresia. The descending aorta is essentially a continuation of the ductus arteriosus, and the ascending aorta and aortic arch represents a diminutive branch of this vessel. Initial management includes a prostaglandin infusion to maintain ductal patency and correction of metabolic acidosis. The patient may require intubation and ventilator adjustment to reduce supplemental oxygen and maintain a P_{CO_2} of about 40 mm Hg to avoid excessive pulmonary flow.

B. Treatment

Surgical approaches to the treatment of this problem include cardiac transplantation and staged reconstruction. In the context of improving results for staged reconstruction, risks of immunosuppression, and limited donor availability, competing risk analysis favors staged repair, and most centers pursue this option as primary therapy for HLHS. Transplantation is generally reserved for very high-risk patients, such as those with depressed RV function, severe tricuspid regurgitation, or significant coronary sinusoids.

The first successful palliation of HLHS was reported by Norwood on a series of infants operated between 1979 and 1981. This procedure has been technically refined over the years, but three essential components remain: atrial septectomy, anastomosis of the proximal pulmonary artery to the aorta with homograft augmentation of the aortic arch, and aortopulmonary shunt. A “hybrid Norwood” procedure is an alternate form of stage I palliation. This procedure involves bilateral pulmonary artery bands and PDA stenting with or without concomittant balloon atrial septostomy. The ultimate goal of surgical palliation in patients with a univentricular heart is the total diversion of all vena caval blood directly into the pulmonary arteries. The Fontan procedure was first successfully performed in a patient with tricuspid atresia but has since evolved as an excellent way to establish physiologic repair for patients with more complex forms of univentricular heart. The superior vena caval blood returns directly via an end-to-side anastomosis with the pulmonary artery (bidirectional Glenn) or through a right atrial-pulmonary artery connection (hemi-Fontan) performed at 4-6 months of age. The inferior vena caval flow is directed to the pulmonary artery with an intra-atrial baffle (lateral tunnel technique) or an extracardiac conduit at 2-4 years of age. All oxygenated pulmonary venous flow empties into the ventricular chamber through the AV valves to be ejected to the systemic circulation, while superior and inferior vena caval blood flows directly to the lungs to acquire oxygen prior to returning to the heart. For the Fontan procedure to be performed with a low operative mortality and an acceptable functional result, certain criteria must be met. Normal pulmonary artery pressure (< 20 mm Hg) and PVR (< 2 Woods units·m²) are the most important prerequisites. Additionally, it is essential that ventricular function and AV valve function be normal. Although the Fontan procedure cannot be considered a truly corrective operation, it offers benefits that cannot be equaled by those of any of the other palliative procedures. The major advantages include restoration of normal systemic oxygen saturation and reduction of ventricular volume overload.

C. Prognosis

Universally fatal only three decades ago, tremendous strides have been made in improving the outcomes for patients with HLHS. Of the three stages, the highest-risk stage of the repair remains the Norwood operation. During the 1990s, the hospital survival for the Norwood procedure across the United States was approximately 40%. A recent Society of Thoracic Surgeons Congenital Heart Surgery Database study reported 81% hospital survival rate for more than 2000 Norwood operations performed in 2009. Currently, interstage (time between the Norwood and hemi-Fontan operation) mortality is about 12%. Reported survivals for the hemi-Fontan and Fontan procedures have also been excellent at 98% for both

operations. Overall, 75% of patients diagnosed with HLHS will survive through the Fontan procedure.

The current results for the Fontan procedure are excellent with hospital mortality ranging from 2% to 9%. The condition of survivors is generally good, and most attain a functional status of New York Heart Association class I or II. The long-term results have been reported with a 93% 5-year survival and a 91% 10-year survival. Although long-term results are encouraging, late complications may be seen. Continued surveillance for arrhythmias, congenital heart failure, protein-losing enteropathy, and hepatic dysfunction remains important.

ACYANOTIC HEART DEFECTS

1. Left-to-Right Shunting

► Atrial Septal Defect

A. General Considerations

Cardiac septation occurs between the third and sixth weeks of fetal development. The septum primum, which arises from the roof of the common atrium and descends inferiorly, initially divides the common atrium. The ostium primum is the opening below the inferior edge of the septum primum, which is obliterated as the septum primum fuses with the endocardial cushions. The ostium secundum forms in the midportion of the septum primum prior to closure of the ostium primum. The septum secundum also arises from the roof of the atrium and descends along the right side of the septum primum and covers the ostium secundum. This creates a flap valve whereby blood from the inferior vena cava may preferentially stream beneath the edge of the septum secundum and through the ostium secundum into the left atrium. After birth, the increase in left atrial pressure usually closes this pathway.

▲ **Figure 19–31.** Sinus venosus and ostium secundum defects in the atrial septum as viewed from the opened right atrium.

An ASD is a hole in the atrial septum (Figure 19–31). ASDs are the third-most common congenital heart defect, occurring in 1 out of 1000 live births and representing 10% of congenital heart defects. The most common ASD is the secundum defect, which occurs when the ostium secundum is too large for complete coverage by the septum secundum. Ostium secundum defects account for about 80% of ASDs. An ostium primum ASD, representing 10% of ASDs, occurs as a result of failure of fusion of the septum primum with the endocardial cushions (ostium primum defect is discussed later in the section on Atrioventricular Septal Defects [AVSD]). A third type of ASD is the sinus venosus defect, seen in about 10% of cases. Sinus venosus ASDs are caused by abnormal fusion of the venous pathways with the atrium and are characterized by defects high in the atrial septum near the orifice of the superior vena cava or, less commonly, low in the atrial septum near the inferior vena cava. Sinus venosus defects are frequently associated with partial anomalous pulmonary venous connection, usually with the right upper pulmonary vein draining into the superior vena cava near the cavoatrial junction. The rarest type of ASD is the unroofed coronary sinus septal defect. This occurs when there is loss of the common wall between the coronary sinus and the left atrium adjacent to the atrial septum. This unroofing of the coronary sinus leads to a communication between the right and left atria at the site of the coronary sinus.

Failure of postnatal fusion of the septum secundum to the septum primum results in a persistent slit-like communication known as a PFO. PFOs are extremely common in the general population, and autopsy studies have demonstrated a prevalence of 27%. PFOs are generally considered separate from other ASDs because of the absence of significant shunting, but they remain important clinically because of the occurrence of paradoxical embolization. A paradoxical embolus is usually a blood clot arising from a systemic vein, which would normally pass to the lungs, but in the presence of a septal defect may instead cross into the systemic circulation.

B. Clinical Findings

ASDs lead to increased pulmonary blood flow secondary to left-to-right shunting. Shunting at the atrial level is determined by the size of the defect and by the relative ventricular compliance (ie, blood preferentially fills the more compliant ventricle). At birth, both chambers are equally compliant, but as PVR falls, the right ventricle remodels and becomes more compliant. Shunting across the atrial septum causes a volume load on the right heart. A volume load is created by additional venous return to a chamber during diastole.

The volume overload from an ASD is usually well tolerated, and patients are frequently asymptomatic. Symptoms tend to develop when the ratio of pulmonary to systemic blood flow (Q_p/Q_s) exceeds two. The most common symptoms are fatigue, shortness of breath, exercise intolerance, and recurrent respiratory infections. Older patients with untreated ASDs tend to develop atrial dysrhythmias, and adults may develop congestive heart failure and RV dysfunction. Pulmonary vascular obstructive disease may develop rarely as a late complication of untreated ASD. Paradoxical embolization is also an important potential complication of ASD.

The classic physical findings in patients with ASDs include fixed splitting of the second heart sound and a systolic ejection murmur at the left upper sternal border due to increased flow across a normal pulmonary valve. A diastolic flow murmur across the tricuspid valve is occasionally audible. A prominent RV lift and increased intensity of the pulmonary component of the second heart sound may occur with pulmonary hypertension. Chest radiography shows cardiomegaly, with enlargement of the right atrium, right ventricle, and pulmonary artery. EKG frequently demonstrates right axis deviation and an incomplete right bundle branch block. When right bundle branch block occurs with a leftward or superior axis, the diagnosis of AVSD should be considered. Echocardiography confirms the diagnosis of ASD and defines the anatomy. Cardiac catheterization is important in selected cases to assess PVR in older patients, but it is used more frequently with therapeutic intent for device closure of ASDs.

C. Treatment

Because of the long-term complications associated with ASD, repair is recommended for all patients with symptomatic defects and in asymptomatic patients in whom the Q_p/Q_s is greater than 1.5. Repair is usually performed in children prior to school age. Closure of ASDs may be performed surgically or using a device deployed in the cardiac catheterization lab.

Surgical repair is usually recommended for large secundum defects and for most other types of ASDs. The heart is usually exposed by median sternotomy. Other surgical approaches have been proposed, including minimally invasive techniques, but there are technical drawbacks associated with each of the alternative approaches. In most cases, a limited midline incision with a partial lower sternal split provides adequate exposure and a cosmetically acceptable scar. The atrial septum is exposed through a right atriotomy. Small secundum defects or PFOs may sometimes be closed primarily by suturing the edge of the septum primum to the edge of the septum secundum. More commonly, larger defects are closed using a patch (polytetrafluoroethylene or autologous pericardium) and a running polypropylene suture. When anomalous pulmonary venous drainage is present, a baffle is created to redirect the flow across the ASD. In all cases, care is taken to deair the left atrium to avoid the complication of air embolization.

The first transcatheter device closure of an ASD was performed in 1976. A number of devices are currently available for percutaneous closure of a secundum ASD, and success rates for device deployment are greater than 90%. Device closure has the advantages of fewer complications and a shorter hospitalization. Device closure of small to moderate secundum ASDs and PFOs has now become the standard of care at most large centers.

Occasionally, adults will present with a newly diagnosed ASD. Many studies have confirmed that ASD closure in adults over the age of 40 increases survival and limits the development of heart failure. When the Q_p/Q_s is less than 1.5 and the ratio of pulmonary to systemic vascular resistance (R_p/R_s) is greater than 0.7, significant pulmonary vascular obstructive disease is usually present. A PVR in excess of 10-12 Woods units·m² represents a contraindication to ASD closure.

D. Prognosis

Operative mortality for ASD repair is close to 0%. Atrial arrhythmias (1.2%) and postpericardiotomy syndrome (4.7%) are the most common postoperative complications. The long-term survival for patients undergoing ASD repair in childhood is normal. The major long-term complication following surgical closure of ASD is the development of supraventricular arrhythmias, although the risk is lowered when the ASD is closed in childhood. The persistence of this

risk despite relief of right-sided volume overload is thought to be related to incomplete atrial remodeling or due to the presence of the atriotomy scar. Longer follow-up is required to determine whether device closure alters the risk of atrial dysrhythmias.

► Ventricular Septal Defect

A. General Considerations

Ventricular septation is a complex process that requires accurate development and alignment of a number of structures including the muscular interventricular septum, the AV septum (arising from the endocardial cushions), and the infundibular septum (which divides the outflow tracts of the right and left ventricles). The membranous septum is a fibrous portion of the ventricular septum, which is adjacent to the central fibrous body (where the mitral, tricuspid, and aortic valve annuli make contact).

VSDs are the most common congenital heart anomalies (with the exception of bicuspid aortic valve, which occurs in about 1.3% of the population). VSDs are present in about 4 of 1000 live births and represent about 40% of congenital heart defects. VSDs are classified based on their location in the ventricular septum (Figure 19–32). The most common defects are perimembranous (80%), which are located in the area of the membranous septum. Inlet defects (5%) are located beneath the septal leaflet of the tricuspid valve and are sometimes called atrioventricular (AV) canal-type defects. Defects located high in the ventricular septum are outlet defects (10%). Outlet VSDs are typically adjacent to both the pulmonary and aortic valves. Outlet defects are also known by several other names, including supracristal, infundibular, or doubly committed subarterial. Outlet defects are more common in the Asian population. Muscular (or trabecular) VSDs (5%) are completely bordered by muscle.

▲ **Figure 19–32.** Anatomic locations of various ventricular septal defects. The wall of the right ventricle has been excised to expose the ventricular septum.

Muscular VSDs are frequently multiple and may be associated with perimembranous or outlet defects. The size of VSDs varies. By definition, a VSD is nonrestrictive when its size (or the cumulative size of multiple defects) is greater than or equal to the size of the aortic annulus.

B. Clinical Findings

A VSD causes increased pulmonary blood flow due to left-to-right shunting primarily during systole. This creates a volume load on the left heart (the left atrium and ventricle receive the increased venous return during diastole). The right ventricle is not volume loaded (blood is ejected from the left ventricle through the VSD and directly into the pulmonary circulation), but it does experience a pressure load. The volume of shunt flow is determined by the size of the defect and by the ratio of R_p/R_s . After birth, the PVR is still high, and shunting across a VSD is sometimes minimal. Over the first several weeks of life, shunting tends to increase as the PVR normally falls. Therefore, a patient with a large VSD may be asymptomatic at birth but eventually develop severe congestive heart failure.

The natural history for patients with isolated VSDs is highly variable. Most VSDs are restrictive and tend to close

spontaneously during the first year of life. Large VSDs are nonrestrictive, resulting in RV and pulmonary pressures that are systemic or nearly systemic, and high pulmonary blood flow with Q_p/Q_s ratios greater than 2.5-3. Moderate VSDs are restrictive, with pulmonary pressures that are one-half systemic (or less) and Q_p/Q_s ratios of 1.5-2.5. Small VSDs are highly restrictive; RV pressures remain normal, and the Q_p/Q_s is less than 1.5. Patients with large VSDs tend to develop symptoms of congestive heart failure by 2 months of age. Untreated, excessive pulmonary blood flow leads to pulmonary vascular obstructive disease by the second year of life. Patients with smaller VSDs may remain asymptomatic. In patients with outlet VSDs, prolapse of the aortic valve may occur, producing aortic insufficiency.

Signs of heart failure in infants with large VSDs include tachypnea, hepatomegaly, poor feeding, and failure to thrive. On physical examination, there is a pansystolic murmur at the left sternal border. Usually, the murmur is louder with smaller defects. The precordium is active. The pulmonary component of the second heart sound is accentuated in the presence of pulmonary hypertension. Chest radiography shows increased pulmonary vascular markings and cardiomegaly. EKG is significant for RV hypertrophy.

Patients with small VSDs have little shunting and are usually asymptomatic, having only a pansystolic murmur. Patients with moderate VSDs manifest symptoms and signs proportional to the degree of shunting.

In patients who have developed significant pulmonary vascular obstructive disease, the volume of left-to-right shunting is decreased, and the murmur may disappear. Eisenmenger physiology results when the shunt flow reverses to right-to-left, creating cyanosis.

The diagnosis of VSD is confirmed by echocardiography, which accurately defines the anatomy and excludes the presence of associated defects. Cardiac catheterization is used selectively in older children and adults in whom elevated PVR is suspected. Pulmonary vascular resistance is calculated by the following formula:

$$PVR = (PA_{\text{mean}} - LA) / Q_p$$

where PA_{mean} is the mean pulmonary artery pressure and LA is the left atrial pressure. The units of resistance by this formulation (using pressures in millimeters of mercury and pulmonary flow in liters per minute) are Woods units (which can be expressed in dynes-sec/cm⁵ by multiplying by 80). PVR may be fixed or reactive, and at the time of cardiac catheterization, response to various pulmonary vasodilators may be assessed.

C. Treatment

The management of a patient with a VSD depends on the size of the defect, the type of the defect, the shunt volume, and the PVR. In general, patients with large defects who have

intractable congestive heart failure or failure to thrive should undergo early surgical repair. If the congestive symptoms can be moderated by medical therapy, then surgery may be deferred until 6 months of age. Patients with moderate VSDs may be safely followed. If closure has not occurred by school age, then surgical closure is indicated. Small VSDs with Q_p/Q_s of less than 1.5 do not require closure. There is a small long-term risk of endocarditis for these patients, but this can be minimized with the appropriate use of prophylactic antibiotics. Patients with outlet VSDs have a significant risk of developing aortic insufficiency due to leaflet prolapse, and, therefore, all of these patients should undergo surgical closure. Older children and adults must undergo catheterization to assess the pulmonary circulation. When there is a fixed PVR greater than 8-10 Woods units-m², then surgery is contraindicated.

Exposure of the ventricular septum is most often achieved by making a right atriotomy and retracting the leaflets of the tricuspid valve. This provides access to perimembranous, inlet, and most trabecular VSDs. Outlet VSDs are frequently best exposed via a pulmonary arteriotomy because the defect lies just beneath the valve. Muscular VSDs located near the ventricular apex can be very difficult to expose, and an apical ventriculotomy may be necessary. Once the defect is exposed, it is closed using a polytetrafluoroethylene patch and a running polypropylene suture, although some centers may prefer other patch material or interrupted suture technique. It is important to understand the anatomy of the conduction tissue when closing VSDs. The AV node is an atrial structure that lies at the apex of an anatomic triangle (known as the triangle of Koch) formed by the coronary sinus, the tendon of Todaro (a prominent band leading from the inferior vena cava and inserting in the atrial septum), and the septal attachment of the tricuspid valve. The node then gives rise to the bundle of His, which penetrates the AV junction beneath the membranous septum. The bundle of His then bifurcates into right and left bundle branches, which pass along either side of the muscular ventricular septum. In the presence of a perimembranous VSD, the bundle of His passes along the posterior and inferior rim of the defect, generally on the left ventricular side. In this critical area, sutures must be placed superficially on the RV side a few millimeters from the edge of the defect. The bundle of His tends to run along the posterior and inferior margin of inlet VSDs as well. The conduction tissue is usually remote from outlet and trabecular VSDs.

Pulmonary artery banding is a palliative maneuver used to protect the pulmonary circulation from excessive blood flow. Pulmonary artery banding is currently performed only in patients who are felt to be poor candidates for VSD closure because of either associated illness or anatomic complexity, such as multiple muscular VSDs ("Swiss cheese" septum). A band is placed around the main pulmonary artery and tightened to achieve a distal pulmonary artery pressure of about one-half systemic. The band is secured to the adventitia of

the pulmonary artery to prevent its migration. Distal migration may result in narrowing and poor growth of one or both branch pulmonary arteries, while proximal migration can cause deformity of the pulmonary valve. Later, when the patient is a candidate for VSD closure, the band must be removed. Repair of the main pulmonary artery at the band site is usually necessary and can typically be accomplished by scar resection and primary closure or patch repair.

Transcatheter devices allow closure of some VSDs in the cardiac catheterization lab. For specific VSDs, such as muscular, device closure may be preferable. Complications with device closure include complete heart block (3.8%), device embolization (0.01%), and aortic insufficiency (0.03%). For simple perimembranous VSDs, the risk of device closure is in excess of traditional surgical closure.

D. Prognosis

Surgical closure of a VSD is associated with a mortality of less than 1%. Potential complications include injury to the conduction tissue and injury to the tricuspid or aortic valves. Transient heart block may result from tissue swelling or injury from retraction, but permanent heart block occurs in less than 2% of cases. When heart block develops after surgery, patients are usually observed for a period of 7-10 days prior to permanent pacemaker implantation. Tricuspid insufficiency may be precipitated by annular distortion or chordal restriction by the VSD patch or sutures. The aortic valve may also be injured by inaccurate suturing (especially in perimembranous and outlet defects). A residual VSD is seen in about 5% of cases, and reoperation is indicated when significant shunting persists ($Q_p/Q_s > 1.5$) or the residual defect is larger than 2 mm in size. The Q_p/Q_s ratio can be calculated by measuring oxygen saturations and using the following formula derived from the Fick equation:

$$Q_p/Q_s = (A_o - SVC)/(PV - PA)$$

where A_o is the aortic (or systemic) saturation, SVC is the saturation in the superior vena cava, PV is the saturation in the pulmonary veins (which is usually estimated to be 95%-100%), and PA is the saturation in the pulmonary arteries. Intraoperative echocardiography is used routinely to identify residual defects, which can then be repaired before the patient leaves the operating room.

► Atrioventricular Septal Defect

A. General Considerations

AVSDs represent a group of congenital abnormalities bound by a variable deficiency of the atrioventricular septum immediately above and below the AV valves. Other terms commonly applied to an AVSD include AV canal defects, endocardial cushion defects, and atrioventricular communis. Complete AVSDs have a single common AV valve orifice resulting in a single five-leaflet valve overlying both the right and left ventricles. Incomplete AVSDs have two separate AV valve orifices (tricuspid and mitral) with the mitral valve invariably having a cleft in the anterior leaflet. While most incomplete AVSDs have no ventricular level shunting, the classification of AVSDs as complete and incomplete depends only on the valve anatomy, not on the presence or absence of a VSD. Incomplete defects without associated ventricular level shunting have also been termed ostium primum ASDs, while those with a VSD have been described as intermediate or transitional AVSDs. AVSDs represent approximately 4% of congenital cardiac anomalies and are frequently associated with other cardiac malformations. AVSDs comprise 30%-40% of the cardiac abnormalities seen in patients with Down syndrome.

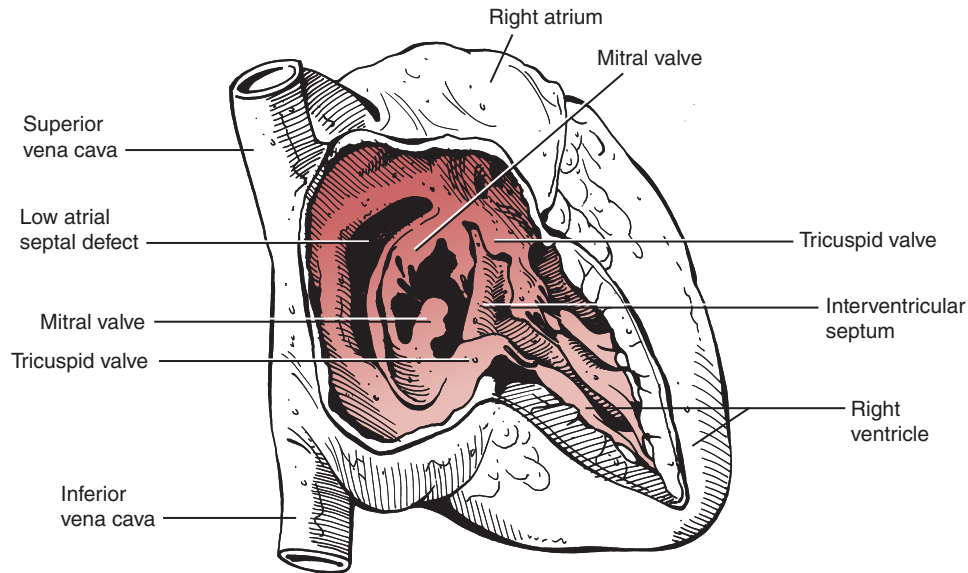

A complete AVSD is characterized by a common atrioventricular orifice, rather than separate mitral and tricuspid orifices, and a deficiency of endocardial cushion tissue, which results in an ASD and an inlet type of VSD (Figure 19–33). AVSDs were subclassified by Rastelli into the following three types according to the morphology of the anterior leaflet of the common AV valve:

Type A: The anterior bridging leaflet is divided and attached to the septum by multiple chordae.

Type B: The anterior bridging leaflet is attached to a papillary muscle in the right ventricle.

Type C: The anterior bridging leaflet is free-floating with no attachments except to the valve annulus.

When both left and right AV valves equally share the common AV valve orifice, the AVSD is termed balanced. Occasionally, the orifice may favor the right AV valve (right dominance) or the left AV valve (left dominance). In marked right dominance, the left AV valve and left ventricle are hypoplastic and frequently coexist with other left-sided abnormalities, including aortic stenosis, hypoplasia of the aorta, and coarctation. Conversely, marked left dominance results in a deficient right AV valve with associated hypoplasia of

▲ **Figure 19-33.** Complete atrioventricular canal. The most common type has a divided anterior bridging leaflet. Both the left and right valvular components are attached to the interventricular septum with long, nonfused chordae. The left and right components of the posterior bridging leaflet are not separated.

the right ventricle, pulmonary stenosis or atresia, and TOF. Patients with severe imbalance require staged single-ventricle reconstruction.

The conduction tissue is displaced in an ASVD and is at risk during the surgical repair. The AV node is located posteriorly and inferiorly of its normal position toward the coronary sinus in the triangle of Koch. This triangle is bounded by the coronary sinus, the posterior attachment of the inferior bridging leaflet, and the rim of the ASD. The bundle of His courses posteriorly and inferiorly to run along the leftward aspect of the crest of the VSD, giving off the left bundle branch and continuing as the right bundle branch.

Cardiac anomalies associated with AVSDs include: PDA (10%) and TOF (10%). Important abnormalities of the left AV valve include single papillary muscle (parachute mitral valve) (2%-6%) and double orifice mitral valve (8%-14%). A persistent left superior vena cava with or without an unroofed coronary sinus is encountered in 3% of patients with an AVSD. Double-outlet right ventricle (2%) significantly complicates or may even preclude complete surgical correction. As mentioned previously, left ventricular outflow tract obstruction from subaortic stenosis or redundant AV valve tissue occurs in 4%-7%.

B. Clinical Findings

The predominant hemodynamic features of an AVSD are the result of left-to-right shunting at the atrial and ventricular

levels. In the absence of ventricular level shunting, the hemodynamics and clinical presentation of a patient with an incomplete AVSD resemble that of a typical secundum ASD with right atrial and RV volume overload. Patients with a complete AVSD with both atrial-level and ventricular-level shunting generally present early in infancy with signs and symptoms of congestive heart failure. In addition, moderate or severe left AV valve regurgitation occurs in approximately 10% of patients with an AVSD worsening the clinical picture. On physical examination, the precordium is hyperactive, often with a prominent thrill. Auscultatory findings include a systolic murmur along the left sternal border, a high-pitched murmur at the apex from the left AV valve regurgitation, and a middiastolic flow murmur across the common A-V valve. In the presence of elevated PVR, there may be a split first heart sound. Significant cardiomegaly and pulmonary overcirculation are found on the CXR. Electrocardiogram reveals biventricular hypertrophy, atrial enlargement, prolonged PR interval, leftward axis, and counterclockwise frontal plane loop. Echocardiography is diagnostic, defining the atrial and ventricular level shunting, valvular anatomy, and any associated anomalies. Up to 90% of untreated individuals with a complete AVSD develop pulmonary vascular disease by 1 year of age due to the large left-to-right shunt, potentially exacerbated by the associated AV valve regurgitation. Patients with trisomy 21 tend to develop pulmonary vascular obstructive disease earlier than

chromosomally normal infants due to small airway disease, chronic hypoventilation, and elevated PCO_2 . Initial aggressive medical management is undertaken to relieve the symptoms of congestive heart failure. Elective surgical correction should be performed by age 3-6 months. Earlier intervention is indicated for failure of medical management.

Cardiac catheterization should be performed for patients over the age of 1 year, for patients with signs or symptoms of increased PVR, or in some cases to further evaluate other associated major cardiac anomalies. If the PVR is high, it is important to remeasure it while the child is breathing 100% oxygen with and without nitric oxide. If the pulmonary resistance falls, it implies that much of the elevated resistance is dynamic and can be managed in the perioperative period by ventilatory manipulation, supplemental oxygen, and nitric oxide. More recently, sildenafil has been shown to decrease elevation in PVR in children with congenital heart disease. Markedly elevated PVR (> 10 Woods units·m²) that does not respond to oxygen administration is generally considered a contraindication to repair.

C. Treatment

Operative treatment is almost always necessary as soon as symptoms are observed to prevent further clinical deterioration. Even in the absence of symptoms, operation is best performed before 6 months of age. Pulmonary artery banding, which permits delaying the repair until the child is larger, is no longer used today except in select complex or single-ventricle cases, extremely low birth weight or prematurity, and very poor clinical condition. This approach exposes the child to the risks of two operations, and the overall mortality exceeds that of primary repair in infancy. Patients with incomplete AVSDs usually require repair within the first few years of life.

Two techniques are widely employed for the repair of complete AVSDs: a 1-patch technique and a 2-patch technique. Incomplete AVSDs are repaired with the single-patch technique. Regardless of which approach is selected, the goals are to close the ASD and VSD and to separate the common AV valve into two nonstenotic, competent valves. The cleft in the anterior leaflet of the mitral valve is generally closed to lessen the risk of long-term mitral regurgitation. For the 2-patch technique, separate patches are used for the ASD and VSD. For the 1-patch technique, the superior and inferior bridging leaflets are divided along a line separating them into right and left components. A single patch is utilized to close both the ventricular and ASDs. The cut edges of the leaflets are then resuspended to the patch. For defects with a small VSD component, a modified single-patch technique may be employed. For this method, a single patch is sewn directly to the rim of the VSD, sandwiching the bridging leaflets between the patch and the crest of the VSD.

The short-term and long-term success of the operation is highly dependent on the status of the PVR and the surgeon's ability to maintain competence of the mitral valve. In developed countries, it is fortunately relatively uncommon for patients to present late in with an AVSD and refractory PVR elevations. Although earlier reports recommend that the cleft in the left AV valve should not be closed and the valve should be treated as a trileaflet structure, most authors now believe that closure of the cleft is an important mechanism in preventing postoperative left AV valve regurgitation. Significant AV valve regurgitation at the conclusion of surgery, severe dysplasia of the left AV valve, and failure to close the cleft of the left AV valve have been identified as important risk factors for reoperation. Significant postoperative left AV valve regurgitation is also a risk factor for operative and long-term mortality. The cleft should not be completely closed in the presence of a single papillary muscle to avoid causing the left AV valve stenosis. In the case of a double-orifice valve, the bridging tissue should not be divided to create a single opening in the valve.

D. Prognosis

Operative mortality is related largely to associated cardiac anomalies and left AV valve regurgitation. Mortality for repair of uncomplicated incomplete AVSDs is 0%-1.6%, while the addition of left AV valve regurgitation increases mortality to 4%-6%. For complete AVSDs, the mortality without left AV valve regurgitation is approximately 4%-5%, compared with 13% when significant degrees of regurgitation are present. The difference in operative mortality between patients with and without regurgitation underscores the importance of careful management of the left AV valve.

The majority of reoperations after repair of AVSD are due to left AV valve regurgitation or the development of sub-aortic stenosis. Significant postoperative AV valve regurgitation occurs in 6%-26% of patients, necessitating reoperation for valve repair or replacement in 3%-12%. The incidence of permanent complete heart block is approximately 1%-2%. Heart block encountered in the immediate postoperative period may be transient due to edema of or trauma to the AV node or bundle of His. However, right bundle branch block is common (22%).

► Patent Ductus Arteriosus

A. General Considerations

The ductus arteriosus is a normal fetal vascular structure that allows blood from the right ventricle to bypass the high-resistance pulmonary vascular bed and pass directly to the systemic circulation. The ductus communicates between the main pulmonary artery (or proximal left pulmonary artery) and the proximal descending thoracic aorta. Histologically, the media of the ductus contains a predominance of smooth muscle cells, while the media of the aorta and pulmonary artery contain well-developed elastic fibers. Vasocontrol of the ductus is mediated by two important mechanisms: oxygen tension and prostaglandin levels. During fetal development, low oxygen tension and high levels of circulating prostaglandin maintain ductal patency. During the final trimester, the ductus becomes less sensitive to prostaglandins and more sensitive to the effects of oxygen tension. Following birth, the rise in oxygen tension and fall in prostaglandins (which were previously supplied principally by the placenta) lead to ductal closure, which is usually complete by 12-24 hours. After closure, the ductus becomes a fibrous cord known as the ligamentum arteriosum. Failure of closure of the ductus leads to the condition called patent ductus arteriosus (PDA) which occurs in about 1 out of 1200 live births and accounts for 7% of congenital heart defect. The incidence is much higher in premature infants (> 20%). This elevated incidence is thought to be related to immaturity of the ductal wall resulting in impaired sensitivity to oxygen tension.

PDA may occur as an isolated defect, or it may occur in association with a number of other anomalies. Patency of the ductus arteriosus is desirable in a number of defects in which there is either inadequate pulmonary blood flow (such as pulmonary atresia) or inadequate systemic blood flow (as in severe coarctation of the aorta). The discovery that extrinsic delivery of prostaglandins can maintain ductal patency has played a critical role in improving the survival of these patients.

B. Clinical Findings

The physiologic manifestation of PDA is shunting of blood across the ductus. The shunt volume is determined by the size of the ductus and by the ratio of pulmonary to systemic vascular resistance. At birth, the PVR drops dramatically and

continues to decline over the first several weeks of life. As a result, shunting across a PDA is from left-to-right. Excessive pulmonary blood flow can lead to congestive heart failure. In extreme cases, hypotension and systemic malperfusion may result. Patients with a large PDA who survive infancy tend to develop pulmonary vascular obstructive disease. Eisenmenger physiology results when the PVR exceeds the systemic vascular resistance, producing a reversal of shunting across the ductus to right-to-left. This leads to cyanosis and, eventually, RV failure. Small PDAs may persist to adulthood without producing any symptoms or physiologic derangement. Endocarditis and endarteritis have been reported as long-term complications of PDA.

In patients with PDA, symptoms are proportional to the shunt volume and the presence of associated defects. Left-to-right shunting produces volume overload of the left heart. Infants with congestive heart failure demonstrate symptoms of tachypnea, tachycardia, and poor feeding. Older children may present with recurrent respiratory infections, fatigue, and failure to thrive. Physical findings include a widened pulse pressure and a continuous “machinery” murmur heard best along the left upper sternal border. Chest radiography shows increased pulmonary vascular markings and left heart enlargement. Left ventricular hypertrophy and left atrial enlargement may be evident on the electrocardiogram. Echocardiography is the diagnostic method of choice. Diagnostic cardiac catheterization is performed only in older patients with suspected pulmonary hypertension to evaluate for pulmonary vascular obstructive disease. More frequently, catheterization is utilized for transcatheter occlusion of the ductus.

C. Treatment

PDA closure is performed for all symptomatic patients. Closure is also recommended for asymptomatic patients due to the risk of heart failure, pulmonary hypertension, and endocarditis. Closure of the ductus may be accomplished by one of three approaches: pharmacologic, surgical, and endovascular. Indomethacin, which is a prostaglandin inhibitor, stimulates PDA closure in premature infants. It is rarely effective in full-term infants. The dosing regimen is 0.1-0.2 mg/kg intravenously at 12- or 24-hour intervals for a total of three doses. This is effective in about 80% of premature babies. Due to its side effects, indomethacin is contraindicated in patients with sepsis, renal insufficiency, intracranial hemorrhage, or bleeding disorders. Failure of indomethacin after two complete courses results in referral for surgical closure.

The surgical approach to PDA is through a left posterolateral thoracotomy via the third or fourth intercostal space. The pleura is incised over the proximal descending thoracic aorta, which allows medial retraction of the vagus nerve. The recurrent laryngeal nerve curves behind the ductus and should be protected throughout the procedure. Dissection is then performed to demonstrate the pertinent anatomy. In

many cases, the ductus is the largest vascular structure present, and it must not be confused with the aorta. Ductal tissue is extremely friable, so direct manipulation is minimized. In premature infants, the ductus is controlled with a single surgical clip; this procedure is commonly performed in the neonatal intensive care unit, thereby avoiding problems associated with patient transfer. In older patients, occlusion of the ductus is achieved with simple silk ligature or, preferably, by division between ligatures to minimize recurrence.

Recently, thoroscopic techniques have been developed to perform PDA ligation. This approach has the potential benefits of decreased pain and quicker recovery. Disadvantages include a substantial learning curve and increased operating time.

A number of endovascular devices have been developed for the purpose of transcatheter occlusion of the PDA. This approach is very successful in older infants, children, and adults with small and moderate sized PDAs and has become the treatment of choice at many centers. Surgical therapy is reserved for PDAs having a large diameter or very short length.

Rarely, an adult will present with a significant PDA. These patients must be carefully evaluated for the presence of pulmonary vascular obstructive disease prior to ductal closure. If the patient is not a candidate for device closure, surgical closure can be problematic. Calcification of the ductal wall is common in adults, which makes ligation hazardous. In some cases, cardiopulmonary bypass may be required with patch closure of the ductus from within the pulmonary artery.

D. Prognosis

Closure of the ductus by surgical or transcatheter techniques is achieved with a mortality that approaches zero. Potential complications include pneumothorax, recurrent laryngeal nerve injury, and chylothorax (from injury to the thoracic duct). Long-term survival should be normal following PDA ligation in most patients. Survival in premature infants depends primarily on the extent of prematurity with its attendant complications.

2. Right-Sided Anomalies

► Pulmonary Stenosis

A. General Considerations

Isolated pulmonary stenosis occurs in 5%-8% of all congenital cardiac anomalies. The pulmonary valve is usually trileaflet with fusion of the commissures. The valve can appear thickened and domed on echocardiography. Most patients have an associated PFO or a secundum ASD. Pulmonary stenosis may be valvular or subvalvular due to muscular narrowing of the infundibulum (Figure 19–34).

▲ **Figure 19–34.** Pulmonary stenosis. **A:** Valvular pulmonary stenosis. **B:** Infundibular pulmonary stenosis.

B. Clinical Findings

Young infants with severe pulmonary stenosis present with failure to thrive, right heart failure, and possibly hypoxic spells. Older children tend to have mild to moderate stenosis that is asymptomatic. They may, however, complain of shortness of breath with exertion or arrhythmias. The murmur of pulmonary stenosis tends to be prominent and therefore is not missed on routine examination. The presence of a systolic ejection murmur should prompt further workup, including an echocardiogram, which is diagnostic. Patients may be followed symptomatically with mild to moderate pulmonary stenosis. Surgical or catheter-based intervention should be considered for a gradient higher than 50 mm Hg, progressive ventricular hypertrophy, or new tricuspid regurgitation.

C. Treatment

Neonates presenting with profound cyanosis from severe pulmonary stenosis need to be placed on PGE₁ to maintain ductal patency. The ductus will maintain adequate pulmonary blood flow so that the patient can be stabilized. For isolated pulmonary stenosis, balloon valvuloplasty by an interventional cardiologist is highly successful and has replaced surgical intervention for the majority of patients. Asymptomatic infants with systemic RV pressures from pulmonary stenosis are also excellent candidates for balloon dilation. Surgical valvotomy or a transannular patch for pulmonary stenosis is reserved for patients who have failed balloon dilation, who have a severely hypoplastic valve annulus, or who have other associated anomalies including muscular infundibular narrowing. Older patients with progressive isolated pulmonary stenosis are excellent candidates for elective balloon dilation when they develop elevated RV pressures.

D. Prognosis

Early mortality for patients with critical pulmonary stenosis is 3%-10%. Restenosis occurs in 10%-25% of patients. Once the outflow obstruction is relieved, the RV hypertrophy and tricuspid insufficiency regress. Although overall survival is excellent for isolated pulmonary stenosis, over 50% of patients will require additional interventions, including repeat balloon dilation, pulmonary valve replacement, and ASD closure. Late atrial and ventricular arrhythmias occur in 38% of patients. Twenty-five year survival is 90%-96%.

► Ebstein's Anomaly

A. General Considerations

Ebstein's malformation was first described by Wilhelm Ebstein in 1866 as a constellation of clinical findings resulting from an abnormality of the tricuspid valve. It has become evident over time that the malformation is a disease of the entire right ventricle and the development of the tricuspid valve. It involves a spectrum of anatomical abnormalities of variable severity, which include apical displacement of the septal and mural leaflets of the tricuspid valve, which have failed to delaminate from the underlying myocardium; thinning or atrialization of the inlet component of the right ventricle, with variable dilation; and malformation of the anterosuperior leaflet, with anomalous attachments, redundancy, and fenestrations. Several other cardiac anomalies are often associated with the RV changes, such as atrial and VSDs, obstruction of the RV outlet, and Wolff-Parkinson-White syndrome. Ebstein's malformation can also afflict the left-sided systemic AV valve in the setting of congenitally corrected transposition.

B. Clinical Findings

The malformation is rare, accounting for no more than 1% of all congenital cardiac anomalies. Due to the significant anatomic variability in the abnormalities of the tricuspid valve and right ventricle, the age at presentation and severity of symptoms can also be highly variable. Patients who present in infancy have the poorest prognosis. There is a high rate of fetal death, hydrops, and pulmonary hypoplasia when the diagnosis is made during fetal life. Cyanosis is the most common presentation in infancy. These patients have severe tricuspid regurgitation with a poorly functioning right ventricle in the face of elevated pulmonary arterial resistance. The result is a state of low cardiac output dependent on right-to-left shunting across the fossa ovalis.

With less severe derangements of the tricuspid valve and preserved ventricular function, patients tend to present later in adolescence or early adulthood. Many patients are asymptomatic and present with a murmur noted on physical examination. In symptomatic patients, a common presentation involves the new onset of atrial arrhythmias or reentrant tachycardia. Exercise tolerance may be diminished, with cyanosis during extreme exertion if an ASD is present. Those patients with an intact atrial septum will often progress to congestive heart failure with increasing cardiomegaly.

Echocardiography is usually sufficient for accurate diagnosis and anatomic evaluation. The degree of displacement, tethering, and dysplasia of the valvar leaflets, as well as the amount of regurgitation, can be determined. Ventricular function and the extent of atrialization of the right ventricle can also be evaluated. Additional abnormalities, including the presence and direction of a shunt at the atrial level, can be assessed. Electrocardiographic findings include incomplete right bundle branch block, right axis deviation, ventricular preexcitation, and atrial arrhythmias. The CXR can vary from normal, in patients with mild anatomic abnormalities, to the classic “wall-to-wall” heart. Cardiac catheterization is rarely necessary.

C. Treatment

As noted previously, neonates often present with profound cyanosis and may require prostaglandins to maintain adequate flow of blood to the lungs during the early neonatal period when pulmonary resistance is high. It is important to distinguish functional from anatomic pulmonary atresia. In patients with functional atresia, it may be possible to wean them from the infusion of prostaglandins while maintaining adequate saturations of oxygen as pulmonary resistance falls. These patients can then be followed for development of further symptoms.

In neonates who cannot be weaned from prostaglandins due to unacceptable levels of hypoxemia, or in those with anatomic pulmonary atresia, it is necessary to construct a systemic-to-pulmonary shunt to maintain adequate pulmonary blood flow. For neonates who also develop significant symptoms of congestive heart failure while on prostaglandin, it is necessary to address the underlying valvar pathology. The options include closure of the tricuspid valve, with or without fenestration, along with construction of a modified Blalock-Taussig shunt, repair of the tricuspid valve if ventricular function is reasonable, or cardiac transplantation.

In the older patient with progressive symptoms, a variety of surgical options exist to address the malformed tricuspid valve. Most are based on techniques designed to mobilize the leading edge of the anterosuperior leaflet, aiming to create a competent monocusp valve with or without plication of the atrialized portion of the right ventricle. There is ongoing debate as to the necessity of obliterating the atrialized portion of the right ventricle. Historically, plication of this portion of the ventricle has been an integral part of most repairs, albeit that no clear physiologic benefit with regards to improved ventricular function has been demonstrated. In addition, the potential exists for injury to the right coronary artery as a result of the plication, which may adversely impact late outcomes and contribute to ventricular arrhythmias.

Replacement of the tricuspid valve is a final option. The late survival free from reoperation, however, has been equivalent to valvar repair. If replacement is required,

heterografts are preferred over mechanical valves due to risks of thrombosis. Other options using tissue valves include the insertion of pulmonary autografts, mitral valve homografts, and “top hat” mounted pulmonary or aortic homografts. When replacing the valve, the sutures should be brought around the coronary sinus, leaving it to drain into the right ventricle so as to minimize potential injury to the AV node. An open antiarrhythmia procedure is frequently performed concomitantly.

D. Prognosis

Ebstein’s malformation is a rare but challenging congenital cardiac defect. The high degree of anatomic variability makes it difficult to have a standardized approach to these children. The symptomatic neonate carries a very grave prognosis. The presence of associated cardiac and other congenital anomalies often make survival impossible. Surgical options are limited at this age and often still result in a poor outcome. Medical management, if possible, is the best, as surgical success improves with age. If surgery is required, conversion to functional tricuspid atresia often offers the best survival, as the ventricle in the severely symptomatic neonate functions poorly. Transplantation remains an option, but the availability of organs limits its utility.

Patients who are not symptomatic in the neonatal period will often remain free from symptoms well into adolescence. Electrophysiologic symptoms usually precede symptoms of congestive heart failure. Indications for repair at these ages include symptoms, cyanosis, and progressive cardiomegaly.

3. Left-Sided Anomalies

▶ Aortic Stenosis

A. General Considerations

Aortic stenosis is a form of left ventricular outflow tract obstruction that may occur at a valvar (70%), subvalvar (25%), or supra-valvar (5%) level. Aortic stenosis occurs in about 4% of patients with congenital heart disease. The severity of aortic stenosis may be graded as mild (peak

pressure gradient < 50 mm Hg), moderate (50 to 75 mm Hg), or severe (> 75 mm Hg).

Valvar aortic stenosis occurs secondary to maldevelopment of the aortic valve. Most commonly, a bicuspid valve is present, although tricuspid and unicuspid valves are also represented. In valvar aortic stenosis, the leaflets are thickened and frequently dysmorphic, and there is a variable degree of leaflet fusion along the commissures. The aortic annulus may be hypoplastic. In 20% of cases, valvar aortic stenosis is associated with other cardiac defects, most commonly coarctation of the aorta, PDA, VSD, or mitral stenosis. Men with valvar aortic stenosis outnumber women by a ratio of 4:1. There is a wide spectrum of clinical presentations of valvar aortic stenosis, but patients tend to present in one of two groups. Neonates and infants with severe aortic stenosis develop symptoms of rapidly progressive congestive heart failure, while older children generally have less severe obstruction and a more slowly progressive course.

Subvalvar aortic stenosis occurs below the level of the aortic valve and may be discrete (80%) or diffuse (20%). Discrete (or membranous) subaortic stenosis is rarely seen in infants and tends to progress over time. This lesion consists of a crescent or circumferential fibrous or fibromuscular membrane that protrudes into the left ventricular outflow tract. The pathogenesis of discrete subaortic stenosis is unknown, but it is thought to be an acquired lesion that develops secondary to a congenital abnormality of the left ventricular outflow tract in which abnormal flow patterns lead to endocardial injury with resultant fibrosis. Although the aortic valve leaflets are usually normal in discrete subaortic stenosis, the turbulent flow created by the obstruction can cause leaflet thickening and progressive aortic insufficiency. Diffuse subaortic stenosis is a more severe form of stenosis that creates a long, tunnel-like obstruction. Diffuse subaortic stenosis should be distinguished from hypertrophic cardiomyopathy. Both forms of subaortic stenosis are associated with a high risk of endocarditis.

Supravalvar aortic stenosis is characterized by thickening of the wall of the ascending aorta. The lesion may be localized (80%) to the region of the sinotubular ridge (at the level of the valve commissures), creating an hourglass deformity, or it may be more diffuse (20%), extending into the aortic arch and its branches. In both varieties, the aortic valve leaflets may be abnormal. The free edges of the aortic valve leaflets may adhere to the aortic wall in the region of intraluminal thickening, and this may lead to reduced coronary blood flow during diastole. Aortic wall thickening may also extend into the coronary ostia and further impair coronary blood flow. Associated cardiac lesions are common, particularly branch pulmonary artery stenoses. A genetic basis for supravalvar aortic stenosis has been established. About 50% of cases of supravalvar aortic stenosis are associated with Williams syndrome, in which a partial deletion of chromosome 7 (including the elastin gene) leads to the triad of

supravalvar stenosis, mental retardation, and a characteristic “elfin” facies. Isolated mutations in the elastin gene have also been shown to produce familial supravalvar aortic stenosis with an autosomal dominant pattern of transmission. There is a significant incidence of endocarditis in patients with supravalvar aortic stenosis. Sudden death is frequently reported and is probably related to coronary obstruction.

B. Clinical Findings

Severe aortic stenosis is usually well-tolerated during fetal development. Although left ventricular output and antegrade flow across the aortic valve are decreased, the right ventricle compensates with increased output, and systemic perfusion is maintained by flow across the ductus. After birth, there is increased venous return to the left heart, and this exacerbates the pressure load created by the stenotic aortic valve, leading to left ventricular dysfunction. As the ductus closes during postnatal life, systemic malperfusion may develop with resulting hypotension, acidosis, and oliguria. Coronary perfusion is also impaired due to the combination of systemic hypotension and elevated left ventricular end-diastolic pressures. Patients with critical aortic stenosis typically exhibit severe left ventricular dysfunction. These patients usually show signs of distress soon after birth. On examination, there is impaired distal perfusion with poor capillary refill and diminished, thready pulses. A systolic ejection murmur may be absent if the cardiac output is severely diminished. Differential cyanosis may be observed due to perfusion of the lower body with desaturated blood shunting through the ductus. The electrocardiogram shows left ventricular hypertrophy, and the CXR displays cardiomegaly and pulmonary congestion. Echocardiography establishes the diagnosis.

In contrast to infants with critical aortic stenosis, older children with valvar aortic stenosis usually present with less severe stenosis (mild or moderate), and most are asymptomatic. Symptoms of angina, syncope, and congestive heart failure are not commonly reported. Congenital valvar aortic stenosis is a progressive lesion, however, and survival is dependent on the severity of stenosis and its rate of progression. Sudden cardiac death is the most common cause of mortality. Endocarditis occurs in less than 1% of patients. The diagnosis of valvar aortic stenosis in older children can frequently be made on physical examination. There is a classic systolic crescendo-decrescendo murmur at the upper sternal border, which radiates to the neck. An ejection click is often present. A visible apical impulse is suggestive of significant left ventricular hypertrophy. In severe cases, the pulse may be weak and delayed (pulsus tardus et parvus). The electrocardiogram shows left ventricular hypertrophy. The CXR is usually normal. Echocardiography accurately defines the level of stenosis and its severity. Using Doppler techniques, the pressure gradient across the stenotic valve

may be estimated using a simplified form of the Bernoulli equation $P = 4V^2$, where P is the pressure gradient and V is the peak flow velocity. Cardiac catheterization is generally reserved for therapeutic intervention.

The clinical findings in subvalvar aortic stenosis are similar to those for valvar stenosis. The signs and symptoms of supra-valvar aortic stenosis are similar to those in other forms of left ventricular outflow tract obstruction. The diagnosis is made by echocardiography, but cardiac catheterization or cardiac MRI is essential to define the aortic, coronary, and pulmonary arterial anatomy prior to surgical intervention.

C. Treatment

The neonate or infant with critical aortic stenosis represents a true emergency. Endotracheal intubation and inotropic support is routine. Ductal patency is maintained with prostaglandins, and acidosis is corrected. All patients with critical aortic stenosis require some form of urgent intervention. The approach is determined by the valve morphology and by the presence of associated defects. In its most extreme form, critical aortic stenosis may be associated with underdeveloped left-sided cardiac chambers and therefore may represent a form of HLHS. In these cases, single-ventricle palliation must be undertaken. For patients with adequate left-sided chambers, relief of aortic stenosis may be achieved by one of the following three approaches: percutaneous balloon valvuloplasty, surgical valvotomy, or aortic valve replacement. Balloon valvuloplasty is generally considered the procedure of choice when the aortic valve annulus is adequate and there are no associated cardiac defects. Alternatively, surgical valvotomy may be accomplished by closed or open techniques. The closed approach is performed using cardiopulmonary bypass without aortic cross-clamping. Dilators of increasing size are passed through a ventriculotomy in the left ventricular apex and advanced across the aortic valve. Some centers prefer open surgical valvotomy, which allows a precise valvotomy under direct vision, although aortic cross-clamping with cardioplegia is necessary. In all cases, the goal of therapy is to relieve stenosis without creating excessive aortic insufficiency. Dramatic clinical improvement is expected following balloon or surgical valve valvotomy, and early survivals of greater than 80% have been reported. The incidence of aortic insufficiency is slightly higher following balloon valvotomy. In most cases, however, stenosis will recur and repeat valvotomy or aortic valve replacement will eventually be required. Aortic valve replacement is problematic in the neonate due to small patient size. In these cases, many consider the best valve replacement to be a pulmonary autograft (Ross procedure) with enlargement of the aortic annulus (Konno aortoventriculoplasty). The Ross–Konno procedure has been used successfully for neonates with critical aortic stenosis in whom the aortic annulus is hypoplastic and for

selected patients in whom valvuloplasty was unsuccessful. Survival following the Ross–Konno procedure in infants has been shown to be excellent. Growth of the pulmonary autograft has been documented, thereby making it an ideal valve replacement for children. Unfortunately, as part of the Ross procedure, the pulmonary valve must be replaced using a cryopreserved homograft, which does not grow, and homograft replacement must be anticipated at intervals as the patient grows.

All patients with severe valvar aortic stenosis should undergo intervention, as should all symptomatic patients with moderate stenosis. Asymptomatic patients with mild or moderate stenosis are generally observed. As described for critical aortic stenosis, the techniques used to relieve aortic stenosis in older patients include percutaneous balloon valvuloplasty, surgical valvotomy, and valve replacement. Balloon valvuloplasty is usually performed as the primary intervention and is associated with a success rate of nearly 90% and a mortality of less than 1%. Open surgical valvotomy is an alternative approach with similar results. For valves that are severely dysplastic, develop restenosis after intervention, or become insufficient as a result of prior intervention, valve replacement may be necessary. For older children, there are more options for valve replacement. The choices include mechanical prostheses, bioprosthetic valves, and tissue substitutes, such as porcine xenografts, cryopreserved human allografts, and pulmonary autografts (Ross procedure). The mechanical valves are the most durable but require chronic anticoagulation. The bioprosthetic and tissue valves do not require long-term anticoagulation but tend to deteriorate over time (with the exception of the pulmonary autograft). The pulmonary autograft has the potential advantage of growth but the homograft used to replace the pulmonary valve will require replacement. Selection of the appropriate replacement valve is a complex decision requiring input from all involved parties.

Intervention for discrete subvalvar stenosis is usually undertaken when the gradient exceeds 30–50 mm Hg or when aortic insufficiency is present. In these patients, resection of the membrane is readily performed by a transaortic approach. In order to reduce the incidence of restenosis, many centers advocate concurrent performance of a septal myectomy to alter the geometry of the left ventricular outflow tract.

When diffuse subaortic stenosis is associated with hypoplasia of the aortic annulus, repair is best achieved with a Konno aortoventriculoplasty, whereby an incision is carried across the aortic annulus and subjacent ventricular septum, the opening patched, and an aortic valve implanted. Patients with an adequate aortic annulus may undergo a septoplasty (modified Konno), in which the septal incision is confined to the immediate subvalvar area and a patch is used to widen the left ventricular outflow tract without replacing the aortic valve.

Operative intervention is indicated for patients with supravalvar aortic stenosis in whom the gradient exceeds 50 mm Hg. A number of operations have been proposed for the treatment of localized supravalvar stenosis. The classical repair involves a longitudinal incision across the obstruction in the ascending aorta, which is extended into the noncoronary sinus. The thickened, hypertrophic ridge is resected by endarterectomy, and the aortotomy is augmented with an elliptical patch. A variation of this repair involves creation of an inverted-Y aortotomy with one limb of the Y extended into the noncoronary sinus and the other into the right coronary sinus. A Y-shaped patch is then used to augment the aortotomy. Finally, the Brom repair is performed by transection of the ascending aorta beyond the supravalvar ridge. Separate incisions are then made through the supravalvar ridge into each sinus of Valsalva. Triangular patches are placed to augment each of these incisions, thereby relieving the supravalvar obstruction. Reconnection of the aortic root to the ascending aorta completes the repair. The repair of the diffuse type of supravalvar stenosis is performed under circulatory arrest with extensive patching of the ascending aorta, transverse arch, and involved arch arteries. Branch pulmonary stenoses are best managed using transcatheter techniques.

D. Prognosis

Operative mortality approaches zero for resection of discrete subaortic stenosis. The recurrence rate of discrete stenosis following membrane resection and myomectomy has been reported to be as low as 4%. Despite the technical complexity of repair of diffuse subaortic stenosis, excellent results have been reported with high survival and freedom from reoperation. The results of surgery for localized supravalvar aortic stenosis are generally good with low operative mortality and excellent long-term survival. The diffuse form is more difficult to treat, and recurrence is more likely. Overall results are much worse when severe bilateral pulmonary artery stenoses are present. The mortality for aortic valve replacement regardless of valve choice is 2%-5%. The need for reoperation is dependent on valve choice and patient size. Early and late ventricular arrhythmias may occur commonly in patients with significant left ventricular hypertrophy.

► Aortic Coarctation

A. General Considerations

Coarctation of the aorta is a narrowing of the proximal descending thoracic aorta distal to the origin of the left subclavian artery, near the insertion of the ductus arteriosus (or ligamentum arteriosum). The severity of luminal narrowing and the length of the aorta affected are variable. Coarctation is thought to occur as a result of ectopic tissue from the ductus arteriosus that migrates into the wall of the adjacent aorta. After birth, as the ductus closes, the ectopic tissue in the aorta also constricts. Frequently, a posterior shelf of tissue is present at the point of most severe obstruction. The aortic obstruction caused by coarctation creates a pressure load on the left ventricle.

The incidence of coarctation is about 0.5 per 1000 live births, and its prevalence is about 7% of congenital heart defects. Coarctation is commonly associated with other heart defects, including bicuspid aortic valve (in more than 50% of cases), PDA, and VSD. Other left-sided obstructive lesions may also be present, such as aortic arch hypoplasia, aortic stenosis, mitral stenosis, and left ventricular hypoplasia. Coarctation is also recognized to occur in association with Turner syndrome.

B. Clinical Findings

Patients with severe coarctation present in the newborn period. Aortic obstruction is so significant that perfusion of the lower body is dependent upon flow from the ductus arteriosus. Spontaneous ductal closure typically worsens the aortic obstruction and may lead to malperfusion of tissues distal to the coarctation. The pressure load on the left ventricle may precipitate congestive heart failure. Patients may develop shock with severe acidosis, oliguria, and diminished distal pulses. Infants with severe coarctation will generally not survive without intervention.

Older children with coarctation are usually asymptomatic. The diagnosis is commonly made on the basis of hypertension in the upper extremities with decreased pulses in the lower extremities. Noninvasive blood pressure measurements in all four extremities help to quantify the severity of aortic obstruction. Older patients tend to develop extensive collateral arteries that bypass the obstruction. Life expectancy for these patients is 34 years without operation typically due to the development of heart failure. Other long-term complications of coarctation include aortic dissection (21%), endocarditis (18%) (frequently involving a

bicuspid aortic valve), intracranial hemorrhage (12%) (from Berry aneurysms, which occur more commonly in patients with coarctation), endarteritis (in the poststenotic area of the aorta at the site of the jet of turbulent flow), and aortic aneurysm.

The diagnosis of coarctation can usually be made clinically. The infant with significant coarctation is frequently asymptomatic at birth but following closure of the ductus develops signs of heart failure such as irritability, tachypnea, and poor feeding. Lower extremity pulses are absent, and upper extremity pulses may be weak. Chest radiography shows cardiomegaly and pulmonary venous congestion. There is a left ventricular strain pattern on the electrocardiogram. Echocardiography is usually diagnostic, demonstrating narrowing of the aorta at the coarctation site with a loss of pulsatility in the descending aorta.

In older children and adults with coarctation, a pressure gradient between the arms and legs usually can be demonstrated by measuring cuff pressures in all four extremities. On chest radiography, rib notching may be evident, secondary to erosion of the inferior rib borders from the development of large intercostal collateral vessels. Echocardiography usually confirms the diagnosis. Anatomic details may also be clarified with CTA and cMRI. Cardiac catheterization is usually not necessary.

C. Treatment

Generally, all patients with coarctation should undergo surgical repair if the gradient is greater than 20 mm Hg. For neonates, the acute medical management includes initiation of PGE₁ for the purpose of reopening the ductus; this maneuver partially relieves the aortic obstruction and augments perfusion of the lower body due to improved antegrade flow across the arch as well as right-to-left flow across the ductus. Prostaglandins are usually effective for reopening the ductus when initiated within 3-7 days of life but are less successful thereafter.

Surgical repair of coarctation is usually performed through a left posterolateral thoracotomy via the third or fourth intercostal space. The descending thoracic aorta, ductus (or ligamentum), transverse aortic arch, and brachiocephalic vessels are mobilized. Care is taken to preserve the vagus nerve and its recurrent laryngeal branch.

The coarctation is usually evident externally by narrowing or posterior indentation; however, the degree of internal narrowing is usually much more severe. A dose of heparin (100 units/kg) may be given intravenously for patients younger than 2 years. Proximal and distal control of the aorta is achieved using clamps. Usually, the proximal clamp is positioned on the transverse arch between the innominate and left carotid vessels with concomitant occlusion of the left carotid and left subclavian. In infants and children, the preferred surgical approach to coarctation is resection

with extended end-to-end repair. A generous resection of the coarctation segment is performed. The proximal aorta is then spatulated along the lesser curvature and the distal aorta along the greater curvature. An extended end-to-end anastomosis is then performed.

In older children and adults, it may not be possible to perform a resection with primary repair without creating excessive tension on the anastomosis, which may lead to hemorrhage or scarring with recurrent coarctation. An alternative strategy is necessary in these cases. Patch aortoplasty may be performed in children in whom further growth is anticipated. The subclavian flap repair augments the narrowed aorta using native arterial tissue. Blood flow to the left arm is maintained by collateral vessels, although long-term studies have demonstrated a slight discrepancy in limb length in some patients. Prosthetic patch material may also be used. By avoiding circumferential prosthetic material, growth potential of the native aorta is preserved. The disadvantage of patch repair is a high risk of aneurysm formation. In adults, where growth is no longer an issue, resection of the coarctation may be performed with subsequent placement of a prosthetic interposition graft (either Dacron or polytetrafluoroethylene).

One of the principal concerns during coarctation repair is interruption of distal aortic blood flow, especially to the spinal cord. The anterior spinal artery is fed by major radicular branches from intercostal arteries. In patients without well-formed collaterals, ischemia of the spinal cord may be precipitated by aortic cross-clamping, and paraplegia may result. Protective measures include induction of mild hypothermia, maintenance of a high proximal aortic pressure, and minimization of cross-clamp time. In older patients, distal aortic perfusion may be maintained by the technique of left heart bypass, where oxygenated blood is taken from the left atrium and delivered to the femoral artery or distal aorta using a centrifugal pump. Overall, the incidence of paraplegia following coarctation repair is less than 1%.

Transcatheter therapy has been proposed for the primary therapy of coarctation, but this approach is controversial due to the incidence of recurrent coarctation, need for multiple interventions, injury to the femoral vasculature (for access), and aneurysm formation. Improved results have been achieved with balloon angioplasty with concurrent stent placement in older children and adults in whom further aortic growth is not anticipated. Balloon angioplasty is widely accepted for the treatment of recurrent coarctation following surgery, with 88%-94% achieving a gradient less than 20 mm Hg.

D. Prognosis

The early mortality following repair of coarctation in neonates is 1%-3%, while the risk in older children and adults is about 1%-2%. The incidence of recurrent coarctation

following resection and end-to-end repair is about 10% whereas catheter-based interventions are associated with reintervention rates of 25% for balloon angioplasty and 5%-40% for stent placement. The long-term survival following repair of coarctation is determined by the presence of associated defects and the persistence of hypertension.

Following repair, patients may develop severe hypertension. This can be managed using intravenous beta-blockers (eg, esmolol) or vasodilators (eg, sodium nitroprusside). Uncontrolled hypertension can lead to the complication of mesenteric arteritis. Hypertension usually resolves within days to weeks after repair, although older children and adults may require lifelong antihypertensive therapy. Repair of coarctation during infancy is thought to minimize the risk of late hypertension.

► Vascular Rings

A. General Considerations

Vascular rings comprise a spectrum of vascular anomalies of the aortic arch, pulmonary artery, and brachiocephalic vessels. The clinically significant manifestation of these lesions is a varying degree of tracheoesophageal compression. These vascular anomalies can be divided into complete vascular rings and partial vascular rings. Complete vascular rings can be divided into double aortic arch and right aortic arch with left ligamentum arteriosum. These two categories can be further subdivided on the basis of the specific anatomy. Incomplete vascular rings include aberrant right subclavian artery, innominate artery compression, and pulmonary artery sling. Other rare variations, which have been described, include left aortic arch with right descending aorta and right ligamentum, and left aortic arch with aberrant right subclavian artery and right ligamentum. The incidence of clinically significant vascular rings is 1%-2% of all congenital heart defects.

Vascular rings and pulmonary slings have been described in conjunction with other cardiac defects, including, TOF,

ASD, branch pulmonary artery stenosis, coarctation, AVSD, VSD, interrupted aortic arch, and aortopulmonary window. Significant associated cardiac anomalies occur in 11%-20% of patients with a vascular ring. A right aortic arch is generally associated with a greater incidence of coexisting anomalies.

By the end of the fourth week of embryonic development, the six aortic or branchial arches have formed between the dorsal aortae and ventral roots. Subsequent involution and migration of the arches results in the anatomically normal or abnormal development of the aorta and its branches. The majority of the first, second, and fifth arches regress. The third arch forms the common carotid artery and proximal internal carotid artery. The right fourth arch forms the proximal right subclavian artery. The left fourth arch contributes to the portion of the aortic arch from left carotid to left subclavian arteries. The proximal portion of the right sixth arch becomes the proximal portion of the right pulmonary artery, while the distal segment involutes. Similarly, the proximal left sixth arch contributes to the proximal left pulmonary artery, and the distal sixth arch becomes the ductus arteriosus.

The pulmonary artery is formed from two vascular precursors as well as through a combination of angiogenesis, the de novo development of new blood vessels, and vasculogenesis, the budding and migration of existing vessels. As stated previously, the proximal pulmonary arteries are based on the sixth arches, whereas the primitive lung buds initially derive their blood supply from the splanchnic plexus. Ultimately, these two segments of the pulmonary artery join to form the vascular network of the lung parenchyma.

B. Clinical Findings

Children with a complete vascular ring generally present within the first weeks to months of life. Typically, children with a double aortic arch present earlier in life than those with a right arch and retroesophageal left ligamentum. In the younger age group, respiratory symptoms predominate, as liquids are generally well tolerated. Respiratory symptoms may include stridor, nonproductive cough, apnea, or frequent respiratory infections. The cough is classically described as “seal bark,” or “brassy.” These symptoms may mimic asthma, respiratory infection, or reflux, and children with vascular rings are often initially misdiagnosed. With the transition to solid food, dysphagia becomes more apparent.

The presentation of a patient with an incomplete vascular ring is variable. Children with innominate artery compression usually present within the first 1-2 years of life with respiratory symptoms. Although, aberrant right subclavian artery is the most common arch abnormality, occurring in approximately 0.5%-1% of the population, it rarely causes symptoms. Classically, when symptoms do occur, they present in the seventh and eighth decade, as the aberrant vessel

becomes ectatic and calcified, causing dysphagia lusoria due to impingement of the artery on the posterior esophagus. An aberrant right subclavian rarely causes symptoms except when it is of an abnormally large caliber or associated with tracheomalacia.

Children with pulmonary artery slings generally present with respiratory symptoms within the first few weeks to months of life. As with complete rings, respiratory symptoms may include stridor, nonproductive cough, apnea, or frequent respiratory infections and may mimic other conditions leading to misdiagnosis. Pulmonary artery slings are associated with complete tracheal rings in 30%-40% of patients, leading to focal or diffuse tracheal stenosis.

The methods for diagnosing a vascular ring are multiple because of the variability in presentation and the spectrum of diagnostic tests available. A child with a presumptive diagnosis of asthma or tracheomalacia may be referred to a pulmonologist and a diagnosis of vascular ring made or suspected initially by CXR and bronchoscopy. In some situations, the diagnosis is made by echocardiography during evaluation for concurrent cardiac defects. Regardless, the diagnosis generally begins with a CXR. Complementary studies may include barium esophagogram, CTA, cMRI, and bronchoscopy. Important modalities to define the tracheal anatomy in a patient with a pulmonary artery sling include CTA, cMRI, or bronchoscopy. Echocardiography may be diagnostic and may be used to rule out other cardiac anomalies. Tracheograms and cardiac catheterizations, which have been used extensively in the past, are rarely currently indicated.

C. Treatment

A double aortic arch occurs when the distal portion of the right dorsal aorta fails to regress. The two arches form a complete ring, encircling the trachea and esophagus. The right arch is dominant in the majority of the cases, followed by left dominant, with codominant arches being the least common. The left and right carotid and subclavian arteries generally arise from their respective arches. The ligamentum arteriosum and descending aorta usually remain on the left.

The approach to repair of a double aortic arch is via a left posterolateral thoracotomy. The procedure can easily be accomplished through a limited, muscle-sparing incision through the third or fourth intercostal space. The pleura is incised, after identifying the vagus and phrenic nerves. The ligamentum or ductus arteriosum is divided while preserving the recurrent laryngeal nerve. The nondominant arch is then divided between two vascular clamps at the point where brachiocephalic flow is optimally preserved. If there is concern regarding the location for division, the arches can be temporarily occluded at various points while monitoring pulse and blood pressure in each limb. If there is an atretic segment, the division is done at the point of the atresia. Dissection around the esophagus and trachea in the region

of the ligamentum/ductus and nondominant arch allows for retraction of the vascular structures and lysis of any residual obstructing adhesions.

There are three anatomic variations for a right arch with a left ligamentum, which cause a complete vascular ring. If the left fourth arch regresses between the aorta and left subclavian, a right aortic arch with aberrant left subclavian artery results. The ligamentum arteriosum is retroesophageal, bridging the left pulmonary artery and aberrant left subclavian, forming a complete vascular ring. If the left fourth arch regresses after the origin of the left subclavian artery but before the arch reaches the dorsal aorta to communicate with the left sixth arch (which becomes the ductus arteriosum), there is mirror-image branching. The ligamentum arteriosum arises directly from the descending aorta, or from a Kommerell diverticulum off of the descending aorta, forming the complete ring. If communication is maintained between the left fourth and sixth arches, there is mirror-image branching with the ligamentum arising from the anterior, mirror-image left subclavian, and a ring is not formed.

The surgical approach for a right aortic arch with retroesophageal left ligamentum arteriosum is the same as for a double arch. The ligamentum is divided, and any adhesions around the esophagus and trachea are lysed. Rarely, the Kommerell diverticulum has been reported to cause compression even after division of the ligamentum. As such, it may be prudent to resect or suspend the diverticulum posteriorly.

In innominate artery compression syndrome, the aortic arch and ligamentum are in their normal leftward position. However, the innominate artery arises partially or totally to the left of midline. As the artery courses from left to right anterior to the trachea, it causes tracheal compression. The symptoms of innominate artery compression may be mild to severe. With mild symptoms and minimal tracheal compression on bronchoscopy, children can be observed expectantly because the symptoms may resolve with growth. Indications for surgery include apnea, severe respiratory distress, significant stridor, or recurrent respiratory tract infection. Several approaches for the correction of innominate artery compression syndrome have been described. These include simple division, division with reimplantation into the right side of the ascending aorta, and suspension to the overlying sternum.

An aberrant right subclavian artery occurs when there is regression of the right fourth arch between the right common carotid and right subclavian arteries. The right subclavian then arises from the leftward descending aorta, laying posterior to the esophagus as it crosses from left to right. Although the artery can compress the esophagus posteriorly, it is rarely the cause of symptoms in children. Surgical treatment involves simple division via a left posterolateral thoracotomy. Rarely, reimplantation or grafting from the right carotid or aortic arch may be necessary.

Normally, the right and left sixth aortic arches contribute to the proximal portions of their respective pulmonary arteries. If the proximal left sixth arch involutes and the bud from the left lung migrates rightward to meet the right pulmonary artery, a pulmonary artery sling is formed. Pulmonary artery slings are associated with complete tracheal rings and tracheal stenosis in 30%-40% of patients. Origin of the right upper lobe bronchus from the trachea ("pig bronchus" or "bronchus suis") has been reported in frequent association with pulmonary artery sling.

Initial attempts at the repair of a pulmonary artery sling involved reimplantation after division of the left pulmonary artery and translocation of the trachea without cardiopulmonary bypass. These early reports had a high incidence of left pulmonary artery thrombosis. This has led some authors to advocate division of the trachea and translocation of the left pulmonary artery. This approach would seem sensible if the trachea were being divided in the course of tracheal reconstruction. However, currently most authors advocate the reimplantation of the left pulmonary artery, which has resulted in excellent results. The procedure is done via a median sternotomy on cardiopulmonary bypass to insure optimal visualization of the repair. Aortic cross-clamping is not necessary. The left pulmonary artery is divided off of the right pulmonary artery, translocated anterior to the trachea, and reimplanted into the main pulmonary artery.

Any necessary reconstruction of the trachea for complete tracheal rings is done concurrently with bronchoscopic assistance. Many techniques for tracheal reconstruction have been described, with resection and primary reanastomosis and sliding tracheoplasty offering the most reliable results.

Over 95% of vascular rings without concurrent cardiac defects can be performed through a left thoracotomy. A right thoracotomy is indicated for the rare cases where there is a right ligamentum arteriosum. A right ligamentum occurs in the setting of a left aortic arch with right descending aorta, where the ligamentum bridges from the descending aorta to the right pulmonary artery forming a complete ring. Right ligamentum arteriosum has also been described with a left aortic arch with aberrant right subclavian artery. In this case, the ligamentum may arise from the aberrant subclavian artery, from a diverticulum off of the arch, or directly from the left arch to the right pulmonary artery. In addition, a double aortic arch with an atretic segment proximal to the right carotid artery is more easily divided through a right thoracotomy. The approach to these anomalies is the same as for a left-sided ring division, with the caveat that the right recurrent laryngeal nerve will loop around the right ligamentum.

Repair of vascular rings has been described using video-assisted thoracoscopic surgery (VATS) both with and without robotic assistance. Candidates for thoracoscopic division are limited to those patients requiring only the division of nonpatent vascular structures. In general, VATS is used for

patients weighing more than 15 kg due to current size limitations of the instruments.

D. Prognosis

Hospital mortality for the repair of a vascular ring was 1.6% in a recent series of 183 patients by Ruzmetov and colleagues. Overall survival was 96% at 35 years. Eight patients were repaired utilizing left pulmonary artery division and reimplantation for pulmonary artery sling, three of whom also required cardiopulmonary bypass for tracheal reconstruction. Of the 183 patients there were no operative mortalities and eight late deaths. All deaths were in patients with other complex cardiac anomalies. The major source of morbidity, as well as mortality, in this and other series is related to the tracheal reconstruction.

▶ Coronary Anomalies

A. General Considerations

Coronary artery anomalies occur in between 0.2% and 1.2% of the population. They can be classified as minor, secondary, or major on the basis of their clinical significance. Minor defects have no functional significance and are usually detected as incidental findings at cardiac catheterization. Secondary defects have no intrinsic significance but alter surgical management when they are present. An example of a secondary defect is an anomalous origin of the left anterior descending from the right coronary artery, which crosses the hypoplastic infundibulum in a patient with TOF. The presence of this vessel may prevent the safe performance of a transannular incision and thereby mandate the use of a conduit. Major defects are the most important form of coronary anomaly because they exert an intrinsically adverse effect on the myocardium. Major anomalies can be subdivided based on anatomy: coronary arteriovenous fistula, anomalous pulmonary origin of a coronary artery, anomalous aortic origin of a coronary artery, myocardial bridging, or coronary artery aneurysm.

Coronary arteriovenous fistula is the most common major coronary anomaly. An abnormal connection exists

between a coronary artery (usually the right) and another vascular structure (usually one of the right heart chambers). Most fistulas are isolated and solitary. The fistula leads to left-to-right shunting, which can produce congestive heart failure. Other symptoms include angina, endocarditis, myocardial infarction, arrhythmia, and sudden death. The diagnosis is suggested by echocardiography and confirmed by catheterization.

The second-most common major coronary anomaly is the origin of a coronary artery from the pulmonary artery. The most common manifestation is the anomalous left coronary artery arising from the pulmonary artery (ALCAPA). The right coronary (or both coronaries) may also arise anomalously from the pulmonary artery but only in very rare cases. ALCAPA is usually well tolerated during fetal development, but after birth, the pulmonary systolic pressure usually drops (following ductal closure and decline in PVR) and the anomalous coronary is perfused with desaturated blood at low pressure. Collateral vessels develop between the normal right coronary artery and the abnormal left coronary, but the benefit is negated due to the development of coronary steal, whereby the collateral blood shunts left to right by retrograde flow in the anomalous coronary into the low-pressure pulmonary artery. Most patients will present between 6 weeks and 3 months of life. Typical symptoms include irritability, difficulty in feeding, and other signs of congestive heart failure. Untreated, ALCAPA is nearly always fatal. Rarely, patients will survive to adulthood and present with symptoms of angina or sudden death. On examination, patients with ALCAPA frequently have a holosystolic murmur of ischemic mitral regurgitation. The pulmonary component of the second heart sound may be pronounced because of pulmonary hypertension. Chest radiography is significant for cardiomegaly and pulmonary edema. Electrocardiographic evidence of ischemia and infarction is usually present. Echocardiography is usually diagnostic and is useful for assessing the severity of left ventricular dysfunction and ischemic mitral regurgitation that are commonly present. Catheterization is occasionally necessary to clarify the anatomy, but this technique is used less frequently because of the risk of inducing life-threatening arrhythmias.

Anomalous aortic origins of the coronary arteries are usually minor defects, but a potentially dangerous abnormality exists when the left main coronary artery arises from the right coronary sinus and passes between the pulmonary artery and aorta. This defect has been associated with cardiac symptoms and sudden death, as has the origin of the right coronary artery from the left coronary sinus (usually when the right coronary is dominant). The etiology of ischemia in both defects is thought to be related to the acute angle of origin and slit-like orifice of the anomalous vessel and the extrinsic compression created by the apposing walls of the aorta and pulmonary artery. These defects usually present in

older patients. Symptomatic patients are treated surgically by coronary artery bypass.

Myocardial bridging occurs when a segment of an epicardial coronary artery (usually the left anterior descending) takes an intramyocardial course over a short segment. Although this is a common incidental finding at cardiac catheterization, this defect has been associated in some cases with myocardial ischemia. Treatment involves dividing the muscle bridge to free the coronary, coronary bypass beyond the bridge, or transcatheter stenting.

Coronary aneurysms occur rarely, usually in conjunction with an inflammatory condition such as Kawasaki syndrome, polyarteritis nodosa, Takayasu arteritis, or syphilis. Coronary aneurysms may thrombose or lead to distal coronary stenosis or embolization. Rupture occurs uncommonly. Treatment ranges from antiplatelet therapy to coronary artery bypass grafting, and possible transplantation.

B. Treatment

All symptomatic fistulas should be occluded, either surgically or by transcatheter techniques. In some cases, coronary bypass grafting may be necessary when distal flow is compromised by fistula occlusion. Treatment of asymptomatic fistulas is controversial, but occlusion should probably be undertaken when significant left-to-right shunting is present.

Surgical repair is indicated for all patients with ALCAPA. Historically, the initial surgical approach involved ligation of the proximal left coronary artery. This served to eliminate coronary steal and allow perfusion of the left coronary system by collaterals from the right. Despite the ease of simple ligation, most centers have abandoned this approach in favor of establishment of a 2-coronary system, which offers better long-term freedom from ischemia. In older patients, this may be achieved by proximal ligation of the left coronary artery in conjunction with coronary artery bypass, ideally with a left internal mammary graft. Coronary bypass is technically difficult in neonates, and a number of alternative operations have been devised to create a direct connection between the aorta and the anomalous coronary artery. Most commonly, this can be achieved by removing the origin of the left coronary artery (along with a button of adjacent pulmonary artery) and reimplanting the vessel directly into the side of the aorta. Another approach involves creation of a side-to-side connection between the aorta and pulmonary artery with placement of an intrapulmonary baffle to direct flow from this connection to the anomalous left coronary ostium.

C. Prognosis

Survival following surgical repair of ALCAPA has improved over the years. Recent reports have suggested an operative mortality of 0%-6%. Ventricular function tends to normalize

after surgery. In most patients, mitral valve function also improves, but for patients with severe mitral regurgitation, concurrent mitral valve repair may be indicated.

MULTIPLE CHOICE QUESTIONS

- Which of the following statements about ventricular septal defects (VSDs) is *false*?
 - The most common type of VSD is perimembranous.
 - Left-to-right shunting through a VSD causes a volume load on the right ventricle.
 - A patient with a large VSD may be asymptomatic at birth, but eventually develop congestive heart failure due to a drop in pulmonary vascular resistance.
 - In the presence of a perimembranous VSD, the bundle of His passes along the posterior and inferior rim of the defect, generally on the left ventricular side.
- Which of the following infants would benefit most from the initiation of PGE₁?
 - Neonate with prenatal diagnosis of aortic coarctation who develops acidosis, oliguria, and diminished pedal pulses 8 hours after birth.
 - Two-day-old neonate with prenatal diagnosis of complete atrioventricular canal with O₂ saturation of 80% and poor systemic perfusion.
 - Six-week-old infant presenting with irritability, poor feeding, and tachypnea who is diagnosed with ALCAPA and no PDA is seen on echocardiogram.
 - One-week-old infant with double aortic arch presenting with increasing respiratory distress.
- A newborn with d-transposition of the great arteries (d-TGA) remains severely cyanotic despite initiation of PGE₁ to maintain ductal patency. What is the recommended next step in management?
 - Initiate inhaled nitric oxide therapy
 - Diuresis with furosemide IV
 - Balloon atrial septostomy
 - Emergent arterial switch operation
- What is the most common major coronary anomaly?
 - Left coronary from the pulmonary artery (ALCAPA)
 - Left anterior descending from the right coronary artery
 - Coronary AV fistula
 - Single coronary
- In which of the following diagnoses is a *primary* catheter-based approach most likely to be recommended over surgery?
 - Isolated aortic coarctation in a neonate
 - Isolated pulmonary stenosis in a neonate
 - PDA in a 1-kg premature infant with heart failure symptoms
 - Symptomatic perimembranous VSD in a 6-month-old infant

Esophagus & Diaphragm

THE ESOPHAGUS

ANATOMY

The esophagus (Figure 20–1) is a muscular tube that serves as a conduit for the passage of food and fluids from the pharynx to the stomach. It originates at the level of the sixth cervical vertebra, posterior to the cricoid cartilage. In the thorax, the esophagus passes behind the aortic arch and the left main stem bronchus, enters the abdomen through the esophageal hiatus of the diaphragm, and terminates in the fundus of the stomach. Its muscle fibers originate from the cricoid cartilage and pharynx above and interdigitate with those of the stomach below. About 2–4 cm of the esophagus is normally located below the diaphragm. The junction between the esophagus and stomach is maintained in its normal intra-abdominal position by the reflection of the peritoneum onto the stomach and of the phrenoesophageal ligament onto the esophagus. The latter is a fibroelastic membrane that lies beneath the peritoneum, on the inferior surface of the diaphragm. When it reaches the esophageal hiatus, the ligament is reflected in an oral direction onto the lower esophagus, where it inserts into the circular muscle layer above the gastroesophageal sphincter, 2–4 cm above the diaphragm.

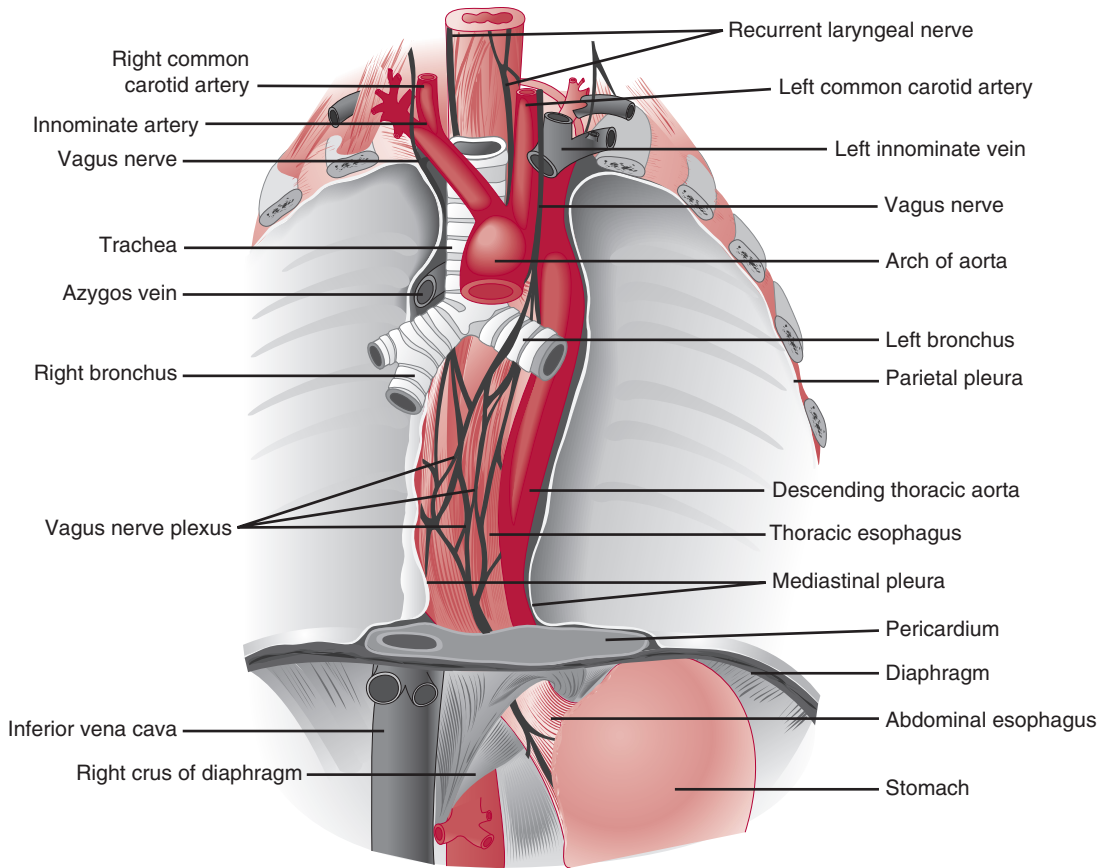

Three anatomic areas of narrowing occur in the esophagus: (1) at the level of the cricoid cartilage (pharyngoesophageal or upper esophageal sphincter [UES]); (2) in the mid thorax, from compression by the aortic arch and the left main stem bronchus; and (3) at the level of the esophageal hiatus of the diaphragm (gastroesophageal or lower esophageal sphincter [LES]).

In the adult, the distance as measured from the upper incisor teeth to the cricopharyngeus muscle is 15–20 cm; to the aortic arch, 20–25 cm; to the inferior pulmonary vein, 30–35 cm; and to the gastroesophageal junction, approximately 40–45 cm.

The mucosal lining of the esophagus consists of stratified squamous epithelium that contains scattered mucous glands throughout. The musculature of the pharynx and upper third of the esophagus is skeletal in type (striated muscle); the remainder is smooth muscle. Physiologically, the entire organ behaves as a single functioning unit, so that no distinction can be made between the upper and lower esophagus from the standpoint of propulsive activity. As in the intestinal tract, the muscle fibers are arranged into inner circular and outer longitudinal layers. The esophagus has no serosal layer. The arterial supply to the esophagus is quite consistent. The upper end is supplied by branches from the inferior thyroid arteries. The thoracic portion receives blood from the bronchial arteries and from esophageal branches originating directly from the aorta. The intercostal arteries may also contribute. The diaphragmatic and abdominal segments are nourished by the left inferior phrenic artery and by the esophageal branches of the left gastric artery. The venous drainage is more complex and variable. The most important veins are those that drain the lower esophagus. Blood from this region passes into the esophageal branches of the coronary vein, a tributary of the portal vein. This connection constitutes a direct communication between the portal circulation and the venous drainage of the lower esophagus and upper stomach. When there is portal hypertension, as in cirrhosis of the liver, blood is shunted upward through the coronary vein and the esophageal venous plexus to eventually pass by way of the azygos vein into the superior vena cava. The esophageal veins may eventually form varices as they become distended when portal hypertension is present.

PHYSIOLOGY

The coordinated activity of the UES, the esophageal body and the LES is responsible for the motor function of the esophagus.

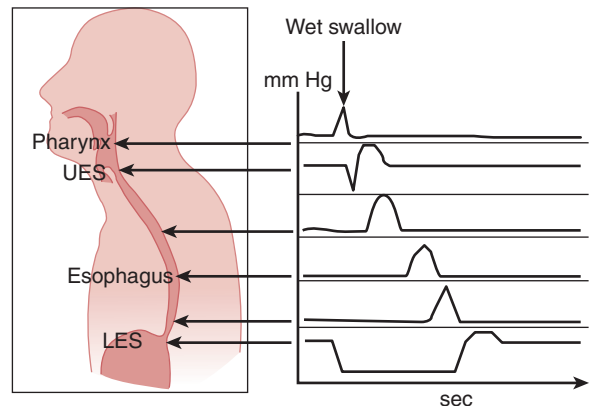

▲ **Figure 20-1.** Anatomy of the esophagus.

1. Upper Esophageal Sphincter

The UES receives motor innervation directly from the brain (nucleus ambiguus). The sphincter is continuously in a state of tonic contraction, with a resting pressure of about 100 mm Hg (anteroposterior axis). The sphincter prevents passage of air from the pharynx into the esophagus and reflux of esophageal contents into the pharynx. During swallowing, a food bolus is moved by the tongue into the pharynx, which contracts while the UES relaxes. After the food bolus has reached the esophagus, the UES regains its resting tone (Figure 20-2).

2. Esophageal Body

When food passes through the UES, a contraction is initiated in the upper esophagus, which progresses distally toward the stomach. The wave initiated by swallowing is referred as primary peristalsis (Figure 20-2). It travels at

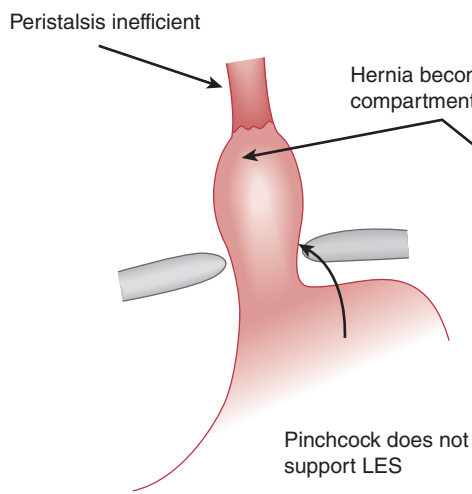

▲ **Figure 20-2.** Swallowing process. Upper esophageal sphincter, esophageal peristalsis, and lower esophageal sphincter in response to swallowing.

a speed of 3-4 cm/s and reaches amplitudes of 60-140 mm Hg in the distal esophagus. Local stimulation by distention at any point in the body of the esophagus will elicit a peristaltic wave from the point of stimulus. This is called secondary peristalsis and aids esophageal emptying when the primary wave has failed to clear the lumen of ingested food, or when gastric contents reflux from the stomach. Tertiary waves are considered abnormal, but they are frequently seen in elderly subjects who have no symptoms of esophageal disease.

3. Lower Esophageal Sphincter

The LES measures 3-4 cm in length and its resting pressure ranges between 15 and 24 mm Hg. At the time of swallowing, the LES relaxes for 5-10 seconds to allow the food bolus to enter the stomach and then regains its resting tone (Figure 20-2). The LES relaxation is mediated by vasoactive intestinal polypeptide and nitric oxide, both nonadrenergic, noncholinergic neurotransmitters. The resting tone depends mainly on intrinsic myogenic activity. The LES has a tendency to relax periodically at times independent from swallowing. These periodic relaxations are called transient

lower esophageal sphincter relaxations to distinguish them from relaxations triggered by swallows. The cause of these transient relaxations is not known, but gastric distention probably plays a role. Transient LES relaxations account for the small amount of physiologic gastroesophageal reflux present in any individual, and are also the most common cause of reflux in patients with gastroesophageal reflux disease (GERD). Decrease in length or pressure of the LES (or both) is responsible for abnormal reflux in the remaining patients. Overall, it is thought that while transient LES relaxation is the most common mechanism of reflux in volunteers and patients with either absent or mild esophagitis, the prevalence of a mechanically defective sphincter (hypotensive and short) increases in patients with severe esophagitis, particularly when Barrett metaplasia is present. The crus of the esophageal hiatus of the diaphragm contributes to the resting pressure of the LES. This *pinchcock* action of the diaphragm is particularly important because it protects against reflux caused by sudden increases of intra-abdominal pressure, such as with coughing or bending. This synergistic action of the diaphragm is lost when a sliding hiatal hernia is present, as the gastroesophageal junction is displaced above the diaphragm (Figure 20-3).

▲ **Figure 20-3.** Pathophysiology of hiatal hernia.

DIAGNOSTIC APPROACH TO ESOPHAGEAL DISEASES

► Symptomatic Evaluation

Esophageal symptoms can be divided into two groups: (1) typical, such as dysphagia, heartburn, and regurgitation and (2) atypical such as chest pain, cough, and hoarseness (Table 20–1). Dysphagia is a unique symptom as it points to an esophageal disorder, either functional (secondary to abnormalities of esophageal peristalsis or lack of coordination between different parts of the esophagus) or mechanical (secondary to a peptic or malignant stricture or an intraluminal mass). Heartburn can also be caused by non-esophageal disorders such as biliary disease, irritable bowel syndrome, coronary artery disease, and psychiatric diseases.

► Upper Gastrointestinal Series

The upper gastrointestinal series test is performed by giving the patient barium to swallow. Subsequently, multiple images are taken, including the esophagus, the gastroesophageal junction, the stomach, and the duodenum (a barium swallow focuses just on the esophagus and the gastroesophageal junction). This test characterizes a hiatal hernia, an esophageal stricture, an esophageal diverticulum, or an intraluminal mass. A cine-esophagram is instead a dynamic evaluation of the swallowing process, and it

is particularly useful in patients with functional dysphagia (secondary to a motility disorder, in the absence of a mechanical cause).

► Upper Endoscopy

This test allows visualization of the mucosal surface of the esophagus, the stomach, and the duodenum. The presence and degree of esophagitis and the presence of an intraluminal mass can be determined, and biopsies taken.

► Endoscopic Ultrasound

This test is used in patients with esophageal cancer to define the depth of penetration of the tumor through the esophageal wall (T) and the presence of enlarged periesophageal lymph nodes (N). Fine-needle aspiration of these nodes can be done, and cytologic analysis of the aspirate performed.

► Esophageal Manometry

Esophageal manometry allows determination of: (1) LES location, length, pressure, and relaxation in response to swallowing; (2) pressure, duration, and velocity of propagation of the peristaltic waves; and (3) location, pressure, relaxation of the UES, and coordination with the pharyngeal contraction.

► Ambulatory 24-Hour pH Monitoring

This test measures reflux of acid from the stomach into the esophagus, and it is considered the gold standard for the diagnosis of GERD. By convention, the catheter is placed 5 cm above the upper border of the manometrically determined LES and is kept in place for 24 hours, during which the patient does not alter the daily activities and diet. In addition to defining whether a pathologic amount of GER is present, the test establishes if there is a temporal correlation between episodes of reflux and symptoms (Figure 20–4). Esophageal impedance is a technique that measures flow of liquids and gas across the gastroesophageal junction, independently of the pH of the gastric refluxate. In association with pH monitoring, impedance is indicated in patients with proton pump inhibitors (PPIs)—resistant typical reflux symptoms and chronic unexplained cough.

► Gastric Scintigraphy

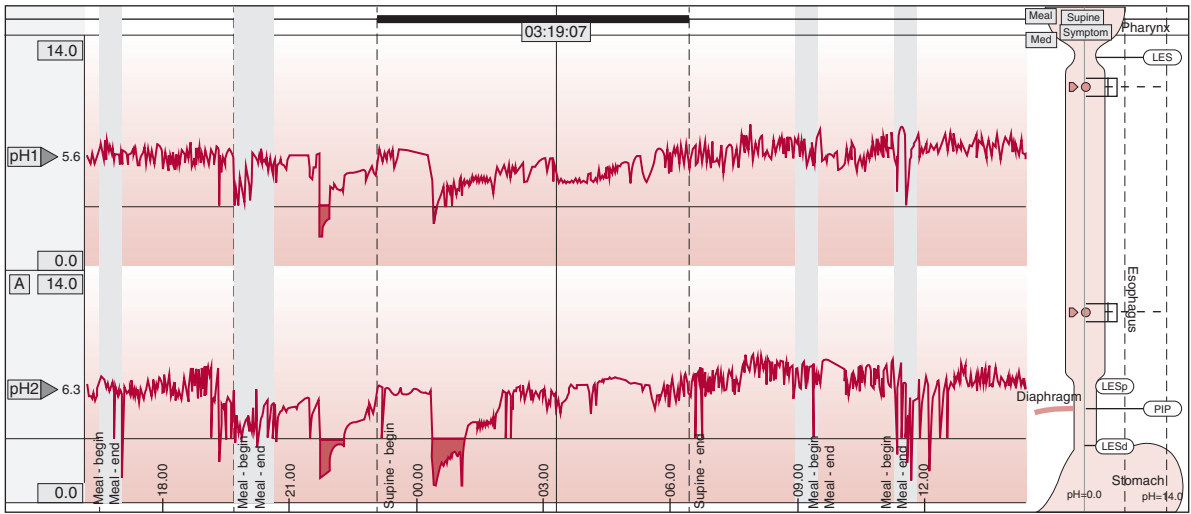

It is indicated in patients who experience postprandial bloating and fullness to measure the gastric emptying of solids and liquids.

► Computerized Axial Tomography

A computerized tomography (CT) scan is used to assess the presence of metastases (lung, liver, adrenals) in patients with esophageal cancer (M).

Table 20–1. Clinical presentation of GERD.

Esophageal	Heartburn Regurgitation Dysphagia
Gastric	Bloating Early satiety Belching Nausea
Pulmonary	Aspiration Asthma Wheezing Cough Dyspnea Fibrosis
Ears, nose, throat	Globus Water brash Hoarseness
Cardiac	Chest pain

▲ **Figure 20-4.** Ambulatory pH monitoring. The superior plot reports the 24-hour pH recording in the proximal esophagus 20 cm above the upper border of the manometrically determined LES. The inferior plot reports the 24-hour pH recording in the distal esophagus 5 cm above the upper border of the manometrically determined LES. A reflux episode occurs when pH falls below pH = 4 and ends when pH returns above 4.

► **Positron Emission Tomography**

A positron emission tomography (PET) scan is used to assess the metastatic spread of esophageal cancer (M). In addition, it might help predict the response of esophageal cancer to neoadjuvant therapy.

► **Laparoscopy/Thoracoscopy**

Laparoscopy or thoracoscopy can be used to stage esophageal cancer, particularly when liver metastases or extensive lymphadenopathy are suspected.

ESOPHAGEAL MOTILITY DISORDERS

The named primary esophageal motility disorders are achalasia, diffuse esophageal spasm, nutcracker esophagus, and the hypertensive LES. They occur in the absence of any other esophageal disorder such as reflux, and their cause is unknown. These disorders present with a combination of dysphagia, regurgitation, chest pain, and heartburn. Esophageal manometry is the key test that differentiates these disorders.

ACHALASIA

ESSENTIALS OF DIAGNOSIS

- Dysphagia
- Regurgitation
- Absence of esophageal peristalsis on esophageal manometry
- Radiologic evidence of distal esophageal narrowing

► **General Considerations**

Esophageal achalasia is characterized by the absence of esophageal peristalsis. In most patients, the LES is hypertensive and fails to relax appropriately in response to swallowing. These abnormalities lead to impaired emptying of food with

consequent stasis in the esophagus. The incidence of achalasia is about 1 in 100,000 persons. It affects men more than women, and it can occur at any age.

► Pathogenesis

The etiology is still unknown, but two theories exist: (1) a degenerative disease of the neurons; and (2) infections of the neurons by a virus (eg, herpes zoster) or another infectious agent. The latter is supported by the fact that similar findings occur in patients with Chagas disease (American trypanosomiasis), a condition in which the infective organism destroys parasympathetic ganglion cells throughout the body, including the heart and the gastrointestinal, urinary, and respiratory tracts. The degeneration of the myenteric plexus of Auerbach determines loss of the postganglionic inhibitory neurons (which contain nitric oxide and vasoactive intestinal polypeptide), which mediate LES relaxation. Because the postganglionic cholinergic neurons are spared, there is unopposed cholinergic stimulation, which increases LES resting pressure and decreases LES relaxation. There is no propagation of peristaltic waves in response to swallowing, but rather the presence of simultaneous contractions.

► Clinical Findings

A. Symptoms and Signs

Dysphagia is the most common symptom, experienced by about 95% of patients. It is often for both solids and liquids. Most patients adapt with changes in their diet and are able to maintain a stable weight, while others eventually experience some weight loss. Regurgitation of undigested food is the second-most common symptom and it is present in about 60% of patients. It occurs more often in the supine position and may lead to aspiration. Heartburn is present in about 40% of patients. It is not due to GER, but rather to stasis and fermentation of undigested food in the distal esophagus. Chest pain also occurs in about 40% of patients, due to esophageal distension, and it is usually experienced at the time of a meal.

B. Imaging Studies

Endoscopy is usually the first test performed to rule out a mechanical obstruction such as a peptic stricture or cancer. A barium swallow usually shows narrowing at the level of the gastroesophageal junction, and slow emptying of contrast (Figure 20–5). A dilated, sigmoid esophagus may be present in patients with longstanding achalasia.

C. Special Tests

Esophageal manometry is the gold standard for establishing the diagnosis of esophageal achalasia. The classic manometric findings are: (1) absence of esophageal peristalsis and (2)

▲ **Figure 20–5.** Esophageal achalasia. Note dilation of the esophageal body, retained barium, and distal esophageal narrowing (bird's beak).

hypertensive LES (in about 50% of patients) that relaxes only partially in response to swallowing. When the esophagus is dilated and sigmoid in shape, it may be difficult to pass the catheter through the gastroesophageal junction into the stomach. In these cases, the catheter may be placed under fluoroscopic or endoscopic guidance. Recently, a new classification of esophageal achalasia has been proposed based on high-resolution manometry: type I, classic, with minimal esophageal pressurization; type II, achalasia with esophageal compression; and type III, achalasia with spasm.

► Differential Diagnosis

Benign strictures due to GER and esophageal carcinoma may mimic the clinical presentation of achalasia. Sometimes an infiltrating tumor of the gastroesophageal junction can mimic not only the clinical and radiological presentation of achalasia but also the manometric profile. This condition, called secondary or pseudo-achalasia, should be suspected

in patients older than 60 years with recent onset of dysphagia (< 6 months) and excessive weight loss. An endoscopic ultrasound or a CT scan with fine cuts is recommended to rule out an underlying malignancy.

► Complications

Aspiration of retained and undigested food can cause repeated episodes of pneumonia. Achalasia is also a risk factor for esophageal squamous cell carcinoma, probably due to the continuous irritation of the mucosa by the retained and fermenting food. Adenocarcinoma can occur in patients who develop GER after either pneumatic dilation or myotomy.

► Treatment

Therapy is palliative, and it is directed toward relief of symptoms by decreasing the outflow resistance caused by the dysfunctional LES. Because peristalsis is absent and does not return after any form of treatment, gravity becomes the key factor that allows emptying of food from the esophagus into the stomach.

► Medical Therapy

Calcium-channel blockers are used to decrease LES pressure. However, because only 10% of patients benefit from this treatment, it should be used primarily in patients who have contraindications to either pneumatic dilation or to surgery.

A. Endoscopic Treatment

Intrasphincteric injection of botulinum toxin is used to block the release of acetylcholine at the level of the LES, thereby restoring the balance between excitatory and inhibitory neurotransmitters. This treatment, however, is of limited value. Only 60% of treated patients still have relief of dysphagia 6 months after treatment, and this number further decreases to 30% (even after multiple injections) 2.5 years later. In addition, it often causes an inflammatory reaction at the level of the gastroesophageal junction, which makes a subsequent myotomy more difficult. It should be used primarily in patients who are poor candidates for dilatation or surgery.

Pneumatic dilation of the LES is considered the most effective nonsurgical treatment of achalasia and has been the main modality of treatment for many years until the advent of minimally invasive surgery in the early 1990s. A balloon is inflated at the level of the gastroesophageal junction to rupture the muscle fibers while trying to leave the mucosa intact. The initial success rate is around 90%, but it decreases in most patients to 50% at 10 years, even after multiple dilations. The perforation rate is about 2%-5%. If a free perforation occurs, patients are taken emergently to the operating room, where closure of the perforation and a myotomy on the contralateral side of the esophagus are performed. The

incidence of post-dilation GER is about 25%-35%. Patients who fail pneumatic dilation are usually treated by a laparoscopic Heller myotomy.

A recent novel approach to achalasia is the per-oral endoscopic esophageal myotomy (POEM). During this procedure the circular muscle fibers of the lower esophagus and the upper stomach are cut through a sub-mucosal tunnel. Long-term follow-up will be needed to assess the long-term results of this procedure.

B. Surgical Treatment

A laparoscopic Heller myotomy and partial fundoplication has progressively become the procedure of choice for esophageal achalasia during the last 20 years. The operation consists of a controlled section of the muscle fibers (myotomy) of the lower esophagus (6 cm) and proximal gastric wall (2-2.5 cm), followed by an anterior or a posterior partial fundoplication to prevent reflux. Patients spend 24-48 hours in the hospital, and return to regular activities in about 2 weeks. The operation effectively relieves symptoms in about 90% of patients, and it is effective even in patients who have a low LES pressure after previous dilation or when the esophagus is dilated. Therefore, it should be preferred to pneumatic dilation whenever surgical expertise is available. The incidence of postoperative reflux is around 25%-35%, and it is usually controlled by acid reducing medications. Persistent or recurrent dysphagia after myotomy can be treated with pneumatic dilation or another myotomy. Esophagectomy is reserved for patients with severe dysphagia who have failed both dilation and myotomy.

DIFFUSE ESOPHAGEAL SPASM

ESSENTIALS OF DIAGNOSIS

- Dysphagia
- Chest pain
- Intermittent symptoms
- Radiologic evidence of tertiary contractions (corkscrew esophagus)
- Intermittent normal and absent peristaltic waves on manometry (> 10%, < 100%)
- Normal 24-h ambulatory pH monitoring

► General Considerations

The cause of diffuse esophageal spasm is not known. Stress might play a role. Progression of diffuse esophageal spasm to achalasia has been documented.

► Clinical Findings

A. Symptoms and Signs

The most common symptom is intermittent chest pain, which varies from slight discomfort to severe spasmodic pain that simulates the pain of coronary artery disease. Most patients complain of dysphagia, but weight loss is uncommon.

B. Imaging Studies

The barium swallow is abnormal in about 70% of patients. Fluoroscopic studies show segmental spasms, areas of narrowing, and irregular uncoordinated peristalsis (corkscrew esophagus) in about 30% of patients. An epiphrenic diverticulum is sometimes present.

C. Manometry

Esophageal manometry is the key test for establishing the diagnosis of diffuse esophageal spasm. The classic manometric findings are: (1) alternation of esophageal peristalsis and simultaneous contractions ($> 10\%$ and $< 100\%$) and (2) normal LES function or abnormalities similar to those seen in achalasia.

D. Ambulatory 24-Hour pH Monitoring

This test is essential as the symptoms and the manometric picture of diffuse esophageal spasm can be caused by GERD. In such cases, treatment should be directed toward reflux because the dysmotility is secondary to the reflux. Therefore, it is crucial to be certain about the diagnosis, as treatment of GERD (acid-reducing medications or a fundoplication) is completely different from that of a primary esophageal motility disorder (pneumatic dilation or myotomy).

► Differential Diagnosis

When chest pain is the predominant symptom, a complete cardiac workup is necessary to exclude a cardiac reason for the pain. Once the heart disease has been excluded, ambulatory pH monitoring must be performed to rule out abnormal GER, which is the most common cause of noncardiac chest pain. Esophageal manometry is the only test that distinguishes diffuse esophageal spasm from other primary esophageal motor disorders. An endoscopy should be performed to confirm the absence of intraluminal lesions.

► Complications

Regurgitation and aspiration may occur, possibly leading to repeated episodes of pneumonia. An epiphrenic diverticulum may be present, secondary to the motor disorder.

► Treatment

The therapeutic approach to diffuse esophageal spasm is similar to that of achalasia. Both disorders can be conceptualized as different points in a spectrum of esophageal motility, where peristalsis is progressively lost. In patients with diffuse esophageal spasm, dysphagia is secondary to abnormalities of the peristalsis and the LES, while the chest pain probably results from esophageal distension from poor emptying. Medical therapy (long-acting nitrates, calcium-channel blocking agents) is relatively ineffective. Pneumatic dilation improves the dysphagia in about 25% of patients. Intrasphincteric injection of botulinum toxin has also given poor results. In contrast, a laparoscopic Heller myotomy and partial fundoplication (as for patients with achalasia) improves both dysphagia and chest pain in about 80% of patients.

The hypertensive lower esophageal sphincter is a rare disorder that manifests with dysphagia and is characterized manometrically by a hypertensive LES (resting pressure > 45 mm Hg), which relaxes in response to swallowing, and normal esophageal peristalsis. Treatment is similar to that of esophageal achalasia.

NUTCRACKER ESOPHAGUS

ESSENTIALS OF DIAGNOSIS

- Chest pain
- Dysphagia
- Intermittent symptoms
- Peristaltic waves propagate normally but have very high amplitude and long duration
- Normal 24-h ambulatory pH monitoring

► General Considerations

The cause of this disorder is not known.

► Clinical Findings

A. Symptoms and Signs

Chest pain is the most common symptom. Patients often come to the attention of gastroenterologists only after a thorough cardiac workup has been performed. About half of the patients complain of dysphagia in addition to chest pain.

B. Imaging Studies

The barium swallow is usually normal. An epiphrenic diverticulum is sometimes present.

C. Manometry

Esophageal manometry is the key test for establishing the diagnosis of nutcracker esophagus. The classic manometric findings are as follows: (1) normal propagation of the peristalsis waves (there are no simultaneous contractions)—the peristaltic waves in the distal esophagus, however, have very high amplitude (> 180 mm Hg) and duration (> 6 sec) and (2) normal LES function or abnormalities similar to those seen in achalasia and diffuse esophageal spasm.

D. Ambulatory 24-Hour pH Monitoring

This test is essential because the symptoms and the manometric picture of nutcracker esophagus can be caused by GERD. In such cases, treatment should be directed toward reflux because the dysmotility is secondary.

► Differential Diagnosis

When chest pain is the predominant symptom, a complete cardiac work up is necessary to exclude a cardiac reason for the pain. Once the heart has been excluded as a cause of the symptom, ambulatory pH monitoring must be performed to rule out abnormal GER, which is the most common cause of noncardiac chest pain. Esophageal manometry is the only test that distinguishes nutcracker esophagus from other primary esophageal motility disorders.

► Complications

Regurgitation and aspiration may occur, possibly leading to repeated pneumonic infections. An epiphrenic diverticulum may be present, secondary to the motor disorder.

► Treatment

The nutcracker esophagus is not as well defined as the other primary esophageal motility disorders for both pathophysiology and treatment. Initially, it was thought that the high pressure of the peristaltic contractions was the cause of the chest pain, so treatment was aimed at decreasing the high amplitude of the peristaltic waves. However, calcium-channel blockers are unable to improve the chest pain even though they decrease the strength of the contractions. Similarly, the results of surgery have been disappointing, as chest pain persists after myotomy in about 50% of patients. Dysphagia is improved in 80% of patients.

ESOPHAGEAL DIVERTICULA

Esophageal diverticula are rare. They are located above the UES (pharyngoesophageal or Zenker diverticulum) or the LES (epiphrenic diverticulum). They are considered pulsion diverticula and are secondary to abnormalities of the sphincters in terms of resting pressure, relaxation in response to swallowing, and coordination with the segment above the sphincter. As a consequence, mucosa and submucosa protrude through the muscular layers, forming the outpouching.

1. Pharyngoesophageal Diverticulum (Zenker Diverticulum)

ESSENTIALS OF DIAGNOSIS

- Dysphagia
- Regurgitation of undigested food (with risk of aspiration)
- Gurgling sounds in the neck
- Halitosis

► General Considerations

This is the most common of the esophageal diverticula and is three times more frequent in men than in women. Most patients are over age 60 years. The condition originates from the posterior wall of the esophagus, in a triangular area of weakness (Killian triangle), limited inferiorly by the upper border of the cricopharyngeal muscle and laterally by the oblique fibers of the inferior constrictor muscles of the pharynx. As the diverticulum enlarges, it tends to deviate from the midline, mostly to the left.

► Pathogenesis

A Zenker diverticulum is due either to lack of coordination between the pharyngeal contraction and the opening

time of the UES or to a hypertensive UES. Because of the increased intraluminal pressure, there is progressive herniation of mucosa and submucosa through the Killian triangle. Occasionally, UES dysfunction can occur in the absence of a diverticulum (cricopharyngeal achalasia). A hereditary syndrome called oculopharyngeal muscular dystrophy, consisting of ptosis and dysphagia, has been described in patients of French-Canadian ancestry. The dysphagia is the result of weak pharyngeal musculature in the face of normal UES function; it is considerably improved by UES myotomy. This syndrome also manifests with cervical dysphagia. A chronic cough may develop in some patients from aspiration of saliva and ingested food.

► Clinical Findings

A. Symptoms

Dysphagia is the most common symptom and occurs in about 80%-90% of patients. Regurgitation of undigested food from the diverticulum often occurs, and can lead to aspiration into the tracheobronchial tree and pneumonia. Patients frequently have halitosis and can hear gurgling sounds in the neck. About 30% of patients have associated GERD.

B. Imaging Studies

A barium swallow clearly shows the position and size of the diverticulum or a prominent cricopharyngeal bar without diverticulum (Figure 20-6).

C. Special Tests

Esophageal manometry shows a lack of coordination between the pharynx and the cricopharyngeus muscle and often a hypertensive UES. In addition, it can show a hypotensive LES and abnormal esophageal peristalsis. Ambulatory pH monitoring determines if abnormal esophageal acid exposure is present. Endoscopy may be dangerous because the instrument can enter the diverticulum rather than the esophageal lumen and cause a perforation.

► Differential Diagnosis

Differential diagnosis includes esophageal stricture, achalasia, and esophageal cancer.

► Treatment

The standard treatment consists of eliminating the functional obstruction at the UES level (myotomy of the cricopharyngeus muscle and the upper 3 cm of the posterior esophageal wall) and excision or suspension of the diverticulum. For small diverticula (< 2 cm), the myotomy alone is sufficient. As an alternative to the conventional

▲ **Figure 20-6.** Pharyngoesophageal diverticulum (Zenker diverticulum).

surgical treatment, a transoral endoscopic approach (using staplers, laser or coagulation through an endoscope that ablate the septum between the diverticulum and the cervical esophagus) can be used for diverticula between 3 and 6 cm in size. If present, GER should be corrected before dividing the UES in order to avoid aspiration. The prognosis is excellent in about 90% of cases. Complications are rare and the patients are usually able to eat the day after the procedure.

2. Epiphrenic Diverticulum

ESSENTIALS OF DIAGNOSIS

- ▶ Dysphagia
- ▶ Regurgitation
- ▶ Diverticulum evident on barium swallow
- ▶ Esophageal motility disorder shown by esophageal manometry

▶ General Considerations

Epiphrenic diverticulum is located in the distal 10 cm of the esophagus. It is not a primary anatomic abnormality but rather the consequence of an underlying motility disorder of the esophagus that causes an outflow obstruction at the level of the gastroesophageal junction, with consequent increase in intraluminal pressure and progressive herniation of mucosa and submucosa through the esophageal muscle layers.

▶ Clinical Findings

A. Symptoms

The symptoms experienced by the patient are in part due to the underlying motility disorder (dysphagia, chest pain) and in part due to the diverticulum *per se* (regurgitation with the risk of aspiration). Some diverticula, however, can be asymptomatic.

B. Imaging Studies

A chest radiograph can show an air-fluid level in the posterior mediastinum. A barium swallow clearly shows the position and size of the diverticulum (Figure 20-7). Endoscopy is important to rule out an esophageal malignancy.

C. Special Tests

In the majority of cases, esophageal manometry shows the underlying motility disorder. Sometimes it is difficult to position the manometry catheter, and endoscopic or fluoroscopic guidance might be necessary.

▲ **Figure 20-7.** Epiphrenic diverticulum.

▶ Differential Diagnosis

A paraesophageal hernia can be confused with an epiphrenic diverticulum. The barium swallow and the endoscopy help in establishing the diagnosis.

▶ Treatment

The treatment is surgical, and the laparoscopic approach is preferred. It consists of: (1) resection of the diverticulum; (2) long myotomy—it is performed in the side of the esophagus opposite to where the diverticulum is located, it extends proximally to the upper border of the neck of the diverticulum and distally for about 2 cm onto the gastric wall; and (3) a partial fundoplication to prevent GER. A laparoscopic diverticulectomy, with myotomy and fundoplication, is successful in 80%-90% of cases.

ESOPHAGEAL MANIFESTATIONS IN SCLERODERMA & OTHER SYSTEMIC DISEASES

Scleroderma and several other systemic diseases may involve the esophagus. In scleroderma or progressive systemic sclerosis, there is involvement of the gastrointestinal tract in up to 90% of patients. The most common site of gastrointestinal involvement is the smooth muscle portion of the esophagus, where atrophy and fibrosis occur. The upper esophagus (striated muscle) and the UES are not involved. As a consequence, LES pressure is low and the peristalsis is weak (low amplitude or abnormal propagation of the peristaltic waves). These changes can be followed by an increased amount of GER with delayed clearance of the refluxed gastric contents. Esophageal symptoms usually appear in patients with the characteristic skin changes and Raynaud syndrome. In addition to heartburn and regurgitation, patients may have respiratory symptoms due to the upward extent of the gastric refluxate and aspiration. Dysphagia may be due to the abnormal peristalsis or to the presence of a peptic stricture. The diagnostic approach is similar to that of patients with GERD:

- A barium swallow may show a hiatal hernia or a stricture.
- Endoscopy shows esophagitis in 50%-60% of patients. Barrett esophagus (BE) is present in about 10% of patients.
- Esophageal manometry usually shows a hypotensive LES. Dysmotility is frequent and can progress to complete loss of peristalsis.
- Ambulatory pH monitoring is essential to establish the diagnosis. It can also measure the presence of acid in the proximal esophagus and pharynx in patients with cough or vocal cord problems.
- Gastric scintigraphy is indicated in patients who experience postprandial bloating and fullness to measure the gastric emptying of solids and liquids.

Similar esophageal changes may also occur in rheumatoid arthritis, Sjögren syndrome, Raynaud disease, and systemic lupus erythematosus. Similar motor abnormalities are occasionally seen in alcoholism, diabetes mellitus, myxedema, multiple sclerosis, and amyloidosis.

Medical management should always be tried first. A PPI is the drug of choice. If gastroparesis is present, a prokinetic medication such as metoclopramide should be added. A fundoplication should be considered particularly in patients with regurgitation, cough, or vocal cord problems.

GASTROESOPHAGEAL REFLUX DISEASE

ESSENTIALS OF DIAGNOSIS

- ▶ Heartburn
- ▶ Regurgitation
- ▶ Sliding hiatal hernia on barium swallow
- ▶ Esophagitis on endoscopy
- ▶ Abnormal esophageal motility on manometry
- ▶ Abnormal esophageal exposure on ambulatory pH monitoring

▶ General Considerations

GERD is the most common upper gastrointestinal disorder of the Western world and accounts for about 75% of esophageal diseases. Heartburn, usually considered synonymous with the presence of abnormal gastroesophageal reflux, is experienced by 20%-40% of the adult population of Western countries. However, because many symptomatic patients treat themselves with over-the-counter medications without consulting a physician, the prevalence of the disease is probably higher than reported. The incidence of reflux symptoms increases with age, and both sexes seem to be equally affected. Symptoms are more common during pregnancy, probably due to hormonal effects on the LES and the increased intra-abdominal pressure due to the enlarging uterus. Recent studies have demonstrated a link between obesity and GERD whereby the body mass index has a direct effect on the severity of reflux.

▶ Pathogenesis

GERD is caused by the abnormal retrograde flow of gastric contents into the esophagus, resulting in symptoms and mucosal damage. A defective LES is the most common cause of GERD. Transient LES relaxations account for the majority of reflux episodes in patients without mucosal damage or with mild esophagitis, while a short and hypotensive LES is more frequently found in patients with more severe esophagitis. In 40%-60% of patients with GERD, abnormalities of esophageal peristalsis are also present. Because esophageal

peristalsis is the main determinant of esophageal clearance (the ability of the esophagus to clear gastric contents refluxed through the LES), patients with abnormal esophageal peristalsis have more severe reflux and slower clearance. Therefore, these patients often have more severe mucosal injury and more frequent atypical symptoms such as cough or hoarseness. A hiatal hernia also contributes to the incompetence of the gastroesophageal junction by altering the anatomic relationship between the esophageal crus and the LES. As the gastroesophageal junction is displaced above the diaphragm, the pinchcock action of the esophageal crus is lost. In patients with large hiatal hernias, the LES is usually shorter and weaker, and the amount of reflux is greater.

► **Clinical Findings**

A. Symptoms

Heartburn, regurgitation, and dysphagia are considered typical symptoms of GERD; however, a clinical diagnosis of GERD based on these symptoms is correct in only 70% of patients (when compared with the results of pH monitoring). A good response to therapy with PPIs is a good predictor of the presence of abnormal reflux. GERD can also cause atypical symptoms such as cough, wheezing, chest pain, hoarseness, and dental erosions. Two mechanisms have been postulated for GERD-induced respiratory symptoms: (1) a vagal reflex arc resulting in bronchoconstriction and (2) microaspiration into the tracheobronchial tree. Ear, nose, and throat symptoms such as hoarseness or dental erosions are instead secondary to the upward extent of the acid with direct damage of the vocal cords or teeth.

B. Barium Swallow

A barium swallow provides information about the presence and size of a hiatal hernia, the presence and length of a stricture, and the length of the esophagus. This test, however, is not diagnostic of GERD, as a hiatal hernia or reflux of barium can be present in the absence of abnormal reflux.

C. Endoscopy

Fifty percent of patients with abnormal reflux do not have esophagitis on endoscopy. Therefore, endoscopy is useful for diagnosing complications of GERD such as esophagitis, BE, or a stricture. In addition, there is major interobserver variation among endoscopists for the low grades of esophagitis (Table 20–2).

D. Esophageal Manometry

This test provides information about the LES (resting pressure, length, and relaxation) and the quality of esophageal peristalsis. In addition, manometry is essential for proper placement of the pH probe for ambulatory pH monitoring (5 cm above the upper border of the LES).

Table 20–2. Endoscopic grading system for esophagitis.

Grade 1	Reddening of the mucosa without ulceration.
Grade 2	Linear ulcerations lined with granulation tissue that bleeds easily when touched.
Grade 3	Ulcerations have coalesced to leave islands of epithelium.
Grade 4	Stricture.

E. Ambulatory pH Monitoring

This test has a sensitivity and specificity of about 92% and is considered the gold standard for diagnosing GERD (Table 20–3). Medications that affect the production of acid by the parietal cells must be stopped 3 days (H₂-blocking agents) to 14 days (PPIs) prior to the study. Diet and exercise are unrestricted during the test in order to mimic a typical day of the patient’s life. This test should be performed: (1) in patients who do not respond to medical therapy, (2) in patients who relapse after discontinuation of medical therapy, (3) before antireflux surgery, or (4) when evaluating atypical symptoms such as cough, hoarseness, and chest pain. Because fewer than 50% of these patients with atypical symptoms experience heartburn or have esophagitis on endoscopy, a pH monitoring study becomes the only way to determine whether abnormal reflux is present, establishing a temporal link between episodes of reflux and symptoms. A pH probe with two sensors, located 5 and 20 cm above the LES, allows determination of the upward extent of the reflux. Tracings are analyzed for a temporal correlation between symptoms and episodes of reflux.

Table 20–3. Normal values for ambulatory 24-hour pH monitoring.

Percentage of total time pH < 4.0	4.5
Percentage of upright time pH < 4.0	8.4
Percentage of supine time pH < 4.0	3.5
Number of episodes of reflux < 4.0	47
Number of episodes > 5 minutes	3.5
Longest episode (minutes)	20
Composite score ¹	14.7

¹The composite score indicates the extent to which the patient’s values deviate from the normal means of the six variables. It allows one to express in a single figure the degree of the patient’s abnormality.

► Differential Diagnosis

Heartburn can be the presenting symptom of irritable bowel syndrome, achalasia, cholelithiasis, coronary artery disease, or psychiatric disorders. Esophageal manometry and pH monitoring are essential to determine with certainty if GERD is present and if reflux is the cause of the symptoms.

► Complications

Esophagitis is the most common complication. Peptic strictures are uncommon, particularly in the era of PPIs. BE is found in about 10%-15% of patients with reflux documented by pH monitoring. Some patients may eventually progress to high-grade dysplasia (HGD) and adenocarcinoma. Respiratory complications vary from chronic cough to asthma, aspiration pneumonia, and even pulmonary fibrosis. Vocal cord and dental damage can also occur.

► Treatment

A. Lifestyle Modifications

Patients should eat frequent small meals during the day (to avoid gastric distention), avoiding fatty foods, spicy foods, and chocolate, as they lower LES pressure. The last meal should be no less than 2 hours before going to bed. In order to increase the effect of gravity, the head of the bed should be elevated over 4- to 6-inch blocks.

B. Medical Therapy

Antacids are useful for patients with mild intermittent heartburn. Acid-suppressing medications are the mainstay of medical therapy. H_2 -blocking agents are usually prescribed for patients with mild symptoms or mild esophagitis. PPIs are superior to H_2 -blocking agents because they determine a more profound control of the acid secretion, with healing of esophagitis in 80%-90% of patients. However, symptoms and esophagitis tend to recur in the majority of patients after discontinuation of therapy, so most patients need chronic maintenance therapy. In addition, about 50% of patients on maintenance PPIs require increasing doses to maintain healing of esophagitis. Acid-suppressing medications only alter the pH of the gastric refluxate, but reflux and aspiration can still occur because of an incompetent LES and ineffective esophageal peristalsis. Moreover, medical therapy is largely ineffective for the treatment of the extraesophageal manifestations of GERD due to the upward extension of the refluxate. PPIs can interfere with calcium absorption causing osteoporosis and fractures. In addition, PPIs can cause *Clostridium difficile* infection, delay in gastric emptying and abnormal cardiac activity due to decreased magnesium levels.

C. Surgical Therapy

The ideal patient for antireflux surgery is the one in whom ambulatory pH monitoring shows abnormal GER and whose heartburn is well controlled by PPIs. A careful selection of patients for surgery is mandatory. The operation is indicated in: (1) young patients who require chronic therapy with PPIs for control of symptoms, (2) patients in whom regurgitation persists during therapy, (3) patients with respiratory symptoms (cough, asthma, aspiration pneumonia, and pulmonary fibrosis), (4) patients with vocal cord damage, and (5) patients with BE. Recent evidence suggests that an effective antireflux operation may promote regression of the columnar epithelium in up to 50% of patients who have a short segment of BE (< 3 cm). In addition, it may arrest the progression from metaplasia to dysplasia. However, since the response to therapy is unpredictable, endoscopic surveillance after laparoscopic fundoplication in patients with BE is recommended.

The goal of surgical therapy is to restore the competence of the LES. A laparoscopic Nissen fundoplication (360°) is considered today the procedure of choice (Figure 20-8) because it increases the resting pressure and length of the LES, decreases the number of transient LES relaxations and improves quality of esophageal peristalsis. The operation is equally safe and effective in young and elderly patients.

The success of the operation is based on the following technical elements:

1. Dissection of the esophagus in the posterior mediastinum to allow 3-4 cm of esophagus to lie without tension below the diaphragm. By bringing the entire stomach and gastroesophageal junction below the diaphragm, a sliding hiatal hernia is reduced.

▲ Figure 20-8. Nissen fundoplication (360°).

2. Division of the short gastric vessels in order to create a “floppy” fundoplication.
3. Approximation of the esophageal crus to decrease the size of the esophageal hiatus, thereby avoiding herniation of the wrap.
4. Construction of a 360° fundoplication over a 56-60 French bougie.

The hospital stay is short (usually 1-2 days), and the postoperative discomfort is minimal. Most patients return to work within 2-3 weeks. Control of symptoms is obtained in about 80%-90% of patients at 10 years after a fundoplication. Failures are treated with either medications or a second operation.

► General Considerations

BE is defined as a change in the esophageal mucosa with replacement of the squamous epithelium by columnar epithelium. About 10%-12% of patients undergoing endoscopy for symptoms of GERD are found to have BE, classified in short segment (< 3 cm in length) or long segment (3 cm or longer). Metaplasia may progress to high-grade dysplasia (HGD) and eventually adenocarcinoma. Thus, adenocarcinoma represents the final step of a sequence of events in which a benign disease (GERD) evolves into a preneoplastic disease and eventually into cancer.

► Pathogenesis

BE is due to reflux of gastric contents (acid and duodenal juice) into the esophagus. When compared to patients with GERD with no mucosal injury or less severe esophagitis, patients with BE have a shorter and weaker LES and decreased amplitude of esophageal peristalsis. As a consequence, the amount of reflux is greater and esophageal clearance is slower. In addition, hiatal hernia is more common in patients with Barrett metaplasia.

► Clinical Findings

A. Symptoms

Patients with BE typically have a long history of GERD. While most patients experience both typical and atypical symptoms of GERD, others may become asymptomatic over time due to the decreased sensitivity of the metaplastic epithelium.

B. Imaging Studies

Barium swallow may show ulcerations, a stricture, or a hiatal hernia. Endoscopy shows presence of “salmon pink” epithelium above the gastroesophageal junction, replacing the whitish squamous epithelium. The diagnosis is confirmed by pathologic examination of the esophageal mucosa and requires the identification of goblet cells, typical for intestinal epithelium.

C. Special Tests

Esophageal manometry often shows a short and hypotensive LES and abnormal esophageal peristalsis (decreased amplitude of peristaltic waves, simultaneous waves). Ambulatory pH monitoring usually shows a severe amount of acid reflux. Esophageal exposure to duodenal juice can be quantified by a fiberoptic probe that measures intraluminal bilirubin as a marker for duodenal reflux. In GERD patients, the prevalence of esophageal bilirubin exposure parallels the degree of mucosal injury, being higher in patients with BE. Nonacid reflux can be measured by impedance-pH monitoring.

BARRETT ESOPHAGUS

ESSENTIALS OF DIAGNOSIS

- GERD symptoms (typical and atypical)
- Endoscopic evidence of “salmon pink” epithelium above gastroesophageal junction
- Specialized columnar epithelium on esophageal biopsy

► Treatment

A. Barrett Esophagus: Metaplasia

The treatment options are similar to those of patients with GERD without metaplasia and consist of either PPIs or a fundoplication. A surgical approach might offer an advantage over medical therapy for the following reasons:

1. Successful elimination of reflux symptoms with PPIs does not guarantee control of an acid reflux. When pH monitoring is performed in asymptomatic BE patients treated with these medications, up to 80% of them still have abnormal acid reflux.
2. PPIs do not eliminate the reflux of bile, a major contributor to the pathogenesis of BE. In contrast, an antireflux operation prevents any form of reflux by restoring the competence of the gastroesophageal junction.
3. A fundoplication may promote regression of the columnar epithelium. Many studies have shown that regression occurs in 15%-50% of patients when the length of the BE segment is less than 3 cm. Regardless of the effect of the fundoplication on symptoms, surveillance endoscopy should be performed every 12-24 months.

B. Barrett Esophagus: Low-Grade Dysplasia

Patients with low-grade dysplasia (LGD) should be treated for 1-2 months with high doses of PPIs (3-4 pills/d), and subsequently the endoscopy should be repeated with multiple biopsies. The rationale for this approach is to decrease the mucosal inflammation by blocking acid secretion, allowing the pathologist a more accurate reading. If the repeated biopsies show metaplasia or HGD, the patient will be treated accordingly. If LGD is confirmed, the patient can continue taking acid-reducing medications or have a laparoscopic fundoplication with ablation of the dysplastic epithelium. Although there is evidence that regression to metaplasia or even disappearance of the columnar epithelium can occur after a successful fundoplication, endoscopic surveillance should be performed every 6-12 months, because of the higher risk of developing esophageal cancer in these patients compared to patients with non-dysplastic BE.

C. Barrett Esophagus: High-Grade Dysplasia

When HGD is found and confirmed by two experienced pathologists, two treatment options are available:

1. Patients can enroll in a program of strict endoscopic surveillance, with endoscopy performed every 3 months and 4-quadrant biopsies obtained for every centimeter of BE. The goal is to detect cancer as soon as it develops but before it becomes invasive and spreads to lymph nodes: the risk of lymph node metastasis is about 20%-30% in patients with submucosal invasive carcinoma

(pT1b). Progression from HGD to cancer occurs in about 50% of patients 5 years after the initial diagnosis is established. This approach is reasonable if the patient is willing to undergo endoscopy every 3 months but unwilling to have an esophagectomy or if severe comorbidities are present.

2. For young and medically fit patients who are unwilling to undergo endoscopy every 3 months, an esophagectomy should be considered. The rationale for an operation is based on the following considerations: (a) cancer is already found in about 30% of patients thought to have HGD; (b) cancer develops in about 50% of patients during follow-up; (c) recent studies have shown that in specialized centers the operation can be performed with minimal morbidity and mortality, and postoperative quality of life similar to that of the general population; and (d) because the prognosis depends on the pathologic staging, waiting exposes patients to the risk of development of invasive cancer with lymph node metastases.

Esophagectomy remains the treatment of choice when: (1) endoscopic expertise is not available; (2) preoperative staging by endoscopic ultrasound is greater than T1aN0; (3) lymph node involvement is shown; (4) patients can not have a rigid follow-up; (5) multi focal dysplasia is present in a long segment; (6) complete eradication is not possible.

D. Endoscopic Treatment Modalities

Because either acid-reducing medications or a fundoplication determine regression in some patients with a short segment only, and because there is no evidence that they block progression to cancer, different modalities have been developed for the endoscopic treatment of the BE. Endoscopic resection is the basis of endoscopic therapy for BE and has been advocated not only as a therapeutic approach but also as a staging tool. The major advantage of the resection is the ability to provide samples of appropriate size and depth for an accurate histopathological diagnosis. Endoscopic Mucosal Resection (EMR) is curative in HGD and T1a lesions, with 5-year survival rates of 98%-100%.

Ablative therapies destroy the BE epithelium allowing replacement with neo-squamous epithelium. Photodynamic therapy is based on the administration of a photosensitizing drug, which is retained in the BE. Light of proper wavelength is then delivered endoscopically, producing an oxidative reaction with complete destruction of the abnormal mucosa in about 50% of patients. This technique, however, is associated with the development of esophageal strictures in about 30% of patients. In addition, islands of columnar epithelium can still be present under the regenerated squamous epithelium. The radio frequency ablation (RFA) seems to avoid these problems and is effective in about 70% of patients.

HIATAL HERNIA

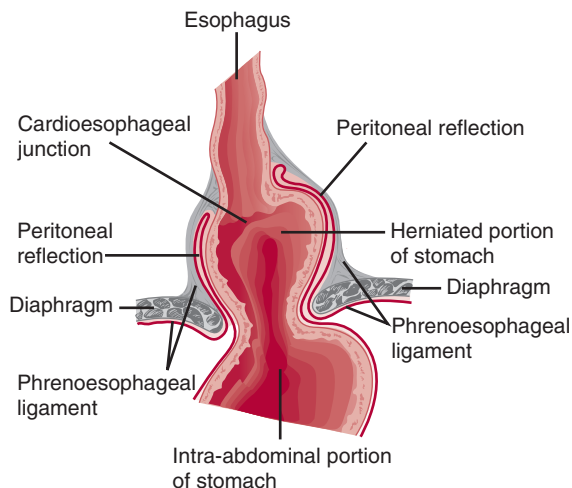

ESSENTIALS OF DIAGNOSIS

- ▶ May be asymptomatic
- ▶ Symptoms secondary to mechanical obstruction: dysphagia, epigastric discomfort, anemia
- ▶ Symptoms secondary to gastroesophageal reflux: heartburn, regurgitation

▶ General Considerations

Obesity, aging, and general weakening of the musculo-fascial structures set the stage for enlargement of the esophageal hiatus and herniation of the stomach into the posterior mediastinum. Hiatal hernias are divided into sliding hiatal hernias (type 1) (Figures 20-9 and 20-10) and paraesophageal hiatal hernias (types 2, 3, or 4) (Figures 20-11 and 20-12). The most common (95%) is the sliding hernia, where the gastroesophageal junction moves above the diaphragm together with some or the entire stomach. Type 2 hernias are characterized by herniation of the gastric fundus into the mediastinum alongside the esophagus, with the gastroesophageal junction remaining in an intra-abdominal position. Since the gastroesophageal sphincteric mechanism functions normally in most of these cases, reflux of gastric contents is uncommon. Type 3 hernias, also called mixed hernias, involve herniation of the stomach with the gastroesophageal junction into the mediastinum. In types 1 and 3, symptoms due to GER may occur along with symptoms secondary to the mechanical obstruction.

▲ **Figure 20-9.** Sliding esophageal hiatal hernia.

Finally, the rare type 4 hernias are characterized by an intrathoracic stomach along with associated viscera such as the spleen, colon, small bowel, or pancreas.

▶ Clinical Findings

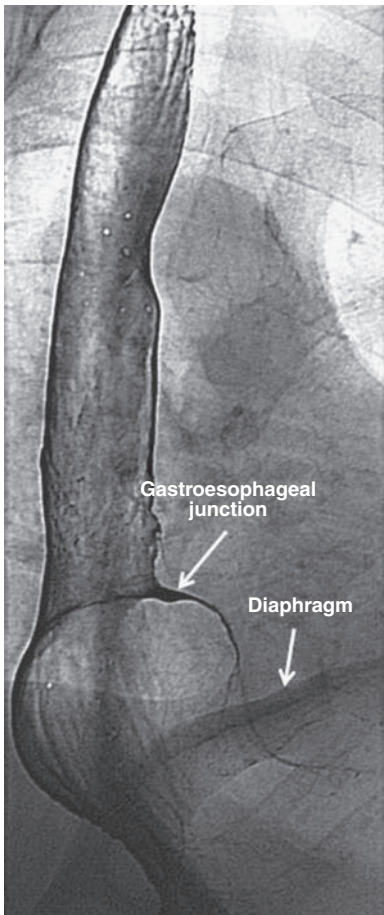

Small hiatal hernias are in most cases asymptomatic, while large hiatal hernias may cause a wide variety of symptoms such as epigastric discomfort, chest pain, postprandial bloating, dysphagia, or respiratory problems (asthma, cough, or dyspnea caused by chronic aspiration). Anemia is secondary to gastric erosions, and it can be the only presenting symptom. In addition, patients may experience symptoms due to GER.

▶ Diagnosis

A barium swallow will delineate the anatomy and the type of hiatal hernia. Endoscopy is important to determine if gastric or esophageal inflammation is present and to rule out cancer. If reflux symptoms are present, manometry and pH monitoring should be performed.

▶ Complications

The most frequent complications of paraesophageal hernia are hemorrhage, incarceration, obstruction, and strangulation. The herniated portion of the stomach often becomes congested, and bleeding occurs from erosions of the mucosa. Obstruction may occur, most often at the esophagogastric junction as a result of torsion and angulation at this point—especially if a large portion (or all) of the stomach herniates into the chest. In paraesophageal hiatal hernia—in contrast to the sliding type—other viscera such as the small and large intestines and spleen may also enter the mediastinum along with the stomach.

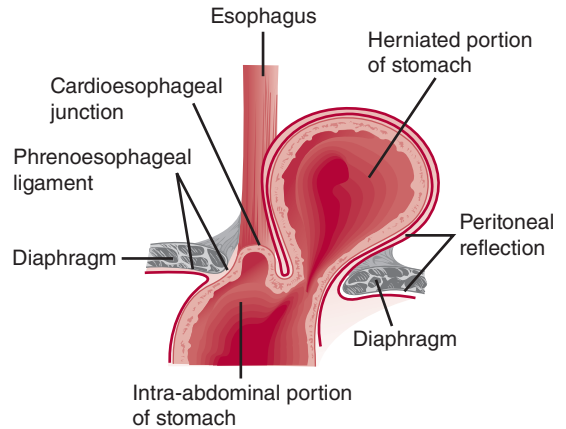

▲ **Figure 20-10.** Large sliding hiatal hernia. Diaphragmatic hiatus is circled.

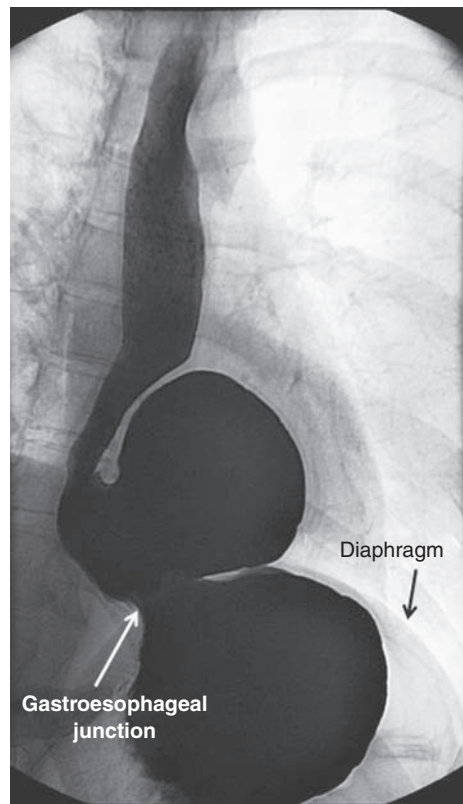

► Treatment

Operative repair is indicated in symptomatic patients. The usual method is to return the herniated stomach below the diaphragm into the abdomen, repair the enlarged esophageal hiatus, and then add a fundoplication. In most cases, the operation can be performed laparoscopically. The results of surgical management are excellent in about 90% of patients.

▲ **Figure 20-12.** Paraesophageal hernia. Note that the cardioesophageal junction remains in its normal anatomic position below the diaphragm.

TUMORS OF THE ESOPHAGUS

1. Benign Tumors of the Esophagus

ESSENTIALS OF DIAGNOSIS

- ▶ Dysphagia, epigastric discomfort
- ▶ Radiographic demonstration of a smooth filling defect within the esophageal lumen

▶ General Considerations

Esophageal leiomyomas are the most common benign tumors of the esophagus. They represent 10% of all gastrointestinal leiomyomas. They originate in the smooth muscle layers, mostly in the lower two-thirds of the esophagus, and they narrow the esophageal lumen. These tumors consist of smooth muscle cells surrounded by a capsule of fibrous tissue. The mucosa overlying the tumor is generally intact, but occasionally it may become ulcerated as a result of pressure necrosis by an enlarging lesion. Leiomyomas are not associated with the development of cancer. Other tumors such as fibromas, lipomas, fibromyomas, and myxomas are rare. Congenital cysts or duplications of the esophagus (the second-most common benign lesion after leiomyomas) may occur at any level, although they are most common in the lower esophagus.

▶ Clinical Findings

Many benign lesions are asymptomatic and are discovered incidentally during the upper gastrointestinal fluoroscopic examination. Benign tumors or cysts grow slowly and become symptomatic only after reaching a size of 5 cm or more. On barium swallow, leiomyomas appear as a smooth filling defect within the esophageal lumen (Figure 20–13). An intraluminal mass covered by normal mucosa can be easily recognized during endoscopy, but biopsies should not be taken because they may make subsequent enucleation of the tumor more difficult. Endoscopic ultrasound and chest CT help in the characterization of the tumor and in the differential diagnosis.

▶ Differential Diagnosis

Leiomyomas, cysts, and duplications can be distinguished from cancer by their classic radiographic appearance. Intraluminal papillomas, polyps, or granulomas may be indistinguishable radiographically from early carcinoma, so their exact nature must be confirmed histologically.

▶ Treatment

Small polypoid intraluminal lesions may be removed endoscopically. The treatment of choice for symptomatic

▲ **Figure 20–13.** Leiomyoma of esophagus. Note smooth, rounded density causing extrinsic compression of esophageal lumen.

leiomyomas is enucleation. While in the past a thoracotomy or a laparotomy was used, today enucleation can be accomplished by either a thoracoscopic or a laparoscopic approach.

2. Carcinoma of the Esophagus

ESSENTIALS OF DIAGNOSIS

- ▶ Progressive dysphagia, initially for solids and later for liquids.
- ▶ Progressive weight loss.
- ▶ Diagnosis established by endoscopy and biopsies.
- ▶ Staging established by endoscopic ultrasound, computed tomography of chest and abdomen, and positron emission tomography. Bronchoscopy indicated for cancer of the midthoracic esophagus.

► General Considerations

The epidemiology of esophageal cancer in the United States has changed considerably during the last 30 years. In the 1970s, squamous cell carcinoma was the most common type of esophageal cancer, accounting for about 90% of the total cases. It was located in the thoracic esophagus and affected mostly black men. Over the past three decades, there has been a progressive increase in the incidence of adenocarcinoma of the distal esophagus and gastroesophageal junction, so that today it accounts for more than 70% of all new cases of esophageal cancer. It is more frequent in white men with GERD and it is linked to BE.

► Pathogenesis

The most common contributing factors for squamous cell carcinoma are cigarette smoking and chronic alcohol exposure. Chronic ingestion of hot liquids or foods, poor oral hygiene, and nutritional deficiencies may play a role. Certain medical conditions such as achalasia, caustic injuries of the esophagus, and Plummer–Vinson syndrome are associated with an increased incidence of squamous cell cancer. GERD is the most common predisposing factor for adenocarcinoma of the esophagus, where adenocarcinoma represents the last event of a sequence that starts with GERD and progresses to metaplasia, HGD, and cancer. Esophageal cancer arises in the mucosa and subsequently invades the submucosa and the muscle layers. Ultimately, structures located next to the esophagus may be infiltrated (tracheobronchial tree, aorta, recurrent laryngeal nerve). At the same time, the tumor tends to metastasize to the lymph nodes (mediastinal, celiac, cervical) and to the liver, lungs, peritoneum, adrenals, and bones.

► Clinical Findings

A. Symptoms

Early esophageal cancer may be asymptomatic. As the cancer grows, dysphagia is the most common symptom. It is initially for solids but eventually it progresses to liquids. Weight loss occurs in more than 50% of patients. Patients can have pain when swallowing. Pain over bony structures may be due to metastases. Hoarseness is usually due to invasion of the right or left recurrent laryngeal nerves with paralysis of the ipsilateral vocal cord. Respiratory symptoms may be due to regurgitation and aspiration of undigested food or to invasion of the tracheobronchial tree, with development of a tracheoesophageal fistula.

B. Imaging Studies

Barium swallow shows the location and the extent of the tumor. Esophageal cancer usually presents as an irregular intraluminal mass or a stricture (Figure 20–14). Endoscopy allows direct visualization and biopsies of

▲ **Figure 20–14.** Barium swallow demonstrating a distal esophageal carcinoma.

the tumor. For tumors of the upper and midesophagus, bronchoscopy is indicated to rule out invasion of the tracheobronchial tree.

C. Special Tests

After the diagnosis is established, it is important to determine the staging of the cancer (Table 20–4). Abdominal and chest CT scans and PET are useful to detect distant metastases and invasion of structures next to the esophagus. Endoscopic ultrasound is the most sensitive test to determine the depth of penetration by the tumor, the presence of enlarged periesophageal lymph nodes, and invasion of structures next to the esophagus. Furthermore, it allows a fine-needle aspiration of enlarged periesophageal lymph nodes. A bone scan is indicated in patients with new onset of bone pain.

► Differential Diagnosis

The differential diagnosis includes peptic strictures due to reflux, achalasia, and benign esophageal tumors.

Table 20–4. AAJCC Staging System (ptnm) of Esophageal Cancer

Primary Tumor (T)	
Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ/high-grade dysplasia
T1	Tumor invades lamina propria, muscularis mucosae, or submucosa
T1a	Tumor invades lamina propria or muscularis mucosae
T1b	Tumor invades submucosa
T2	Tumor invades muscularis propria
T3	Tumor invades adventitia
T4	Tumor invades adjacent structures
T4a	Resectable tumor invading pleura, pericardium or diaphragm
T4b	Unresectable tumor invading other adjacent structures, eg, aorta, vertebral body, trachea
Regional Lymph Nodes (N)	
Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	1-2 regional lymph nodes involved
N2	3-6 regional lymph nodes involved
N3	7 or more regional lymph nodes involved
Distant Metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis

► Treatment

Treatment is based on the stage of the cancer. In patients with early esophageal cancer (pT1a), an esophagectomy can be avoided, because of the very low risk of lymph nodes metastasis (0%-3%), and EMR and RFA are very effective. However, patients need to undergo a very strict endoscopic follow-up to detect possible early recurrence.

Patients with invasive esophageal cancer (T1b and T2) are considered candidates for esophagectomy if the following criteria are met: (1) no evidence of spread of the tumor to structures next to the esophagus such as the tracheobronchial tree, the aorta, or the recurrent laryngeal nerve; (2) no evidence of distant metastases; (3) the patient is fit from a cardiac and respiratory point of view. An esophagectomy can be performed by using an abdominal and a cervical incision (with blunt dissection of the thoracic esophagus

through the esophageal hiatus; *transhiatal esophagectomy*) or by using an abdominal and a right chest incision (*trans-thoracic esophagectomy*). After removal of the esophagus, continuity of the gastrointestinal tract is reestablished by using either the stomach or the colon. The transhiatal esophagectomy offers the advantage of avoiding the chest incision, with decreased compromise of lung function and decreased postoperative discomfort. The validity of the trans-hiatal esophagectomy as a cancer operation was initially questioned because part of the operation is not done under direct vision and because of the small number of resected lymph nodes. However, many retrospective studies and prospective randomized trials have shown no difference in survival between the two operations, suggesting that it is not the type of operation that influences survival but rather the stage of the disease at the time the operation is performed. The morbidity rate of the operation is around 30%, and it is mostly due to cardiac (arrhythmias), respiratory (atelectasis, pleural effusion), and septic complications (anastomotic leak, pneumonia). The mortality rate in specialized and “high volume” centers is less than 5%. These results are due to the presence of an experienced team composed of surgeons, anesthesiologists, intensivists, cardiologists, radiologists, and nurses.

The best treatment for patients with locally advanced cancer (T3-4N0-3, T2-N1-3) includes a combination of radiotherapy and chemotherapy used in order to improve local (radiotherapy) and distant control of the disease (chemotherapy), followed by surgery. Overall, it seems that the combination of neoadjuvant therapy followed by surgery offers the best survival benefit. This is particularly true in the subgroup of patients (about 20%) who have a “complete pathologic response” (no tumor found in the specimen).

Nonoperative therapy is reserved for patients who are not candidates for surgery because of local invasion of the tumor, metastases, or a poor functional status. The goal of therapy in these patients is palliation of the dysphagia. The following treatment modalities are available to achieve this goal:

1. Expandable, coated, metallic stents can be deployed by endoscopy under fluoroscopic guidance in order to keep the esophageal lumen open. They are particularly useful when a tracheoesophageal fistula is present.
2. Laser therapy (Nd:YAG laser) relieves dysphagia in up to 70% of patients. However, multiple sessions are usually required to keep the esophageal lumen open.
3. Radiation therapy is successful in relieving dysphagia in about 50% of patients.

The stage of the disease is the most important prognostic factor. Overall 5-year survival for esophageal cancer remains around 25%.

OTHER SURGICAL DISORDERS OF THE ESOPHAGUS

PERFORATION OF THE ESOPHAGUS

ESSENTIALS OF DIAGNOSIS

- ▶ History of recent instrumentation of the esophagus or severe vomiting
- ▶ Pain in the neck, chest, or upper abdomen
- ▶ Signs of mediastinal or thoracic sepsis within 24 hours
- ▶ Radiographic evidence of an esophageal leak

▶ General Considerations

Esophageal perforations can result from iatrogenic instrumentation (eg, endoscopy, balloon dilation), severe vomiting, external trauma, and other rare causes. The subsequent clinical manifestations are influenced by the site of the perforation (ie, cervical or thoracic) and, in the case of thoracic perforations, whether or not the mediastinal pleura has been ruptured. Morbidity resulting from esophageal perforation is principally due to infection. Immediately after injury, the tissues are contaminated by esophageal contents, but infection has not become established; surgical closure of the defect will usually prevent the development of serious infection. If more than 24 hours have elapsed since the time

of injury, severe contamination has occurred. At this time, the esophageal defect usually breaks down if it is surgically closed, and measures to treat mediastinitis and empyema may not be adequate to avoid a fatal outcome. Although serious infection usually occurs if surgical repair is delayed, a few cases of minor instrumental perforations can be managed by antibiotics without operation.

A. Instrumental Perforations

Medical instrumentation is the most common cause of esophageal perforation (diagnostic or therapeutic endoscopy). Instrumental perforations are most likely to occur in the cervical esophagus. The endoscope may press the posterior wall of the esophagus against osteoarthritic spurs of the cervical vertebrae, causing contusion or laceration. The cricopharyngeal area is the most common site of injury. Perforations of the thoracic esophagus may occur at any level but are most common at the natural sites of narrowing, at the level of the left main stem bronchus and at the diaphragmatic hiatus. Perforations during pneumatic dilatation for achalasia (2%-6%) occur proximal to the gastroesophageal junction.

B. Spontaneous (Postemetic) Perforation (Boerhaave Syndrome)

Spontaneous perforation usually occurs in the absence of preexisting esophageal disease, but 10% of patients have reflux esophagitis, esophageal diverticulum, or carcinoma. Most cases follow a bout of heavy eating and drinking. The perforation most frequently occurs in the left posterolateral wall, 3-5 cm above the gastroesophageal junction. The tear results from excessive intraluminal pressure, usually caused by violent retching and vomiting. Some cases have also been associated with childbirth, defecation, convulsions, heavy lifting, and forceful swallowing. The overlying pleura are also torn, so both the mediastinum and the pleural cavity are contaminated with esophageal contents. The second-most common site of perforation is at the midthoracic esophagus, on the right side at the level of the azygous vein.

▶ Clinical Findings

A. Signs and Symptoms

The principal early manifestation is pain, which is felt in the neck with cervical perforations and in the chest or upper abdomen with perforations of the thoracic esophagus. The pain may radiate to the back. With cervical perforations, pain is followed by crepitus in the neck, dysphagia, and signs of infection. Perforations of the thoracic esophagus, which communicate with the pleural cavity in about 75% of cases, are usually accompanied by tachycardia, tachypnea, dyspnea, and the early development of hypotension. With perforation into the chest, pneumothorax is

produced, followed by hydrothorax and, if not promptly treated, empyema. The left chest is involved in 70% and the right chest in 20%; involvement is bilateral in 10%. Escape of air into the mediastinum may result in a “mediastinal crunch,” which is produced by the heart beating against air-filled tissues (Hamman sign). If the pleura remain intact, mediastinal emphysema appears more rapidly, and pleural effusion is slow to develop.

B. Imaging Studies

X-ray studies are important to demonstrate that perforation has occurred and to locate the site of the injury. In perforations of the cervical esophagus, x-rays show air in the soft tissues, especially along the cervical spine. The trachea may be displaced anteriorly by air and fluid. Later, widening of the superior mediastinum may be seen. With thoracic perforations, mediastinal widening and pleural effusion with or without pneumothorax are the usual findings. An esophagogram using water-soluble contrast medium should be performed promptly in every patient suspected of having an esophageal perforation (Figure 20–15). If a leak is not seen, the examination should be repeated using barium. A CT scan of the chest is also useful to localize the perforation and eventually to drain mediastinal fluid collections.

▲ **Figure 20–15.** Extravasation of contrast material through instrumental perforation of upper thoracic esophagus. Note loculi of air and fluid anterior to esophagus, indicating that mediastinitis has already developed.

C. Special Studies

Thoracentesis will reveal cloudy or purulent fluid, depending on how much time has passed since the time of perforation. The amylase content of the fluid is elevated, and serum amylase levels may also be high as a result of absorption of amylase from the pleural cavity.

► Treatment

Broad-spectrum antibiotics should be given immediately. The infection is usually polymicrobial with *Staphylococcus*, *Streptococcus*, *Pseudomonas*, and *Bacteroides*. Early operation is appropriate for all but a few cases, and every effort should be made to operate before the perforation is 24 hours old. For lesions treated within this time limit, the operation should consist of closure of the perforation and external drainage. External drainage alone may suffice for small cervical perforations, which may be difficult to find. Patients with achalasia in whom perforation has resulted from balloon dilation should have the tear in the esophagus repaired and a Heller myotomy performed on the opposite side of the esophagus. Definitive therapy (eg, resection) should also be performed in patients with other surgical conditions, such as esophageal carcinoma.

Primary repair has a high failure rate if the perforation is older than 24 hours. The classic recommendation in this situation has been to isolate the perforation (ie, to minimize further contamination) by performing a temporary cervical esophagostomy, ligating the esophagus just proximal to the gastroesophageal junction, and placing a feeding jejunostomy for enteral nutrition. Alternatively, the segment of esophagus where the perforation is located can be resected, bringing the proximal end of esophagus out through the neck and closing the distal end. The mediastinum is drained, and a feeding jejunostomy is created. Later, the esophagostomy is taken down, and stomach or colon interposed to bridge the gap. Blunt esophagectomy may be feasible as emergency treatment of instrumental perforation in a patient with lye stricture.

Nonoperative management consisting of antibiotics alone may be all that is necessary in a few selected cases of instrumental perforation. This approach should be confined to patients without thoracic involvement (eg, pneumothorax or hydrothorax) whose esophagogram demonstrates just a short extraluminal sinus tract without wide mediastinal spread (ie, the contamination is limited) and who have no systemic signs of sepsis (eg, hypotension and tachypnea). Recently, esophageal stents have been placed for the treatment of iatrogenic, intrathoracic esophageal perforations.

The survival rate is 90% when surgical treatment is accomplished within 24 hours. The rate drops to about 50% when treatment is delayed.

INGESTED FOREIGN OBJECTS

Most cases of ingested foreign objects occur in children who swallow coins or other small objects. In adults, the problem most often consists of esophageal meat impaction or, less commonly, lodged bones or toothpicks. Dentures and esophageal disease, such as a benign stricture, are the principal predisposing factors in adults. Prisoners and mentally ill persons occasionally swallow foreign objects intentionally.

About 90% of swallowed foreign objects pass into the stomach and from there into the intestine and are eventually passed without problems. Ten percent hang up in the esophagus. If they traverse the esophagus, objects whose dimensions exceed 2-5 cm tend to remain in the stomach. Ten percent of ingested foreign objects require endoscopic removal, and 1% requires surgery. About 10% of ingested foreign objects enter the tracheobronchial tree.

The patient's history usually defines the problem adequately. The patient with a foreign object in the esophagus may or may not experience dysphagia or chest pain.

► Specific Kinds of Ingested Foreign Objects

A. Coins

Pennies and dimes usually pass into the stomach, but larger coins will lodge in the esophagus at or just beyond the cricopharyngeus. It is important to know if a swallowed coin has remained in the esophagus, and whether or not the patient has symptoms is an unreliable basis for making the determination. Therefore, anteroposterior and lateral chest x-rays should be obtained to determine whether the coin is in the esophagus or trachea. Small children should be x-rayed from the base of the skull to the anus in order to find any additional coins in the gut.

Coins in the esophagus should be removed promptly, since complications may occur if treatment delay exceeds 24 hours. The procedure is best accomplished with a grasping forceps passed through a flexible endoscope. Sedation is adequate for older children or adults, but general endotracheal anesthesia is required in order to protect the airway of infants and young children. A smooth foreign body too large to grasp with a forceps can be removed by passing a dilating balloon beyond it and then withdrawing the endoscope and balloon as a unit. If the object is small enough (< 20 mm), it may be pushed into the stomach.

Once a coin has passed into the stomach, it can be observed by periodic x-rays for as long as a month before the conclusion is reached that spontaneous elimination is unlikely and endoscopic removal is indicated.

B. Meat Impaction

Meat is the most common foreign object that lodges in the esophagus of adults, and many affected patients have underlying esophageal disease. The site of meat impaction is usually at the cricopharyngeus muscle or in the distal esophagus in patients with achalasia, diffuse esophageal spasm, or a stricture.

No x-rays (especially barium studies) are indicated, for they make the endoscopist's task more difficult. If obstruction is complete and the patient cannot handle saliva, endoscopy should be performed as an emergency to prevent aspiration. If the clinical findings are minor, however, endoscopy can be postponed for up to 12 hours to see whether the food will pass spontaneously.

Meat can usually be removed as a single piece using a polypectomy snare passed through a flexible endoscope. In some cases, a meat bolus can be pushed into the stomach, which is safe so long as it passes with minimal pressure. After the esophagus has been cleared, it should be checked endoscopically for underlying disease. An esophageal stricture should be dilated if the esophageal wall is not acutely inflamed as a result of the meat impaction.

C. Sharp and Pointed Objects

Bones, safety pins, hat pins, razor blades, toothpicks, nails, and many others constitute this group of foreign objects. The general principles of management are: (1) to remove these objects endoscopically by grasping and pulling a blunt side (eg, the hinge of an open safety pin) with forceps, (2) to remove a piece of glass or a razor blade by pulling it into the lumen of a rigid esophagoscope, or (3) to operate if neither of these methods appears to be safe. Sharp or pointed objects in the stomach should be removed surgically, since 25% of them will perforate the intestine, usually near the ileocecal valve, if they exit the pylorus.

D. Button Batteries

These small batteries are swallowed by children, just like coins, but unlike coins, they are highly corrosive and should be removed urgently before a serious complication such as an esophagotracheal or esophagoaortic fistula develops.

E. Cocaine Packets

Cocaine smugglers may swallow small packets of cocaine in balloons or condoms. Rupture of just one of these packets can be fatal, so attempts at endoscopic removal are unsafe.

If it appears that the packets will pass spontaneously, the patient may be watched; otherwise, surgical removal is indicated.

CAUSTIC INJURIES OF THE ESOPHAGUS

ESSENTIALS OF DIAGNOSIS

- ▶ History of ingestion of caustic liquids or solids
- ▶ Burns of the lips, mouth, tongue, and oropharynx
- ▶ Chest pain and dysphagia

▶ General Considerations

Ingestion of strong solutions of acid or alkali or of solid substances of similar nature produces extensive chemical burns. The injury usually represents a suicide attempt in adults and accidental ingestion in children. Strong alkali produces “liquefaction necrosis,” which involves dissolution of protein and collagen, saponification of fats, dehydration of tissues, thrombosis of blood vessels, and deep penetrating injuries. Acids produce a “coagulation necrosis” involving eschar formation, which tends to shield the deeper tissues from injury. Depending on the concentration and the length of time the irritant remains in contact with the mucosa, sloughing of the mucous membrane, edema and inflammation of the submucosa, infection, perforation, and mediastinitis may develop.

Ingested lye in solid form tends to adhere to the mucosa of the pharynx and proximal esophagus. Severe acute esophageal necrosis is rare, and the main clinical problems are early edema and late stricture formation, principally of the proximal esophagus. Liquid caustics commonly produce much more extensive esophageal necrosis, and occasionally even tracheoesophageal and esophagoaortic fistulas. If the patient survives the acute phase, a lengthy nondilatable stricture often develops.

Ingestion of strong acid characteristically produces great injury to the stomach, with the esophagus remaining intact in over 80% of cases. The result may be immediate gastric necrosis or late antral stenosis.

Nearly all severe injuries are caused by strong alkali. Weak alkali and acid are associated with less extensive lesions.

▶ Clinical Findings

A. Symptoms and Signs

Systemic symptoms roughly parallel the severity of the caustic burn. The most common finding is inflammatory edema of the lips, mouth, tongue, and oropharynx; in the absence of visible injury in this area, severe esophageal damage is rare. Patients with serious esophageal burns often experience chest pain and dysphagia and drooling of large amounts of saliva. Pain on swallowing may be intense. If the damage is severe, the patient often appears toxic, with high fever, prostration, and shock. The absence of toxicity does not rule out severe injury. Tracheobronchitis accompanied by coughing and increased bronchial secretions is frequently noted. Stridor may be present, and in a few patients respiratory obstruction progresses rapidly and requires tracheostomy for relief. Complete esophageal obstruction due to edema, inflammation, and mucosal sloughing may develop within the first few days.

B. Esophagoscopy

Endoscopy is the key test in the evaluation of caustic trauma to the esophagus. Determination of the extent of injury by esophagoscopy contributes substantially to therapeutic decisions. Endoscopy should be performed after the initial resuscitation, usually within 24 hours of admission. The scope is inserted far enough to gauge the most serious degree of burn, which is classified as first-, second-, or third-degree, as defined in Table 20–5.

Table 20–5. Endoscopic grading of corrosive burns of esophagus and stomach.

Grade	Definition	Endoscopic Findings
First-degree	Superficial mucosal injury	Mucosal hyperemia and edema; superficial mucosal desquamation
Second-degree	Full-thickness mucosal involvement. No or partial-thickness muscular injury	Sloughing of mucosa. Hemorrhage, exudate, ulceration, pseudomembrane formation, and granulation tissue when examined late
Third-degree	Full-thickness esophageal or gastric injury with extension into adjacent tissues	Sloughing of tissues with deep ulceration. Complete obliteration of esophageal lumen by edema; charring and eschar formation; full-thickness necrosis; perforation

Reproduced, with permission, from Estrera A et al: Corrosive burns of the esophagus and stomach: a recommendation for an aggressive surgical approach. *Ann Thorac Surg* 1986;41:276.

C. Radiology

A chest x-ray should be taken in all patients. It may show signs of esophageal perforation (subcutaneous emphysema, pneumomediastinum, pneumothorax) or aspiration (pulmonary infiltrates). An esophagogram is indicated in the initial evaluation if perforation is suspected and in later stages to detect the presence of a stricture.

► Treatment

Patients should be hospitalized and intravenous fluids and antibiotics should be administered. The use of steroids is still controversial. A nasogastric tube placed under fluoroscopic or endoscopic guidance allows stenting of the esophagus, preventing complete obstruction of the lumen.

Patients with first-degree burns do not require aggressive therapy and may be discharged from the hospital after a short period of observation. Second-degree and minor spotty third-degree injuries are treated by inserting a nasogastric tube. Nutrition can be given through the nasogastric tube or parenterally. Periodic esophagograms are obtained in follow-up to look for stricture formation, which is treated early in its development by dilations and eventually resection.

Third-degree burns involving extensive esophagogastric necrosis require emergency esophagogastrectomy, esophagostomy, and feeding jejunostomy. Esophagectomy is best performed by the blunt technique using a laparotomy and cervical incision. It is sometimes necessary to resect adjacent organs (eg, transverse colon) that have also been damaged. Reconstruction by substernal colon interposition is performed 8-12 weeks later.

Early and proper management of caustic burns provides satisfactory results in most cases. The ingestion of strong acid or alkaline solutions with extensive immediate destruction of the mucosa produces profound pathologic changes that may result in fibrous strictures that require dilations and, in some cases, esophagectomy and colon interposition.

Chirica M et al: Late morbidity after colon interposition for corrosive esophageal injury: risk factors, management, and outcome. A 20-years experience. *Ann Surg* 2010;252:271-280.

ESOPHAGEAL BANDS, WEBS, OR RINGS

A narrow mucosal ring (Schatzki ring) may develop at the lower end of the esophagus. Most patients are relatively free from symptoms. Dysphagia occurs when the ring is less than 12 mm in diameter. In most cases, the ring is located at the squamocolumnar junction and occurs in a patient with GERD. Being confined to the mucosa, it differs from an inflammatory (peptic) stricture, which involves all layers of the esophagus. A barium swallow clearly identifies the

problem. Treatment consists of endoscopic dilation of the ring and treatment of the associated reflux (acid-reducing medications or fundoplication).

Müller M et al: Is the Schatzki ring a unique esophageal entity? *World J Gastroenterol* 2011;21(17):2838-2843.

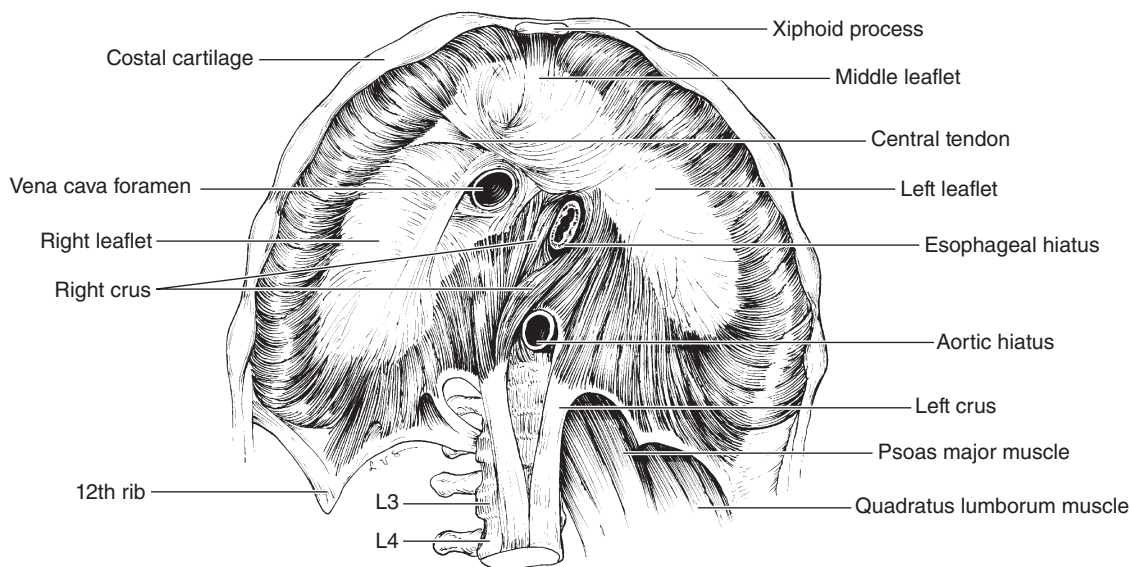

THE DIAPHRAGM

The diaphragm (Figure 20-16) is a musculotendinous, dome-shaped structure attached posteriorly to the first, second, and third lumbar vertebrae, anteriorly to the lower sternum and laterally to the costal arches. It separates the abdominal and the thoracic cavities. The diaphragm allows the passage of various normal structures through anatomic foramina. The aortic hiatus lies posteriorly at the level of the twelfth thoracic vertebra, and through it pass the aorta, the thoracic duct, and the azygos venous system. The esophageal hiatus lies immediately anteriorly and slightly to the left at the level of the tenth thoracic vertebra and is separated from the aortic hiatus by the decussation of the right crus of the diaphragm. Through this hiatus pass the esophagus and the vagus nerves. At the level of the ninth thoracic vertebra and slightly to the right of the esophageal hiatus is the vena caval foramen, which allows passage of the inferior vena cava and small branches of the phrenic nerve. The phrenic arteries arising directly from the aorta supply the diaphragm along with the lower intercostal arteries and the terminal branches of the internal mammary arteries.

PARASTERNAL OR RETROSTERNAL (FORAMEN OF MORGAGNI) HERNIA & PLEUROPERITONEAL (FORAMEN OF BOCHDALEK) HERNIA

Failure of fusion of the sternal and costal portions of the diaphragm anteriorly in the midline creates a defect (foramen of Morgagni) through which hernias can occur. Normally, the diaphragm becomes fused, allowing only the internal mammary arteries and their superior epigastric branches, along with lymphatics, to pass through this area. Posterolaterally, failure of fusion of the pleuroperitoneal canal creates a defect through which viscera may herniate to produce a foramen of Bochdalek hernia (Figure 20-17).

Although both types of hernia are congenital, symptoms in the Morgagni hernia usually do not develop until middle life or later. This type of hernia is more frequent in women. These hernias are mostly right-sided and have a hernia sac. The most common contents are the omentum, the colon, and the stomach. On the other hand, the Bochdalek hernia occurs more frequently on the left side and may cause severe respiratory distress at birth, requiring an emergent opera-

▲ **Figure 20-16.** Inferior surface of the diaphragm.

tion. Routine chest films show a retrosternal solid mass, a retrosternal air-filled viscus, or similar findings in the posterolateral thorax if a Bochdalek hernia is present. Chest CT confirms the diagnosis and identifies the contents of the hernia.

Elective surgical repair is indicated in most instances to prevent complications. An emergent operation may become necessary in the newborn infant who develops progressive cardiorespiratory insufficiency. Repair of the defect by a transabdominal approach is preferable, and the results are excellent. A minimally invasive approach (laparoscopic or thoracoscopic) has been recently used.

 Nasr A et al: Foramen of Morgagni hernia: presentation and treatment. *Thorac Surg Clin* 2009;19:463-468.

TRAUMATIC DIAPHRAGMATIC HERNIA

Traumatic rupture of the diaphragm may occur as a result of penetrating wounds or severe blunt external trauma. Lacerations usually occur in the tendinous portion of the diaphragm, most often on the left side. The liver provides protection to diaphragmatic injury on the right side except from penetrating wounds. Abdominal viscera may immediately herniate through the defect in the diaphragm into the pleural cavity or may gradually insinuate themselves into the thorax over a period of months or years.

▶ **Clinical Findings**

Diaphragmatic ruptures present in two ways. In the acute form, the patient has recently experienced blunt trauma or a penetrating wound to the chest, abdomen, or back. The

▲ **Figure 20-17.** Sites of congenital diaphragmatic herniation.

clinical manifestations are essentially those of the associated injuries, but occasionally, massive herniation of abdominal viscera through the diaphragm causes respiratory insufficiency. In the chronic form, the diaphragmatic tear is unrecognized at the time of the original injury. Sometime later, symptoms (eg, pain, bowel obstruction) appear from herniation of viscera. Respiratory symptoms in such cases are less common.

Plain films of the chest may show a radiopaque area and occasionally an air-fluid level if hollow viscera have herniated. If the stomach has entered the chest, the abnormal path of a nasogastric tube may be diagnostic. Ultrasonography, CT scan, and MRI may demonstrate the diaphragmatic rent. Barium study of the colon may show irregular patches of barium in the colon above the diaphragm or a smooth colonic outline if the colon does not contain feces.

► Differential Diagnosis

Traumatic rupture of the diaphragm must be differentiated from atelectasis, space-consuming tumors of the lower pleural space, pleural effusion, and intestinal obstruction due to other causes.

► Complications

Hemorrhage and obstruction may occur. If herniation is massive, progressive cardiorespiratory insufficiency may threaten life. The most severe complication is strangulating obstruction of the herniated viscera.

► Treatment

For acute ruptures, a transabdominal (most commonly) or transthoracic route is used depending on the procedure required to treat ancillary injuries. When the diaphragmatic tear is the only injury, it is usually fixed by laparotomy. Chronic injuries can be repaired by either approach. Asymptomatic tears of the diaphragm with herniated viscera should be repaired, because the risk of strangulating obstruction is high. Laparoscopy is very useful for both diagnosis and treatment. Surgical repair of the rent in the diaphragm is curative, and the prognosis is excellent. The diaphragm supports sutures well, so recurrence is practically unknown.

Fiscion V et al: Laparoscopic repair of intrathoracic liver herniation after traumatic rupture of the diaphragm. *Surg Endosc* 2011;25:3423-3425.

Hanna WC et al: Acute traumatic diaphragmatic injury. *Thorac Surg Clin* 2009;19:485-489.

TUMORS OF THE DIAPHRAGM

Primary tumors of the diaphragm are not common. The majority are benign lipomas. Pericardial cysts develop in

the space between the heart and the diaphragm and are usually unilocular and on the right side. Fibrosarcoma, the most common primary malignant diaphragmatic tumor, is extremely rare.

Benign tumors are usually asymptomatic. Since their benign nature cannot be established except by histology, all lesions of this type should be excised through an appropriate thoracotomy or thoracoabdominal approach.

MULTIPLE CHOICE QUESTIONS

- Esophageal achalasia is characterized by
 - Absence of esophageal peristalsis
 - Heartburn in more than 50% of patients
 - Low intraluminal pH due to GERD
 - All of the above
- Which of the following sentences about Zenker diverticulum is wrong?
 - It is the most common diverticulum of the esophagus.
 - It is a consequence of an underlying esophageal motility disorder.
 - Aspiration of diverticular contents is frequent.
 - The surgical treatment consists of LES myotomy, resection of the diverticulum or its suspension.
- A 54-year-old patient has heartburn. The correct workup includes
 - Esophageal manometry, 24-hour pH monitoring and upper endoscopy.
 - Upper endoscopy and 24-hour pH monitoring.
 - Nothing, the patient has gastro-esophageal reflux and needs surgery.
 - Nothing; the patient has gastro-esophageal reflux and needs treatment with proton pump inhibitors.
- Barrett esophagus
 - Becomes more symptomatic over time due to the mucosal inflammation
 - Is linked to duodeno-gastro-esophageal reflux
 - Is classified short if less than 2 cm
 - Is characterized by the presence of fundic type cells
- Treatment of esophageal cancer includes
 - EMR/RFA for a T1a lesion
 - Neoadjuvant therapy followed by surgery for locally advanced cancer
 - Intraesophageal stenting for patients with dysphagia and solid organ metastases
 - All of the above

The Acute Abdomen

Elisha G. Brownson, MD
Katherine Mandell, MD

21

An “acute abdomen” denotes any sudden, spontaneous, nontraumatic, severe abdominal pain, typically of less than 24 hours duration. The acute abdomen requires rapid and specific diagnosis as several etiologies demand urgent operative intervention. Because there is frequently a progressive underlying intra-abdominal disorder, undue delay in diagnosis and treatment may adversely affect outcome.

The approach to a patient with an acute abdomen must be orderly and thorough. An acute abdomen should be suspected even in a patient with only mild or atypical presentations. Increasingly, certain patient populations present with atypical complaints, including the immunocompromised, elderly and gastric bypass patients. The history and physical examination often suggest the probable cause, allow formation of a differential diagnosis, and guide the choice of initial diagnostic studies. The clinician must then decide if in-hospital observation is warranted, if additional tests are needed, if early operation is indicated, or if nonoperative treatment would be more suitable.

All clinicians should be familiar with the presenting pattern of the most common causes of an acute abdomen (Table 21–1) and their atypical presentations in certain patient populations. Moreover, they should be familiar with regional specific disease patterns. While the most common cause of abdominal pain in patients presenting to the emergency department is nonspecific discomfort, missing treatable causes of abdominal pain can be disastrous for the patient.

HISTORY

► Abdominal Pain

History taking by an experienced physician is key to focusing the evaluation of a patient with an acute abdomen. Taking a patient history is an active process whereby a large number of diagnostic possibilities are considered in order to systematically eliminate less likely conditions.

Pain is the most common and predominant presenting feature of an acute abdomen. Careful consideration of the location, severity, mode of onset and progression, and the character of the pain will suggest a preliminary list of diagnoses.

A. Location of Pain

The location of pain serves only as a rough guide to the diagnosis; “typical” descriptions are reported in only two-thirds of cases. This variability is due to atypical pain patterns, a shift of maximum intensity away from the primary site, or advanced or severe disease. In patients presenting with diffuse peritonitis, generalized pain may completely obscure the precipitating event. Fortunately, some general patterns do emerge that provide clues to diagnosis and narrow the differential of the acute abdomen. Pain confined to either upper quadrant may be evaluated by anatomic consideration of acute conditions affecting underlying organs.

Because of the complex dual visceral and parietal sensory networks innervating the abdominal area, pain is not as precisely localized in the abdomen as in the extremities. Visceral sensation is mediated primarily by afferent C fibers located in the walls of hollow viscera and in the capsules of solid organs. Unlike cutaneous pain, visceral pain is elicited by distention, inflammation or ischemia stimulating the receptor neurons, or by direct involvement (eg, malignant infiltration) of sensory nerves. Visceral pain is a centrally perceived sensation, generally slow in onset, dull, poorly localized and protracted. The pain may be due to increased wall tension or luminal distention or forceful smooth muscle contraction (colic) producing diffuse, deep-seated pain. Visceral pain is most often felt in the midline because of the bilateral sensory supply to the spinal cord. Because different visceral structures are associated with different sensory levels in the spine

Table 21–1. Common causes of the acute abdomen.¹**Gastrointestinal Tract Disorders**

**Nonspecific abdominal pain*
**Appendicitis*
**Small and large bowel obstruction*
**Perforated peptic ulcer*
Incarcerated hernia
Bowel perforation
Meckel's diverticulitis
Boerhaave syndrome
**Diverticulitis*
 Inflammatory bowel disorders
 Mallory–Weiss syndrome
 Gastroenteritis
 Acute gastritis
 Mesenteric adenitis
 Parasitic infections

Liver, Spleen, and Biliary Tract Disorders

**Acute cholecystitis*
Acute cholangitis
Hepatic abscess
Ruptured hepatic tumor
Spontaneous rupture of the spleen
 Splenic infarct
 Biliary colic
 Acute hepatitis

Pancreatic Disorders

**Acute pancreatitis*

Urinary Tract Disorders

**Ureteral or renal colic*
 Acute pyelonephritis
 Acute cystitis
 Renal infarct

Gynecologic Disorders

Ruptured ectopic pregnancy
Twisted ovarian tumor
Ruptured ovarian follicle cyst
**Acute salpingitis*
 Dysmenorrhea
 Endometriosis

Vascular Disorders

Ruptured aortic and visceral aneurysms
Acute ischemic colitis
Mesenteric thrombosis

Peritoneal Disorders

Intra-abdominal abscesses
 Primary peritonitis
 Tuberculous peritonitis

Retroperitoneal Disorders

Retroperitoneal hemorrhage

¹The most common causes are marked with an asterisk (*). Conditions in italic type often require urgent operation. Please see specific chapters for management.

(Table 21–2), visceral pain may be felt in the midepigastrium, periumbilical area, lower abdomen, or flank areas (Figure 21–1) depending on the organ involved.

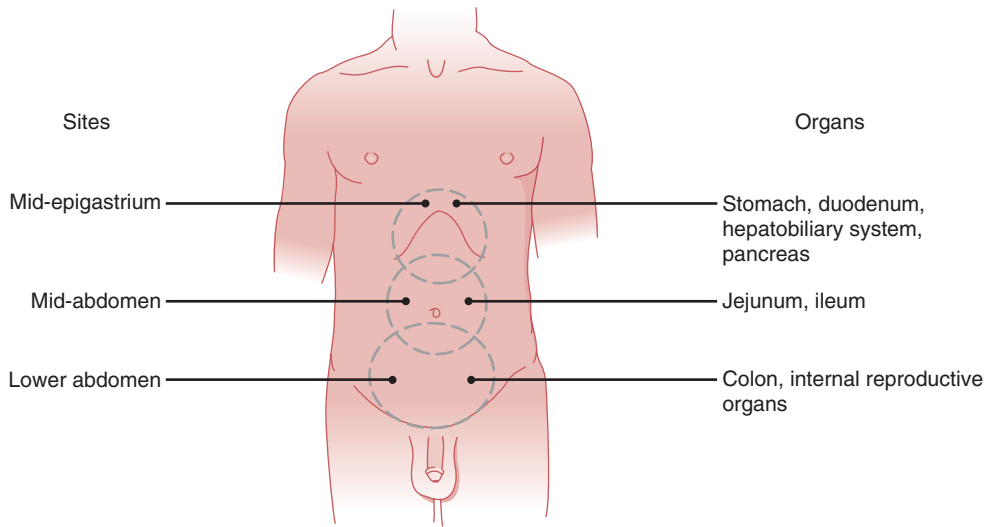

Table 21–2. Sensory levels associated with visceral structures.

Structures	Nervous System Pathways	Sensory Level
Liver, spleen and central part of diaphragm	Phrenic nerve	C3-5
Peripheral diaphragm, stomach, pancreas, gallbladder and small bowel	Celiac plexus and greater splanchnic nerve	T6-9
Appendix, colon and pelvic viscera	Mesenteric plexus and lesser splanchnic nerve	T10-11
Sigmoid colon, rectum, kidney, ureters and testes	Lowest splanchnic nerve	T11-L1
Bladder and rectosigmoid	Hypogastric plexus	S2-4

In contrast, parietal pain is mediated by both C and A delta nerve fibers, the latter being responsible for the transmission of more acute, sharper, better localized pain sensation. Direct irritation of the somatically innervated parietal peritoneum by pus, bile, urine, or gastrointestinal secretions leads to a more precisely localized pain. Parietal pain is more easily localized than visceral pain because the somatic afferent fibers are directed to only one side of the nervous system. The cutaneous distribution of parietal pain corresponds to the T6-L1 areas. Abdominal parietal pain is conventionally described as occurring in one of the four abdominal quadrants or in the epigastric or central abdominal area.

Abdominal pain may be referred or may shift to sites removed from the primarily affected organs (Figure 21–2). Referred pain denotes noxious (usually cutaneous) sensations perceived at a site distant from that of a strong primary stimulus. Distorted central perception of the site of pain is due to the confluence of afferent nerve fibers from disparate areas within the posterior horn of the spinal cord. For example, pain due to subdiaphragmatic irritation by air, peritoneal fluid, blood, or a mass lesion is referred to the shoulder via the C4-mediated (phrenic) nerve. Pain may also be referred to the shoulder from supradiaphragmatic lesions such as pleurisy or lower lobe pneumonia. Although more often perceived in the right scapular region, referred biliary pain may mimic angina pectoris if it is perceived in the anterior chest or left shoulder areas.

Spreading or shifting pain parallels the course of the underlying condition. The site of pain at onset should be distinguished from the site at presentation. The chronology of a patient's pain may be as important as the location itself. Beginning classically in the epigastric or periumbilical region, the initial visceral pain of acute appendicitis shifts

▲ **Figure 21-1.** Visceral pain sites.

to become sharper parietal pain localized in the right lower quadrant when the overlying peritoneum becomes directly inflamed (Figure 21-2). With a perforated peptic ulcer, pain

almost always begins in the epigastrium, but as leaked gastric contents track down the right paracolic gutter, pain may descend to the right lower quadrant.

▲ **Figure 21-2.** Referred pain and shifting pain in the acute abdomen. Solid circles indicate the site of maximum pain; dashed circles indicate sites of lesser pain.

B. Mode of Onset and Progression of Pain

The mode of onset of pain reflects the nature and severity of the underlying process. Onset may be explosive (within seconds), rapidly progressive (within 1-2 hours), or gradual (over several hours). Unheralded, excruciating generalized pain suggests an intra-abdominal catastrophe such as a perforated viscus or rupture of an aneurysm, ectopic pregnancy, or abscess. Accompanying systemic signs (tachycardia, sweating, tachypnea, shock) soon supersede the abdominal disturbances and underscore the need for rapid resuscitation and laparotomy.

A less dramatic clinical picture is steady, mild pain becoming intensely centered in a well-defined area within 1-2 hours. Any of the above conditions may present in this manner, but this is more typical of acute cholecystitis, acute pancreatitis, strangulated bowel, mesenteric infarction, renal or ureteral colic and proximal small bowel obstruction.

Finally, some patients initially have slight—at times only vague—abdominal discomfort that is fleetingly present diffusely throughout the abdomen. It may be unclear whether these patients even have an acute abdomen or whether the illness is likely to be a matter for medical rather than surgical attention. Associated gastrointestinal symptoms are infrequent at first, and systemic symptoms are absent. Eventually,

the pain and abdominal findings become more pronounced, steady and are localized to a smaller area. This gradual onset pattern leading to a more localized pain may reflect a slowly developing condition or the body's defensive efforts to cord off an acute process. This broad category includes acute appendicitis (especially with the appendix in a retrocecal position), incarcerated hernias, distal small bowel and large bowel obstructions, uncomplicated peptic ulcer disease, walled-off (often malignant) visceral perforations, some genitourinary and gynecologic conditions, and milder forms of the rapid-onset group mentioned in the first paragraph.

C. Character of Pain

The nature, severity and periodicity of pain provide useful clues to the underlying pathology (Figure 21-3). Pain may be continual or intermittent. Steady pain is more common and often indicates a process that will lead to peritoneal inflammation. It may be constant in severity or fluctuate, but it is always present. Sharp superficial constant pain due to peritoneal irritation is typical of perforated ulcer or a ruptured appendix, ovarian cyst, or ectopic pregnancy. Intermittent, crampy pain (colic) may occur for short or long periods but is punctuated by pain free intervals and is most characteristic of obstruction of a hollow viscus. The gripping, mounting pain

▲ **Figure 21-3.** The location and character of pain are helpful in the differential diagnosis of the acute abdomen.

of small bowel obstruction (and occasionally early pancreatitis) is usually intermittent, vague, deep-seated and crescendo at first but becomes sharper, unremitting and better localized. Unlike the disquieting but bearable pain associated with bowel obstruction, pain caused by lesions occluding smaller conduits (bile ducts, uterine tubes, ureters) rapidly becomes unbearably intense. The pain-free intervals reflect intermittent smooth muscle contractions. In the strict sense, the term “biliary colic” is a misnomer because biliary pain does not remit as bile ducts do not have peristaltic movements.

The quality of a patient’s pain leads to the use of certain descriptors to describe different types of pain and may be typical of certain pathologies. The “aching discomfort” of ulcer pain, the “stabbing, breathtaking” pain of acute pancreatitis and mesenteric infarction, the “gripping” pain of a bowel obstruction and the “tearing” pain of ruptured aortic aneurysm remain apt descriptions. Despite the use of such descriptive terms, the quality of visceral pain is not a reliable clue to its cause.

The intensity of a patient’s pain may relate to the severity of the insult. Agonizing pain denotes serious or advanced disease. Colicky pain is usually promptly alleviated by analgesics. Ischemic pain due to strangulated bowel or mesenteric thrombosis is only slightly assuaged even by narcotics. Nonspecific abdominal pain is usually mild, but mild pain may also be found with perforated ulcers that have become localized and in mild acute pancreatitis. An occasional patient will deny pain but complain of a vague feeling of abdominal fullness that feels as though it might be relieved by a bowel movement. This visceral sensation (gas stoppage sign) is due to reflex ileus induced by an inflammatory lesion walled off from the free peritoneal cavity, as in retrocecal appendicitis.

Past episodes of pain and factors that aggravate or relieve pain should be noted. Pain caused by localized peritonitis, especially when it affects upper abdominal organs, tends to be exacerbated by movement or deep breathing.

The location, character and severity of the pain in relation to its duration of onset and presence of systemic symptoms help to differentiate rapidly progressive surgical conditions (eg, intestinal ischemia) from more indolent or medical causes (eg, ruptured ovarian cyst) and allows formation of a differential diagnosis.

► Other Symptoms Associated with Abdominal Pain

Anorexia, fever, nausea and vomiting, constipation/obstipation, or diarrhea, often accompany abdominal pain, but are nonspecific symptoms and have limited diagnostic value.

A. Vomiting

When sufficiently stimulated by secondary visceral afferent fibers, the medullary vomiting centers activate efferent

fibers to induce reflex vomiting. Hence, pain in the acute surgical abdomen usually precedes vomiting, whereas the reverse holds true in medical conditions. Vomiting is a prominent symptom in upper gastrointestinal diseases such as Boerhaave syndrome, Mallory–Weiss syndrome, acute gastritis and acute pancreatitis. Severe, uncontrollable retching provides temporary pain relief in moderate attacks of pancreatitis. The absence of bile in the vomitus is a feature of pyloric stenosis or gastric outlet obstruction. Where associated findings suggest bowel obstruction, the onset and character of vomiting may indicate the level of the lesion. Recurrent vomiting of bile-stained fluid is typical of proximal small bowel obstruction. In distal small or large bowel obstruction, prolonged nausea precedes vomiting, which may become feculent in late cases. Although vomiting may present in either acute appendicitis or nonspecific abdominal pain, coexisting nausea and anorexia are more suggestive of the former condition.

B. Constipation

Reflex ileus is often induced by visceral afferent fibers stimulating efferent fibers of the sympathetic autonomic nervous system (splanchnic nerves) to reduce intestinal peristalsis. Hence, paralytic ileus undermines the value of constipation in the differential diagnosis of an acute abdomen. Constipation itself is hardly an absolute indicator of intestinal obstruction. However, obstipation (the absence of passage of both stool and flatus) strongly suggests mechanical bowel obstruction if there is progressive painful abdominal distention or repeated vomiting.

C. Diarrhea

Copious watery diarrhea is characteristic of gastroenteritis and other medical causes of an acute abdomen. Blood-stained diarrhea suggests ulcerative colitis, Crohn disease, or bacillary or amebic dysentery. It is also found with ischemic colitis but often absent in intestinal infarction due to superior mesenteric artery occlusion.

D. Fever

Fever is a marker of inflammation and may be present in a variety of surgical conditions in the abdomen if they are allowed to progress. The sensitivity of this finding is low as the ability of many patient populations to mount a fever is compromised and for most diseases leading to acute abdomen fever is low grade or absent.

E. Other Specific Symptoms

These are extremely helpful if present. Significant weight loss may suggest cancer or more chronic mesenteric ischemia. Jaundice suggests hepatobiliary disorders. Hematochezia or hematemesis may suggest a gastroduodenal lesion or

Mallory–Weiss syndrome; melena a lower GI bleed or colonic ischemia and hematuria, ureteral colic, or cystitis. The passage of blood clots or necrotic mucosal debris may be the sole evidence of advanced intestinal ischemia.

► Other Relevant Aspects of the History

A. Past Medical History

A complete past medical history is crucial to identify both medical conditions related to the presentation of the acute abdomen as well as conditions of associated pulmonary, renal and cardiac systems that may mimic the acute abdomen in their presentation. Many chronic medical conditions complicate the patient's presentation and increase their surgical risk. An assessment of the patient's cardiovascular and pulmonary status should always be done before proceeding to the operating room. Liver disease should be noted as it increases risk for gastrointestinal bleeding, and in severe disease may be complicated by ascites and spontaneous bacterial peritonitis. In patients with vascular disease or atrial fibrillation mesenteric ischemia should be included in the differential. Inflammatory bowel disease can cause severe abdominal pain often treated medically but may be complicated by processes requiring more emergent intervention including intra-abdominal abscess, stricture, obstruction, or perforation.

A patient should also be asked about any history of recent trauma. Delayed splenic bleeding is one of the more common examples of traumatic injuries presenting in delayed fashion.

B. Operation History

Any history of a previous abdominal, groin, vascular, or thoracic operation may be relevant to the current illness. Particular attention to the mode of operation (laparoscopic, open, endovascular) and any anatomic reconstructions may clarify aspects of the current complaint. If possible within the time constraints imposed by the urgency of the current problem, operative notes and pathology reports should be obtained and reviewed.

C. Gynecologic History

The menstrual history is crucial to the diagnosis of ectopic pregnancy, mittelschmerz (due to a ruptured ovarian follicle) and endometriosis. A history of vaginal discharge or dysmenorrhea may denote pelvic inflammatory disease. A complete sexual history should be performed if indicated, and all women of childbearing age should be evaluated for possibility of pregnancy.

D. Medication History

The average patient is taking an increasing number of medications, which may have direct impact on their man-

agement. NSAIDs or aspirin may be a cause of a gastric or duodenal ulcer. Anticoagulants have been implicated in retroperitoneal and intramural duodenal and jejunal hematomas. Additionally, patients who are anticoagulated, or are on antiplatelet therapy may require correction or further consideration prior to operative management. Oral contraceptives have been implicated in the formation of benign hepatic adenomas and in mesenteric venous infarction. Corticosteroids or other chemotherapeutics and immunosuppressive medications, may mask the clinical signs of even advanced peritonitis.

Alcohol use should be interrogated as it can be associated with liver disease, ulcers, gastritis and pancreatitis.

E. Family History

Family history often provides the best information about medical or hereditary causes of an acute abdomen.

F. Travel History

Travel history may raise the possibility of amebic liver abscess or hydatid cyst, malarial spleen, tuberculosis, *Salmonella typhi* infection of the ileocecal area, or dysentery.

FORMING A DIFFERENTIAL DIAGNOSIS LIST

Following a thorough history, the examiner should formulate an early differential diagnosis list using the subsequent physical examination findings to test the various diagnostic possibilities. The age and gender of the patient should assist in guiding the development of the differential diagnosis. Mesenteric adenitis mimics acute appendicitis in the young, gynecologic disorders complicate the evaluation of abdominal pain in women of childbearing age, and malignant and vascular diseases are more common in the elderly. Knowledge of the common causes of abdominal pain and their incidence in various populations is also helpful. Acute cholecystitis, appendicitis, bowel obstruction, cancer and vascular conditions are the common causes of a surgical acute abdomen in older patients. In children, appendicitis accounts for one-third of all abdominal pain and nonspecific abdominal pain for much of the remainder. Causes of an acute abdomen reflect disease patterns of the indigenous population, and awareness of common causes within the physician's locale improves diagnostic accuracy.

PHYSICAL EXAMINATION

The tendency to concentrate on the abdomen should be resisted in favor of a methodical and complete physical examination. Examination should begin with an initial assessment of the patient's vital signs. A patient with systemic signs of shock should be aggressively resuscitated concurrently with any ongoing evaluation. Auscultation of

the heart and lungs should also be performed both to rule out sources of abdominal pain due to disorders within the chest (esophageal, cardiac, pulmonary) as well as being part of the preoperative evaluation.

The abdominal examination should be done with the patient in the supine position. A systematic approach to the abdominal examination (Table 21–3) is key to success. The physical examination allows the clinician to search for specific signs that confirm or rule out differential diagnostic possibilities (Table 21–4).

- 1. General observation** General observation affords a fairly reliable indication of the severity of the clinical situation. Most patients, although uncomfortable, remain calm. The writhing of patients with visceral pain (eg, intestinal or ureteral colic) contrasts with the rigidly motionless bearing of those with parietal pain (eg, acute appendicitis, generalized peritonitis). Diminished responsiveness or an altered sensorium is suggestive of more advanced or significant disease and may herald imminent cardiopulmonary collapse.
- 2. Systemic signs** Systemic signs usually accompany rapidly progressive or advanced disorders of the acute abdomen. Extreme pallor, hypotension, hypothermia, tachycardia, tachypnea and diaphoresis suggest major intra-abdominal hemorrhage (eg, ruptured aortic aneurysm or tubal pregnancy). Given such findings, one must proceed rapidly with the examination and any tests to exclude extra-abdominal causes and institute treatment. If extra-abdominal pathology is excluded, these are markers of severe or rapidly progressive intra-abdominal pathology and are indication for emergent laparotomy.
- 3. Fever** Constant low-grade fever is common in inflammatory conditions such as diverticulitis, acute cholecystitis and appendicitis. High fever with lower abdominal tenderness in a young woman without signs of systemic illness suggests acute salpingitis.

Table 21–3. Steps in physical examination of the acute abdomen.

1. Global assessment, vital signs	7. Special signs
2. Inspection	8. External hernias and male genitalia
3. Auscultation	9. Rectal examination
4. Cough tenderness	10. Pelvic examination
5. Percussion	
6. Palpation	
• Guarding or rigidity	
• Local palpation	
• Rebound tenderness	
• Deep tenderness	
• Bump tenderness	
• Masses	

Table 21–4. Physical findings in various causes of acute abdomen.

Condition	Helpful Signs
Perforated viscus	Scaphoid, tense abdomen; diminished bowel sounds (late); loss of liver dullness; guarding or rigidity.
Peritonitis	Motionless; absent bowel sounds (late); cough and rebound tenderness; guarding or rigidity.
Inflamed mass or abscess	Tender mass (abdominal, rectal, or pelvic); bump tenderness; special signs (Murphy, psoas, or obturator).
Intestinal obstruction	Distention; visible peristalsis (late); hyperperistalsis (early) or quiet abdomen (late); diffuse pain without rebound tenderness; hernia or rectal mass (some).
Paralytic ileus	Distention; minimal bowel sounds; no localized tenderness.
Ischemic or strangulated bowel	Not distended (until late); bowel sounds variable; severe pain but little tenderness; rectal bleeding (some).
Bleeding	Pallor, shock; distention; pulsatile (aneurysm) or tender (eg, ectopic pregnancy) mass; rectal bleeding (some).

Disorientation or extreme lethargy combined with a very high fever ($> 39^{\circ}\text{C}$) or fever with chills and rigors signifies impending septic shock. This is most often due to advanced peritonitis, acute cholangitis, or pyelonephritis. However, fever is often mild or absent in elderly, chronically ill, or immunosuppressed patients despite a serious acute abdomen.

4. Examination of the Acute Abdomen

- (a) Inspection** The abdomen should be thoughtfully inspected before palpation. One should look for old surgical scars, hernias, evidence of trauma, stigmata of liver disease, obvious masses, distention and signs of peritonitis. A tensely distended abdomen with an old surgical scar suggests both the presence and the cause (adhesions) of small bowel obstruction. A scaphoid contracted abdomen is seen with perforated ulcer; visible peristalsis occurs in thin patients with advanced bowel obstruction; and soft doughy fullness is seen in early paralytic ileus or mesenteric thrombosis.
- (b) Auscultation** Auscultation of the abdomen should also precede palpation. Peristaltic rushes synchronous with colic are heard in mid-small bowel obstruction and in early acute pancreatitis. They differ from the high-pitched hyperperistaltic sounds unrelated to the crampy pain of gastroenteritis, dysentery and fulminant ulcerative colitis. An abdomen that is silent except for infrequent tinkly or

squeaky sounds characterizes late bowel obstruction or diffuse peritonitis. Except for these more extreme patterns, the many auscultatory variants heard in abdominal conditions render them largely useless for specific diagnosis.

- (c) **Coughing to elicit pain** The patient should be asked to cough and point to the area of maximal pain. Peritoneal irritation so demonstrated may be confirmed afterward without causing unnecessary pain by rigorous testing for rebound tenderness. This same localization may also be achieved with a foot tap or bed bump. Unlike the parietal pain of peritonitis, colic is visceral pain and is seldom aggravated by deep inspiration or coughing.
- (d) **Percussion** Percussion serves several purposes. Tenderness on percussion is akin to eliciting rebound tenderness; both reflect peritoneal irritation and parietal pain. With a perforated viscus, free air accumulating under the diaphragm may efface normal liver dullness. Tympany near the midline in a distended abdomen denotes air trapped within distended bowel loops. Free peritoneal fluid may be detected by demonstrating shifting dullness.
- (e) **Palpation** Palpation is performed with the patient resting in a comfortable supine position. Incisional and periumbilical hernias are noted. Tenderness that connotes localized peritoneal inflammation is the most important finding in patients with an acute abdomen. Its extent and severity are determined first by one- or two-finger palpation, beginning away from the area of cough tenderness and gradually advancing toward it. Tenderness is usually well demarcated in acute cholecystitis, appendicitis, diverticulitis and acute salpingitis. If there is poorly localized tenderness unaccompanied by guarding, one should suspect gastroenteritis or some other inflammatory intestinal process without peritonitis. Compared with the degree of pain, unexpectedly little or vaguely localized tenderness is elicited in uncomplicated hollow viscus obstruction, walled-off or deep-seated perforations (eg, retrocecal appendicitis or diverticular phlegmon) and in very obese patients. Severe pain out of proportion to examination is a hallmark for mesenteric ischemia.

Rebound tenderness is elicited by applying deep gentle pressure to the area of concern and then releasing the pressure rapidly. It is a marker of peritoneal inflammation but its usefulness may be confounded if the patient is startled by the abrupt release and interprets that as pain.

Guarding is assessed by placing both hands over the abdominal muscles and depressing the fingers gently. Properly performed, this maneuver is comforting to the

patient. If there is voluntary spasm, the muscle will be felt to relax when the patient inhales deeply through the mouth. With true involuntary spasm, however, the muscle will remain taut and rigid (board like) throughout respiration. Except for rare neurologic disorders—and, for unknown reasons, renal colic—only peritoneal inflammation produces rectus muscle rigidity. Unlike peritonitis, renal colic induces spasm confined to the ipsilateral rectus muscle.

When the patient raises his or her head from the bed, the abdominal muscles will be tensed. Tenderness persists in abdominal wall conditions (eg, rectus hematoma), whereas deeper peritoneal pain due to intraperitoneal disease is lessened (Carnett test). Hyperesthesia may be demonstrable in abdominal wall disorders or localized peritonitis, but it is more prominent in herpes zoster, spinal root compression and other neuromuscular problems. Trigger point sensitivity, lateral costal rib tip tenderness and pain exacerbated by spinal motion reflect parietal abdominal wall conditions that subside dramatically after infiltration with local anesthetic agents.

Abdominal masses are usually detected by deep palpation. Superficial lesions such as a distended gallbladder or appendiceal abscess are often tender and have discrete borders. Deeper masses may be adherent to the posterior or lateral abdominal wall and are often partially walled off by overlying omentum and small bowel. As a result, their borders are ill-defined and only dull pain may be elicited by palpation. Examples include pancreatic phlegmon and ruptured aortic aneurysm.

- (f) **Maneuvers** Even if a mass cannot be directly felt, its presence may be inferred by other maneuvers. A large psoas abscess may cause pain when the hip is passively extended or actively flexed against resistance (iliopsoas sign). Internal and external rotation of the flexed thigh may exert painful pressure (obturator sign) on a loop of the small bowel entrapped within the obturator canal (obturator hernia). Bump tenderness over the lower costal ribs indicates an inflammatory condition affecting the diaphragm, liver, spleen, or its adjacent structures. Referred pain to McBurney's point from the left lower quadrant (Rovsing's sign), is associated with acute appendicitis. If one suspects abdominal guarding is masking an acutely inflamed gallbladder, the right subcostal area should be palpated while the patient inhales deeply. Inspiration will be arrested abruptly by pain (Murphy's sign), or the gallbladder fundus may be felt as it strikes the examining fingers during descent of the diaphragm. Pain in the shoulder indicates irritation of the diaphragm by fluid such as blood, pus, gastric contents, or stool. Kehr sign is left shoulder pain associated with hemoperitoneum. Costovertebral angle tenderness is common in acute pyelonephritis.

Since they are not invariably present, these special signs are helpful in conjunction with a compatible history and related physical findings.

- (g) **Inguinal and femoral rings; male genitalia** The inguinal and femoral rings in both sexes and the genitalia in male patients should be examined.
- (h) **Rectal examination** A rectal examination should be performed in most patients with an acute abdomen. Diffuse tenderness is nonspecific, but right-sided rectal tenderness accompanied by lower abdominal rebound tenderness is indicative of peritoneal irritation due to pelvic appendicitis or abscess. Other useful findings include a rectal tumor, blood-stained stool, or occult blood (detected by guaiac testing).
- (i) **Pelvic examination** An acute abdomen is incorrectly diagnosed more often in women than in men, particularly in younger age groups. A pelvic examination is vital in women with vaginal discharge, dysmenorrhea, menorrhagia, or left lower quadrant pain. A properly performed pelvic examination is invaluable in differentiating among acute pelvic inflammatory diseases that do not require operation and acute appendicitis, twisted ovarian cyst, or tubo-ovarian abscess.

INVESTIGATIVE STUDIES

The history and physical examination by themselves provide the diagnosis in two-thirds of cases of an acute abdomen. Supplementary laboratory and radiologic examinations are indispensable for diagnosis of many surgical conditions, for exclusion of medical causes not treated by operation and for assistance in preoperative preparation. Even in the absence of a specific diagnosis, there may be enough information on which to base a rational decision about management. Additional studies are worthwhile if they are likely to significantly alter or improve therapeutic decisions. A more liberal use of diagnostic studies is justified in elderly or seriously ill patients, in whom the history and physical findings may be less reliable.

The availability and reliability of certain studies vary in different hospitals. When selecting a study the invasiveness, risk and cost-effectiveness should be considered. Test results must be interpreted within the clinical context of each case. Basic studies should be obtained in all but the most desperately ill patients, while other less vital tests may be requested later as indicated.

► Laboratory Investigations

A. Blood Studies

Hemoglobin, hematocrit, white blood cell and differential counts taken on admission are highly informative. Both a rising

or marked leukocytosis ($> 13,000/\mu\text{L}$) as well as a leucopenia ($< 5000/\mu\text{L}$) are indicative of serious infection. The differential counts should be reviewed as the presence of increased neutrophils (left shift) may suggest the presence of infection, even when the white blood cell count is normal. Additionally, the presence of bands may indicate severe infection.

Serum electrolytes, urea nitrogen and creatinine are important, especially if hypovolemia is expected (ie, due to shock, copious vomiting or diarrhea, or delay in presentation). Creatinine is considered imperative prior to obtaining radiographic imaging with iodized contrast agents due to potential renal injury. Arterial blood gas with lactate should be obtained in patients with hypotension, generalized peritonitis, pancreatitis, possible ischemic bowel and septicemia. Elevated serum lactate may indicate bowel ischemia due to the correlation with anaerobic metabolism. However, this is nonspecific and may be elevated in other clinical scenarios, such as dehydration, cocaine use, or liver failure. Unsuspected metabolic acidosis may be the first clue to serious disease.

A raised serum amylase or more specifically lipase level corroborates a clinical diagnosis of acute pancreatitis. Moderately elevated amylase values must be interpreted with caution, since abnormal levels frequently accompany strangulated or ischemic bowel, twisted ovarian cyst, or perforated ulcer. Lipase is more specific to pancreatitis.

In patients with suspected hepatobiliary disease, liver function tests (serum bilirubin, alkaline phosphatase, aspartate aminotransferase, alanine aminotransferase, albumin and globulin) are useful to differentiate medical from surgical hepatic disorders and to gauge the severity of underlying parenchymal disease.

Clotting studies (platelet counts, prothrombin time and partial thromboplastin time) may be obtained in certain patients in anticipation of surgical intervention. They should be evaluated in patients on anticoagulants such as Coumadin, to ensure therapeutic levels or alert the clinician that correction is needed prior to surgical intervention. Prothrombin time is also a marker of the synthetic function of the liver in those with advanced liver disease. A peripheral blood smear should be considered if the history hints at a hematologic abnormality (cirrhosis, petechiae, etc). The erythrocyte sedimentation rate, often nonspecifically raised in the acute abdomen, is of dubious diagnostic value; a normal value does not exclude serious surgical illness.

A specimen of clotted blood for cross matching should be sent whenever urgent surgery is anticipated or there is suspicion of hemorrhage. **Beta** HCG serum testing is routinely performed at many institutions in lieu of urine testing. This should be performed on all women of childbearing age.

B. Urine Tests

Urinalysis is easily performed and may reveal useful information. Dark urine or a raised specific gravity reflects

mild dehydration in patients with normal renal function. Hyperbilirubinemia may give rise to tea-colored urine that froths when shaken. Microscopic hematuria or pyuria can confirm ureteral colic or urinary tract infection and obviate a needless operation. Dipstick testing (for albumin, bilirubin, glucose and ketones) may reveal a medical cause of an acute abdomen. Pregnancy tests should be ordered on all women of childbearing age if serum testing was not performed.

C. Stool Tests

Gastrointestinal bleeding is not a common feature of the acute abdomen. Nonetheless, testing for occult fecal blood should be routinely performed. A positive test points to a mucosal lesion that may be responsible for large bowel obstruction or chronic anemia, or it may reflect an unsuspected carcinoma.

Stool samples for culture should be taken in patients with suspected gastroenteritis, dysentery, or cholera. *Clostridium difficile* should be on the differential of anyone with a recent course of antibiotic therapy.

► Imaging Studies

Radiographic imaging has become an invaluable aid in the evaluation, diagnosis and even treatment of the acute abdomen. It is of utmost importance that the surgeon, who is familiar with the clinical scenario of the patient, reviews all images. It should be remembered that patients in distress with concern for abdominal catastrophe may be moved to the operating room without any confirmatory imaging.

A. Plain Chest X-Ray Studies

An upright chest x-ray is essential in all cases of an acute abdomen. Not only is it vital for preoperative assessment, but it may also demonstrate supradiaphragmatic conditions that simulate an acute abdomen (eg, lower lobe pneumonia or ruptured esophagus). An elevated hemidiaphragm or pleural effusion may direct attention to subphrenic inflammatory lesions. Subdiaphragmatic air, if present, suggests perforated viscous and may forego the need for additional imaging. An upright chest radiograph is more sensitive than abdominal plain films for free intraperitoneal air.

B. Plain Abdominal X-Ray Studies

Plain supine films of the abdomen should be obtained only selectively. In general, erect (or lateral decubitus) views contribute little additional information except in suspected intestinal obstruction and rarely eliminate the need for further imaging. Plain films are indicated in patients with signs and symptoms of intestinal obstruction, or in patients with suspected foreign body ingestion. They are inappropriate in pregnant patients, unstable individuals in whom clear physical signs mandating laparotomy already exist,

or patients with only mild, resolving nonspecific pain. When looking at plain radiographs one should observe the gas pattern of the hollow viscera; an abnormal bowel gas pattern suggests paralytic ileus, mechanical bowel obstruction, or pseudo-obstruction. Bowel obstructions are usually accompanied with findings of gaseous distention, air-fluid levels, distended cecum and a paucity of air in the rectum. Colonic dilatation is seen in toxic megacolon or volvulus (Figure 30–15). “Thumbprint” impressions on the colonic wall are noted in about half of patients with ischemic colitis. Radiopaque densities may be seen with biliary, renal, or ureteral calculi; as well as in the case of foreign bodies. Although gallstones and renal calculi can be seen on plain films further imaging is almost always obtained obviating the need for a plain radiograph.

Free air under the hemidiaphragm suggests a perforated viscous, although it does not identify the source. Its presence in approximately 80% of perforated ulcers corroborates the clinical diagnosis. Massive pneumoperitoneum is observed in free colonic perforations. Biliary tree air designates a biliary-enteric communication, such as a gallstone ileus. Air delineating the portal venous system characterizes pylephlebitis.

C. Ultrasonography

Ultrasonography is becoming more common in the early evaluation of abdominal pain and may be used at the bedside by a trained physician. It is one of the first examinations for right upper quadrant pain that is biliary in nature. Ultrasonography has a diagnostic sensitivity of about 80% for acute appendicitis and is most useful in pregnant patients due to its safe modality and lower cost. It becomes technically difficult in the third trimester due to the large gravid uterus. Ultrasound also plays a role in evaluating a variety of gynecologic causes of abdominal pain. Color Doppler studies can distinguish avascular cysts and twisted masses from inflammatory and infectious processes. Ultrasound with Doppler may also be useful in evaluating for flow through the mesenteric vessels.

D. Computed Tomography Scan

Computed tomography (CT) scan of the abdomen is now generally routinely and rapidly available. This has proved extremely useful in the evaluation of abdominal complaints for patients who do not already have clear indications for laparotomy or laparoscopy. CT provides excellent diagnostic accuracy. Whether contrast is used should be carefully weighed on an individual basis. IV contrast administration may be limited by creatinine impairment. Oral contrast is useful to distinguish bowel from remaining abdominal contents. It can be administered orally or rectally; oral administration adds significant time to obtaining imaging and may not be appropriate in severely ill patients. With newer

scanners the use of oral contrast is often unnecessary unless looking for bowel perforation or anastomotic leak. Newer low-dose CT scans are becoming available which reduce radiation exposure and provide advantages for pediatric imaging. CT scans should be used sparingly in pregnancy because of the risk radiation poses to the fetus, especially in the first trimester. Ultrasound or MRI are preferred imaging techniques in pregnancy.

CT can identify small amounts of free intraperitoneal gas and sites of inflammatory diseases that may prompt (appendicitis, tubo-ovarian abscess) or postpone (noncomplicated diverticulitis, pancreatitis, hepatic abscess) operation. It should not replace or delay operation in a patient for whom the findings will not change the decision to operate. CT has proven helpful in the diagnosis of appendicitis, especially where examination and laboratory data may not be clear, and is recommended in women, where other pelvic pathology may explain the presence of right lower quadrant pain.

E. Angiography

CT angiography (CTA), percutaneous invasive angiographic studies, or magnetic resonance angiography (MRA), are indicated if intestinal ischemia or ongoing hemorrhage are suspected. They should precede any gastrointestinal contrast study that might obscure film interpretation. Selective visceral angiography is a reliable method of diagnosing mesenteric infarction. Emergency angiography may confirm a ruptured liver adenoma or carcinoma or an aneurysm of the splenic artery or other visceral artery. Additionally it can be therapeutic for coiling or embolizing aneurysmal disease. In patients with massive lower gastrointestinal bleeding, angiography may identify the bleeding site, suggest the likely diagnosis (eg, vascular ectasia, polyarteritis nodosa), and be therapeutic if embolization can be performed. Angiography is of little value in ruptured aortic aneurysm or if frank peritoneal findings (peritonitis) are present. It is contraindicated in unstable patients with severe shock or sepsis and seldom warranted if other findings or tests already dictate the need for laparotomy or laparoscopy. A patient's renal function should be considered before contrast is administered. MRA is useful when a patient is unable to undergo IV contrast administration (due to either renal impairment or contrast dye allergy). It is additionally used as an alternative imaging modality in pregnancy.

F. Gastrointestinal Contrast X-Ray Studies

Gastrointestinal contrast studies should not be requested routinely or be regarded as screening studies. They are helpful only if a specific condition being considered can be verified or treated by a contrast x-ray examination. For suspected perforations of the esophagus or gastroduodenal area without pneumoperitoneum, a water-soluble contrast medium (eg, meglumine diatrizoate [Gastrografin]) is pre-

ferred. If there is no clinical evidence of bowel perforation, a barium enema may identify the level of a large bowel obstruction or even reduce a sigmoid volvulus or intussusception. Upper GI contrast studies can also be helpful in the bariatric patient population to evaluate for leak or gastric pouch emptying.

G. Radionuclide Scans

The utility of radionuclide scans has been greatly decreased by the routine availability of urgent CT scans. Liver-spleen scans, HIDA scans and gallium scans may be useful for localizing intra-abdominal abscesses in rare cases. Radionuclide blood pool or Tc-sulfur colloid scans may identify sources of slow or intermittent intestinal bleeding. Technetium pertechnetate scans may reveal ectopic gastric mucosa in Meckel diverticulum.

► Endoscopy

Proctosigmoidoscopy is indicated in any patient with suspected large bowel obstruction, grossly bloody stools, or a rectal mass. Minimal air should be used for bowel insufflation to minimize iatrogenic bowel perforation. Besides reducing a sigmoid volvulus, colonoscopy may also locate the source of bleeding in cases of lower gastrointestinal hemorrhage that has subsided. Gastroduodenoscopy and endoscopic retrograde cholangiopancreatography (ERCP) are usually done electively to evaluate less urgent inflammatory conditions (eg, gastritis, peptic disease) in patients without alarming abdominal signs. However, urgent ERCP may be indicated in cases of suspected cholangitis.

► Paracentesis

Although performing paracentesis is becoming increasingly rare, it is important to understand that in patients with free peritoneal fluid, aspiration of blood, bile, or bowel contents is a strong indication for laparotomy. On the other hand, infected ascitic fluid may establish a diagnosis in spontaneous bacterial peritonitis, tuberculous peritonitis, or chylous ascites, which rarely require surgery.

► Laparoscopy

Laparoscopy is a therapeutic as well as diagnostic modality. The role of laparoscopy has broadened to be a useful modality in the treatment of abdominal emergencies. In certain cases it has been associated with decreased pain and faster recovery times. Its use is dependent on surgeon experience and hospital and OR equipment and staffing.

In cases of unclear diagnosis, laparoscopy helps guide surgical planning and avoid unneeded laparotomies. In young women, it may distinguish a nonsurgical problem (ruptured graafian follicle, pelvic inflammatory disease, tubo-ovarian disease) from appendicitis. In obese patients, it

may allow for a smaller, less morbid incision. In obtunded, elderly, or critically ill patients, who often have deceptive manifestations of an acute abdomen, it may facilitate earlier treatment in those with positive findings while eliminating the added morbidity of a laparotomy in negative cases. Any patient undergoing laparoscopy must be suited to tolerate conversion to an open procedure when necessary.

Laparoscopy has become the standard of care for operative treatment of appendicitis and cholecystitis. For acute cholecystitis, laparoscopy performed within 48 hours of symptom onset significantly reduces the risk of conversion to an open procedure, reinforcing the importance of early diagnosis. Laparoscopy may also be used in treating small bowel obstructions, and can result in lower morbidity and a faster return to normal diet.

DIAGNOSTIC UNCERTAINTY

As the surgeon gathers data, the differential diagnosis is narrowed and associated with a clear direction of plan. The plan of action should focus on whether the patient will need to:

- go directly to the operating room,
- be admitted for surgical observation and expected operative intervention,
- be admitted for surgical observation or further diagnostics, or
- be admitted to medical service for nonoperative abdominal pain.

Several patient populations may fall out of the expected presentation of the patient with an acute abdomen. The clinical picture in early cases is often unclear. The following observations should be borne in mind:

1. Acute abdominal pain persisting for over 6 hours should be regarded as having a surgical problem requiring in-hospital evaluation. Well-localized pain and tenderness usually indicate a surgical condition. Systemic hypoperfusion with generalized abdominal pain is seldom nonsurgical.
2. Acute appendicitis and intestinal obstruction are the most frequent final diagnoses in cases erroneously believed at first to be nonsurgical. Appendicitis should remain a foremost concern if sepsis or an inflammatory lesion is suspected. It is the commonest cause of bizarre peritoneal findings producing ileus or intestinal obstruction. Pelvic appendicitis, with mild abdominal pain, vomiting and frequent loose stools, simulates gastroenteritis. Atypical presentations of appendicitis are encountered during pregnancy.
3. Salpingitis, dysmenorrhea, ovarian lesions and urinary tract infections complicate the evaluation of the acute abdomen in young women. Diagnostic errors can be avoided by taking a careful gynecologic history and performing a pelvic examination and urinalysis. Always consider a pregnancy test.
4. Unusual types or atypical manifestations of intestinal obstruction are easily missed. Emesis, abdominal distention and air-fluid levels on x-ray may be negligible in Richter hernia, proximal or closed-loop small bowel obstructions and early cecal volvulus. Intestinal obstruction in an elderly woman who has not had a previous operation suggests an incarcerated femoral hernia or, rarely, an obturator hernia or gallstone ileus.
5. Elderly or cardiac patients with severe unrelenting diffuse abdominal pain but no peritoneal signs may have intestinal ischemia. Arterial blood pH and lactate should be measured and visceral angiography or CTA performed expeditiously.
6. Medical causes of the acute abdomen should be considered and excluded if possible before exploratory laparotomy is planned (Table 21–5). Upper abdominal pain may be encountered in myocardial infarction, acute pulmonary conditions, pancreatitis and acute hepatitis. Generalized or migratory abdominal discomfort may be felt in acute rheumatic fever, polyarteritis nodosa and other vasculitides. Acute bursitis and hip joint disorders can produce pain radiating into the lower quadrants.
7. Beware of acute cholecystitis, acute appendicitis and perforated peptic ulcer in patients already hospitalized for an illness affecting another organ system.

SPECIAL POPULATIONS

► Elderly

Due to the rising elderly population, physicians should expect to encounter more patients in this age group. Elderly patients presenting with an acute abdomen are more likely to require surgical intervention. These patients often have one or more medical comorbidities complicating their presentation. For example, patients with cardiovascular disease, whether known or unknown, will be more likely to present with acute mesenteric ischemia as a cause of abdominal pain. One of the most frequent causes of acute abdominal pain in the elderly is bowel obstruction. The etiology of these bowel obstructions will differ from younger populations with malignancy and hernias higher on the differential. Elderly patients tend to present later in their course of illness. Many will have past surgical history, which can make operative intervention technically challenging. Although surgical intervention for the acute abdomen in the elderly is safe and necessary, the perioperative morbidity and mortality rates are higher, largely due to medical comorbidities and more limited reserve.

► Bariatrics

Obesity is increasingly prevalent in the United States and weight loss surgery has become relatively commonplace. This patient population presents both its own differential for the acute abdomen and its own anatomic challenge to the surgeon. Physical examination findings may be vague due to the patient's body habitus. Tachycardia is an ominous sign that should not be dismissed. Common causes of acute abdomen in the bariatric population include marginal ulcers, obstruction due to internal hernias or adhesions and gastric band complications. Due to the common formation of gallstones following rapid weight loss, cholecystitis is another frequent cause of the acute abdomen in post bypass patients.

► Pregnancy

Pregnant women can present with confounding symptoms. Normal pregnancy may be associated with nausea and vomiting, or mild leukocytosis. Physical examination may also be misleading due to the shift in organs secondary to their enlarged uterus. The most common cause of the acute abdomen in pregnancy is appendicitis. Appendicitis in pregnancy may present with pain in atypical locations due to displacement by the uterus. Pain may be present in the right upper quadrant or if the appendix is pushed posteriorly, patients may not demonstrate peritoneal pain. Once diagnosed, early operative intervention is indicated as ruptured appendicitis leads to increased risk of fetal loss.

Table 21–6. Indications for urgent operation in patients with an acute abdomen.

Physical Findings

- Involuntary guarding or rigidity, especially if spreading
- Increasing or severe localized tenderness
- Tense or progressive distention
- Tender abdominal or rectal mass with high fever or hypotension
- Rectal bleeding with shock or acidosis
- Equivocal abdominal findings along with septicemia (high fever, marked or rising leukocytosis, mental changes, or increasing glucose intolerance in a diabetic patient)
 - Bleeding (unexplained shock or acidosis, falling hematocrit)
 - Suspected ischemia (acidosis, fever, tachycardia)
 - Deterioration on conservative treatment

Radiologic Findings

- Pneumoperitoneum
- Gross or progressive bowel distention
- Free extravasation of contrast material
- Space-occupying lesion on scan, with fever
- Mesenteric occlusion on angiography

Endoscopic Findings

- Perforated or uncontrollably bleeding lesion

► Immunocompromised

Immunosuppressed patients present a unique challenge, as their immune response will not mount the same presentation as an otherwise healthy patient. This population includes patients with HIV/AIDS, diabetics, patients on chemotherapy, transplant patients and patients on steroid therapy. Immunosuppressed patients have a wider differential including many obscure medical etiologies, such as various opportunistic infections. Due to the lack of inflammatory response, physical examination may present as not concerning. The examiner should be wary of a “benign examination” in light of an otherwise concerning clinical picture. These patients often do not mount an expected leukocytosis. Delayed diagnosis may be devastating as patients often present with advanced disease, shock, or peritonitis, with limited reserve.

INDICATIONS FOR SURGICAL EXPLORATION

The need for operation is apparent when the diagnosis is certain, but surgery sometimes must be undertaken before a precise diagnosis is reached. Table 21–6 lists some indications for urgent laparotomy or laparoscopy. Among patients with acute abdominal pain, those over age 65 years more often require operation (33%) than do younger patients (15%).

A liberal policy of exploration is advisable in patients with inconclusive but persistent right lower quadrant tenderness. Pain in the left upper quadrant infrequently requires urgent laparotomy and its cause can usually await elective confirmatory studies.

PREOPERATIVE MANAGEMENT

After initial assessment, parenteral analgesics for pain relief should not be withheld. In moderate doses, analgesics neither obscure useful physical findings nor mask their subsequent development. Indeed, abdominal masses may become obvious once rectus spasm is relieved. Pain that persists in spite of adequate doses of narcotics suggests a serious condition often requiring operative correction.

Resuscitation of acutely ill patients should proceed based on their intravascular fluid deficits and systemic diseases. Medications should be restricted to essential requirements. Particular care should be given to use of cardiac drugs and corticosteroids and to control of diabetes. Antibiotics are indicated for some infectious conditions or as prophylaxis in the perioperative period.

A nasogastric tube should be inserted in patients with hematemesis or copious vomiting, suspected bowel obstruction, or severe paralytic ileus. This precaution may prevent aspiration in patients suffering from drug overdose or alcohol intoxication, patients who are comatose or debilitated, or elderly patients with impaired cough reflexes. A urinary catheter should be placed in patients with systemic hypoperfusion. In some elderly patients, it eliminates the cause of pain (acute bladder distention) or unmasks relevant abdominal signs.

Informed consent for surgery may be difficult to obtain when the diagnosis is uncertain. It is prudent to discuss with the patient and family the possibility of multiple-staged operations, temporary or permanent stomal openings, impotence or sterility and postoperative mechanical ventilation. Whenever the exact diagnosis is uncertain—especially in young or frail or severely ill patients—a frank preoperative discussion of the diagnostic dilemma and reasons for laparotomy or laparoscopy will reduce postoperative anxieties and misunderstanding.

MULTIPLE CHOICE QUESTIONS

- Of the following causes of abdominal pain, which occurs more frequently in patients less than 50 years old compared with older patients?
 - Bowel obstruction
 - Cholecystitis
 - Appendicitis
 - Diverticulitis
 - Mesenteric Ischemia
- Which of the following is correct regarding the role of the abdominal plain films in evaluation of the acute abdomen?
 - They can exclude serious disease.
 - They are most useful when intestinal obstruction is part of the differential diagnosis.
 - They are an important part of the work up in patients presenting to the emergency department with abdominal pain.
 - They are the most sensitive test for a perforated viscus.
 - They have a high sensitivity in detecting disease including appendicitis, cholecystitis, renal stones and GI bleeding.
- A 65-year-old man is brought to the ED with abrupt onset of acute abdominal pain. He appears uncomfortable and moaning. Initial vitals: BP 110/88 mm Hg, HR 125 beats/min and irregular, respiratory rate 24 breaths/min. His abdominal examination is remarkable for a non-distended abdomen with no tenderness elicited on examination. Which of the following would be the most helpful next step?
 - Admit with observation
 - PO challenge
 - Basic labs including CBC, basic metabolic panel, amylase and lipase
 - Upright plain abdominal x-ray
 - ABG and Lactate
- A 32-year old woman with 30 week pregnancy arrives to the emergency department complaining of nausea, one episode of emesis and right lower quadrant pain. Ultrasound performed does not visualize the appendix. WBC is 14. The next best step is
 - Admit with observation
 - CT scan abdomen/pelvis with PO/IV contrast
 - MRI abdomen/pelvis
 - Exploratory laparoscopy
 - Exploratory laparotomy

5. All of the following are indications for urgent operative intervention EXCEPT
- A. A 49-year-old man with 12 hours of right lower quadrant pain, rebound tenderness and WBC 17.
 - B. A 45-year-old diabetic woman with 18 hours of right upper quadrant pain, WBC 12 and ultrasound demonstrating pericholecystic fluid, thickened gallbladder wall and gallstones.
 - C. A 52-year-old man with 2 days of bilateral lower quadrant pain and guarding on physical examination, WBC 18 and CT abdomen/pelvis which showing peri-sigmoidal fat stranding and extraluminal air.
 - D. A 65-year-old man with 1 day of mild abdominal pain and reports of bright red blood per rectum. Normotensive, but hematocrit on admission 24% (baseline Hct 42%).
 - E. A 78-year-old intubated woman, HR 110 beats/min, BP 95/60 mm Hg. Chest x-ray obtained to confirm endotracheal tube placement shows sub-diaphragmatic air.

Peritoneal Cavity

Matthew Brady, MD

Eric Mahoney, MD

THE PERITONEUM AND ITS FUNCTIONS

The peritoneum is the thin serous membrane that lines the peritoneal cavity. It is the largest serous surface layer in the human body and its surface area is similar to the skin. The structure is made up of a single, flat, layer of mesothelial cells, rich in microvilli. Beneath the mesothelium are a basement membrane and a loose collagen network containing vascularized connective tissue with scattered fibroblasts and macrophages. Normally there is between 5 and 20 mL of free peritoneal fluid, this can vary in women, peaking after ovulation. Normal peritoneal fluid has a specific gravity less than 1.016, protein concentration less than 3g/dL, pH between 7.5 and 8, and a white blood cell count less than 3000/ μ L. The peritoneum is divided anatomically into parietal and visceral components. The parietal peritoneum underlies the anterior, later, and posterior abdominal walls as well as the undersurface of the diaphragm and pelvic basin. The visceral peritoneum is reflected over the viscera within the abdominal cavity.

Once thought to be a passive barrier, the peritoneum is now understood to have numerous functions. The mesothelial cells secrete phosphatidylcholine, which provides a near frictionless environment within the peritoneum and allows intraperitoneal organs to glide over one another during peristalsis and movement. With its large surface area and semi permeable nature, it participates in fluid exchange with the extracellular fluid space at rates of over 500 mL/h. The circulation of peritoneal fluid is directed toward lymphatics on the undersurface of the diaphragm where particulate matter, up to 20 μ m in size, is cleared via stomas in the diaphragmatic mesothelium and emptied into the right thoracic duct.

The peritoneum has a vigorous response to injury and inflammation. Normally sterile, the peritoneum participates in recognizing and eliminating bacteria. Mesothelial cells secrete opsonins that promote bacterial destruction,

express CD40 and are aid in antigen presentation, and express intercellular adhesion molecule 1 (ICAM-1) and vascular cell adhesion molecule 1 (VCAM-1) which aid in attachment and activation of lymphocytes, granulocytes, and monocytes in response to infectious pathogens. The mesothelial cells secrete tPA under normal conditions which participates in intraperitoneal adhesiolysis. The peritoneum has significant wound healing functions as well, secreting multiple inflammatory mediators including vascular endothelial growth factor (VEGF), PAI, and nitrogen monoxide, TGF beta, and TNF alpha in response to trauma. In response to injury, the peritoneum produces a large proinflammatory response with fibrin deposition and activation of coagulation pathways as well. Imbalance between fibrin deposition and fibrinolysis following peritoneal traumatization can lead to the organization of fibrin deposits between adjacent structures and development of intraperitoneal adhesions which will be discussed further in later sections. Unlike with cutaneous wound healing, following injury to the mesothelium there is uniform recreation of the mesothelial monolayer within 5-10 days.

PRIMARY PERITONITIS

Primary (spontaneous) peritonitis occurring in the absence of gastrointestinal perforation is caused mainly by hematogenous spread but occasionally by transluminal or direct bacterial invasion of the peritoneal cavity. Impairment of the hepatic reticuloendothelial system and compromised peripheral destruction of bacteria by neutrophils promotes bacteremia, which readily infects ascitic fluid that has reduced bacterium-killing capacity. Primary peritonitis is most closely associated with cirrhosis and advanced liver disease with a low ascitic fluid protein concentration. It is also seen in patients with the nephrotic syndrome or systemic lupus erythematosus, or after splenectomy during childhood. Recurrence is common in cirrhosis and often proves fatal.

► Clinical Findings

The clinical presentation simulates secondary bacterial peritonitis, with abrupt onset of fever, abdominal pain, distention, and rebound tenderness. However, one-fourth of patients have minimal or no peritoneal symptoms. Most have clinical and biochemical manifestations of advanced cirrhosis or nephrosis. Leukocytosis, hypoalbuminemia, and a prolonged prothrombin time are characteristic findings. The diagnosis hinges upon examination of the ascitic fluid, which reveals a white blood cell count greater than 500/ μ L and more than 25% polymorphonuclear leukocytes. A blood-ascitic fluid albumin gradient greater than 1.1 g/dL, a raised serum lactic acid level, or a reduced ascitic fluid pH (< 7.31) supports the diagnosis. Bacteria are seen on Gram-stained smears in only 25% of cases. Culture of ascitic fluid inoculated immediately into blood culture media at the bedside usually reveals a single enteric organism, most commonly *Escherichia coli*, *Klebsiella*, or streptococci, but *Listeria monocytogenes* has been reported in immunocompromised hosts.

► Treatment

Antibiotic prophylaxis is of no proven value. Systemic antibiotics with third-generation cephalosporins (eg, cefotaxime) or a β -lactam-clavulanic acid combination along with supportive treatment are begun once the diagnosis has been established.

TUBERCULOUS PERITONITIS

► Pathophysiology

Tuberculous peritonitis is encountered in 0.5% of new cases of tuberculosis. It presents as a primary infection without active pulmonary, intestinal, renal, or uterine tube involvement. Its cause is reactivation of a dormant peritoneal focus derived from hematogenous dissemination from a distant

nidus or breakdown of mesenteric lymph nodes. Some cases occur as a systemic manifestation of extra-abdominal infection. Multiple small, hard, raised, whitish tubercles studding the peritoneum, omentum, and mesentery are the distinctive finding. A cecal tuberculoma, matted lymph nodes, or omental involvement may form a palpable mass.

The disease affects young persons, particularly women, and is more prevalent in countries where tuberculosis is still endemic. AIDS patients are especially susceptible to development of extrapulmonary tuberculosis such as this.

► Clinical Findings

Chronic symptoms (lasting more than a week) include abdominal pain and distention, fever, night sweats, weight loss, and altered bowel habits. Ascites is present in about half of cases, especially if the disease is of long standing, and may be the primary manifestation. A mass may be felt in a third of cases. The differential diagnosis includes Crohn disease, carcinoma, hepatic cirrhosis, and intestinal lymphoma. One-fourth of patients have acute symptoms suggestive of acute bowel obstruction or peritonitis that mimics appendicitis, cholecystitis, or a perforated ulcer.

Detection of an extra-abdominal site of tuberculosis, evident in half of cases, is the single most useful diagnostic clue. Pleural effusion is present in up to 50% of patients. Paracentesis, laparoscopy, or peritoneal biopsy is applicable only in patients with ascites. The peritoneal fluid is characterized by a protein concentration above 3 g/dL with less than 1.1 g/dL serum-ascitic fluid albumin difference and lymphocyte predominance among white blood cells. Definitive diagnosis is possible in 80% of cases by culture (often taking several weeks) and direct smear. A purified protein derivative (PPD) skin test is useful only when positive (about 80% of cases). Hematologic and biochemical studies are seldom helpful, and leukocytosis is uncommon. The sedimentation rate is elevated in many cases. The presence of high-density ascites or soft tissue masses on ultrasonography or computed tomography (CT) scan supports the diagnosis. Young patients from endemic areas who present with classic symptoms or who have suggestive imaging findings should undergo diagnostic laparoscopy, which may obviate laparotomy.

► Treatment

In chronic cases, nonoperative therapy is preferable if the diagnosis can be established. Most patients presenting with acute symptoms are diagnosed only by laparotomy. In the absence of intestinal obstruction or perforation, only a biopsy of a peritoneal or omental nodule should be taken. Obstruction due to constriction by a tuberculous lesion usually develops in the distal ileum and cecum, although multiple skip areas along the small bowel may exist. Localized short segments of diseased bowel are best treated

by resection with primary anastomosis. Multiple strictured areas may be managed either by side-to-side bypass or a stricturoplasty of partially narrowed segments.

Combination antituberculosis chemotherapy should be started once the diagnosis is confirmed or considered likely. A favorable response is the rule, but isoniazid and rifampin must be continued for 18 months postoperatively.

GRANULOMATOUS PERITONITIS

► Pathophysiology

Talc (magnesium silicate), cornstarch glove lubricants, gauze fluffs, and cellulose fibers from disposable surgical fabrics may elicit a vigorous granulomatous (a delayed hypersensitivity) response in some patients 2-6 weeks after laparotomy. The condition is uncommon now that surgeons wipe clean their gloves before handling abdominal viscera. Less rarely, granulomatous peritonitis may develop as a hypersensitivity reaction to other foreign material (eg, intestinal ascariasis or food particles from a perforated ulcer).

► Clinical Findings

Besides abdominal pain, which is often out of proportion to the low-grade fever, there may be nausea and vomiting, ileus, and other systemic complaints. Abdominal tenderness is usually diffuse but mild. Free abdominal fluid, if detectable, should be tapped and inspected for the diagnostic Maltese cross pattern of starch particles.

► Treatment

Reoperation achieves little and should be avoided if the diagnosis can be made. Most patients undergo reexploration because they present an erroneous impression of postoperative bowel obstruction or peritoneal sepsis. The diffuse hard, white granulomatous masses studding the peritoneum and omentum are easily mistaken for cancer or tuberculosis unless a biopsy specimen is taken to demonstrate foreign body granulomas.

If granulomatous peritonitis is suspected, the response to treatment with corticosteroids or other anti-inflammatory agents is often so dramatic as to be diagnostic in itself. After clinical improvement, intravenous methylprednisolone can be replaced by oral prednisone for 2-3 weeks. The disease is self-limited and does not predispose to late intestinal obstruction.

ACUTE BACTERIAL SECONDARY PERITONITIS

► Pathophysiology

Peritonitis is an inflammatory or suppurative response of the peritoneal lining to direct irritation. Peritonitis can occur after perforating, inflammatory, infectious, or

Table 22-1. Common causes of peritonitis.

Severity	Cause	Mortality Rate (%)
Mild	Appendicitis Perforated gastroduodenal ulcers Acute salpingitis	< 10
Moderate	Diverticulitis (localized perforations) Nonvascular small bowel perforation Gangrenous cholecystitis Multiple trauma	< 20
Severe	Large bowel perforations Ischemic small bowel injuries Acute necrotizing pancreatitis Postoperative complications	20-80

ischemic injuries of the gastrointestinal or genitourinary system. Common examples are listed in Table 22-1. Secondary peritonitis results from bacterial contamination originating from within viscera or from external sources (eg, penetrating injury). It most often follows disruption of a hollow viscus. Extravasated bile and urine, although only mildly irritating when sterile, are markedly toxic if infected and provoke a vigorous peritoneal reaction. Gastric juice from a perforated duodenal ulcer remains mostly sterile for several hours, during which time it produces a chemical peritonitis with large fluid losses; but if left untreated, it evolves within 6-12 hours into bacterial peritonitis. Intraperitoneal fluid dilutes opsonic proteins and impairs phagocytosis. Furthermore, when hemoglobin is present in the peritoneal cavity, *E coli* growing within the cavity can elaborate leukotoxins that reduce bactericidal activity. Limited, localized infection can be eradicated by host defenses, but continued contamination invariably leads to generalized peritonitis and eventually to septicemia with multiple organ failure.

Factors that influence the severity of peritonitis include the type of bacterial or fungal contamination, the nature and duration of the injury, and the host's nutritional and immune status. The grade of peritonitis varies with the cause. Clean (eg, proximal gut perforations) or well-localized (eg, ruptured appendix) contaminations progress to fulminant peritonitis relatively slowly (eg, 12-24 hours). In contrast, bacteria associated with distal gut or infected biliary tract perforations quickly overwhelm host peritoneal defenses. This degree of toxicity is also characteristic of postoperative peritonitis due to anastomotic leakage or contamination. Conditions that ordinarily cause mild peritonitis may produce life-threatening sepsis in an immunocompromised host.

► Causative Organisms

Systemic sepsis due to peritonitis occurs in varying degrees depending on the virulence of the pathogens, the bacterial load, and the duration of bacterial proliferation and synergistic interaction. Except for spontaneous bacterial peritonitis, peritonitis is almost invariably polymicrobial; cultures usually contain more than one aerobic and more than two anaerobic species. The microbial picture reflects the bacterial flora of the involved organ. As long as gastric acid secretion and gastric emptying are normal, perforations of the proximal bowel (stomach or duodenum) are generally sterile or associated with relatively small numbers of gram-positive organisms. Perforations or ischemic injuries of the distal small bowel (eg, strangulated hernia) lead to infection with aerobic bacteria in about 30% of cases and anaerobic organisms in about 10% of cases. Fecal spillage, with a bacterial load of 10^{12} or more organisms per gram, is extremely toxic.

Aerobic bacteria account for the majority of bacterial contamination and include both Gram-negative and Gram-positive species. The most frequent Gram-negative organisms encountered include *E coli*, *Klebsiella*, *Enterobacter*, *Proteus mirabilis*, and infrequently *Pseudomonas aeruginosa*. Among the more common Gram-positive organisms seen are *Enterococcus*, *Streptococcus*, and less commonly *Staphylococcus aureus*, and Coagulase-negative *Staphylococcus*. *Bacteroides*, clostridia, and other anaerobes make up the common anaerobic pathogens encountered. Fungi are rarely encountered though may be present in immunocompromised patients, when present, *Candida* are the predominant species.

Intraoperative cultures were obtained frequently in the past if purulence was encountered in the surgical field. Given the polymicrobial nature of peritonitis following intestinal tract perforations these cultures may provide little information that impact postoperative management.

► Clinical Findings

By estimating the severity of peritonitis from clinical and laboratory findings, the need for specific organ-supportive care and surgery can be determined.

See Chapter 21 for details of radiologic and other investigations.

► Symptoms & Signs

The clinical manifestations of peritonitis reflect the severity and duration of infection and the age and general health of the patient. Physical findings can be divided into: (1) abdominal signs arising from the initial injury and (2) manifestations of systemic infection. Acute peritonitis frequently presents as an acute abdomen. Local findings include abdominal pain, tenderness, guarding or rigidity, distention, free peritoneal air, and diminished bowel sounds—signs that reflect parietal peritoneal irritation and resulting ileus. Systemic findings include fever, chills or rigors, tachycardia, sweating, tachypnea, restlessness, dehydration, oliguria, disorientation, and, ultimately, refractory shock. Shock is due to the combined effects of hypovolemia and septicemia with multiple organ dysfunction. Recurrent unexplained shock is highly predictive of serious intraperitoneal sepsis.

The findings in abdominal sepsis are modified by the patient's age and general health. Physical signs of peritonitis are subtle or difficult to interpret in both very young and very old patients as well as in those who are chronically debilitated, immunosuppressed, or receiving corticosteroids and in postoperative patients. Paracentesis or diagnostic peritoneal lavage may be occasionally useful in equivocal cases and in senile or confused patients. A white blood cell count of greater than 200 cells/ μ L is indicative of peritonitis, with virtually no false-positive and minimal false-negative errors. Delayed recognition is a major cause of the high mortality rate of peritonitis.

Familial Mediterranean fever (periodic peritonitis, familial paroxysmal polyserositis) is a rare genetic condition that affects individuals of Mediterranean genetic background. Its exact cause is unknown. Patients present with recurrent bouts of abdominal pain and tenderness along with pleuritic or joint pain. Fever and leukocytosis are common. Colchicine prevents but does not treat acute attacks. Provocative testing by infusion of metaraminol (10 mg) induces abdominal pain within 2 days.

Laparoscopy has superseded laparotomy in suspect individuals. Free fluid and inflamed peritoneal surfaces are found, but smears and cultures are negative. The appendix should be removed to simplify diagnosis in subsequent episodes. Secondary amyloidosis with renal failure is a late complication that is preventable by a long-term colchicine therapy.

► Treatment

A. Preoperative Care

The presentation of patients with peritoneal inflammation following bacterial contamination can range from mild to life threatening. It is necessary to approach each patient with the same goals of diagnosis and prompt treat-

ment in mind. Initial management consists of assessing the patient's resuscitative needs and determining underlying pathology. Once resuscitation is begun, antibiotics administration and other supportive care measures should be pursued followed by imaging and treatment considerations.

1. Antibiotics—Antibiotic administration should be initiated once the diagnosis is made. Antibiotics should be directed against the most likely source and cover the aerobic and anaerobic organisms commonly encountered in gut perforation. Intravenous antibiotics are first line to ensure therapeutic serum levels in the early course of treatment given like ileus and unreliable oral absorption.

While antibiotics are a mainstay in the preoperative treatment of secondary peritonitis, their role in the postoperative period is less clear. Extended postoperative antibiotic courses may offer little benefit when compared with discontinuing antibiotics in the first 24 hours postoperatively in the prevention of intraperitoneal abscess or surgical site infection but can place patients at higher risk for antibiotic related complications and add to resistance in the community.

If the decision is made to continue antibiotics in the postoperative course historically they have been continued until the patient has been afebrile with a normal white blood cell count and a white blood cell count differential with less than 3% band forms. Provided the patient is tolerating a diet there is no added benefit to using intravenous antibiotics over comparable oral agents.

Fraser JD et al: A complete course of intravenous antibiotics vs a combination of intravenous and oral antibiotics for perforated appendicitis in children: a prospective, randomized trial. *J Pediatr Surg* 2010;45:1198.

2. Peritoneal lavage—In diffuse peritoneal contamination, irrigation with copious amounts of warm isotonic crystalloid solution removes gross particulate matter as well as blood and fibrin clots. The addition of antiseptics or antibiotics to the irrigating solution is generally useless or even harmful because of induced adhesions (eg, tetracycline, povidone-iodine). All fluid in the peritoneal cavity should be aspirated because it may hamper local defense mechanisms by diluting opsonins and removing surfaces upon which phagocytes destroy bacteria.

In cases of localized peritoneal contamination irrigation of the peritoneum is not advisable. Recent publications discourage the use of peritoneal irrigation in the surgical bed, favoring the use of suction alone, when encountering collections of purulence and spillage intraoperatively as it is associated with reduced rates of postoperative intraperitoneal abscess and surgical site infections.

Hartwich JE et al: The effects of irrigation on outcomes in cases of perforated appendicitis in children. *J Surg Res* 2013;180(2):222-225.

Moore CB et al: Does use of intraoperative irrigation with open or laparoscopic appendectomy reduce post-operative intra-abdominal abscess? *Am Surg* 2011;77:78.

► Complications

Postoperative complications are frequent and may be divided into local and systemic problems. Deep wound infections, residual abscesses and intraperitoneal sepsis, anastomotic breakdown, and fistula formation usually become manifest toward the end of the first postoperative week. Persistent high or swinging fever, inability to wean off cardiac inotropes, generalized edema with unexplained continued high fluid requirements, increased abdominal distention, prolonged mental apathy and weakness, or general failure to improve despite intensive treatment may be the sole indicators of residual intra-abdominal infection. This should prompt a thorough examination of the patient for infected catheters and an abdominal CT scan. Percutaneous catheter drainage of localized abscesses or open reexploration is undertaken as needed (see next section).

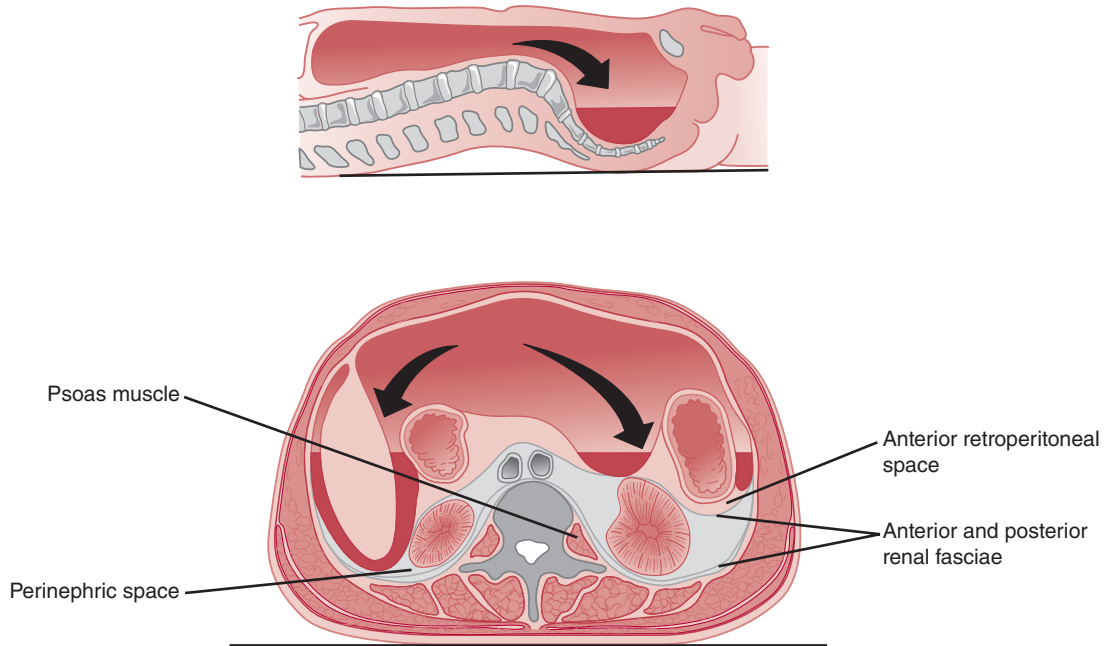

► Prognosis

The overall mortality rate of generalized peritonitis is about 40% (Table 22-1). Factors contributing to a high mortality rate include the type of primary disease and its duration, associated multiple organ failure before treatment, and the age and general health of the patient. Mortality rates are consistently below 10% in patients with perforated ulcers or appendicitis, in young patients, in those having less extensive bacterial contamination, and in those diagnosed and operated upon early. Patients with distal small bowel or colonic perforations or postoperative sepsis tend to be older, to have concurrent medical illnesses and greater bacterial contamination, and to have a greater propensity to renal and respiratory failure; their mortality rates are about 50%. Markedly poor physiologic indices (eg, APACHE II or Mannheim Peritonitis Index), reduced cardiac status, and low preoperative albumin levels identify high-risk patients who require intensive treatment to reduce a daunting mortality rate.

INTRAPERITONEAL ABSCESSES

► Pathophysiology

An intra-abdominal abscess is a collection of infected fluid within the abdominal cavity. Gastrointestinal perforations, postoperative complications, and penetrating injuries are

▲ **Figure 22-1.** Lateral (*top*) and cross-sectional (*bottom*) views of the abdomen, showing fluid gravitating to the dependent areas of the peritoneal cavity. The retroperitoneal compartments are also outlined.

the most common etiologies. An abscess forms by one of two modes. It may develop: (1) adjacent to a diseased viscus (eg, with perforated appendix, Crohn enterocolitis, or diverticulitis) or (2) as a result of external contamination (eg, postoperative subphrenic abscesses). In one-third of cases, the abscess occurs as a sequela of generalized peritonitis. Interloop and pelvic abscesses form if extravasated fluid gravitating into a dependent or localized area becomes secondarily infected (Figure 22-1).

Bacteria-laden fibrin and blood clots and neutrophils contribute to the formation of an abscess. The pathogenic organisms are similar to those responsible for peritonitis, but anaerobic organisms occupy an important role. Experimentally, mixed aerobic (*E coli*) and anaerobic (*Bacteroides fragilis*) infections, especially in conjunction with adjuvants (eg, feces or barium), reduce intraperitoneal O_2 and pH, thereby fostering anaerobic proliferation and abscess formation.

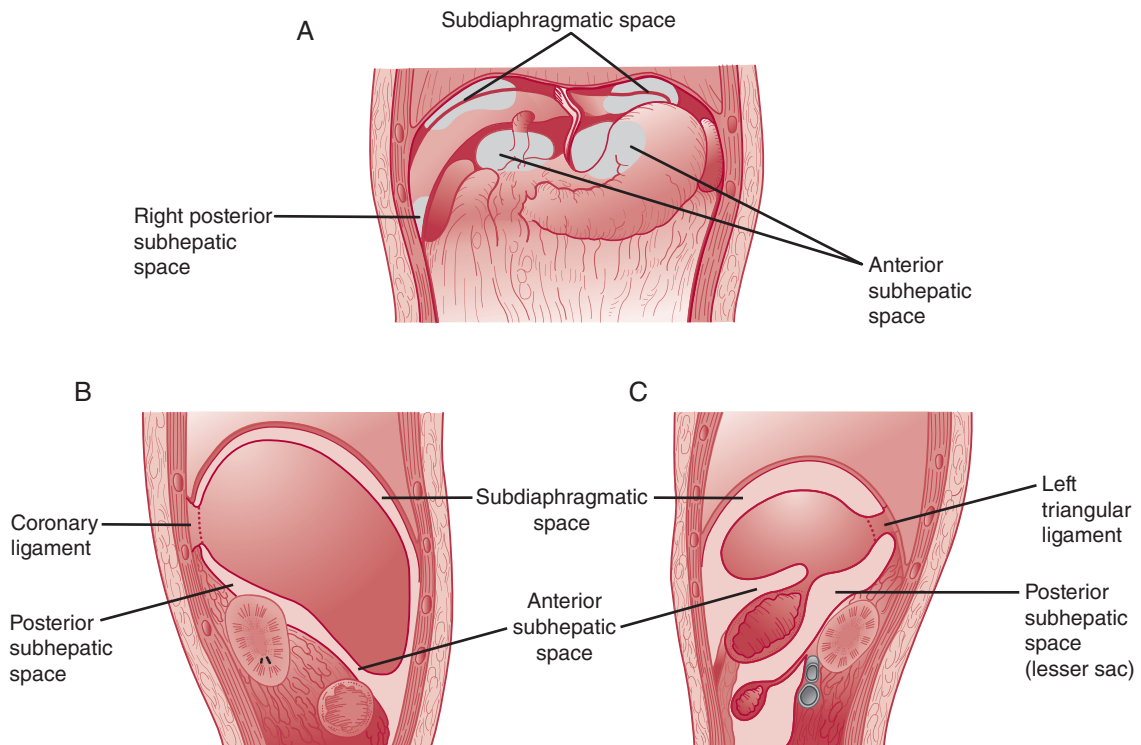

► Sites of Abscesses

The areas in which abscesses commonly occur are defined by the configuration of the peritoneal cavity with its dependent lateral and pelvic basins (Figure 22-1), together with the natural divisions created by the transverse mesocolon and

the small bowel mesentery. The supracolic compartment, located above the transverse mesocolon, broadly defines the subphrenic spaces (Figure 22-2A). Within this area, the subdiaphragmatic (suprahepatic) and subhepatic areas of the subphrenic space may be distinguished. The subdiaphragmatic space on each side occupies the concavity between the hemidiaphragms and the domes of the hepatic lobes. The inferior limits of its posterior recess are the attachments of the coronary and triangular ligaments on the dorsal—not superior—aspect of the diaphragm. Anteriorly, the lower limits are defined on the right by the transverse colon and on the left by the anterior stomach surface, omentum, transverse colon, spleen, and phrenicocolic ligament. Although each subdiaphragmatic space is continuous over the convex liver surface, inflammatory adhesions may delimit an abscess in an anterior or posterior position (Figure 22-2B). The falciform ligament separates the right and left subdiaphragmatic divisions.

The right subhepatic division (Figure 22-2B) of the subphrenic space is located between the undersurfaces of the liver and gallbladder superiorly and the right kidney and mesocolon inferiorly. The anterior bulge of the kidney partitions this space into an anterior (gallbladder fossa) and posterior (Morison pouch) section.

The left subhepatic space also has an anterior and posterior part (Figure 22-2C). The smaller anterior subhepatic space

▲ **Figure 22-2.** Subphrenic spaces. **A:** Anterior view. **B:** Right lateral view. **C:** Left lateral view.

lies between the undersurface of the left lobe and the anterior surface of the stomach. Left subdiaphragmatic collections often extend into this anterior subhepatic area. The posterior subhepatic space is the lesser sac, which is situated behind the lesser omentum and stomach and lies anterior to the pancreas, duodenum, transverse mesocolon, and left kidney. It extends posteriorly to the attachment of the left triangular ligament superiorly on to the hemidiaphragm. The lesser sac communicates with both the right subhepatic and right paracolic spaces through the narrow foramen of Winslow.

The infracolic compartment, below the transverse mesocolon, includes the pericolic and pelvic areas (Figure 22-3). The diagonally aligned root of the small bowel mesentery divides the mid-abdominal area between the fixed right and left colons into right and left infracolic spaces. Each lateral paracolic gutter and lower quadrant area communicates freely with the pelvic cavity. However, while right paracolic collections may track upward into the subhepatic and subdiaphragmatic spaces, the phrenicocolic ligament hinders fluid migration along the left paracolic gutter into the left subdiaphragmatic area.

The most common abscess sites are in the lower quadrants, followed by the pelvic, subhepatic, and subdiaphragmatic spaces (Table 22-2).

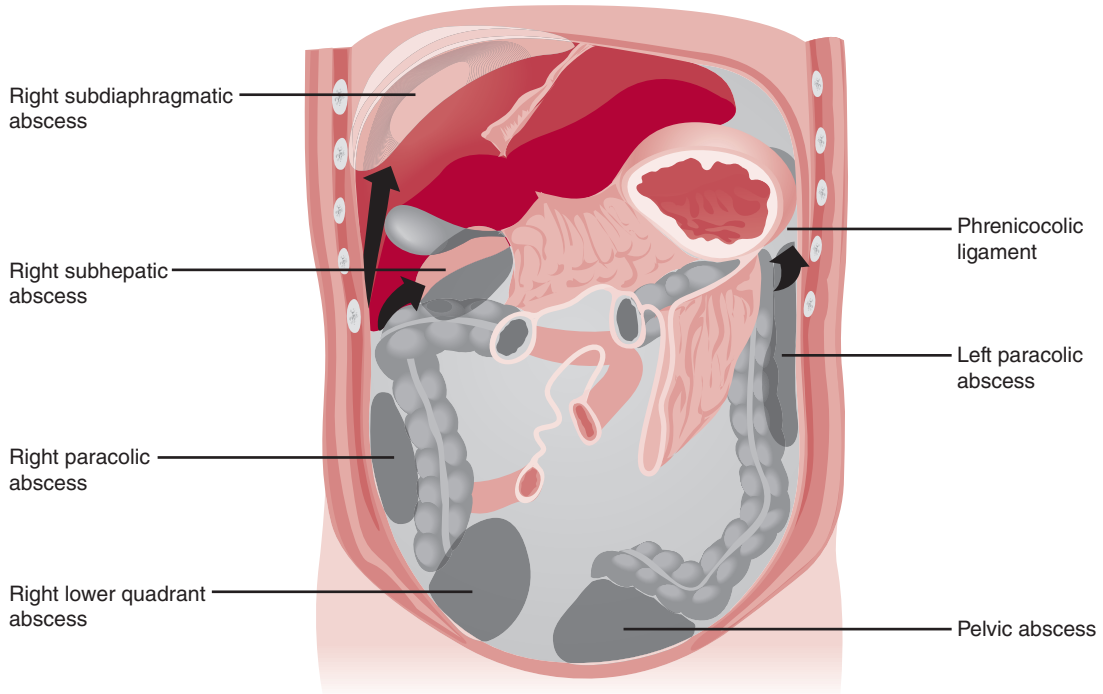

Table 22-2. Common sites and causes of intraperitoneal abscesses.

Site	Cause
Right lower quadrant	Appendicitis, perforated ulcer, regional enteritis
Left lower quadrant	Colorectal perforation (diverticulitis, carcinoma, inflammatory bowel diseases)
Pelvis	Appendicitis, colorectal perforation, gynecologic sepsis, postoperative complications
Subphrenic region	Postoperative complications following gastric or hepatobiliary surgery or splenectomy, perforated ulcer, acute cholecystitis, appendicitis, pancreatitis (lesser sac)
Interloop	Postoperative bowel perforation

► Clinical Findings

A. Symptoms and Signs

An intraperitoneal abscess should be suspected in any patient with a predisposing condition. Fever, tachycardia, and pain may be mild or absent, especially in patients receiving antibiotics. A deep-seated or posteriorly situated abscess

▲ **Figure 22-3.** The infracolic peritoneal compartment and common abscess sites. Note how paracolic fluid on the right side can migrate up into the subphrenic spaces, whereas collections on the left side are prevented from doing so by the phrenicocolic ligament.

may exist in seemingly well individuals whose only symptom is persistent fever. Not infrequently, prolonged ileus or a sluggish recovery in a patient who has had recent abdominal surgery or peritoneal sepsis, rising leukocytosis, or nonspecific radiologic abnormality provides the initial clue. A mass is seldom felt except late in patients with lower quadrant or pelvic lesions. Irritation of contiguous structures may produce lower chest pain, dyspnea, referred shoulder pain or hiccup, or basilar atelectasis or effusion in subphrenic abscesses; or diarrhea or urinary frequency in pelvic abscesses. The diagnosis is more difficult in postoperative, chronically ill, confused, or diabetic patients and in those receiving immunosuppressive drugs, a group particularly susceptible to septic complications.

Sequential multiple organ failure—principally respiratory, renal, or hepatic failure—or stress-induced gastrointestinal bleeding with disseminated intravascular coagulopathy is highly suggestive of intra-abdominal infection.

B. Laboratory Findings

A raised leukocyte count, abnormal liver or renal function test results, hyperglycemia, and abnormal arterial blood gases are nonspecific signs of infection. Serial post-

operative measurement of serum lysozyme (derived from phagocytic cells) is a promising but not widely available test that appears to be highly specific for intra-abdominal pus. Persistently positive blood cultures point strongly to an intra-abdominal focus. A cervical smear demonstrating gonococcal infection is of specific value in diagnosing tubo-ovarian abscess.

C. Imaging Studies

1. X-ray studies—Plain x-rays may suggest an abscess in up to one half of cases. In subphrenic abscesses, the chest x-ray may show pleural effusion, a raised hemidiaphragm, basilar infiltrates, or atelectasis. Abnormalities on plain abdominal films include an ileus pattern, soft tissue mass, air-fluid levels, free or mottled gas pockets, effacement of properitoneal or psoas outlines, and displacement of viscera. Many of these findings are vague or nonspecific, but they may suggest the need for a CT scan. Barium contrast studies interfere with and have been largely superseded by other imaging techniques. A water-soluble upper gastrointestinal series may reveal an unsuspected perforated viscus or outline perigastric and lesser sac abscesses.

2. Ultrasonography—Real-time ultrasonography is sensitive (about 80% of cases) in diagnosing intra-abdominal abscesses. The findings consist of a sonolucent area with well-defined walls containing fluid or debris of variable density. Bowel gas, intervening viscera, skin incisions, and stomas interfere with ultrasound examinations, limiting their efficacy in postoperative patients. Nevertheless, the procedure is readily available, portable, and inexpensive, and the findings are specific when correlated with the clinical picture. Ultrasonography is most useful when an abscess is clinically suspected, especially for lesions in the right upper quadrant and the paracolic and pelvic areas.

3. CT scan—CT scan of the abdomen, the best diagnostic study, is highly sensitive (over 95% of cases) and specific. Neither gas shadows nor exposed wounds interfere with CT scanning in postoperative patients, and the procedure is reliable even in areas poorly seen on ultrasonography. Abscesses appear as cystic collections with density measurements of between 0 and 15 attenuation units. Resolution is increased by contrast media (eg, sodium diatrizoate) injected intravenously or instilled into hollow viscera adjacent to the abscess. One drawback of CT scan is that diagnosis may be difficult in areas with multiple thick-walled bowel loops or if a pleural effusion overlies a subphrenic abscess, so occasionally a very large abscess is missed. CT-guided or ultrasonography-guided needle aspiration can distinguish between sterile and infected collections in uncertain cases.

4. Magnetic resonance imaging—The scanning time, patient inaccessibility during scan acquisition, and upper respiratory motion have limited the usefulness of MRI in the investigation of upper abdominal abscesses. CT scan is generally preferable.

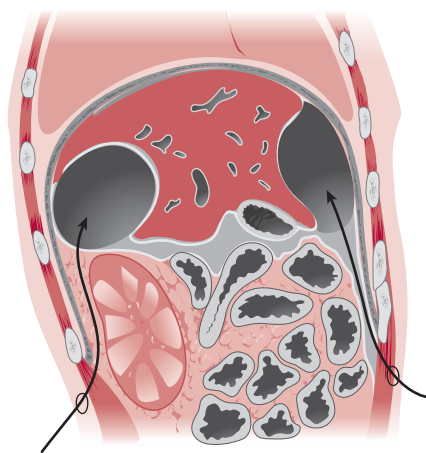

► Treatment

Treatment consists of prompt and complete drainage of the abscess, control of the primary cause, and adjunctive use of effective antibiotics. Depending upon the abscess site and the condition of the patient, drainage may be achieved by operative or nonoperative methods. Percutaneous drainage is the preferred method for single, well-localized, superficial bacterial abscesses that do not have fistulous communications or contain solid debris. Following CT scan or ultrasonographic delineation, a needle is guided into the abscess cavity, infected material is aspirated for culture, and a suitably large drainage catheter is inserted.

Postoperative irrigation is vital to remove debris and ensure catheter patency. This technique is not appropriate for multiple or deep (especially pancreatic) abscesses or for patients with ongoing contamination, fungal infections, or thick purulent or necrotic material. Percutaneous drainage can be performed in about 75% of cases. The success rate

exceeds 80% in simple abscesses but is often less than 50% in more complex ones. It is heavily influenced by the availability of appropriate equipment and the experience of the radiologist performing the drainage. Complications include septicemia, fistula formation, bleeding, and peritoneal contamination.

Open drainage is reserved for abscesses for which percutaneous drainage is inappropriate or unsuccessful. These include many cases where there is a persistent focus of infection (eg, diverticulitis or anastomotic dehiscence) that needs to be controlled. In cases without evidence of continued soiling, the direct extraperitoneal route has the advantage of establishing dependent drainage without contaminating the rest of the peritoneal cavity. Only light general anesthesia or even local anesthesia is necessary, and surgical trauma is minimized. Right anterior subphrenic abscesses can be drained by a subcostal incision (Figure 22-4). Posterior subdiaphragmatic and subhepatic lesions can be decompressed posteriorly through the bed of the resected twelfth rib (Figure 22-4) or by a lateral extraperitoneal method. Most lower quadrant and flank abscesses can be drained through a lateral extraperitoneal approach. Pelvic abscesses can often be detected on pelvic or rectal examination as a fluctuant mass distorting the contour of the vagina or rectum. If needle aspiration directly through the vaginal or rectal wall returns pus, the abscess is best drained by making an incision in that area. In all cases, digital or direct exploration must ensure that all loculations are broken down. Penrose and sump drains are used to allow continued drainage postoperatively until the infection has resolved. Serial sono-

▲ **Figure 22-4.** Extraperitoneal approaches to the right subphrenic spaces. An abscess in the anterior subhepatic space usually requires transperitoneal drainage. Posterior abscesses may also be drained laterally.

grams or imaging studies help document obliteration of the abscess cavity.

Transperitoneal exploration is indicated if the abscess cannot be localized preoperatively, if there are several or deep-lying lesions, if an enterocutaneous fistula or bowel obstruction exists, or if previous drainage attempts have been unsuccessful. This is especially likely in postoperative patients with multiple abscesses and persistent peritoneal soiling. The need to achieve complete drainage fully justifies the greater stress of laparotomy and the small possibility that infection might be spread to other uninvolved areas. Laparoscopy alone is often inadequate, especially in critically toxic patients without a localized focus.

Satisfactory drainage is usually evidenced by improving clinical findings within 3 days after starting treatment. Failure to improve indicates inadequate drainage, another source of (or ongoing) sepsis, or organ dysfunction. Additional localizing studies and repeated percutaneous or operative drainage should be undertaken urgently (ie, within 24-48 hours, depending on the seriousness of the case). Failure to acknowledge adequate progress delays essential studies and incurs higher mortality.

► Prognosis

The mortality rate of serious intra-abdominal abscesses is about 30%. Deaths are related to the severity of the underlying cause, delay in diagnosis, multiple organ failure, and incomplete drainage. Right lower quadrant and pelvic abscesses are usually caused by perforated ulcers and appendicitis in younger individuals. They are readily diagnosed and treated, and the mortality rate is less than 5%. Diagnosis is often delayed in older patients; this increases the likelihood of multiple organ failure. Decompensation of two major organ systems is associated with a mortality rate of over 50%. Subphrenic, deep, and multiple abscesses frequently require operative drainage and are associated with a mortality rate of over 40%. An untreated residual abscess is nearly always fatal. Postoperative abscesses, in addition to their deleterious effects on patient's health, add a significant cost to hospitalizations due to extended length of stay, diagnosis, and treatment.

RETROPERITONEAL & RETROFASCIAL ABSCESSSES

► Pathophysiology

The large retroperitoneal space, extending from the diaphragm to the pelvis, is divided into anterior and posterior compartments (Figure 22-1). The anterior portion includes structures between the posterior peritoneum and the perinephric fascia (pancreas, parts of the duodenum, and the ascending and descending colon). The posterior portion contains the adrenals, kidneys, and perinephric spaces. The compartment posterior to the transversalis fascia is involved in retrofascial abscesses.

Abscesses occur less commonly in the retroperitoneum than in the peritoneal cavity. Retroperitoneal abscesses arise chiefly from injuries or infections in adjacent structures: gastrointestinal tract abscesses due to appendicitis, pancreatitis, penetrating posterior ulcers, regional enteritis, diverticulitis, or trauma; genitourinary tract abscesses due to pyelonephritis; and spinal column abscesses due to osteomyelitis or disk space infections.

Psoas abscesses may be primary or secondary. Primary psoas abscesses, which occur without associated disease of other organs, are caused by hematogenous spread of *S aureus* from an occult source and are predominantly seen in children and young adults. They are more common in underdeveloped countries. Secondary psoas abscesses result from spread of infection from adjacent organs, principally from the intestine, and are therefore most often polymicrobial. The most common cause is Crohn disease.

The pyogenic bacteria (*E coli*, *Bacteroides*, *Proteus*, *Klebsiella*) have replaced *Mycobacterium tuberculosis* as the major causative organism. Surprisingly, only a single causative organism is involved in over one-half of cases. A positive blood culture—especially with *Bacteroides*—is an ominous finding.

► Clinical Findings

Although they may be symptomless, retroperitoneal abscesses tend to develop in patients with obvious acute illnesses. Fever and abdominal or flank pain are prominent features, sometimes accompanied by anorexia, weight loss, and nausea and vomiting. The clinical findings in patients with psoas abscess consist of hip pain, flexion of the hip with pain on extension, and a positive iliopsoas sign. Abdominal, thigh, and back pain may also occur. The diagnosis is apt to be overlooked when pain in the hip aggravated by walking is the major complaint. The differential diagnosis includes retroperitoneal tumors and hematomas. Radionuclide scanning, bowel contrast studies, and urograms are the common preliminary investigations, but CT scanning most accurately delineates these lesions. Gas bubbles are diagnostic of an

abscess. Awareness of the overall clinical picture is essential for CT scanning to differentiate retroperitoneal abscesses from neoplasms or hematomas. Abscesses are confined to specific compartments, whereas malignant lesions, by contrast, frequently violate peritoneal and fascial barriers and can invade bone.

► Treatment

Principles of antibiotics and drainage are the mainstay of treating these abscesses as well. Drainage by catheter has a lower success rate for retroperitoneal than intraperitoneal abscesses for the following reasons: (1) retroperitoneal abscesses often dissect along planes, giving a stellate instead of globular shape; (2) they often contain necrotic debris that will not pass through catheters; and (3) they often invade adjacent muscle (eg, psoas abscess). Operation is indicated if there is no clinical improvement following percutaneous drainage. An extraperitoneal approach via the flank is preferred for upper retroperitoneal and perinephric abscesses—and one via the perineum presacally between the anus and the coccyx for pelvic lesions. Transperitoneal exploration may be unavoidable for deep anterior retroperitoneal abscesses. Resection of necrotic or diseased organs, debridement of the affected compartment, and thorough drainage should be accomplished.

The surgical mortality rate is about 25%. Failure of the fever to subside within 3 days indicates inadequate drainage and persistent sepsis that will prove fatal if not corrected promptly.

► Adhesions

Peritoneal adhesions are a frequent and complex problem following intra-abdominal and pelvic surgery. They are a source of major morbidity and significant health care spending, estimated at over a billion dollars annually. Postoperative peritoneal adhesions form in over 90% of open abdominal surgery. Pelvic adhesions account for 12% of infertility cases in women. They can cause pain and are a source of bowel obstructions. They impair operative exposure in future operations, increase operative times as well as intraoperative complications. Peritoneal trauma and ischemia leads to an imbalance between fibrin deposition and the normal fibrinolytic capacity within the peritoneal cavity, favoring the former. Following injury and ischemia, the peritoneum secretes a serosanguinous exudate rich in fibrin, protoglycans, glycosaminoglycans, and hyaluronic acid. The injured mesothelial cells express tissue factor causing activation of the coagulation cascade which augments fibrin deposition within the secreted exudate. Various chemokines and cytokines attract inflammatory cells to the peritoneum. Hypoxia leads to expression of a fibroblast phenotype that has less fibrinolytic capacity than in the unperturbed state. These fibroblasts infiltrate areas of fibrin deposition and

form collagen to create more organized adhesive bands. Transforming growth factor beta1 (TGF-beta1) is upregulated in peritoneal inflammation and has a significant role in adhesion formation through reduction in fibrinolysis. Plasminogen activator inhibitor (PAI) is secreted by the mesothelium following peritoneal injury and ischemia; it acts to promote fibrin deposition by binding 1:1 with both tissue plasminogen activator (tPA) and urokinase plasminogen activator (uPA). The binding of PAI to uPA and tPA inhibits the conversion of plasminogen to plasmin which is critical for fibrinolysis. Tumor necrosis factor alpha (TNF-alpha) upregulation leads to decreased tPA production and simultaneous increased PAI-1 production by mesothelial cells. VEGF is an angiogenic factor responsible for the neovascularization of peritoneal adhesions, transforming simple adhesions into dense and vascularized fibrous bands that are unable to undergo fibrinolysis. Substance P, a proinflammatory peptide, is upregulated within the peritoneum following peritoneal insult; its interaction with neurokinin-1 receptor leads to a down regulation of metalloproteinases which are integral in fibrinolysis within the peritoneum as well as changes in tPA and PAI-1 expression.

► Prevention & Treatment

Current available strategies to minimize adhesions include careful operative technique and barrier methods. Precise surgical technique and gentle tissue handling is critical to minimize peritoneal and serosal damage to limit the inflammatory response responsible for adhesion formation. Minimizing hemorrhage and obtaining complete hemostasis is necessary as activation of the coagulation cascade causes increased fibrin deposition within the peritoneal cavity which further potentiates adhesion formation. It is also important to avoid contaminating the peritoneum with foreign materials such as particles from powdered gloves, fibers from gowns, gauze pads, surgical drapes, and towels which can all promote foreign body reaction and inflammation. Sutures should be minimally reactive as well to limit foreign body reactions. Laparoscopy has been associated with decreased intraperitoneal adhesions through multiple proposed mechanisms including the haemostatic effect of intraperitoneal tamponade during carbon dioxide insufflations of the abdomen and decreased tissue manipulation leading to decreased denudation of the mesothelium.

To date the only commercially available tools used to prevent postoperative adhesions are barrier methods. Barriers exist in solid, liquid, and sprayable forms. They inhibit postoperative adhesion formation by physically separating areas of inflamed and injured peritoneum during the most active early stages of adhesiogenesis. Barriers such as hyaluronic acid carboxymethylcellulose, Seprafilm Genzyme, are dissolvable and typically remain present within the peritoneal cavity for up to 2 weeks. A large disadvantage of solid barrier methods is that they are only effective at the site the

barrier is placed, also they are often difficult to handle and use during laparoscopy. These barriers are associated with the risk of anastomotic leak if wrapped around fresh bowel anastomoses, as well as small increased fistula and peritonitis rates. Liquid barriers have the added benefit of conferring hydro-flotation in between loops of bowel to help prevent adhesions, though this effect is often shortlived depending on the rate of absorption of the liquid by the peritoneum.

There is significant research using pharmacologic agents, by both systemic and by intraperitoneal injection, in adhesion prevention. HMG-CoA reductase inhibitors have been studied for their role in augmenting the profibrinolytic environment of the peritoneum. Angiotensin receptor blocking agents have been shown to downregulate TGF-beta expression and decrease intraperitoneal adhesion formation. Neurokinin-1 receptor antagonists have been shown to decrease adhesion formation in animal models by blocking the actions of Substance P, increasing concentrations of matrix metalloproteinases, and altering tPA and PAI-1 levels within the peritoneum.

TUMORS OF THE PERITONEUM AND RETROPERITONEUM

Tumors affecting the peritoneum are of both primary peritoneal origin and more commonly secondary implants from intraperitoneal malignancies. Primary peritoneal malignancies include mesothelial tumors, epithelial tumors, and smooth muscle tumors. Secondary peritoneal tumors can

arise from metastatic lesions, infectious origins, and other nonmalignant origins such as endometriosis.

► Peritoneal Mesothelioma

Peritoneal mesothelioma is one of few primary peritoneal neoplasms. It arises from the mesothelium which lines the peritoneal cavity. Mesothelioma of the peritoneum can be diffuse or localized, localized having a more favorable prognosis. Four subtypes, epithelioid, sarcomatoid, mixed or biphasic, and well-differentiated papillary exist. Well-differentiated papillary is usually found in women of reproductive age, has a high cure rate following resection alone distinguishing it from the others. Epithelioid subtypes have a more favorable prognosis when compared with sarcomatoid, which is rarer and more aggressive. Mixed, or biphasic, subtypes are those with both epithelioid and sarcomatoid components. Its incidence is approximately 300-500 new cases being diagnosed in the United States each year. As with pleural mesothelioma, there is an association with an asbestos exposure history. The peritoneal cavity is the second most common site for malignant mesothelioma accounting for approximately 10%-15% of all new malignant mesothelioma cases. Mean age of presentation is in the fifth decade of life. Men are affected more often than women though the divide is less striking when compared with pleural-based mesothelioma.

► Clinical Findings

Presenting symptoms are vague, nonspecific, and frequently cause a delay in diagnosis as patients and practitioners pursue workup and treatment of more benign gastrointestinal tract diseases. Patients most often present with abdominal pain and later increased abdominal girth. Additional presenting signs and symptoms include new hernia, abdominal mass, anorexia, nausea, constipation, and diarrhea. Intestinal obstruction is a late finding in the course of peritoneal mesothelioma.

Diagnosis can be difficult not only given the vague presenting symptoms but also because it can mimic other peritoneal malignancies. Laboratory tests are often unrevealing. CA125 and soluble mesothelin related protein are both commonly elevated, though they have a low specificity. Other tumor markers are not useful in the diagnosis. CT with intravenous contrast typically will demonstrate sheet like thickening of the peritoneum with peritoneal nodules in diffuse cases and distinct masses with peritoneal studding in localized subtypes. In patients who cannot receive iodinated contrast for CT imaging, MRI can be used. Presence of ascites on CT can be variable, ranging from minimal to massive amounts. Laparoscopy with tissue biopsy or CT guided tissue biopsy with immunohistochemical staining for calretinin, cytokeratin 5/6, mesothelin, and Wilms tumor 1 antigen remain the gold standard for diagnosis.

If peritoneal mesothelioma is suspected, laparoscopic tracts should be excised at the time of operation given its propensity to seed port sites. Cytology is of little use in making the diagnosis.

► Treatment

Peritoneal mesothelioma is highly malignant neoplasm; mean time from diagnosis to death is less than 1 year without treatment. Current advances in the past decade with debulking surgery and intraperitoneal chemotherapy has extended survival in many patients though these treatments are not yet standardized. At laparotomy the goal is cytoreduction with excision of all tumor deposits greater than 2.5 mm. A midline laparotomy is used for adequate exposure of the abdomen and pelvic contents. Right and left upper peritoneal quadrants, splenectomy, antrectomy, greater omentectomy, lesser omentum stripping, cholecystectomy, sigmoid colectomy, and pelvic peritoneal resection are performed as required to eliminate all tumor deposits larger than 2.5 mm. Completeness of cytoreduction is the most important factor influencing survival.

Hyperthermic (40.5-43°C) intraperitoneal chemotherapy (HIPEC) is being used as adjuvant therapy and has been associated with median survival times of 54 months. Not yet standardized, common regimens include intraperitoneal mitomycin c, doxorubicin, and cisplatin. No prospective comparisons between cytoreduction with and without HIPEC are available. Factors that are contraindications to undergo cytoreduction and HIPEC include inability to perform adequate cytoreduction, advanced age, poor function status, extra-abdominal metastases, hepatic parenchymal metastases, and bulky retroperitoneal disease.

DESMOPLASTIC SMALL ROUND CELL TUMOR

Desmoplastic small round cell tumors are rare primary peritoneal tumors which are highly aggressive and confer a poor prognosis when diagnosed. This predominantly affects young men, greater than 90% of cases, in the third and fourth decade of life. As with other peritoneal malignancies the presenting signs and symptoms are nonspecific leading to delays in diagnosis. CT is the main imaging modality; typical findings include peritoneal thickening, nodules, heterogeneous intraperitoneal masses often with calcifications and central, low attenuation foci representing

necrotic cores within the masses. Mesenteric lymphadenopathy is often present. Given the rarity of the disease, few consensus guidelines exist for its treatment to date and survival even with resection remains less than 20% at 5 years.

Koniari K et al: Intraabdominal desmoplastic small round cell tumor: report of a case and literature review. *Int J Surg Case Rep* 2011;2:293.

PSEUDOMYXOMA PERITONEI

This unusual disease is caused by a low-grade mucinous cystadenocarcinoma of the appendix or ovary that secretes large amounts of mucus-containing epithelial cells. It should be distinguished from benign appendiceal mucocele, which may also have local mucinous deposits but carries a favorable outlook. Patients seldom complain until advanced stages of disease, at which time they have abdominal distention and pain and, in many instances, intermittent or chronic partial small bowel obstruction. Weight loss and other features of cancer are uncommon. The shed neoplastic cells spread freely to two main areas: the upper abdominal sites of peritoneal fluid resorption (undersurface of diaphragm and omentum) and the dependent peritoneal areas (pelvis and lateral abdominal gutters). Distant metastases and visceral involvement are rare. CT scans show a distinctive peritoneal scalloping of the liver margin, calcified plaques, ascites, and low-density masses. Ultrasound features include anechoic areas in the peritoneum, starburst and scalloped appearance of the liver and mobile echogenic foci in the pelvis.

► Treatment

At laparotomy, the surgeon should remove as much of the primary lesion and gelatinous material as possible. The omentum also should be resected. This often necessitates right hemicolectomy. If there is no apparent primary tumor, the appendix, and, in women, both ovaries should be removed. Some surgeons advocate radical peritonectomy (including splenectomy, cholecystectomy, appendectomy, sigmoid colectomy, and hysterectomy) to eliminate potential areas of microscopic spread. Whether the higher morbidity incurred is justified remains debated.

Current therapy favors very early intraperitoneal fluorouracil-based adjuvant chemotherapy. Systemic chemotherapy is generally useless. Adjuvant intracavitary radiotherapy has also been advocated, especially for patients with residual disease. Reexploration should be undertaken either as a planned second-look laparotomy or to debulk residual tumor responsible for recurrent obstruction or debilitating mucous ascites. Recent studies quote 10 and 15 year respective survival rates of 63% and 59% when combining cytoreductive surgery with HIPEC.

RETROPERITONEAL FIBROSIS

This uncommon entity, is characterized by extensive fibrotic encasement of retroperitoneal tissues. Over two-thirds of cases are idiopathic and the rest secondary to drugs (eg, methysergide, beta-adrenergic blocking agents), retroperitoneal hemorrhage, perianeurysmal inflammation, irradiation, urinary extravasation, or cancer. The fibrosis represents an allergic reaction to insoluble lipid (ceroid) that has leaked from atheromatous plaques, especially those within the aorta. The urinary tract may be involved with a diagnostic triad of hydronephrosis and hydroureter (usually bilateral), medial deviation of the ureters, and extrinsic ureteric compression near the L4-5 level. Desmoplastic involvement of the small and large bowel may give rise to obstructive symptoms. Most patients are men older than 50 who present with renal failure or obstructive uropathy. Pain in the low back or flank is common. Pyuria is present in most patients. The diagnosis is suggested by a CT scan that shows the fibrotic process and any coexisting aneurysmal changes in the aorta. MRI may distinguish fibrosis from lymphoma or metastatic carcinoma. Withdrawal of suspect drugs is usually followed by gradual improvement.

Severe urinary obstruction should be decompressed by ureteric stents or nephrostomy. Prednisone (30-60 mg daily) and immunosuppression have been tried but with inconclusive benefits. These agents should be started early postoperatively before marked fibrosis develops. Tamoxifen has produced regression of desmoid tumors. If surgery becomes necessary, a thick rubbery or fibrotic plaque containing chronic inflammatory cells is found at exploration. Multiple biopsy specimens should be taken to exclude cancer. Ureterolysis should be attempted, and there may be some advantage to wrapping omentum around the freed ureters to reduce the risk of subsequent entrapment. Laparoscopic ureterolysis may occasionally be feasible. The outlook is good as long as there is no underlying cancer.

THE OMENTUM

The omentum is an organ consisting of highly vascularized tissue containing mostly adipose and some lymphoid tissue, described as milky patches, within folds of peritoneum. It is pliable, mobile, and concentrates itself in areas of inflammation within the peritoneal cavity. Anatomically it consists of both greater and lesser components. The greater omentum drapes from the greater curvature of the

stomach anteriorly, descends to cover the small intestines, and turns back on itself inserting onto the transverse colon posteriorly, comprising four layers of peritoneum when fused. During embryology, it derives from the dorsal mesogastrium beginning in the fourth week of gestation. Its blood supply is from the right and left gastroepiploic arteries which arise from the gastroduodenal and splenic arteries respectively and its venous drainage exits to the portal system. The lesser omentum is a much thinner structure and extends from the porta hepatis to the inferior curvature of the stomach. During embryology the lesser omentum derives from the septum transversum. Containing mostly fat and lymphocytes, it has active roles in immune function, inflammation, and infection control within the peritoneal cavity. Its role in maintaining the intraperitoneal cavity is a long known function of the omentum, describe as “the abdominal policeman” by Rutherford Morrison in the early 20th century as he noted it frequently to be in areas of infection and perforation within the peritoneal cavity. Its role in the immune and inflammatory function has grown considerably since that time. If foreign bodies are present in the peritoneal cavity the omentum enlarges in size and mass with expansion of stromal cells rich in tissue and vascular growth factors as well as pluripotent stem cells. These functions allow it to participate in both tissue regeneration and revascularization in areas of intraperitoneal injury, infection, and inflammation.

Shah S et al: Cellular basis of tissue regeneration by omentum. *PLoS One* 2012;7:e38368.

► Torsion & Infarction

Primary (spontaneous) torsion of the omentum may develop if a free portion is fixed by an adhesion or trapped within a hernia. Rotation around the pedicle occludes the blood supply and leads to ischemic necrosis.

Clinically, torsion presents as acute abdominal pain with nausea and vomiting. Tenderness is confined to the involved area, usually on the right side but away from McBurney's point. A mobile, tender mass is noted in one-third of cases. These features may suggest acute appendicitis or cholecystitis but are not typical of those diseases. The clinical findings usually mandate surgical exploration, which reveals sero-sanguineous fluid, a normal appendix, and the hemorrhagic necrotic segment of omentum. Resection of the affected portion is curative.

► Tumors & Cysts

The omentum is frequently involved secondarily by intra-abdominal malignant tumors, especially gastrointestinal and ovarian adenocarcinomas. Primary cysts or vascular anomalies, usually incidentally discovered at laparotomy, are readily resected.

MULTIPLE CHOICE QUESTIONS

1. The peritoneal cavity
 - A. Is lined by an epithelial surface
 - B. Typically contains 100-200 mL of serous fluid
 - C. Has a fluid pH of 6.5-6.9
 - D. Is divided anatomically into parietal and visceral components
 - E. Includes a parietal peritoneal surface investing the small and large bowel
2. Primary bacterial peritonitis
 - A. Is common during pregnancy.
 - B. Typically affects peritoneal fluid containing a high concentration of albumin.
 - C. Is a complication of hypothyroidism.
 - D. Is most frequently associated with cirrhosis and ascites.
 - E. None of the above.
3. Secondary peritonitis is bacterial contamination
 - A. That typically spreads from a hematogenous source
 - B. That often originates from gastrointestinal sources
 - C. That can usually be treated by antibiotics alone
 - D. That usually is mono-microbial
 - E. Of the tissues adjacent to the peritoneal cavity (bladder, kidney) that spreads through lymphatic channels to the peritoneum

Stomach & Duodenum

Gerard M. Doherty, MD

23

I. STOMACH

The stomach receives food from the esophagus and has four functions: (1) it acts as a reservoir that permits eating reasonably large quantities of food at intervals of several hours; (2) food contained in the stomach is mixed, and delivered into the duodenum in amounts regulated by its chemical nature and texture; (3) the first stages of protein and carbohydrate digestion are carried out in the stomach; and (4) a few substances are absorbed across the gastric mucosa.

ANATOMY

The anatomy of the stomach in Figures 23-1, 23-2, and 23-3 illustrates the structure supporting the functions.

The cardia is located at the gastroesophageal junction. The fundus is the portion of the stomach that lies cephalad to the gastroesophageal junction. The corpus is the capacious central part; division of the corpus from the pyloric antrum is marked approximately by the angular incisure, a crease on the lesser curvature just proximal to the “crow’s-foot” terminations of the nerves of Latarjet (Figure 23-3). The pylorus is the boundary between the stomach and the duodenum.

The cardiac gland area is the small segment located at the gastroesophageal junction. Histologically, it contains principally mucus-secreting cells, though a few parietal cells are sometimes present. The oxyntic gland area is the portion containing parietal (oxyntic) cells and chief cells (Figure 23-2). The boundary between this region and the adjacent pyloric gland area is reasonably sharp, since the zone of transition spans a segment of only 1–1.5 cm. The pyloric gland area constitutes the distal 30% of the stomach and contains the G cells that manufacture gastrin. Mucous cells are common in the oxyntic and pyloric gland areas.

As in the rest of the gastrointestinal tract, the muscular wall of the stomach is composed of an outer longitudinal and an inner circular layer. An additional incomplete inner

layer of obliquely situated fibers is most prominent near the lesser curvature but is of less substance than the other two layers.

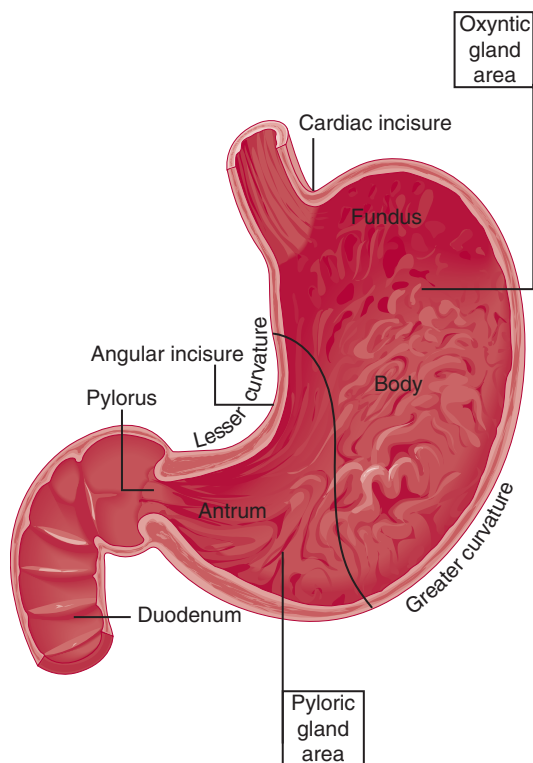

► Blood Supply

The blood supply of the stomach and duodenum is illustrated in Figure 23-3. The left gastric artery supplies the lesser curvature and connects with the right gastric artery, a branch of the common hepatic artery. In 60% of persons, a posterior gastric artery arises off the middle third of the splenic artery and terminates in branches on the posterior surface of the body and the fundus. The greater curvature is supplied by the right gastroepiploic artery (a branch of the gastroduodenal artery) and the left gastroepiploic artery (a branch of the splenic artery). The mid-portion of the greater curvature corresponds to a point at which the gastric branches of this vascular arcade change direction. The fundus of the stomach along the greater curvature is supplied by the vasa brevia, branches of the splenic and left gastroepiploic arteries.

The blood supply to the duodenum is from the superior and inferior pancreaticoduodenal arteries, which are branches of the gastroduodenal artery and the superior mesenteric artery, respectively. The stomach contains a rich submucosal vascular plexus. Venous blood from the stomach drains into the coronary, gastroepiploic, and splenic veins before entering the portal vein. The lymphatic drainage of the stomach, which largely parallels the arteries, partially determines the direction of spread of gastric neoplasms.

► Nerve Supply

The parasympathetic nerves to the stomach are shown in Figure 23-3. As a rule, two major vagal trunks pass through the esophageal hiatus in close approximation to the esophageal muscle. The nerves are originally located to the right and left of the esophagus and stomach during embryonic

▲ **Figure 23–1.** Names of the parts of the stomach. The line drawn from the lesser to the greater curvature depicts the approximate boundary between the oxyntic gland area and the pyloric gland area. No prominent landmark exists to distinguish between antrum and body (corpus). The fundus is the portion cranial to the esophago-gastric junction.

development. When the foregut rotates, the lesser curvature turns to the right and the greater curvature to the left, and corresponding shifts in location of the vagal trunks follow. Hence, the right vagus supplies the posterior and the left the anterior gastric surface. About 90% of the vagal fibers are sensory afferent; the remaining 10% are efferent.

In the region of the gastroesophageal junction, each trunk bifurcates. The anterior trunk sends to the liver a division that travels in the lesser omentum. The bifurcation of the posterior trunk gives rise to fibers that enter the celiac plexus and supply the parasympathetic innervation to the remainder of the gastrointestinal tract as far as the mid-transverse colon. Both trunks, after giving rise to their extragastric divisions, send some fibers directly onto the surface of the stomach and others along the lesser curvature (anterior and posterior nerves of Latarjet) to supply the

distal part of the organ. As shown in Figure 23–3, a variable number of vagal fibers ascend with the left gastric artery after having passed through the celiac plexus.

The preganglionic motor fibers of the vagal trunks synapse with ganglion cells in the Auerbach plexus (plexus myentericus) between the longitudinal and circular muscle layers. Postganglionic cholinergic fibers are distributed to the cells of the smooth muscle layers and the mucosa.

The adrenergic innervation to the stomach consists of postganglionic fibers that pass along the arterial vessels from the celiac plexus.

PHYSIOLOGY

► Motility

Storage, mixing, trituration, and regulated emptying are accomplished by the muscular apparatus of the stomach. Peristaltic waves originate in the body and pass toward the pylorus. The thickness of the smooth muscle increases in the antrum and corresponds to the stronger contractions that can be measured in the distal stomach. The pylorus behaves as a sphincter, though it normally allows a little to-and-fro movement of chyme across the junction.

An electrical pacemaker situated in the fundal musculature near the greater curvature gives rise to regular (3/min) electrical impulses (pacesetter potential, basic electrical rhythm) that pass toward the pylorus in the outer longitudinal layer. Every impulse is not always followed by a peristaltic muscular contraction, but the impulses determine the maximal peristaltic rate. The frequency of peristalsis is governed by a variety of stimuli mentioned below. Each contraction follows sequential depolarization of the underlying circular muscle resulting from arrival of the pacesetter potential.

Peristaltic contractions are more forceful in the antrum than the body and travel faster as they progress distally. Gastric chyme is forced into the funnel-shaped antral chamber by peristalsis; the volume of contents delivered into the duodenum by each peristaltic wave depends on the strength of the advancing wave and the extent to which the pylorus closes. Most of the gastric contents that are pushed into the antral funnel are propelled backward as the pylorus closes and pressure within the antral lumen rises. Five to 15 mL enter the duodenum with each gastric peristaltic wave.

The volume of the empty gastric lumen is only 50 mL. By a process called receptive relaxation, the stomach can accommodate about 1000 mL before intraluminal pressure begins to rise. Receptive relaxation is an active process mediated by vagal reflexes and abolished by vagotomy. Peristalsis is initiated by the stimulus of distention after eating. Various other factors have positive or negative influences on the rate and strength of contractions and the rate of gastric emptying. Vagal reflexes from the stomach have a facilitating

▲ **Figure 23–2.** Histologic features of the mucosa in the oxyntic gland area. Each gastric pit drains three to seven tubular gastric glands. **A:** The neck of the gland contains many mucous cells. Oxyntic (parietal) cells are most numerous in the mid-portion of the glands; peptic (chief) cells predominate in the basal portion. **B:** Drawing from photomicrograph of the gastric mucosa.

influence on peristalsis. The texture and volume of the meal both play a role in the regulation of emptying; small particles are emptied more rapidly than large ones, which the organ attempts to reduce in size (trituration). The osmolality of gastric chyme and its chemical makeup are monitored by duodenal receptors. If osmolality is greater than 200 mosm/L, a long vagal reflex (the enterogastric reflex) is activated, delaying emptying. Gastrin causes delay in emptying. Gastrin is the only circulating gastrointestinal hormone to have a physiologic effect on emptying.

► Gastric Juice

The output of gastric juice in a fasting subject varies between 500 and 1500 mL/d. After each meal, about 1000 mL are secreted by the stomach.

The components of gastric juice are as follows.

A. Mucus

Mucus is a heterogeneous mixture of glycoproteins manufactured in the mucous cells of the oxyntic and pyloric gland areas. Mucus provides a weak barrier to the diffusion of H^+ and probably protects the mucosa. It also acts as a lubricant and impedes diffusion of pepsin.

B. Pepsinogen

Pepsinogens are synthesized in the chief cells of the oxyntic gland area (and to a lesser extent in the pyloric area) and are stored as visible granules. Cholinergic stimuli, either vagal or intramural, are the most potent pepsinogens, though gastrin and secretin are also effective. The precursor zymogen is activated when pH falls below 5.00, a process that entails severance of a polypeptide fragment from the larger molecule. Pepsin cleaves peptide bonds, especially those containing phenylalanine, tyrosine, or leucine. Its optimal pH is about 2.00. Pepsin activity is abolished at pH greater than 5.00, and the molecule is irreversibly denatured at pH greater than 8.00.

C. Intrinsic Factor

Intrinsic factor, a mucoprotein secreted by the parietal cells, binds with vitamin B_{12} of dietary origin and greatly enhances absorption of the vitamin. Absorption occurs by an active process in the terminal ileum.

Intrinsic factor secretion is enhanced by stimuli that evoke H^+ output from parietal cells. Pernicious anemia is characterized by atrophy of the parietal cell mucosa, deficiency

▲ **Figure 23-3.** Blood supply and parasympathetic innervation of the stomach and duodenum.

in intrinsic factor, and anemia. Subclinical deficiencies in vitamin B₁₂ have been described after operations that reduce gastric acid secretion, and abnormal Schilling tests in these patients can be corrected by the administration of intrinsic factor. Total gastrectomy creates a dependence on parenteral administration of vitamin B₁₂.

D. Electrolytes

The unique characteristic of gastric secretion is its high concentration of hydrochloric acid, a product of the parietal cells. As the concentration of H⁺ rises during secretion, that of Na⁺ drops in a reciprocal fashion. K⁺ remains relatively constant at 5–10 mEq/L. Chloride concentration remains near 150 mEq/L, and gastric juice maintains its isotonicity at varying secretory rates.

► The Parietal Cell & Acid Secretion

Many of the key events in acid secretion by gastric parietal cells are illustrated in Figure 23-4. The onset of secretion is accompanied by striking morphologic changes in the apical membranes. Resting parietal cells are characterized by

an infolding of the apical membrane, called the secretory canaliculus, which is lined by short microvilli. Multiple membrane-bound tubulovesicles and mitochondria are present in the cytoplasm. With stimulation, the secretory canaliculus expands, the microvilli become long and narrow and filled with microfilaments, and the cytoplasmic tubulovesicles disappear. The proton pump mechanism for acid secretion is located in the tubulovesicles in the resting state and in the secretory canaliculus in the stimulated state.

The basal lateral membrane contains the receptors for secretory stimulants and transfers HCO₃⁻ out of the cell to balance the H⁺ output at the apical membrane. Active uptake of Cl⁻ and K⁺ conduction also occur at the basal lateral membrane. Separate membrane-bound receptors exist for histamine (H₂ receptor), gastrin, and acetylcholine. The intracellular second messengers are cyclic adenosine monophosphate (cAMP) for histamine and Ca²⁺ for gastrin and acetylcholine.

Acid secretion at the apical membrane is accomplished by a membrane-bound H⁺/K⁺-ATPase (the proton pump); H⁺ is secreted into the lumen in exchange for K⁺.

▲ **Figure 23–4.** Diagram of a parietal cell, showing the receptor systems and ion pathways in the basal lateral membrane and the apical membrane transition from a resting to a stimulated state. Ach, acetylcholine; CaM, calmodulin; G, gastrin; H, histamine; MF, microfilaments; SC, secretory canaliculus; TV, tubulovesicles. (Redrawn, with permission, from Malinowska DH, Sachs G: Cellular mechanisms of acid secretion. *Clin Gastroenterol.* 1984;13(2):309–326.)

► Mucosal Resistance in the Stomach & Duodenum

The healthy mucosa of the stomach and duodenum is provided with mechanisms that allow it to withstand the potentially injurious effects of high concentrations of luminal acid. Disruption of these mechanisms may contribute to acute or chronic ulceration.

The surface of the gastric mucosa is coated with mucus and secretes HCO₃⁻ in addition to H⁺. Protected by the blanket of mucus, the surface pH is much higher than the luminal pH. HCO₃⁻ secretion is stimulated by cAMP, prostaglandins, cholinomimetics, glucagon, cholecystokinin, and by as yet unidentified paracrine hormones. Inhibitors of HCO₃⁻ secretion include nonsteroidal anti-inflammatory agents, alpha-adrenergic agonists, bile acids, ethanol, and acetazolamide. Increases in luminal H⁺ result in increased HCO₃⁻ secretion, probably mediated by tissue prostaglandins.

Gastric mucus is a gel composed of high-molecular-weight glycoproteins and 95% water. Since it forms an unstirred layer, it helps the underlying mucosa to maintain a higher pH than that of gastric juice, and it also acts as a barrier to the diffusion of pepsin. At the surface of the layer of mucus, peptic digestion continuously degrades mucus, while below it is continuously being replenished by mucous cells. Gastric acid is thought to enter the lumen through thin spots in the mucus overlying the gastric glands. Secretion of mucus is stimulated by luminal acid and perhaps by cholinergic stimuli. The layer of mucus is damaged by exposure to nonsteroidal anti-inflammatory agents and is enhanced by topical prostaglandin E₂.

Mucosal defects produced by mechanical or chemical trauma are rapidly repaired by adjacent normal cells that spread to cover the defect, a process that can be enhanced experimentally by adding HCO₃⁻ to the nutrient side of the mucosa.

The duodenal mucosa possesses defenses similar to those in the stomach: the ability to secrete HCO_3^- and mucus and rapid repair of mucosal injuries.

► Regulation of Acid Secretion

The regulation of acid secretion can best be described by considering separately those factors that enhance gastric acid production and those that depress it. The interaction of these forces is what determines the levels of secretion observed during fasting and after meals.

A. Stimulation of Acid Secretion

Acid production is usually described as the result of three phases that are excited simultaneously after a meal. The separation into phases is of value principally for descriptive purposes.

1. Cephalic phase—Stimuli that act upon the brain lead to increased vagal efferent activity and acid secretion. The sight, smell, taste, or even thought of appetizing food may elicit this response. The effect is vagally mediated and is abolished by vagotomy. The vagal stimuli have a direct effect on the parietal cells to increase acid output.

2. Gastric phase—Food in the stomach (principally protein hydrolysates and hydrophobic amino acids) stimulates gastrin release from the antrum. Gastric distention has a similar but less intense effect.

The presence of food in the stomach excites long vagal reflexes, impulses that pass to the central nervous system via vagal afferents and return to stimulate the parietal cells.

A third aspect of the gastric phase involves the sensitizing effect of distention of the parietal cell area to gastrin that is probably mediated through local intramural cholinergic reflexes.

3. Intestinal phase—The role of the intestinal phase in the stimulation of gastric secretion has been incompletely investigated. Various experiments have shown that the presence of food in the small bowel releases a humoral factor, named entero-oxyntin, that evokes acid secretion from the stomach.

B. Inhibition of Acid Secretion

Without systems to limit secretion, unchecked acid production could become a serious clinical problem. Examples can be found (Billroth II gastrectomy with retained antrum) where acid production rose after surgical procedures that interfered with these inhibitory mechanisms.

1. Antral inhibition—pH below 2.50 in the antrum inhibits the release of gastrin regardless of the stimulus. When the pH reaches 1.20, gastrin release is almost completely blocked. If the normal relationship of parietal cell mucosa

to antral mucosa is changed so that acid does not flow past the site of gastrin production, serum gastrin may increase to high levels, with marked acid stimulation. Somatostatin in gastric antral cells serves a physiologic role as an inhibitor of gastrin release (a paracrine function).

2. Intestinal inhibition—The intestine participates in controlling acid secretion by liberating hormones that inhibit both the release of gastrin and its effects on the parietal cells. Secretin blocks acid secretion under experimental conditions but not as a physiologic action. Fat in the intestine is the most potent method of inhibition, affecting gastrin release and acid secretion.

► Integration of Gastric Physiologic Function

Ingested food is mixed with salivary amylase before it reaches the stomach. The mechanisms stimulating gastric secretion are activated. Serum gastrin levels increase from a mean fasting concentration of about 50 pg/mL to 200 pg/mL, the peak occurring about 30 minutes after the meal. Food in the lumen of the stomach is exposed to high concentrations of acid and pepsin at the mucosal surface. Food settles in layers determined by sequence of arrival, but fat tends to float to the top. The greatest mixing occurs in the antrum. Antral contents therefore become more uniformly acidic than those in the body of the organ, where the central portion of the meal tends to remain alkaline for a considerable time, allowing continued activity of the amylase.

Peptic digestion of protein in the stomach is only about 5%–10% complete. Carbohydrate digestion may reach 30%–40%. A lipase originating from the tongue initiates the first stages of lipolysis in the stomach.

The gastric contents are delivered to the duodenum at a rate determined by the volume and texture of the meal, its osmolality and acidity, and its content of fat. A meal of lean meat, potatoes, and vegetables leaves the stomach within 3 hours. A meal with a very high fat content may remain in the stomach for 6–12 hours.

PEPTIC ULCER

Peptic ulcers result from the corrosive action of acid gastric juice on a vulnerable epithelium. Depending on circumstances, they may occur in the esophagus, the duodenum, the stomach itself, the jejunum after surgical construction of a gastrojejunostomy, or the ileum in relation to ectopic gastric mucosa in Meckel diverticulum. When the term peptic ulcer was first used, it was thought that the most important factor was the peptic activity in gastric juice. Since then, evidence has implicated acid as the chief injurious agent; in fact, it is axiomatic that if gastric juice contains no acid, a (benign) peptic ulcer cannot be present. Appreciation of the role of acid has led to the emphasis on therapy with antacids and H_2 blocking agents for the medical therapy of ulcers and to operations

that reduce acid secretion as the major surgical approach. In the case of duodenal and gastric ulcers, *Helicobacter pylori* must colonize and weaken the mucosa before acid is able to do the damage, and therapy directed against this organism has a more definitive effect on the disease.

It has been estimated that about 2% of the adult population in the United States suffers from active peptic ulcer disease, and about 10% of the population will have the disease during their lifetime. Men are affected three times as often as women. Duodenal ulcers are ten times more common than gastric ulcers in young patients, but in the older age groups the frequency is about equal. Probably as a result of a declining prevalence of *H pylori* infection, the incidence has declined to less than half what it was 30 years ago.

In general terms, the ulcerative process can lead to four types of disability: (1) Pain is the most common. (2) Bleeding may occur as a result of erosion of submucosal or extraintestinal vessels as the ulcer becomes deeper. (3) Penetration of the ulcer through all layers of the affected gut results in perforation if other viscera do not seal the ulcer. (4) Obstruction may result from inflammatory swelling and scarring and is most likely to occur with ulcers located at the pylorus or gastroesophageal junction, where the lumen is narrowest.

The clinical features and prognosis of duodenal ulcer and gastric ulcer are sufficiently different to be dealt with separately here.

DUODENAL ULCER

ESSENTIALS OF DIAGNOSIS

- ▶ Epigastric pain often relieved by food or antacids
- ▶ Epigastric tenderness
- ▶ Normal or increased gastric acid secretion
- ▶ Signs of ulcer disease on upper gastrointestinal x-rays or endoscopy
- ▶ Evidence of *H pylori* infection

▶ General Considerations

Duodenal ulcers may occur in any age group but are most common in the young and middle-aged (20–45 years). They appear in men more often than women. About 95% of duodenal ulcers are situated within 2 cm of the pylorus, in the duodenal bulb.

Considerable evidence implicates *H pylori* as the principal cause of duodenal ulcer disease. This microaerophilic gram-negative curved bacillus can be found colonizing patches of gastric metaplasia within the duodenum in 90% of patients with this disease. The bacilli remain on the surface of the mucosa rather than invading it. They are thought

to render the duodenum more vulnerable to the injurious effects of acid and pepsin by releasing urease or other toxins.

The epidemiology of peptic ulcer disease reflects the prevalence of *H pylori* infection in different populations. In areas of the world where peptic ulcer is uncommon (eg, rural Africa), human infection is rare. Duodenal ulcer disease has emerged as a major clinical entity in Western society only since the latter part of the 19th century. The incidence reached a peak about 35 years ago and then declined to reach a lower plateau a few years ago. These changes are thought to be explained by variations in *H pylori* infection resulting from public health factors. Within countries like the United States, the distribution of *H pylori* is explainable by a fecal-oral theory of transmission. The prevalence of infection is higher among lower socioeconomic groups. Interestingly, only a minority of infected persons develop ulcers. *H pylori* also has an important role in the etiology of gastric ulcer, gastric cancer, and gastritis. The 10% of duodenal ulcers that are not associated with helicobacter infection are caused by nonsteroidal anti-inflammatory drugs and other agents.

Gastric acid secretion is characteristically higher than normal in patients with duodenal ulcer compared with normal subjects, but only one-sixth of the duodenal ulcer population have secretory levels that exceed the normal range (ie, acid secretion in normal subjects and those with duodenal ulcer overlap considerably), so the disease cannot be explained simply as a manifestation of increased acid production. Whether acid secretion increases in response to helicobacter infection is doubted. One possibility is that the patches of metaplastic gastric epithelium in the duodenum on which helicobacter take up residence result from the action of acid. Then the colonized patches undergo ulceration.

Chronic liver disease, chronic lung disease, and chronic pancreatitis have all been implicated as increasing the possibility of duodenal ulceration.

▶ Clinical Findings

A. Symptoms and Signs

Pain, the presenting symptom in most patients, is usually located in the epigastrium and is variably described as aching, burning, or gnawing. Radiologic survey studies indicate, however, that some patients with active duodenal ulcer have no gastrointestinal complaints.

The daily cycle of the pain is often characteristic. The patient usually has no pain in the morning until an hour or more after breakfast. The pain is relieved by the noon meal, only to recur in the later afternoon. Pain may appear again in the evening, and in about half of cases, it arouses the patient during the night. Food, milk, or antacid preparations give temporary relief.

When the ulcer penetrates the head of the pancreas posteriorly, back pain is noted; concomitantly, the cyclic pattern

of pain may change to a more steady discomfort, with less relief from food and antacids.

Varying degrees of nausea and vomiting are common. Vomiting may be a major feature even in the absence of obstruction.

The abdominal examination may reveal localized epigastric tenderness to the right of the midline, but in many instances no tenderness can be elicited.

B. Endoscopy

Gastroduodenoscopy is useful in evaluating patients with an uncertain diagnosis, those with bleeding from the upper intestine, and those who have obstruction of the gastroduodenal segment and for assessing response to therapy.

C. Diagnostic Tests

1. Gastric analysis—A gastric analysis may be indicated in certain cases. The standard gastric analysis consists of the following: (a) Measurement of acid production by the unstimulated stomach under basal fasting conditions; the result is expressed as H^+ secretion in mEq/h and is termed the basal acid output (BAO). (b) Measurement of acid production during stimulation by histamine or pentagastrin given in a dose maximal for this effect. The result is expressed as H^+ secretion in mEq/h and is termed the maximal acid output (MAO).

Interpretation of the results is outlined in Table 23–1.

2. Serum gastrin—Depending on the laboratory, normal basal gastrin levels average 50–100 pg/mL, and levels over 200 pg/mL can almost always be considered high.

Gastrin concentrations may rise in hyposecretory and hypersecretory states. In the former conditions (eg, atrophic gastritis, pernicious anemia, acid-suppressant medications), the cause is higher antral pH with loss of antral inhibition for gastrin release. More important clinically is elevated gastrin levels with concomitant hypersecretion, where the high gastrin level is responsible for the increased acid and resulting peptic ulceration. The best-defined clinical condition in

Table 23–1. Mean values for acid output during gastric analysis for normals and patients with duodenal ulcer. The upper limits of normal are basal, 5 meq/h; maximal, 30 meq/h.

	Sex	Mean Acid Output (meq/h)	
		Normal	Duodenal Ulcer
Basal	Male	2.5	5.5
	Female	1.5	3
Maximal (pentagastrin)	Male	30	40
	Female	20	30

this category is Zollinger–Ellison syndrome (gastrinoma). Antrum attached to the duodenum, but out of continuity with the gastric alimentary flow after gastrectomy (retained antrum), is another cause of elevated gastrin driving excess gastric acid secretion.

A fasting serum gastrin determination should be obtained in patients with peptic ulcer disease that is unusually severe or refractory to therapy.

D. Radiographic Studies

On an upper gastrointestinal series or CT scan with gastrointestinal contrast, the changes induced by duodenal ulcer consist of duodenal deformities and an ulcer niche. Inflammatory swelling and scarring may lead to distortion of the duodenal bulb, eccentricity of the pyloric channel, or pseudodiverticulum formation. The ulcer itself may be seen either in profile or, more commonly, *en face*.

► Differential Diagnosis

The most common diseases simulating peptic ulcer are (1) chronic cholecystitis, in which cholecystograms show either nonfunctioning of the gallbladder or stones in a functioning gallbladder; (2) acute pancreatitis, in which the serum amylase is elevated; (3) chronic pancreatitis, in which endoscopic retrograde cholangiopancreatography (ERCP) shows an abnormal pancreatic duct; (4) functional indigestion, in which x-rays are normal; and (5) reflux esophagitis.

► Complications

The common complications of duodenal ulcer are hemorrhage, perforation, and duodenal obstruction. Each of these is discussed in a separate section. Less common complications are pancreatitis and biliary obstruction.

► Prevention

Prevention of ulcer disease entails avoidance of *H pylori* infection.

► Treatment

Acute duodenal ulcer can be controlled by suppressing acid secretion in most patients, but the long-term course of the disease (ie, frequency of relapses and of complications) is unaffected unless *H pylori* infection is eradicated. Surgical therapy is recommended principally for the treatment of complications: bleeding, perforation, or obstruction.

A. Medical Treatment

The goals of medical therapy are: (1) to heal the ulcer and (2) to cure the disease. Treatment in the first category is

aimed at decreasing acid secretion or neutralizing acid. The principal drugs consist of H_2 receptor antagonists (eg, cimetidine, ranitidine) and proton pump blockers (eg, omeprazole, pantoprazole).

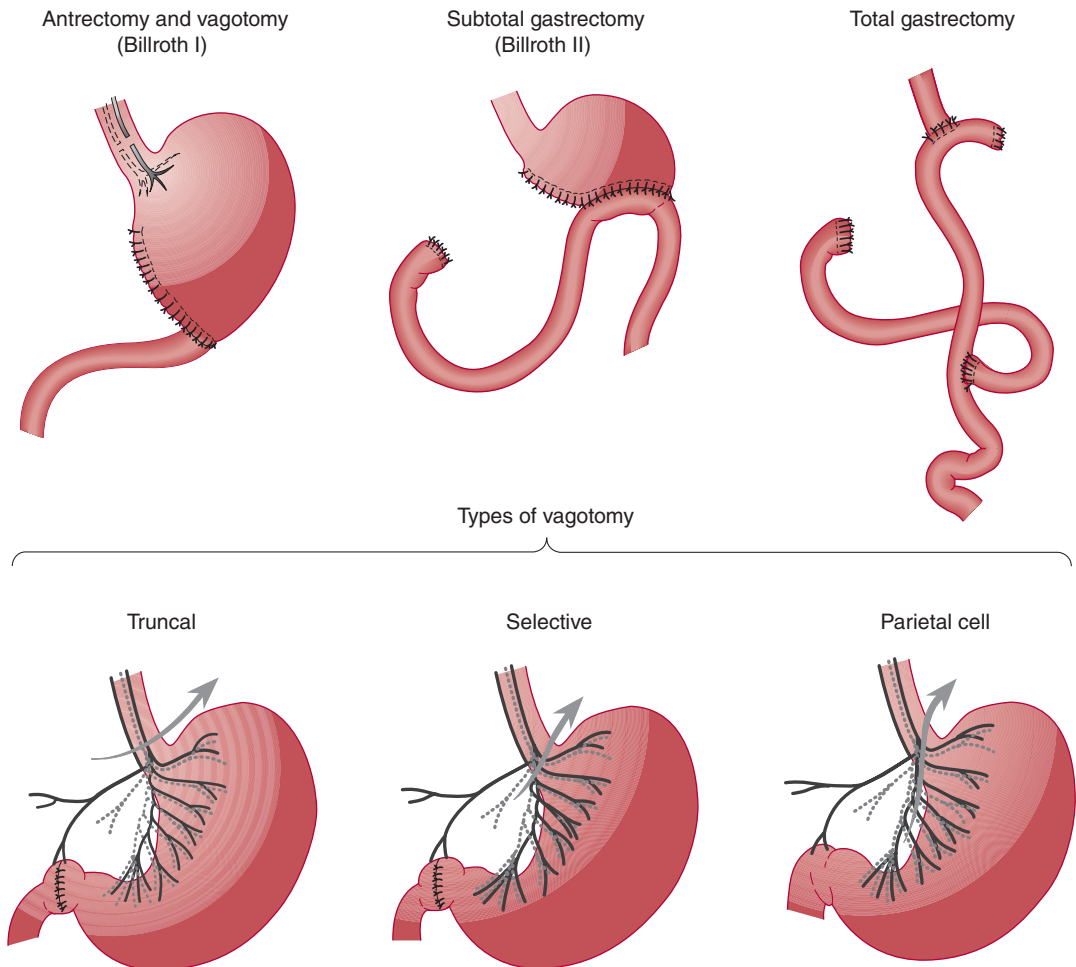

After the ulcer has healed, discontinuation of therapy results in an 80% recurrence rate within 1 year, which may be avoided by chronic nighttime administration of a single dose of acid suppressive agent. A better approach is to treat the *H pylori* infection along with the ulcer, since eradication of *H pylori* diminishes recurrent ulceration unless the infection recurs—an uncommon event. The following combination is an effective regimen: lansoprazole, 30 mg twice daily for 14 days; amoxicillin, 1 g twice daily for 14 days; and clarithromycin, 500 mg twice daily for 14 days.

B. Surgical Treatment

If medical treatment has been optimal, a persistent ulcer may be judged intractable, and surgical treatment is indicated. This is now uncommon.

The surgical procedures that can cure peptic ulcer are aimed at reduction of gastric acid secretion. Excision of the ulcer itself is not sufficient for either duodenal or gastric ulcer; recurrence is nearly inevitable with such procedures.

The surgical methods of treating duodenal ulcer are vagotomy (several varieties) and antrectomy plus vagotomy. All of these procedures can be performed laparoscopically. With rare exceptions, one of the vagotomy operations is sufficient (Figure 23–5).

▲ **Figure 23–5.** Various types of operations currently popular for treating duodenal ulcer disease. Total gastrectomy is reserved for Zollinger-Ellison syndrome. The choice among the other procedures should be individualized according to principles discussed in the text.

1. Vagotomy—Truncal vagotomy consists of resection of a 1- or 2-cm segment of each vagal trunk as it enters the abdomen on the distal esophagus. The resulting vagal denervation of the gastric musculature produces delayed emptying of the stomach in many patients unless a drainage procedure is performed. The method of drainage most often selected is pyloroplasty (Heineke–Mikulicz procedure, Figure 23–6); gastrojejunostomy is used less often. Neither procedure gives a superior functional result, and pyloroplasty is less time consuming.

Vagal denervation of just the parietal cell area of the stomach is called parietal cell vagotomy or proximal gastric vagotomy. The technique spares the main nerves of Latarjet (Figures 23–3 and 23–5) but divides all vagal branches that terminate on the proximal two-thirds of the stomach. Since antral innervation is preserved, gastric emptying is relatively normal, and a drainage procedure is unnecessary. Nevertheless, parietal cell vagotomy plus pyloroplasty gives better results (ie, fewer recurrent ulcers) than parietal cell vagotomy alone. Parietal cell vagotomy appears to have about the same effectiveness as truncal or selective vagotomy

for curing the ulcer disease, but dumping and diarrhea are much less frequent.

The vagotomy procedures have the advantages of technical simplicity and preservation of the entire gastric reservoir capacity. The principal disadvantage is recurrent ulceration in about 10% of patients. The recurrence rate after parietal cell vagotomy is about twice as high in patients with prepyloric ulcer, and most surgeons use a different operation for an ulcer in this location.

2. Antrectomy and vagotomy—This operation entails a distal gastrectomy of 50% of the stomach, with the line of gastric transection carried high on the lesser curvature to conform with the boundary of the gastrin-producing mucosa.

The terms antrectomy and hemigastrectomy are loosely synonymous. The proximal remnant may be reanastomosed to the duodenum (Billroth I resection) or to the side of the proximal jejunum (Billroth II resection). The Billroth I technique is most popular, but there is no conclusive evidence that the results are superior. When creating a Billroth II

▲ **Figure 23–6.** Heineke–Mikulicz pyloroplasty. A longitudinal incision has been made across the pylorus, revealing an active ulcer in the duodenal bulb. The insert shows the transverse closure of the incision that widens the gastric outlet. The accompanying vagotomy is not shown.

(gastrojejunostomy) reconstruction, the surgeon may bring the jejunal loop up to the gastric remnant either anterior to the transverse colon or posteriorly through a hole in the transverse mesocolon. Since either method is satisfactory, an antecolic anastomosis is elected in most cases because it is simpler. Truncal vagotomy is performed as described in the preceding section; antrectomy by itself will not prevent a high recurrence rate. In most instances, the surgeon will be able to remove the ulcerated portion of duodenum in the course of resection.

Vagotomy and antrectomy is associated with a low incidence of marginal ulceration (2%) and a generally good overall outcome, but the risk of complications is higher than after vagotomy without resection.

3. Subtotal gastrectomy—This operation consists of resection of two-thirds to three-fourths of the distal stomach. After subtotal gastrectomy for duodenal ulcer, a Billroth II reconstruction is preferable. Subtotal gastrectomy is largely of historical interest.

► Complications of Surgery for Peptic Ulcer

A. Early Complications

Duodenal stump leakage, gastric retention (poor gastric emptying), and hemorrhage may develop in the immediate postoperative period.

B. Late Complications

4. Recurrent ulcer (marginal ulcer, stomal ulcer, anastomotic ulcer)—Recurrent ulcers formed in about 10% of duodenal ulcer patients treated by vagotomy and pyloroplasty or parietal cell vagotomy; and in 2%–3% after vagotomy and antrectomy or subtotal gastrectomy without chronic acid suppression. Recurrent ulcers nearly always develop immediately adjacent to the anastomosis on the intestinal side.

The usual complaint is upper abdominal pain, which is often aggravated by eating and improved by antacids. In some patients, the pain is felt more to the left in the epigastrium, and left axillary or shoulder pain is occasionally reported. About a third of patients with stomal ulcer have major gastrointestinal hemorrhage. Free perforation is less common (5%).

Diagnosis and treatment are essentially the same as for the original ulcer.

5. Gastrojejunocolic and gastrocolic fistula—A deeply eroding ulcer may occasionally produce a fistula between the stomach and colon. Most examples have resulted from recurrent peptic ulcer after an operation that included a gastrojejunal anastomosis.

Severe diarrhea and weight loss are the presenting symptoms in over 90% of cases. Abdominal pain typical of recurrent peptic ulcer often precedes the onset of the diarrhea.

Bowel movements number 8–12 or more a day; they are watery and often contain particles of undigested food.

The degree of malnutrition ranges from mild to very severe. Laboratory studies reveal low serum proteins and manifestations of fluid and electrolyte depletion. Appropriate tests may reflect deficiencies in both water-soluble and fat-soluble vitamins.

An upper gastrointestinal series reveals the marginal ulcer in only 50% of patients and the fistula in only 15%. Barium enema unfaillingly demonstrates the fistulous tract.

Initial treatment should replenish fluid and electrolyte deficits. The involved colon and ulcerated gastrojejunal segment should be excised and colonic continuity reestablished. Vagotomy, partial gastrectomy, or both are required to treat the ulcer diathesis and prevent another recurrent ulcer. Results are excellent in benign disease. In general, the outlook for patients with a malignant fistula is poor.

6. Dumping syndrome—Symptoms of the dumping syndrome are noted to some extent by most patients who have an operation that impairs the ability of the stomach to regulate its rate of emptying. Within several months, however, dumping is a clinical problem in only 1%–2% of patients. Symptoms fall into two categories: cardiovascular and gastrointestinal. Shortly after eating, the patient may experience palpitations, sweating, weakness, dyspnea, flushing, nausea, abdominal cramps, belching, vomiting, diarrhea, and, rarely, syncope. The degree of severity varies widely, and not all symptoms are reported by all patients. In severe cases, the patient must lie down for 30–40 minutes until the discomfort passes.

Diet therapy to reduce jejunal osmolality is successful in all but a few cases. The diet should be low in carbohydrate and high in fat and protein content. Sugars and carbohydrates are least well tolerated; some patients are especially sensitive to milk. Meals should be taken dry, with fluids restricted to between meals. This dietary regimen ordinarily suffices, but anticholinergic drugs may be of help in some patients; others have reported improvement with supplemental pectin in the diet, or the use of somatostatin analogs.

7. Alkaline gastritis—Reflux of duodenal juices into the stomach is an invariable and usually innocuous situation after operations that interfere with pyloric function, but in some patients, it may cause marked gastritis. The principal symptom is postprandial pain, and the diagnosis rests on endoscopic and biopsy demonstration of an edematous inflamed gastric mucosa. Since a minor degree of gastritis is found in most patients after Billroth II gastrectomy, the endoscopic findings are to some degree nonspecific. Persistent severe pain is an indication for surgical reconstruction. Roux-en-Y gastrojejunostomy with a 40-cm efferent jejunal limb is the treatment of choice.

8. Anemia—Iron deficiency anemia develops in about 30% of patients within 5 years after partial gastrectomy. It is caused by failure to absorb ingested iron bound in an organic molecule. Before this diagnosis is accepted, the patient should be checked for blood loss, marginal ulcer, or an unsuspected tumor. Inorganic iron—ferrous sulfate or ferrous gluconate—is indicated for treatment and is absorbed normally after gastrectomy.

Vitamin B₁₂ deficiency and megaloblastic anemia appear in a few cases after gastrectomy.

9. Postvagotomy diarrhea—About 5%–10% of patients who have had truncal vagotomy require treatment with antidiarrheal agents at some time, and perhaps 1% are seriously troubled by this complication. The diarrhea may be episodic, in which case the onset is unpredictable after symptom-free intervals of weeks to months. An attack may consist of only one or two watery movements or, in severe cases, may last for a few days. Other patients may continually produce 3–5 loose stools per day.

Most cases of postvagotomy diarrhea can be treated satisfactorily with constipating agents.

10. Chronic gastroparesis—Chronic delayed gastric emptying is seen occasionally after gastric surgery. Prokinetic agents (eg, metoclopramide) are often helpful, but some cases are refractory to any therapy except a completion gastrectomy and Roux-en-Y esophagojejunostomy (ie, total gastrectomy).

ZOLLINGER-ELLISON SYNDROME (GASTRINOMA)

ESSENTIALS OF DIAGNOSIS

- ▶ Peptic ulcer disease (often severe) in 95%
- ▶ Gastric hypersecretion
- ▶ Elevated serum gastrin
- ▶ Non-B islet cell tumor of the pancreas or duodenum

▶ General Considerations

Zollinger-Ellison syndrome is manifested by gastric acid hypersecretion caused by a gastrin-producing tumor (gastrinoma). The normal pancreas does not contain appreciable amounts of gastrin. Most gastrinomas occur in the submucosa of the duodenum; others are found in the

pancreas and rarely as primary tumors of the liver or ovary. About one-third of patients have the multiple endocrine neoplasia type I syndrome (MEN 1), which is characterized by a family history of endocrinopathy and the presence of tumors in other glands, especially the parathyroid glands and pituitary. Patients with MEN 1 usually have multiple gastrinomas. Those without MEN 1 usually have solitary gastrinomas that are often malignant. The tumors may be as small as 2–3 mm and are often difficult to find.

The diagnosis of cancer can be made only with findings of metastases or blood vessel invasion, because the histologic pattern is similar for benign and malignant tumors.

▶ Clinical Findings

A. Symptoms and Signs

Symptoms associated with gastrinoma are principally a result of acid hypersecretion—usually from peptic ulcer disease. Some patients with gastrinoma have severe diarrhea from the large amounts of acid entering the duodenum, which can destroy pancreatic lipase and produce steatorrhea, damage the small bowel mucosa, and overload the intestine with gastric and pancreatic secretions. About 5% of patients present with diarrhea only.

Ulcer symptoms are often refractory to large doses of antacids or standard doses of H₂ blocking agents. Hemorrhage, perforation, and obstruction are common complications. Marginal ulcers appear after surgical procedures that would cure the ordinary ulcer diathesis.

B. Laboratory Findings

Hypergastrinemia in the presence of acid hypersecretion is necessary for the diagnosis of gastrinoma. Gastrin levels are normally inversely proportionate to gastric acid output; therefore, diseases that result in increased gastric pH may cause a rise in serum gastrin concentration (eg, pernicious anemia, atrophic gastritis, gastric ulcer, postvagotomy state, and acid-suppressing medications). Serum gastrin levels should be measured in any patient with suspected gastrinoma or ulcer disease severe enough to warrant consideration of surgical treatment. H₂ receptor blocking agents, omeprazole, or antacids frequently increase serum gastrin concentrations and should be avoided for several days before gastrin measurements are made. It is often helpful to measure gastric acid secretion to rule out H⁺ hypersecretion as a cause of hypergastrinemia.

The normal gastrin value is less than 200 pg/mL. Patients with gastrinoma usually have levels exceeding 500 pg/mL and sometimes 10,000 pg/mL or higher. Patients with borderline gastrin values (eg, 200–500 pg/mL) and acid secretion in the range associated with ordinary duodenal ulcer disease should have a secretin provocative test. Following intravenous administration of secretin (two units/kg as

a bolus), a rise in the gastrin level of > 150 pg/mL within 15 minutes is diagnostic.

Marked basal acid hypersecretion (> 15 mEq H^+ per hour) occurs in most Zollinger-Ellison patients who have an intact stomach. In a patient who has previously undergone an acid-reducing operation, a basal acid output of 5 mEq/h or more is suggestive. Since the parietal cells are already under near maximal stimulation from hypergastrinemia, there is little increase in acid secretion following an injection of pentagastrin, and the ratio of basal to maximal acid output (BAO/MAO) characteristically exceeds 0.6.

Hypergastrinemia and gastric acid hypersecretion may occur in patients with gastric outlet obstruction, retained antrum after a Billroth II gastrojejunostomy, and antral gastrin cell hyperactivity (hyperplasia). These conditions are differentiated from gastrinoma by use of the secretin test. Because associated hyperparathyroidism is so common, serum calcium concentrations should be measured in all patients with gastrinoma.

Serum levels of neuron-specific enolase, β -hCG, and chromogranin-A are often elevated in patients with functioning neuroendocrine tumors. Although they are probably of no physiologic importance, the high levels of these peptides may be useful in following the results of therapy.

C. Imaging Studies

A CT or MR scan often demonstrates the pancreatic tumors. Somatostatin-receptor scintigraphy is extremely sensitive for detection of gastrinoma primary and metastatic sites. Transhepatic portal vein blood sampling to find gradients of gastrin production has been supplanted by the intra-arterial secretin test. Infusion of secretin into the artery supplying a functional gastrinoma causes an increase in hepatic vein gastrin levels. This invasive test is usually reserved for difficult situations.

Although used less frequently now with the availability of endoscopy, an upper gastrointestinal series can show ulceration in the duodenal bulb, though ulcers sometimes appear in the distal duodenum or proximal jejunum. The presence of ulcers in these distal (“ectopic”) locations is nearly diagnostic of gastrinoma. The stomach contains prominent rugal folds, and secretions are present in the lumen despite overnight fasting. The duodenum may be dilated and exhibit hyperactive peristalsis. Edema may be detected in the small bowel mucosa. The barium flocculates in the intestine, and transit time is accelerated.

► Treatment

A. Medical Treatment

Initial treatment should consist of proton pump inhibitor (eg, omeprazole 20–40 mg, once or twice daily) or H_2

blocking agents (eg, cimetidine, 300–600 mg, four times daily; ranitidine, 300–450 mg, four times daily). The dose should be adjusted to keep gastric H^+ output below 5 mEq in the hour preceding the next dose.

B. Surgical Treatment

Resection is the ideal treatment for gastrinoma and is appropriate in all patients with apparently localized disease and no other significant limitations to their survival. Surgical cure may be possible when there are resectable metastases in peripancreatic lymph nodes or the liver. Overall, about 70% of patients have immediate biochemical cure, and about 30% of patients remain disease-free after 5 years.

Every patient with sporadic Zollinger-Ellison syndrome should be considered a candidate for tumor resection. The preoperative workup should include a CT or MR scan of the pancreas and somatostatin-receptor scintigraphy. Regardless of other findings, exploratory laparotomy is then recommended in the absence of evidence of unresectable metastatic disease. If the tumor is found in the pancreas, it is enucleated if possible. Operative ultrasound may help in the examination of the pancreas. Most lesions will be found either in the head of the pancreas or in the duodenum. All patients should have longitudinal duodenotomy and palpation of the duodenal mucosa to identify the frequent primary tumors in this site.

► Prognosis

Since H_2 blocking agents become less effective with time, omeprazole is eventually required in medically treated patients. Because it is usually multifocal, the disease can rarely be cured surgically in patients with MEN 1. Malignant gastrinomas can cause death from growth of metastases.

GASTRIC ULCER

ESSENTIALS OF DIAGNOSIS

- Epigastric pain
- Ulcer demonstrated by x-ray
- Acid present on gastric analysis

► General Considerations

The peak incidence of gastric ulcer is in patients aged 40–60 years, or about 10 years older than the average for those with duodenal ulcer. Ninety-five percent of gastric ulcers are located on the lesser curvature, and 60% of these are within 6 cm of the pylorus. The symptoms and complications of gastric ulcer closely resemble those of duodenal ulcer.

Gastric ulcers may be separated into three types with different causes and different treatments. Type I ulcers, the most common variety, are found in patients who on the average are 10 years older than patients with duodenal ulcers and who have no clinical or radiographic evidence of previous duodenal ulcer disease; gastric acid output is normal or low. The ulcers are usually located within 2 cm of the boundary between parietal cell and pyloric mucosa, but always in the latter. As noted above, 95% are on the lesser curvature, usually near the incisura angularis.

Antral gastritis is universally present, being most severe near the pylorus and gradually diminishing. This is associated in most cases with the presence of *H pylori* beneath the mucus layer, on the luminal surface of epithelial cells, and gastric ulcer disease is probably the result of infection with this organism.

Type II ulcers are located close to the pylorus (prepyloric ulcers) and occur in association with (most often following) duodenal ulcers. The risk of cancer is very low in these gastric ulcers. Acid secretion measured by gastric analysis is in the range associated with duodenal ulcer.

Type III ulcers occur in the antrum as a result of chronic use of nonsteroidal anti-inflammatory agents.

Ulcer identified on x-ray or by endoscopy could be an ulcerated malignant tumor rather than a simple benign ulcer. Efforts must be expended during the *initial* stage of the workup to establish this distinction. Despite the generally discouraging results of surgery for gastric adenocarcinoma, those whose tumors are difficult to distinguish from benign ulcer have a 50%–75% chance of cure after gastrectomy.

► Clinical Findings

A. Symptoms and Signs

The principal symptom is epigastric pain relieved by food or antacids, as in duodenal ulcer. Epigastric tenderness is a variable finding. Compared with duodenal ulcer, the pain in gastric ulcer tends to appear earlier after eating, often within 30 minutes. Vomiting, anorexia, and aggravation of pain by eating are also more common with gastric ulcer.

Achlorhydria is defined as no acid (pH > 6.00) after pentagastrin stimulation. *Achlorhydria* is incompatible with the diagnosis of benign peptic ulcer and suggests a malignant gastric ulcer. About 5% of malignant gastric ulcers will be associated with this finding.

B. Upper Endoscopy and Biopsy

Upper endoscopy should be performed as part of the initial workup to attempt to find malignant lesions. The rolled-up margins of the ulcer that produce the meniscus sign on x-ray can often be distinguished from the flat edges characteristic of a benign ulcer. Multiple (preferably six) biopsy specimens and brush biopsy should be obtained from the edge of the lesion. False positives are rare; false negatives occur in 5%–10% of malignant ulcers.

C. Imaging Studies

Upper gastrointestinal x-rays can show an ulcer, usually on the lesser curvature in the pyloric area. In the absence of a tumor mass, the following suggest that the ulcer is malignant: (1) the deepest penetration of the ulcer is not beyond the expected border of the gastric wall; (2) the meniscus sign is present (ie, a prominent rim of radiolucency surrounding the ulcer), caused by heaped-up edges of tumor; and (3) cancer is more common (10%) in ulcers greater than 2 cm in diameter. Coexistence of duodenal deformity or ulcer favors a diagnosis of benign ulcer in the stomach.

► Differential Diagnosis

The characteristic symptoms of gastric ulcer are often clouded by nonspecific complaints. Uncomplicated hiatal hernia, atrophic gastritis, chronic cholecystitis, irritable colon syndrome, and undifferentiated functional problems are distinguishable from peptic ulcer only after appropriate radiologic studies and sometimes not even then.

Gastroscopy and biopsy of the ulcer should be performed to rule out malignant gastric ulcer.

► Complications

Bleeding, obstruction, and perforation are the principal complications of gastric ulcer. They are discussed separately elsewhere in this chapter.

► Treatment

A. Medical Treatment

Medical management of gastric ulcer is the same as for duodenal ulcer. The patient should be questioned regarding the use of ulcerogenic agents, which should be eliminated as far as possible.

Repeat endoscopy should be obtained to document the rate of healing. After 4–16 weeks (depending on the initial size of the lesion and other factors), healing usually has reached a plateau. In order to cure the disease and avoid recurrent ulcers, *H pylori* must be eradicated. The success of therapy in this regard can be checked by serologic testing for *H pylori* antibodies.

B. Surgical Treatment

Before the significance of *H pylori* in the etiology of gastric ulcer was appreciated, the most effective surgical treatment was distal hemigastrectomy (including the ulcer); somewhat less effective but still useful in high-risk patients was vagotomy and pyloroplasty. Parietal cell vagotomy for prepyloric ulcers was followed by a high (eg, 30%) recurrence rate, but parietal cell vagotomy plus pyloroplasty worked well.

Intractability to medical therapy has now become a rare indication for surgery in gastric ulcer disease, since H₂ receptor antagonists or omeprazole can bring the condition under control, and treatment of *H pylori* infection can almost eliminate the problem of recurrence. Consequently, surgery is needed principally for complications of the disease: bleeding, perforation, or obstruction.

Lee CW, Sarosi GA Jr. Emergency ulcer surgery. *Surg Clin North Am* 2011 Oct;91(5):1001-1013.

UPPER GASTROINTESTINAL HEMORRHAGE

Upper gastrointestinal hemorrhage may be mild or severe but should always be considered an ominous manifestation that deserves thorough evaluation. Bleeding is the most common serious complication of peptic ulcer, portal hypertension, and gastritis, and these conditions taken together account for most episodes of upper gastrointestinal bleeding in the average hospital population.

The major factors that determine the diagnostic and therapeutic approach are the amount and rate of bleeding. Estimates of both should be made promptly and monitored and revised continuously until the episode has been resolved. It is important to know at the outset that bleeding stops spontaneously in 75% of cases; the remainder includes those who will require surgery, experience complications, or die.

Hematemesis or melena is present except when the rate of blood loss is minimal. Hematemesis of either bright-red or dark blood indicates that the source is proximal to the ligament of Treitz. It is more common from bleeding that originates in the stomach or esophagus. In general, hematemesis denotes a more rapidly bleeding lesion, and a high percentage of patients who vomit blood require surgery. Coffee-ground vomitus is due to vomiting of blood that has been in the stomach long enough for gastric acid to convert hemoglobin to methemoglobin.

Most patients with melena (passage of black or tarry stools) are bleeding from the upper gastrointestinal tract, but melena can be produced by blood entering the bowel at any point from mouth to cecum. The conversion of red blood to dark depends more on the time it resides in the intestine than on the site of origin. The black color of melanic stools is probably caused by hematin, the product of oxidation of

heme by intestinal and bacterial enzymes. Melena can be produced by as little as 50–100 mL of blood in the stomach. When 1 L of blood was instilled into the upper intestine of experimental subjects, melena persisted for 3–5 days, which shows that the rate of change in character of the stool is a poor guide to the time bleeding stops after an episode of hemorrhage.

Hematochezia is defined as the passage of bright-red blood from the rectum. Bright-red rectal blood can be produced by bleeding from the colon, rectum, or anus. However, if intestinal transit is rapid during brisk bleeding in the upper intestine, bright-red blood may be passed unchanged in the stool.

▶ Tests for Occult Blood

Normal subjects lose about 2.5 mL of blood per day in their stools, presumably from minor mechanical abrasions of the intestinal epithelium. Between 50 and 100 mL of blood per day will produce melena. Tests for occult blood in the stool should be able to detect amounts between 10 and 50 mL/d. False-positive results may be due to dietary hemoglobin, myoglobin, or peroxidases of plant origin. Iron ingestion does not give positive reactions. The sensitivity of the guaiac slide test (Hemoccult) is in the desired range, and this is the best test available at present.

▶ Initial Management

In an apparently healthy patient, melena of a week or more suggests that the bleeding is slow. In this type of patient, admission to the hospital should be followed by a deliberate but nonemergency workup. However, patients who present with hematemesis or melena of less than 12 hours' duration should be handled as if exsanguination were imminent. The approach entails a simultaneous series of diagnostic and therapeutic steps with the following initial goals: (1) assess the status of the circulatory system and replace blood loss as necessary; (2) determine the amount and rate of bleeding; (3) slow or stop the bleeding by ice-water lavage; and (4) discover the lesion responsible for the episode. The last step may lead to more specific treatment appropriate to the underlying condition.

The patient should be admitted to the hospital and a history and physical examination performed. Experienced clinicians are able to make a correct diagnosis of the cause of bleeding from clinical findings in only 60% of patients. Peptic ulcer, acute gastritis, esophageal varices, esophagitis, and Mallory-Weiss tear account for over 90% of cases (Table 23–2). Questions concerning the symptoms and predisposing factors should be asked. The patient should be questioned about salicylate intake and any history of a bleeding tendency.

Of the diseases commonly responsible for acute upper gastrointestinal bleeding, only portal hypertension is associ-

ated with diagnostic clues on physical examination. However, gastrointestinal bleeding should not be automatically attributed to esophageal varices in a patient with jaundice, ascites, splenomegaly, spider angiomas, or hepatomegaly; over half of cirrhotic patients who present with acute hemorrhage are bleeding from gastritis or peptic ulcer.

Blood should be drawn for cross-matching, hematocrit, hemoglobin, creatinine, and tests of liver function. An intravenous infusion should be started and, in the presence of massive bleeding, a large-bore nasogastric tube inserted. In cases of melena, the gastric aspirate should be examined to verify the gastroduodenal source of the hemorrhage, but about 25% of patients with bleeding duodenal ulcers have gastric aspirates that test negatively for blood. The tube must be larger than the standard nasogastric tube (16F) so the stomach can be lavaged free of liquid blood and clots. After its contents have been removed, the stomach should be irrigated with copious amounts of ice water or saline solution until blood no longer returns. If the patient was bleeding at the time the nasogastric tube was inserted, iced saline irrigation usually stops it. The large tube can then be exchanged for a standard nasogastric tube attached to continuous suction so further blood loss can be measured.

It is common to give H₂ receptor antagonists or omeprazole, though controlled trials have shown no benefit. If bleeding continues or if tachycardia or hypotension is present, the patient should be monitored and treated as for hemorrhagic shock.

In acute rapid hemorrhage, the hematocrit may be normal or only slightly low. A very low hematocrit without obvious signs of shock indicates more gradual blood loss.

All of the above tests and procedures can be performed within 1 or 2 hours after admission. By this time, in most instances, bleeding is under control, blood volume has been restored to normal, and the patient is being adequately monitored so that recurrent bleeding can be detected promptly. When this stage is reached, additional diagnostic tests should be performed.

► Diagnosis of Cause of Bleeding

Once the patient is stabilized, endoscopy should be the first study. In general, endoscopy should be performed within 24 hours after admission, and under these circumstances the source of bleeding can be demonstrated in about 80% of cases. Longer delays have a lower diagnostic yield. Two lesions are seen in about 15% of patients. An upper gastrointestinal series should be performed if endoscopy is equivocal or unavailable. Although the diagnostic information provided by endoscopy does not appear to have resulted in decreased blood loss or improved outcome, endoscopic therapy, in the form of sclerosis of varices or injection of a bleeding ulcer, may do so. Having the diagnosis will also help in planning subsequent treatment, including the surgical approach if operation becomes necessary.

Rarely, selective angiography will have diagnostic or therapeutic usefulness. For diagnosis, it is most helpful when other studies fail to demonstrate the cause of bleeding. Infusion through the angiographic catheter of vasoconstrictors (eg, vasopressin) and embolization of the bleeding vessel with Gelfoam may be able to halt the bleeding in special cases.

► Later Management

Although a precise diagnosis of the cause of the bleeding may be valuable in later management, the patient must not be allowed to slip out of clinical control during the search for definitive diagnostic information. The decision for emergency surgery depends more on the rate and duration of bleeding than on its specific cause.

The need for transfusion should be determined on a continuing basis, and blood volume must be maintained. Blood pressure, pulse, central venous pressure, hematocrit, hourly urinary volume, and amount of blood obtained from the gastric tube or from the rectum all enter into this assessment. Many studies have shown the tendency to underestimate blood loss and inadequately transfuse massively bleeding patients who truly need aggressive therapy. Continued slow bleeding is best monitored by serial determinations of the hematocrit.

Several factors are associated with a worse prognosis with continued medical management of the bleeding episode. These are not absolute indications for laparotomy, but they should alert the clinician that emergency surgery may be required.

High rates of bleeding or amounts of blood loss predict high failure rates with medical treatment. Hematemesis is usually associated with more rapid bleeding and a greater blood volume deficit than melena. The presence of hypotension on admission to the hospital or the need for more than four units of blood to achieve circulatory stability implies a worse prognosis; if bleeding continues and subsequent transfusion requirements exceed one unit every 8 hours, continued medical management is usually unwise.

Total transfusion requirements also correlate with death rates. Death is uncommon when fewer than seven units of blood have been used, and the death rate rises progressively thereafter.

In general, bleeding from a gastric ulcer is more dangerous than bleeding from gastritis or duodenal ulcer, and patients with gastric ulcer should always be considered for early surgery. Regardless of the cause, if bleeding recurs after it has once stopped, the chances of success without operation are lower. Most patients who rebleed in the hospital should have consideration of surgery.

Patients over age 60 years tolerate continued blood loss less well than younger patients, and their bleeding should be stopped before secondary cardiovascular, pulmonary, or renal complications arise.

In 85% of patients, bleeding stops within a few hours of admission. About 25% of patients rebleed once bleeding has stopped. Rebleeding episodes are concentrated within the first 2 days of hospitalization, and if the patient has had no further bleeding for a period of 5 days, the chance of rebleeding is low. Rebleeding is most common in patients with varices, peptic ulcer, anemia, or shock. About 10% of patients require surgery to control bleeding, and most of these patients have bleeding ulcers or, less commonly, esophageal varices. The death rate is 30% among patients who rebleed and 3% among those who do not. The mortality rate is also high in the elderly and in patients who are already hospitalized at the onset of bleeding.

HEMORRHAGE FROM PEPTIC ULCER

Approximately 20% of patients with peptic ulcer experience a bleeding episode, and this complication is responsible for about 40% of the deaths from peptic ulcer. Peptic ulcer is the most common cause of massive upper gastrointestinal hemorrhage, accounting for over half of all cases. Chronic gastric and duodenal ulcers have about the same tendency to bleed, but the former produce more severe episodes.

Bleeding ulcers in the duodenum are usually located on the posterior surface of the duodenal bulb. As the ulcer

penetrates, the gastroduodenal artery is exposed and may become eroded. Since no major blood vessels lie on the anterior surface of the duodenal bulb, ulcerations at this point are not as prone to bleed. Patients with concomitant bleeding and perforation usually have two ulcers, a bleeding posterior ulcer and a perforated anterior one. Postbulbar ulcers (those in the second portion of the duodenum) bleed frequently, though ulcers are much less common in this site than near the pylorus.

In some patients, the bleeding is sudden and massive, manifested by hematemesis and shock. In others, chronic anemia and weakness due to slow blood loss are the only findings. The diagnosis is unreliable when based on clinical findings, so endoscopy should be performed early (ie, within 24 hours) in most cases.

In the preceding section, the management of acute upper gastrointestinal hemorrhage, the selection of diagnostic tests, and the factors suggesting the need for operation were discussed. Most patients (75%) with bleeding peptic ulcer can be successfully managed by medical means alone. Initial therapeutic efforts usually halt the bleeding. H₂ blockers and proton pump inhibitors decrease the risk of bleeding but have no effect on active bleeding.

After 12–24 hours have passed and the bleeding has clearly stopped, a patient who feels hungry should be fed. Twice-daily hematocrit readings should be ordered as a check on slow continued blood loss. Stools should be tested daily for the presence of blood; they will usually remain guaiac-positive for several days after bleeding stops.

Rebleeding in the hospital has been attended by a death rate of about 30%. Considering early surgery for those who rebleed could improve this figure. Patients who are over age 60 years, present with hematemesis, are actively bleeding at the time of endoscopy, or whose admission hemoglobin is below 8 g/dL have a higher risk of rebleeding. About three times as many patients with gastric ulcer (30%) rebleed compared with those with duodenal ulcer. Most instances of rebleeding occur within 2 days from the time the first episode has stopped. In one study, only 3% of patients who stopped bleeding for this long bled again.

► Endoscopic Therapy

Treatments administered through the endoscope may stop active bleeding or prevent rebleeding. Effective methods include injection into the ulcer of epinephrine, epinephrine plus 1% polidocanol (a sclerosing agent), or ethanol; application of clips to bleeding areas; or cautery using the heater probe, monopolar electrocautery, or the Nd:YAG laser. At least two modalities should be available to the endoscopist in the event one is unsuitable for a specific case or fails to work. Except for the laser, all are inexpensive. The indications for treatment are: (1) active bleeding at the time of endoscopy and (2) the presence of a visible vessel in the base

of the ulcer. When treatment fails the first time, it may often be repeated with a good chance of success. It is important, however, not to allow the patient to deteriorate during non-operative attempts at halting the bleeding.

► Emergency Surgery

Less than 10% of patients bleeding from a peptic ulcer require emergency surgery. Selection of those most likely to survive with surgical compared with medical treatment rests on the rate of blood loss and the other factors associated with a poor prognosis.

The overall death rate is significantly less after vagotomy and pyloroplasty than after gastrectomy for bleeding ulcer, and rebleeding occurs with about equal frequency after either procedure.

During laparotomy, the first step is to make a pyloroplasty incision if the endoscopic diagnosis is a bleeding duodenal ulcer. If a duodenal ulcer is found, the bleeding vessel should be suture-ligated and the duodenum and antrum inspected for additional ulcers. The pyloroplasty incision should then be closed and a truncal vagotomy performed. If the posterior wall of the duodenal bulb has been destroyed by a giant duodenal ulcer, a gastrectomy and Billroth II gastrojejunostomy may be preferable, since this somewhat uncommon ulcer is especially prone to bleed again if left in continuity with the stomach. Gastric ulcers can be handled by either gastrectomy or vagotomy and pyloroplasty. A thorough search should always be made for second ulcers or other causes of bleeding.

► Prognosis

The death rate for an acute massive hemorrhage is about 15%. Careful study of the causes of death suggests that this figure could be improved by: (1) more precise blood replacement, since undertransfusion is the cause of some complications and deaths; and (2) earlier surgery in selected patients who fall into serious-risk categories, since the tendency has been to perform surgery on too few patients too late in the illness. Patients who stop bleeding should be treated as outlined in the section on duodenal ulcer.

MALLORY-WEISS SYNDROME

Mallory-Weiss syndrome is responsible for about 10% of cases of acute upper gastrointestinal hemorrhage. The lesion consists of a 1- to 4-cm longitudinal tear in the gastric

mucosa near the esophagogastric junction; it usually follows a bout of forceful retching. The disruption extends through the mucosa and submucosa but not usually into the muscularis mucosae. About 75% of these lesions are confined to the stomach, 20% straddle the esophagogastric junction, and 5% are entirely within the distal esophagus. Two-thirds of patients have a hiatal hernia.

The majority of patients are alcoholics, but the tear may appear after severe retching for any reason. Several cases have been reported following closed-chest cardiac compression.

► Clinical Findings

Typically, the patient first vomits food and gastric contents. This is followed by forceful retching and then bloody vomitus. Rapid increases in gastric pressure, sometimes aggravated by hiatal hernia, cause the tear. Actual rupture of the distal esophagus can also be produced by vomiting (Boerhaave syndrome), but the difference seems to depend on vomiting of food in rupture and nonproductive retching in gastric mucosal tear.

Esophagogastroscopy is the most practical means of making the diagnosis.

► Treatment & Prognosis

Initially, the patient is handled according to the general measures prescribed for upper gastrointestinal hemorrhage. In about 90% of patients, the bleeding stops spontaneously after ice-water lavage of the stomach. Patients who are still bleeding vigorously by the time endoscopy is performed are likely to require surgery. The bleeding can sometimes be controlled by endoscopic therapy (eg, electrocautery). If bleeding persists, surgical repair of the tear will be required.

If the diagnosis has been made before laparotomy, the surgeon should make a long, high gastrotomy after the abdomen is opened. The tear may be difficult to expose adequately. The search must be thorough, since in about 25% of patients there are two tears. A running absorbable acid suture should be used to oversee the lesion. Postoperative recurrence is rare.

PYLORIC OBSTRUCTION DUE TO PEPTIC ULCER

The cycles of inflammation and repair in peptic ulcer disease may cause obstruction of the gastroduodenal junction as a result of edema, muscular spasm, and scarring. To the extent that the first two factors are involved, the obstruction may be reversible with medical treatment. Obstruction is usually due to duodenal ulcer and is less common than either bleeding or perforation. The few gastric ulcers that obstruct are close to the pylorus. Obstruction due to peptic ulcer must be differentiated from that caused by a malignant tumor of

the antrum or of the pancreas. Malignancy is becoming the more common cause, and it may be difficult to identify.

► Clinical Findings

A. Symptoms and Signs

Most patients with obstruction have a long history of symptomatic peptic ulcer, and as many as 30% have been treated for perforation or obstruction in the past. The patient often notes gradually increasing ulcer pains over weeks or months, with the eventual development of anorexia, vomiting, and failure to gain relief from antacids. The vomitus often contains food ingested several hours previously, and absence of bile staining reflects the site of blockage. Weight loss may be marked if the patient has delayed seeking medical care.

Dehydration and malnutrition may be obvious on physical examination but are not always present. A succussion splash can often be elicited from the retained gastric contents. Peristalsis of the distended stomach may be visible on gross inspection of the abdomen, but this sign is relatively rare. Most patients have upper abdominal tenderness. Tetany may appear with advanced alkalosis.

B. Laboratory Findings

Anemia is present in about 25% of patients. Prolonged vomiting leads to metabolic alkalosis with dehydration. Measurement of serum electrolytes shows hypochloremia, hypokalemia, hyponatremia, and increased bicarbonate. Vomiting depletes the patient of Na^+ , K^+ , and Cl^- ; the latter is lost in excess of Na^+ and K^+ as HCl. Gastric HCl loss causes extracellular HCO_3^- to rise, and renal excretion of HCO_3^- increases in an attempt to maintain pH. Large amounts of Na^+ are excreted in the urine with the HCO_3^- . Increasing Na^+ deficit evokes aldosterone secretion, which in turn brings about renal Na^+ conservation at the expense of more renal loss of K^+ and H^+ . Glomerular filtration rate may drop and produce a prerenal azotemia. The eventual result of the process is a marked deficit of Na^+ , Cl^- , K^+ , and H_2O . Treatment involves replacement of water and NaCl until a satisfactory urine flow has been established. KCl replacement should then be started.

C. Saline Load Test

This is a simple means of assessing the degree of pyloric obstruction and is useful in following the patient's progress during the first few days of nasogastric suction.

Through the nasogastric tube, 700 mL of normal saline (at room temperature) is infused over 3–5 minutes, and the tube is clamped. Thirty minutes later, the stomach is aspirated and the residual volume of saline recorded. Recovery of more than 350 mL indicates obstruction. It must be recognized that the results of a saline load test do not predict how

well the stomach will handle solid food. Solid emptying can be measured with technetium-99 m-labeled chicken liver.

D. Imaging Studies

Plain abdominal x-rays may show a large gastric fluid level. An upper gastrointestinal series should not be performed until the stomach has been emptied, because dilution of the barium in the retained secretions makes a worthwhile study impossible.

E. Endoscopy

Upper endoscopy is usually indicated to rule out the presence of an obstructing neoplasm.

► Treatment

A. Medical Treatment

A large (32F) tube should be passed and the stomach emptied of its contents and lavaged until clean. After the stomach has been completely decompressed, a smaller tube should be inserted and placed on suction for several days to allow pyloric edema and spasm to subside and to permit the gastric musculature to regain its tone. A saline load test may be performed at this point to provide a baseline for later comparison. If chronic obstruction has produced severe malnutrition, total parenteral nutrition should be instituted.

After decompression of the stomach for 48–72 hours, the saline load test should be repeated. If this indicates sufficient improvement, the tube should be withdrawn and a liquid diet may be started. Gradual resumption of solid foods is permitted as tolerated.

B. Surgical Treatment

If 5–7 days of gastric aspiration do not result in relief of the obstruction, the patient should be treated surgically. Persistence of nonoperative effort beyond this point in the absence of progress rarely achieves the result hoped for. Failure of the obstruction to resolve completely (eg, if the patient can take only liquids) and recurrent obstruction of any degree are indications for surgery.

Surgical treatment may consist of a truncal or parietal cell vagotomy and drainage procedure (Figure 23–5). Truncal vagotomy and gastrojejunostomy is the easiest to perform laparoscopically.

► Prognosis

About two-thirds of patients with acute obstruction fail to improve sufficiently on medical therapy and require operation to relieve the blockage. Patients who respond to medical treatment should be treated as outlined in the section on duodenal ulcer.

PERFORATED PEPTIC ULCER

Perforation complicates peptic ulcer about half as often as hemorrhage. Most perforated ulcers are located anteriorly, though occasionally gastric ulcers perforate into the lesser sac. The 15% death rate correlates with increased age, female gender, and gastric perforations. The diagnosis is overlooked in about 5% of patients, most of whom do not survive.

Anterior ulcers tend to perforate instead of bleed because of the absence of protective viscera and major blood vessels on this surface. In less than 10% of cases, acute bleeding from a posterior “kissing” ulcer complicates the anterior perforation, an association that carries a high death rate. Immediately after perforation, the peritoneal cavity is flooded with gastroduodenal secretions that elicit a chemical peritonitis. Early cultures show either no growth or a light growth of streptococci or enteric bacilli. Gradually, over 12–24 hours, the process evolves into bacterial peritonitis. Severity of illness and occurrence of death are directly related to the interval between perforation and surgical closure.

In an unknown percentage of cases, the perforation becomes sealed by adherence to the undersurface of the liver. In such patients, the process may be self-limited, but an intraperitoneal abscess develops in many.

► Clinical Findings

A. Symptoms and Signs

Perforation usually elicits a sudden, severe upper abdominal pain whose onset can be recalled precisely. The patient may or may not have had preceding chronic symptoms of peptic ulcer disease. Perforation rarely is heralded by nausea or vomiting, and it typically occurs several hours after the last meal. Shoulder pain, if present, reflects diaphragmatic irritation. Back pain is uncommon.

The initial reaction consists of a chemical peritonitis caused by gastric acid or bile and pancreatic enzymes. The peritoneal reaction dilutes these irritants with a thin exudate, and as a result the patient’s symptoms may temporarily improve before bacterial peritonitis occurs. The physician who sees the patient for the first time during this symptomatic lull must not be misled into interpreting it as representing bona fide improvement.

The patient appears severely distressed, lying quietly with the knees drawn up and breathing shallowly to minimize abdominal motion. Fever is absent at the start. The abdominal muscles are rigid owing to severe involuntary spasm. Epigastric tenderness may not be as marked as expected because the board-like rigidity protects the abdominal viscera from the palpating hand. Escaped air from the stomach may enter the space between the liver and abdominal wall, and upon percussion the normal dullness over the liver will be tympanitic. Peristaltic sounds are reduced or absent. If

delay in treatment allows continued escape of air into the peritoneal cavity, abdominal distention and diffuse tympany may result.

The above description applies to the typical case of perforation with classic findings. In as many as one-third of patients, the presentation is not as dramatic, diagnosis is less obvious, and serious delays in treatment may result from failure to consider this condition and to obtain the appropriate abdominal x-rays. Many of these atypical perforations occur in patients already hospitalized for some unrelated illness, and the significance of the new symptom of abdominal pain is not appreciated.

Lesser degrees of shock with minimal abdominal findings occur if the leak is small or rapidly sealed. A small duodenal perforation may slowly leak fluid that runs down the lateral peritoneal gutter, producing pain and muscular rigidity in the right lower quadrant, and thus raising a problem of confusion with acute appendicitis.

Perforations may be sealed by omentum or by the liver, with the later development of a subhepatic or subdiaphragmatic abscess.

B. Laboratory Findings

A mild leukocytosis in the range of 12,000/ μ L is common in the early stages. After 12–24 hours, this may rise to 20,000/ μ L or more if treatment has been inadequate. The mild rise in the serum amylase value that occurs in many patients is probably caused by absorption of the enzyme from duodenal secretions within the peritoneal cavity. Direct measurement of fluid obtained by paracentesis may show very high levels of amylase.

C. Imaging Studies

Plain x-ray or CT scan of the abdomen reveals free subdiaphragmatic air in 85% of patients.

If no free air is demonstrated and the clinical picture suggests perforated ulcer, an emergency CT scan with gastrointestinal contrast, or upper gastrointestinal series should be performed. If the perforation has not sealed, the diagnosis is established by noting escape of the contrast material from the lumen.

► Differential Diagnosis

The differential diagnosis includes acute pancreatitis and acute cholecystitis. The former does not have as explosive an onset as perforated ulcer and is usually accompanied by high serum levels of lipase and amylase. Acute cholecystitis with perforated gallbladder could mimic perforated ulcer closely but free air would not be present with ruptured gallbladder. Intestinal obstruction has a more gradual onset and is characterized by less severe pain that is crampy and accompanied by vomiting.

The simultaneous onset of pain and free air in the abdomen in the absence of trauma usually means perforated peptic ulcer. Free perforation of colonic diverticulitis and acute appendicitis are other rare causes.

► Treatment

The diagnosis is often suspected before the patient is sent for confirmatory imaging. Whenever a perforated ulcer is considered, the first step should be to pass a nasogastric tube and empty the stomach to limit further contamination of the peritoneal cavity. Blood should be drawn for laboratory studies, and intravenous antibiotics (eg, cefazolin, cefoxitin) should be started. If the patient's overall condition is precarious owing to delay in treatment, fluid resuscitation should precede diagnostic measures. Imaging should be obtained as soon as the clinical status will permit.

The simplest surgical treatment, laparoscopy (or laparotomy) and suture closure of the perforation solves the immediate problem. The closure most often consists of securely plugging the hole with omentum (Graham-Steele closure) sutured into place rather than bringing together the two edges with sutures. All fluid should be aspirated from the peritoneal cavity, but drainage is not indicated. Reperforation is rare in the immediate postoperative period.

About three-fourths of patients whose perforation is the culmination of a history of chronic symptoms continue to have clinically severe ulcer disease after simple closure. This had led to a more aggressive treatment policy involving a definitive ulcer operation for most patients with acute perforation (eg, parietal cell vagotomy plus closure of the perforation or truncal vagotomy and pyloroplasty). Now that ulcer disease can be cured by eradicating *H pylori*, the value of anything more than simple closure is limited.

Concomitant hemorrhage and perforation are most often due to two ulcers, an anterior perforated one and a posterior one that is bleeding. Perforated ulcers that also obstruct cannot be treated by suture closure of the perforation alone. Vagotomy plus gastroenterostomy or pyloroplasty should be performed. Perforated anastomotic ulcers require a vagotomy or gastrectomy, since in the long run, closure alone is nearly always inadequate.

Nonoperative treatment of perforated ulcer consists of continuous gastric suction and the administration of antibiotics in high doses. Although this has been shown to be effective therapy, with a low death rate, it is occasionally accompanied by a peritoneal and subphrenic abscess, and side effects are greater than with laparoscopic closure.

► Prognosis

About 15% of patients with perforated ulcer die, and about a third of these are undiagnosed before surgery. The death rate of perforated ulcer seen early is low. Delay in treatment,

advanced age, and associated systemic diseases account for most deaths.

STRESS GASTRODUODENITIS, STRESS ULCER, & ACUTE HEMORRHAGIC GASTRITIS

The term stress ulcer has been used to refer to a heterogeneous group of acute gastric or duodenal ulcers that develop following physiologically stressful illnesses. There are four major etiologic factors associated with such lesions: (1) shock, (2) sepsis, (3) burns, and (4) central nervous system tumors or trauma.

► Etiology

A. Stress Ulcer

Acute ulcers following major surgery, mechanical ventilation, shock, sepsis, and burns (Curling ulcers) have enough common features to suggest they evolve by a similar pathogenetic mechanism.

Hemorrhage is the major clinical problem, though perforation occurs in about 10% of cases. Despite the predilection of stress ulcers to develop in the parietal cell mucosa, in about 30% of patients the duodenum is affected, and sometimes both stomach and duodenum are involved. Morphologically, the ulcers are shallow, discrete lesions with congestion and edema but little inflammatory reaction at their margins. Gastroduodenal endoscopy performed early in traumatized or burned patients has shown acute gastric erosions in the majority of patients within 72 hours after the injury. Such studies illustrate how frequently the disease process remains subclinical; clinically apparent ulcers develop in about 20% of susceptible patients. Clinically evident bleeding is usually seen 3–5 days after the injury, and massive bleeding generally does not appear until 4–5 days later.

Decreased mucosal resistance is the first step, which may involve the effects of ischemia (with production of toxic superoxide and hydroxyl radicals) and circulating toxins, followed by decreased mucosal renewal, decreased production of endogenous prostanooids, and thinning of the surface mucus layer. Decreased gastric mucosal blood flow also plays a role by decreasing the supply of blood buffers available to neutralize hydrogen ions that are diffusing into the weakened mucosa. Experimental evidence has implicated platelet-activating factor, released by endotoxin, as a possible mediator of gut ulceration in sepsis. The mucosa is thus rendered more vulnerable to acid-pepsin ulceration and lysosomal enzymes. Acid hypersecretion may be involved to some extent, since burn patients who manifest serious bleeding have higher gastric acid output than patients with a more benign course. Disruption of the gastric mucosal barrier to back diffusion of acid has been found in less than half of patients and is now thought to be a manifestation of the disease rather than a cause.

B. Cushing Ulcers

Acute ulcers associated with central nervous system tumors or injuries differ from stress ulcers because they are associated with elevated levels of serum gastrin and increased gastric acid secretion. Morphologically, they are similar to ordinary gastroduodenal peptic ulcers. Cushing ulcers are more prone to perforate than other kinds of stress ulcers.

C. Acute Hemorrhagic Gastritis

This disorder may share some causative factors with the above conditions, but the natural history is different and the response to treatment considerably better. Most of these patients can be controlled medically. When surgery is required for alcoholic gastritis, a high proportion of patients are cured by pyloroplasty and vagotomy.

► Clinical Findings

Hemorrhage is nearly always the first manifestation. Pain rarely occurs. Physical examination is not contributory except to reveal gross or occult fecal blood or signs of shock.

► Prevention

Acid suppressing medications given prophylactically to critically ill patients decrease the incidence of stress erosions and overt bleeding. Sucralfate is also effective. Patients receiving total parenteral nutrition appear to be protected by this therapy and experience no increased benefit from H₂ antagonists.

► Treatment

Initial management should consist of gastric lavage with chilled solutions and measures to combat sepsis if present. H₂ receptor blockers are of no value in the actively bleeding patient, but they probably decrease the rate of rebleeding once bleeding has stopped.

Perform laparotomy if the nonoperative regimen fails to halt the bleeding. Surgical treatment should consist of vagotomy and pyloroplasty, with suture of the bleeding points, or vagotomy and subtotal gastrectomy. There is a trend toward the first of these options, particularly in the sickest patients. When it occurs, rebleeding is nearly always from an ulcer left behind at the initial procedure. Rarely, total gastrectomy has had to be used because of the extent of ulceration and severity of bleeding or because of rebleeding after a lesser operation.

Ali T, Harty RF. Stress-induced ulcer bleeding in critically ill patients. *Gastroenterol Clin North Am* 2009 Jun;38(2):245-265.

GASTRIC CARCINOMA

There are about 21,000 new cases of carcinoma of the stomach in the United States annually. The incidence has dropped to one-third of what it was 40 years ago. This may reflect changes in the prevalence of *H pylori* infection, which has a role in the etiology of this disease. *H pylori* is known to be a cause of chronic atrophic gastritis, which in turn is a recognized precursor of gastric adenocarcinoma. Epidemiologic studies have linked gastric *H pylori* infection with a 3.6-fold to 18-fold (all patients vs. women) increase in the risk of developing carcinoma of the body or antrum (not the cardia), and the risk is proportionate to serum levels of *H pylori* antibodies.

The present incidence in American men is 10 new cases per 100,000 population per year. The highest rate, 63 per 100,000 men, is observed in Costa Rica; in eastern and central European countries, it is about 35 per 100,000 per year. Epidemiologic studies suggest that the incidence of gastric carcinoma is related to low dietary intake of vegetables and fruits and high intake of starches. Carcinoma of the stomach is rare under age 40 years, from which point the risk gradually climbs. The mean age at discovery is 63. It is about twice as common in men as in women.

Gastric epithelial cancers are nearly always adenocarcinomas. Squamous cell tumors of the proximal stomach involve the stomach secondarily from the esophagus. Five morphologic subdivisions correlate loosely with the natural history and outcome.

1. Ulcerating carcinoma (25%)—This consists of a deep, penetrating ulcer-tumor that extends through all layers of the stomach. It may involve adjacent organs in the process. The edges are shallow by contrast with overhanging edges noted in benign ulcers.

2. Polypoid carcinomas (25%)—These are large, bulky intraluminal growths that tend to metastasize late.

3. Superficial spreading carcinoma (15%)—Also known as early gastric cancer, superficial spreading carcinoma is confined to the mucosa and submucosa. Metastases are present in only 30% of cases. Even when metastases are present, the prognosis after gastrectomy is much better than for the more deeply invading lesions of advanced gastric cancer. In Japan, screening programs have been so successful that early gastric cancer now constitutes 30% of surgical cases, and survival rates have improved accordingly.

4. Linitis plastica (10%)—This variety of spreading tumor involves all layers with a marked desmoplastic reaction in which it may be difficult to identify the malignant cells. The stomach loses its pliability. Cure is rare because of early spread.

5. Advanced carcinoma (35%)—This largest category contains the big tumors that are found partly within and

partly outside the stomach. They may originally have qualified for inclusion in the preceding groups but have outgrown that early stage.

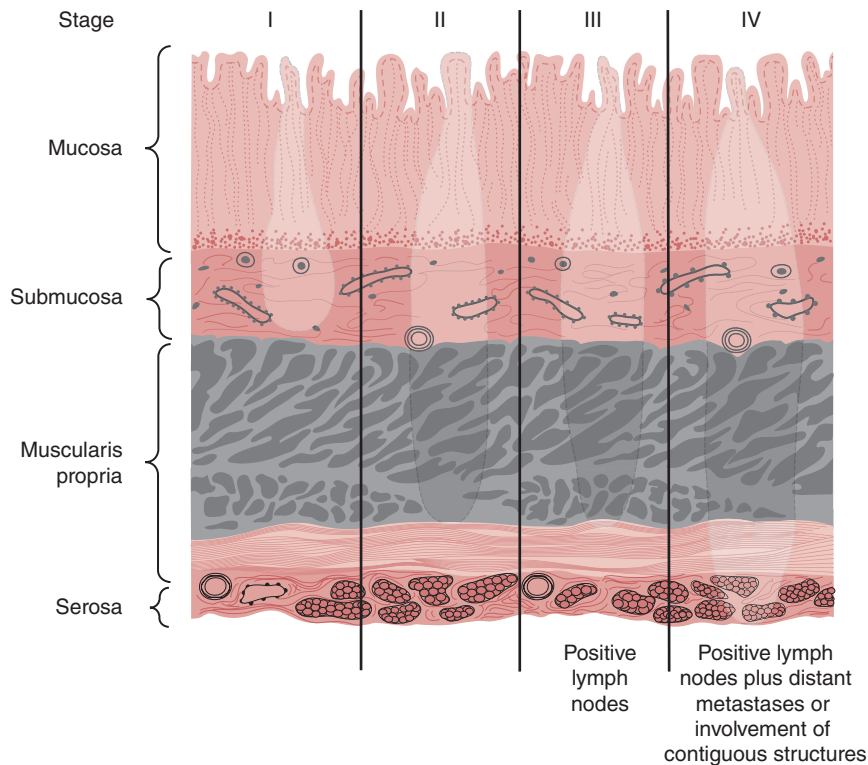

Gastric adenocarcinomas can also be classified by degree of differentiation of their cells. In general, rate and extent of spread correlate with lack of differentiation. Some tumors are found histologically to excite an inflammatory cell reaction at their borders, and this feature indicates a relatively good prognosis. Tumors whose cells form glandular structures (intestinal type) have a somewhat better prognosis than tumors whose cells do not (diffuse type); the diffuse type is often associated with a substantial stromal component. The intestinal type of tumor accounts for a much larger proportion of cases in countries such as Japan and Finland where gastric cancer is especially common. The gradual decline in incidence in these areas is due principally to decreased occurrence of the intestinal type of tumor. Signet ring carcinomas, which contain more than 50% signet ring cells, have become increasingly more common and now constitute one-third of all cases. They behave as the diffuse type of cancer and occur more frequently in women, in younger patients, and in the distal part of the stomach. Previous *H pylori*—infection is not

associated with the development of any specific histologic type of gastric cancer.

Extension occurs by intramural spread, direct extraluminal growth, and lymphatic metastases. Pathologic staging, which correlates closely with survival, is illustrated in Figure 23–7. Three-fourths of patients have metastases when diagnosed. Within the stomach, proximal spread exceeds distal spread. The pylorus acts as a partial barrier, but tumor is found in 25% of cases in the first few centimeters of the bulb.

Early gastric cancer, defined as a primary lesion confined to the mucosa and submucosa with or without lymph node metastases, is associated with an excellent prognosis (5-year survival rate of 90%) after resection. In Japan, mass screening programs detect about 30% of patients with this lesion, whereas in the United States, only 10% of patients have early gastric cancer.

Forty percent of tumors are in the antrum, predominantly on the lesser curvature; 30% arise in the body and fundus, 25% at the cardia, and 5% involve the entire organ. Frequency of location has gradually changed, so that proximal lesions are more common now than 10–20 years ago. Benign ulcers develop at the greater curvature and cardia

▲ **Figure 23–7.** Staging system for gastric carcinoma. The darkly shaded areas represent cancers with different depths of mucosal penetration.

less commonly than malignant ones. Ulcers at these points are particularly suspect for neoplasm.

► Clinical Findings

A. Symptoms and Signs

The earliest symptom is usually vague postprandial abdominal heaviness that the patient does not identify as a pain. Sometimes the discomfort is no different from other vague dyspeptic symptoms that have been intermittently present for years, but the frequency and persistence are new.

Anorexia develops early and may be most pronounced for meat. Weight loss, the most common symptom, averages about 6 kg. True postprandial pain suggesting a benign gastric ulcer is relatively uncommon, but if it is present, one may be misled if subsequent x-rays show an ulcer. Vomiting may be present and becomes a major feature if pyloric obstruction occurs. It may have a coffee-ground appearance owing to bleeding by the tumor. Dysphagia may be the presenting symptom of lesions at the cardia.

An epigastric mass can be felt on examination in about one-fourth of cases. Hepatomegaly is present in 10% of cases. The stool will be positive for occult blood in half of patients, and melena is seen in a few. Otherwise, abnormal physical findings are confined to signs of distant spread of the tumor. Metastases to the neck along the thoracic duct may produce a Virchow node. Rectal examination may reveal a Blumer shelf, a solid peritoneal deposit anterior to the rectum. Enlarged ovaries (Krukenberg tumors) may be caused by intraperitoneal metastases. Further dissemination may involve the liver, lungs, brain, or bone.

B. Laboratory Findings

Anemia is present in 40% of patients. Carcinoembryonic antigen levels are elevated in 65%, usually indicating extensive spread of the tumor.

C. Imaging Studies

An upper gastrointestinal series is diagnostic for many tumors, but the overall false-negative rate is about 20%. Major diagnostic problems are posed by ulcerating tumors, a few of which may not be distinguishable radiologically from benign peptic ulcers. The differential features are listed in the section on gastric ulcer, but x-rays alone will not establish a diagnosis of benign ulcer. All patients with a newly discovered gastric ulcer should undergo upper endoscopy and gastric biopsy.

D. Gastroscopy and Biopsy

Large gastric carcinomas can usually be identified as such by their gross appearance at endoscopy. All gastric lesions, whether polypoid or ulcerating, should be examined by

taking multiple biopsy and brush cytology specimens during endoscopy. False negative results are seen occasionally as a result of sampling error, and a minimum of six biopsies is necessary for greatest accuracy.

► Treatment

Surgical resection is the only curative treatment. About 85% of patients are operable, and in 50% the lesions are amenable to resection; of the resectable lesions, half are potentially curable (ie, no signs of spread beyond the limits of resection). Preoperative chemotherapy with a multidrug regimen is recommended for most patients.

The surgical objective should be to remove the tumor, an adjacent uninvolved margin of stomach and duodenum, the regional lymph nodes, and, if necessary, portions of involved adjacent organs. The proximal margin should be a minimum of 6 cm from the gross tumor. If the tumor is located in the antrum, a curative resection would entail distal gastrectomy with *en bloc* removal of the omentum, a 3- to 4-cm cuff of duodenum and the subpyloric lymph nodes, and, in some instances, excision of the left gastric artery and nearby lymph nodes. Reconstruction after gastrectomy may be by either a Billroth I or II procedure, but the latter is preferable because postoperative growth of residual tumor near the pylorus may obstruct a gastroduodenal anastomosis early.

Total gastrectomy with splenectomy is required for tumors of the proximal half of the stomach and for extensive tumors (eg, linitis plastica). Whether or not the spleen should be removed in such cases is a subject of debate. Alimentary continuity is most often reestablished by a Roux-en-Y esophagojejunostomy. Construction of an intestinal pouch as a substitute food reservoir (eg, Hunt-Lawrence pouch) is of no nutritional value, and it increases the risks of immediate complications.

Esophagogastrectomy plus splenectomy with intrathoracic esophagogastrostomy is the operation usually performed for tumors of the cardia. The procedure is usually done through two separate incisions: first, a laparotomy for the gastric part, and then a right posterolateral thoracotomy for the anastomosis.

The propensity for proximal submucosal spread must be appreciated at surgery. It is often advisable to perform a frozen section at the proximal margin before constructing the anastomosis. If tumor is found, the gastrectomy should be extended.

Palliative resection is usually indicated if the stomach is still movable and life expectancy is estimated to be more than 1–2 months. Palliative gastrectomy is usually performed to remove an antral lesion and prevent obstruction, but in selected cases, total gastrectomy is appropriate palliative treatment if the operation can be done safely and the amount of extragastric tumor is minimal. Whenever technically

feasible, palliative gastrectomy is preferable to palliative gastrojejunostomy.

Adjuvant chemotherapy after curative surgery is recommended, particularly for patients who have undergone preoperative chemotherapy and responded.

► Prognosis

In the United States, the overall 5-year survival rate is about 12%. The 5-year survival rate for patients with early gastric cancer is about 90%. The 5-year survival rates in relation to the extent of spread are stage I, 70%; stage II, 30%; stage III, 10%; and stage IV, 0%.

Death from tumor may follow dissemination to other organs or may be the result of progressive gastric obstruction and malnutrition.

Ajani JA, Bentrem DJ, Besh S, et al: Gastric cancer, version 2.2013: featured updates to the NCCN Guidelines. *J Natl Compr Canc Netw* May 1, 2013;11(5):531-546.

GASTRIC POLYPS

Gastric polyps are single or multiple benign tumors that occur predominantly in the elderly. Those located in the distal stomach are more apt to cause symptoms. Whenever gastric polyps are discovered, gastric cancer must be ruled out.

Gastric polyps can be classified histologically as hyperplastic, adenomatous, or inflammatory. Other polypoid lesions, such as leiomyomas and carcinoid tumors, are discussed elsewhere. Hyperplastic polyps, which constitute 80% of cases, consist of an overgrowth of normal epithelium; they are not true neoplasms and have no relationship to gastric cancer. About 30% of adenomatous polyps contain a focus of adenocarcinoma, and adenocarcinoma can be found elsewhere in the stomach in 20% of patients with a benign adenomatous polyp. The incidence of cancer in an adenomatous polyp rises with increasing size. Lesions with a stalk and those less than 2 cm in diameter are usually not malignant. About 10% of benign adenomatous polyps undergo malignant change during prolonged follow-up.

Anemia may develop from chronic blood loss or deficient iron absorption. Over 90% of patients are achlorhydric after maximal stimulation. Vitamin B₁₂ absorption is deficient in 25%, although megaloblastic anemia is present in only a few.

Excision with a snare through the endoscope can be performed safely for most polyps. Otherwise, surgical excision is indicated for polyps greater than 1 cm in diameter or when cancer is suspected. Single polyps may be excised through a gastrotomy and a frozen section performed. If the polyp is found to be carcinoma, an appropriate type of gastrectomy is indicated. Partial gastrectomy should be performed for multiple polyps in the distal stomach. If

10–20 polyps are distributed throughout the stomach, the antrum should be removed and the fundic polyps excised. Total gastrectomy may be required for symptomatic diffuse multiple polyposis.

These patients should be followed because they have an increased risk of late development of pernicious anemia or gastric cancer. Recurrent polyps are uncommon.

GASTRIC LYMPHOMA & PSEUDOLYMPHOMA

Lymphoma is the second-most common primary cancer of the stomach but constitutes only 2% of the total number, 95% being adenocarcinomas. Almost all are non-Hodgkin lymphomas and are generally classified as B cell mucosa-associated lymphoid tissue (MALT) lymphomas. They are further subclassified as low-grade or high-grade based on nuclear pattern. About 20% of patients manifest a second primary cancer in another organ.

The principal symptoms are epigastric pain and weight loss, similar to those of carcinoma. Characteristically, the tumor has attained bulky proportions by the time it is discovered; by comparison with adenocarcinoma of the stomach, the symptoms from a gastric lymphoma are usually mild in relation to the size of the lesion. A palpable epigastric mass is present in 50% of patients. Imaging studies will demonstrate the lesion, although it usually is mistaken for adenocarcinoma or benign gastric ulcer. Gastroscopy with biopsy and brush cytology provides the correct diagnosis preoperatively in about 75% of cases. If a pathologic diagnosis has not been made, the surgeon may incorrectly judge the lesion to be inoperable carcinoma because of its large size. Preoperative staging should include a CT scan and bone marrow biopsy.

Treatment of limited extent, low-grade gastric lymphoma consists of antibiotic treatment for *H pylori*, if present. More extensive disease may require therapy with external beam radiation or rituximab.

Gastric pseudolymphoma consists of a mass of lymphoid tissue in the gastric wall, often associated with an overlying mucosal ulcer. It is thought to represent a response to chronic inflammation. The lesion is not malignant, though the presentation, which includes pain, weight loss, and a mass on imaging, cannot be distinguished from a malignant lesion.

Treatment of gastric pseudolymphoma consists of resection. The distinction from lymphoma is made on histologic examination of the specimen, which shows mature germinal centers in pseudolymphoma. No additional therapy is indicated postoperatively.

Zelenetz AD, Wierda WG, Abramson JS, et al. for the National Comprehensive Cancer Network. Non-Hodgkin's lymphomas, version 1.2013. *J Natl Compr Canc Netw* 2013 Mar 1;11(3):257-272.

GASTRIC LEIOMYOMAS & GASTROINTESTINAL STROMAL TUMOR

Leiomyomas are common submucosal growths that are usually asymptomatic but may cause intestinal bleeding. GIST (previously called leiomyosarcomas) may grow to a large size and most often present with bleeding. Radiologically, the tumor usually contains a central ulceration caused by necrosis from outgrowth of its blood supply. In most cases the tumor arises from the proximal stomach. It may grow into the gastric lumen, remain entirely on the serosal surface, or even become pedunculated within the abdominal cavity. Spread is by direct invasion or blood-borne metastases. CT scans provide useful information on the amount of extragastric extension. Leiomyomas should be removed by enucleation or wedge resection. After the more radical resections required for leiomyosarcomas, the 5-year survival rate is 20%. If technically possible, complete resection of metastases (eg, peritoneal, hepatic) in addition to the primary tumor may improve the outcome. The results are affected by tumor size, DNA ploidy pattern, and tumor grade. Lesions that exhibit 10 or more mitoses in a high-powered field rarely can be cured. Imatinib mesylate is an effective systemic agent used for disseminated disease and as an adjuvant therapy after complete resection.

MÉNÉTRIÉRIE DISEASE

Ménétrier disease, a form of hypertrophic gastritis, consists of giant hypertrophy of the gastric rugae; high, normal, or low acid secretion; and excessive loss of protein from the thickened mucosa into the gut, with resulting hypoproteinemia. Clinical manifestations include edema, diarrhea, anorexia, weight loss, and skin rash. Chronic blood loss may also be a problem. Indigestion may respond to antacids, but this treatment does not improve the gastric pathologic process or secondary hypoproteinemia. The hypertrophic rugae present as enormous filling defects on upper gastrointestinal imaging and are frequently misinterpreted as carcinoma. The protein leak from the gastric mucosa may respond to atropine (and other anticholinergic drugs), hexamethonium bromide, eradication of *H pylori*, or H₂ blocking agents or omeprazole. Rarely, total gastrectomy is indicated for severe intractable hypoproteinemia, anemia, or inability to exclude cancer. Medical management is best for most patients, though the gastric abnormalities and hypoproteinemia may persist. Some cases gradually evolve into atrophic gastritis. In children the disease characteristically is self-limited and benign. There is an increased risk of adenocarcinoma of the stomach in adults with Ménétrier disease.

PROLAPSE OF THE GASTRIC MUCOSA

This uncommon lesion occasionally accompanies small pyloric gastric ulcers. Episodes of vomiting and abdominal

pain simulate peptic ulcer disease. X-ray shows prolapse of antral folds into the duodenum. One must be alert to the presence of gastric or duodenal ulcer as the underlying cause.

Antrectomy with a Billroth I anastomosis is occasionally required. Generally, conservative treatment suffices.

GASTRIC VOLVULUS

The stomach may rotate about its longitudinal axis (organo-axial volvulus) or a line drawn from the mid-lesser to the mid-greater curvature (mesenteroaxial volvulus). The former is more common and is often associated with a paraesophageal hiatal hernia. In other patients, eventration of the left diaphragm allows the colon to rise and twist the stomach by pulling on the gastrocolic ligament.

Acute gastric volvulus produces severe abdominal pain accompanied by a diagnostic triad (Borchardt triad): (1) vomiting followed by retching and then inability to vomit, (2) epigastric distention, and (3) inability to pass a nasogastric tube. The situation calls for immediate laparotomy to prevent death from acute gastric necrosis and shock. Emergency imaging shows blockage at the point of the volvulus. The death rate is high.

Chronic volvulus is more common than acute. It may be asymptomatic or may cause crampy intermittent pain. Cases associated with paraesophageal hiatal hernia should be treated by repair of the hernia and anterior gastropexy. When cases are due to eventration of the diaphragm, the gastrocolic ligament should be divided the entire length of the greater curvature. The colon rises to fill the space caused by the eventration, and the stomach will resume its normal position, to be fastened by a gastropexy.

GASTRIC DIVERTICULA

Gastric diverticula are uncommon and usually asymptomatic. Most are pulsion diverticula consisting of mucosa and submucosa only, located on the lesser curvature within a few centimeters of the esophagogastric junction. Those in the prepyloric region generally possess all layers and are more likely to be symptomatic. A few patients have symptoms from hemorrhage of inflammation within a gastric diverticulum, but for the most part these lesions are incidental findings on imaging or endoscopy. Radiologically, they can be confused with a gastric ulcer.

BEZOAR

Bezoars are concretions formed in the stomach. Trichobezoars are composed of hair and are usually found in young girls who pick at their hair and swallow it. Phytobezoars consist of agglomerated vegetable fibers. Pressure by the mass can create a gastric ulcer that is prone to bleed or perforate.

The postgastrectomy state predisposes to bezoar formation because pepsin and acid secretion are reduced and the triturating function of the antrum is gone. Orange segments or other fruits that contain a large amount of cellulose have been implicated in most cases. Improper mastication of food is a contributing factor that can sometimes be obviated by providing the patient with properly fitted dentures. The fruit may remain in the stomach or pass into the small intestine and cause obstruction.

Large semisolid bezoars of *Candida albicans* have also been found in postgastrectomy patients. Some can be fragmented with the gastroscope. The patient should also be treated with oral nystatin.

Patients with symptomatic gastric bezoars may complain of abdominal pain. Ulceration and bleeding are associated with a death rate of 20%.

Nearly all gastric bezoars can be broken up and dispersed by endoscopy. Neglected lesions with complications (ie, bleeding or perforation) require gastrectomy.

II. DUODENUM

DUODENAL DIVERTICULA

Diverticula of the duodenum are found in 20% of autopsies and 5%–10% of the upper gastrointestinal imaging. Symptoms are uncommon and only 1% of those found by x-ray warrant surgery.

Duodenal pulsion diverticula are acquired outpouchings of the mucosa and submucosa, 90% of which are on the medial aspect of the duodenum. They are rare before age 40. Most are solitary and within 2.5 cm of the ampulla of Vater. There is a high incidence of gallstone disease of the gallbladder in patients with juxtapaillary diverticula. Diverticula do not occur in the first portion of the duodenum, where diverticular configurations are due to scarring by peptic ulceration or cholecystitis.

A few patients have chronic postprandial abdominal pain or dyspepsia caused by a duodenal diverticulum. Treatment is with antacids and anticholinergics.

Serious complications are hemorrhage or perforation from inflammation, pancreatitis, and biliary obstruction. Bile acid-bilirubinate enteroliths are occasionally formed by bile stasis in a diverticulum. Enteroliths can precipitate diverticular inflammation or biliary obstruction and, rarely, have caused bowel obstruction after entering the intestinal lumen.

Surgical treatment is required for complications and, rarely, for persistent symptoms. Excision and a two-layer closure are usually possible after mobilization of the duodenum and dissection of the diverticulum from the pancreas. Removal of the diverticulum and closure of the defect are superior to simple drainage in the case of perforation. If biliary obstruction appears in a patient whose bile duct empties into

a diverticulum, excision might be more hazardous than a side-to-side choledochoduodenostomy.

The rare wind sock type of intraluminal diverticulum usually presents with vague epigastric pain and postprandial fullness, though intestinal bleeding or pancreatitis is occasionally observed. The diagnosis can be made by imaging studies. The diverticulum can be excised through a nearby duodenotomy. In some cases, the narrow diverticular outlet can be enlarged endoscopically.

DUODENAL TUMORS

Tumors of the duodenum are rare. Carcinoma of the ampulla of Vater is discussed in Chapter 26.

1. Malignant Duodenal Tumors

Most malignant duodenal tumors are adenocarcinomas, leiomyosarcomas, or lymphomas. They appear in the descending duodenum more often than elsewhere. Pain, obstruction, bleeding, obstructive jaundice, and an abdominal mass are the modes of presentation. Duodenal carcinomas, particularly those in the third and fourth portions of the duodenum, are often missed on barium x-ray studies. Endoscopy and biopsy will usually be diagnostic if the examiner is suspicious enough and can reach the lesion.

If possible, adenocarcinomas and leiomyosarcomas should be resected. Pancreaticoduodenectomy is usually necessary if the tumor is localized. Unresectable lesions should be treated by radiotherapy. Biopsy and radiotherapy are recommended for lymphoma.

After curative resections, the 5-year survival rate is 30%. The overall 5-year survival rate is 18%.

2. Benign Duodenal Tumors

Brunner gland adenomas are small submucosal nodules that have a predilection for the posterior duodenal wall at the junction of the first and second portions. Sessile and pedunculated variants are seen. Symptoms are due to bleeding or obstruction. Leiomyomas may also be found in the duodenum and ordinarily are asymptomatic.

Neuroendocrine tumors of the duodenum are often endocrinologically active, producing gastrin, somatostatin, or serotonin. Simple excision is the treatment of choice.

Heterotopic gastric mucosa, presenting as multiple small mucosal nodules, is an occasional endoscopic finding of no clinical significance.

Villous adenomas of the duodenum may give rise to intestinal bleeding or may obstruct the papilla of Vater and cause jaundice. As in the colon, the risk of malignant change is high—about 50%. Small pedunculated villous adenomas may be snared during endoscopy, but sessile tumors must be locally excised via laparotomy. Tumors that contain malignant tissue should be treated by a Whipple procedure.

SUPERIOR MESENTERIC ARTERY OBSTRUCTION OF THE DUODENUM

Rarely, obstruction of the third portion of the duodenum is produced by compression between the superior mesenteric vessels and the aorta. It most commonly appears after rapid weight loss following injury, including burns. Patients in body casts are particularly susceptible.

The superior mesenteric artery normally leaves the aorta at an angle of 50–60 degrees, and the distance between the two vessels where the duodenum passes between them is 10–20 mm. These measurements in patients with superior mesenteric artery syndrome average 18 degrees and 2.5 mm. Acute loss of mesenteric fat is thought to permit the artery to drop posteriorly, trapping the bowel like a scissors.

Skepticism exists regarding the frequency of this condition in adults who have not experienced acute loss of weight. Most often the patient in question is a thin, nervous person whose complaints of dyspepsia and occasional emesis are more properly explained on a functional basis. When a clear-cut example is encountered, it may actually represent a form of intestinal malrotation with duodenal bands.

The patient complains of epigastric bloating and crampy pain relieved by vomiting. The symptoms may remit in the prone position. Anorexia and postprandial pain lead to additional malnutrition and weight loss.

Upper gastrointestinal imaging demonstrates a widened duodenum proximal to a sharp obstruction at the point where the artery crosses the third portion of the duodenum. When the patient moves to the knee-chest position, the passage of gastrointestinal contrast is suddenly unimpeded.

Many patients whose superior mesenteric artery makes a prominent impression on the duodenum are asymptomatic, and in ambulatory patients one should hesitate to attribute vague chronic complaints to this finding.

Involvement of the duodenum by scleroderma leads to duodenal dilatation and hypomotility and an x-ray and clinical picture highly suggestive of superior mesenteric artery syndrome. In the latter, increased duodenal peristalsis should be demonstrable proximal to the arterial blockage, whereas diminished peristalsis characterizes scleroderma. Patients with duodenal scleroderma usually have dysphagia from concomitant esophageal involvement.

Malrotation with duodenal obstruction by congenital bands can mimic this syndrome.

Postural therapy may suffice. The patient should be placed prone when symptomatic or in anticipation of postprandial difficulties. Ambulatory patients should be instructed to assume the knee-chest position, which allows the viscera and the artery to rotate forward off the duodenum.

Chronic obstruction may require section of the suspensory ligament and mobilization of the duodenum, or a duodenojejunostomy to bypass the obstruction. Patients

with various forms of malrotation should be treated by mobilizing the duodenojejunal flexure, which releases the duodenum from entrapment by congenital bands.

REGIONAL ENTERITIS OF THE STOMACH & DUODENUM

The proximal intestine and stomach are rarely involved in regional enteritis, though this disease has now been reported in every part of the gastrointestinal tract from the lips to the anus. Most patients with Crohn disease in the stomach or duodenum have ileal involvement as well.

Pain can in many instances be relieved by antacids. Intermittent vomiting from duodenal stenosis or pyloric obstruction is frequent. The x-ray finding of a cobblestone mucosa or stenosis would be suggestive when associated with typical changes in the ileum. The endoscopic appearance is fairly characteristic, and biopsy with the peroral suction device usually gives an adequate specimen for histologic confirmation of the diagnosis.

Medical treatment is nonspecific and consists principally of corticosteroids during exacerbations. Surgery may be indicated for disabling pain or obstruction. If the disease is localized to the stomach, a partial gastrectomy can be performed. Duodenal involvement most often requires a gastrojejunostomy to bypass the obstruction. Vagotomy should also be performed to prevent development of a marginal ulcer. Recurrent Crohn disease involving the anastomosis is an occasional late complication, but it can usually be managed successfully by reoperation.

Internal fistulas involving the stomach or duodenum usually represent extensions from primary disease in the ileum or colon. Surgical treatment consists of resection of the diseased ileum or colon and closure of the fistulous opening in the upper gut.

MULTIPLE CHOICE QUESTIONS

1. The blood supply to the stomach
 - A. Typically includes direct branches from the celiac axis and superior mesenteric artery
 - B. Includes predominant supply of the greater curve of the stomach by the left gastric artery
 - C. Includes the right gastroepiploic artery, which is usually a branch of the splenic artery
 - D. May include a posterior gastric artery that is typically a branch of the splenic artery
 - E. Is anatomically separate from the blood supply to the spleen

2. The four functions of the stomach include all of these except
 - A. It mixes the food and controls delivery into the duodenum.
 - B. It is the site of the initial stage of protein and carbohydrate digestion.
 - C. It acts as a reservoir for food.
 - D. It is the site of the assembly of micelles for nutrient absorption.
 - E. A few substances are absorbed across the gastric mucosa.

3. Reconstruction of gastrointestinal continuity after resection of portions of the stomach
 - A. Usually includes a roux-en-Y reconstruction after distal gastrectomy
 - B. Cannot be done by Billroth I reconstruction after total gastrectomy
 - C. Includes a gastroduodenostomy for Billroth II reconstruction
 - D. Has a risk of duodenal stump leak after Billroth I reconstruction
 - E. May require conversion to a Billroth II reconstruction if a patient develops bile gastritis after a Billroth I approach

4. Vagotomy
 - A. Can impair the appropriate relaxation of the pylorus
 - B. Has several variations, but each denervates the pylorus
 - C. Has become more widely applied as ulcer therapy since the introduction of acid-suppressing medications (H₂-blockers and proton pump inhibitors)
 - D. Impairs gallbladder emptying
 - E. Can include division of both the left (posterior) and right (anterior) vagus nerve trunks

5. Management of gastric outlet obstruction
 - A. Is typically required for complications due to distal gastric diverticulae or polyps
 - B. Should include urgent operation in most patients
 - C. Initially includes gastric decompression and acid suppression
 - D. Is commonly required in the management of duodenal ulcer disease
 - E. Is best managed operatively by distal gastrectomy and Billroth I reconstruction

24

Liver & Portal Venous System

Simon Turcotte, MD, MSc
William R. Jarnagin, MD

SURGICAL ANATOMY

► Sectors and Segments

The liver develops as an embryologic outpouching from the duodenum. The liver is one of the largest organs in the body, representing up to 2% of the total body weight. The relationship of the liver to the other abdominal organs is shown in Figure 24–1. In classic descriptions, the liver was characterized as having four lobes: right, left, caudate, and quadrate; however, this is an overly simplistic view that fails to consider the more complex segmental anatomy, which is depicted in Figure 24–2.

The anatomical right and left hemilivers are separated by an imaginary line running from the medial aspect of the gallbladder fossa to the inferior vena cava, running parallel with the fissure of the round ligament (Figure 24–3). This division is known as the Cantlie line or the principal plane and marks the course of the middle hepatic vein. The liver is divided into four sectors and eight segments based on the branching of the portal triads and hepatic veins. The structures of the portal triad (hepatic artery, portal vein, and biliary duct) are separate in their extrahepatic course but enter the hepatic hilum ensheathed within a thickened layer of the Glisson capsule.

The three main hepatic veins divide the liver into four sectors, each of which is supplied by a portal pedicle: the right posterior sector (segments VI and VII), the right anterior sector (segments V and VIII), the left medial sector (segment IV), and the left lateral sector (segments II and III) (Figure 24–2). The caudate lobe (segment I) is an exception because its venous drainage is directly into the vena cava and therefore independent of the major hepatic veins. The four sectors delimited by the hepatic veins are called the portal sectors, and these portions of the parenchyma are supplied by independent portal pedicles arising from the right or left main pedicles. The divisions separating the sec-

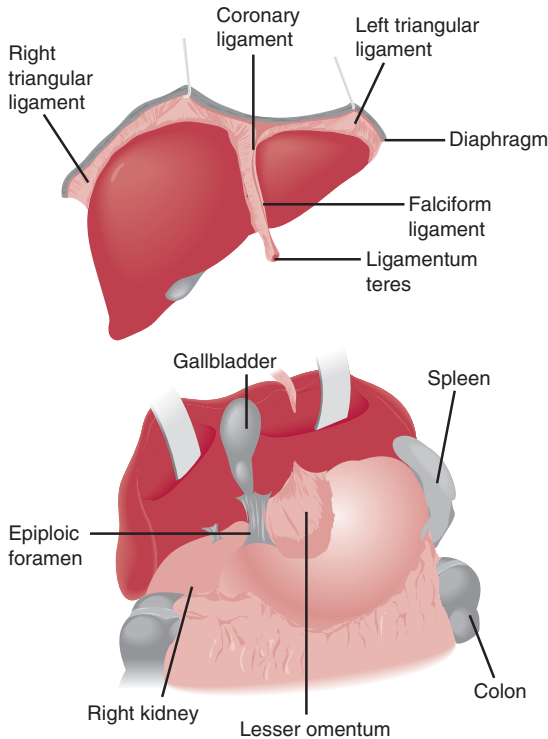

tors are called portal scissurae, within each of which runs a hepatic vein. Further branching of the pedicles subdivides the sectors into segments. The liver is thus subdivided into eight segments, with the caudate lobe designated as segment I. Segments I–IV comprise the left liver, and segments V–VIII, the right. Each segment is supplied by an independent portal pedicle, which forms the basis of sublobar segmental resections.

► Portal Circulation

The portal vein is formed by the confluence of the splenic and superior mesenteric veins at the level of the second lumbar vertebra behind the head of the pancreas (Figure 24–4). It runs for approximately 6–9 cm to the hilum of the liver, where it divides into the main right and left branches. The left gastric vein usually enters the portal vein on its anteromedial aspect just cephalad to the margin of the pancreas, in which case it must be ligated during the surgical construction of a portacaval shunt; in 25% of cases, the left gastric vein joins the splenic vein. Other small venous tributaries from the pancreas and duodenum are less constant but must be anticipated during surgical mobilization of the portal vein.

The inferior mesenteric vein often drains into the splenic vein to the left of its junction with the superior mesenteric vein; alternatively, it may empty directly into the superior mesenteric vein.

In the hepatoduodenal ligament, the portal vein lies dorsal and slightly medial to the common bile duct. Portacaval lymph nodes are encountered along the right lateral aspect of the portal vein, running from the level of the duodenum to the base of the liver and extending posteriorly to the common hepatic artery and celiac axis. These lymph nodes are routinely removed during resections for certain malignancies and must be dissected before a portacaval shunt can be created.

▲ **Figure 24-1.** Relationships of the liver to adjacent abdominal organs. The liver is invested with peritoneum except on the posterior surface, where the peritoneum reflects onto the diaphragm forming the right and left triangular ligaments.

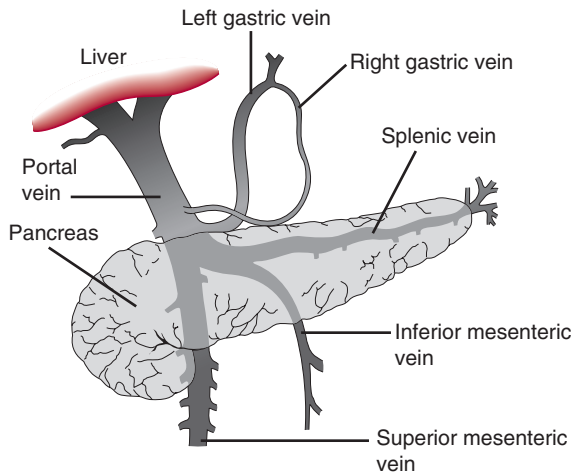

▲ **Figure 24-3.** Anatomy of the veins of the liver. The major lobar fissure, also referred to as the principal plane or Cantlie line, is represented by the dashed line and divides the anatomical right and left liver. Branches of the hepatic artery and biliary ducts follow those of the portal vein. The darker vessels represent the hepatic veins and vena cava; the lighter system represents the portal vein and its branches.

► **Venous Blood Supply**

The anatomy of venous blood supply is shown in Figure 24-2. Both the portal and hepatic venous systems lack valves. The main portal vein terminates in the porta hepatis by dividing into right and left branches. The right branch typically has a short extrahepatic course before subsequently dividing into anterior and posterior sectoral divisions, often high within the porta hepatic or intrahepatically. The left branch has a longer extrahepatic course, running first along the base of segment IV and then entering the umbilical fissure,

▲ **Figure 24-2.** Segmental anatomy of the liver. Each of the eight segments numbered. Segment I (caudate) is not shown but indicated at the back of the liver, posterior to the middle hepatic vein. Segments I-IV comprise the anatomical left liver, and segments V-VIII, the right. The most common major hepatic resections performed and the segments removed with each are indicated. LT, ligamentum teres; LPV, left portal vein; RHV, right hepatic vein; M&LHV, middle and left hepatic veins originating from a common trunk; RPV, right portal vein.

▲ **Figure 24–4.** Anatomic relationships of portal vein and branches.

where it gives rise to branches to segments II, III, and IV; a large branch to the caudate lobe generally arises from the left portal vein prior to its entry into the umbilical fissure. Variations in the normal portal venous anatomy occur but are less common than aberrancies in the arterial supply or the biliary drainage. The most common anomaly of the portal venous system is separate origins of the right anterior and posterior sectoral branches. The left portal vein may drain primarily into the right anterior pedicle.

The hepatic veins represent the final common pathway for the central veins of the lobules of the liver. There are three major hepatic veins: left, right, and middle. The right hepatic vein drains into the vena cava independently, while the middle and left hepatic veins typically join just outside the liver, forming a common trunk. The middle hepatic vein runs in the principal plane (Cantlie line) and provides drainage for segment IV and the anterior sector of the right liver (segments V and VIII). The left hepatic vein drains segments II and III, while the right hepatic vein drains the posterior sector (segments VI and VII) and provides additional drainage to the anterior sector. A small venous tributary runs within the umbilical fissure, providing accessory drainage of segments III and IV and emptying into the left hepatic vein. Several small accessory veins enter the inferior vena cava directly from the posterior aspect of the right lobe and must be carefully ligated during mobilization and resection of the right liver.

► Arterial Blood Supply

The common hepatic artery arises from the celiac axis, ascends in the hepatoduodenal ligament, and gives rise to

the right gastric, gastroduodenal, and proper hepatic arteries; the proper hepatic artery then divides into the right and left hepatic arterial branches in the liver hilum. The hepatic artery supplies approximately 25% of the 1500 mL of blood that enters the liver each minute; the remaining 75% is supplied by the portal vein.

Variations of the standard arterial anatomy of the liver are relatively common, seen in up to 40% of patients. The most common variants involve different origins of the right or left hepatic artery. A replaced right hepatic artery arises entirely from the superior mesenteric artery and courses posteriorly and to the right of the common bile duct within the porta hepatis, which is in contrast to its normal position to the left of the duct. Recognition of this anatomical variant is critical during operations on the extrahepatic biliary tree. An accessory right hepatic artery also arises from the superior mesenteric artery and is found in the same location within the porta hepatis but supplies only a portion of the right liver; in this situation, a separate right branch arising from its normal position off the proper hepatic artery is typically present. An accessory or replaced left hepatic artery arises from the left gastric artery and enters the liver through the gastrohepatic ligament. Up to 25% of patients have a replaced or accessory right hepatic artery, and a similar proportion have a replaced or accessory left hepatic artery. Within the liver, the hepatic arterial branches travel with segmental bile ducts and portal vein branches, and remain as portal triads in subsegmentations, found at each angle of the hexagonal-shape liver lobules.

► Biliary Drainage

The biliary tree arises within the liver from bile canaliculi, formed from specialized segments of the hepatocyte membrane. Bile canaliculi join to form progressively larger channels, resulting in segmental bile ducts that drain each segment. The right anterior and right posterior sectoral ducts unite to form the main right hepatic duct, while the union of ducts draining segments II, III, and IV forms the left hepatic duct. The left hepatic duct typically is longer and has a longer extrahepatic course than the right hepatic duct. Drainage of segment I (caudate lobe) is principally into the left hepatic duct, but additional smaller ducts enter the right hepatic duct or drain directly into the hepatic duct confluence, which is formed by the union of the major lobar ducts to form the common hepatic duct. The common hepatic duct descends within the hepatoduodenal ligament for a variable distance to the point of insertion of the cystic duct of the gallbladder to give rise to the common bile duct.

Anatomic variations in the biliary ductal anatomy are seen in approximately 30% of patients and most often

involve the right hepatic duct. In approximately 25% of patients, the duct from the right posterior sector joins the common hepatic duct or the left hepatic duct independently. Recognition of this variation is crucial for the surgeon performing a left hepatectomy for avoiding injury of the right posterior biliary drainage. Variations are far less common on the left side.

► Lymphatics

Lymphatics draining superficial lobules of the liver follow a subcapsular course to the diaphragm, to the suspensory ligaments of the liver, or to the posterior mediastinum, while others enter the porta hepatis. Lymphatics arising from lobules deep within the liver travel either with the hepatic veins along the vena cava or with the portal veins into the porta hepatis. Most of the lymphatic drainage of the liver is to the hepatoduodenal ligament.

NERVES

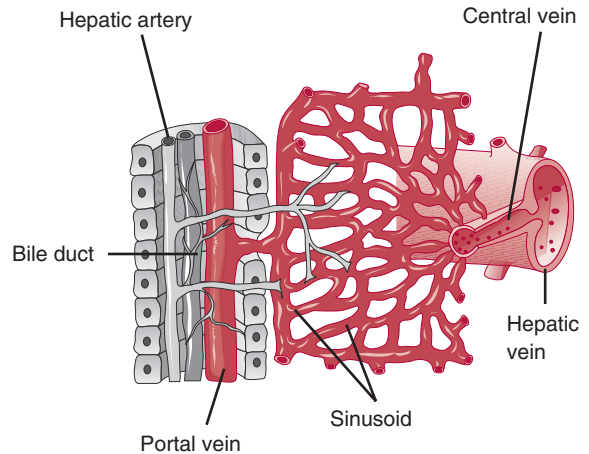

The liver and biliary tree are innervated by sympathetic fibers arising from T7 to T10 and by parasympathetic fibers from the right and left vagus nerves. The postganglionic sympathetic nerves arise from the celiac ganglia. Fibers derived from the celiac ganglia and vagus nerves form a plexus of nerves that run along the anterior and posterior aspects of the hepatic artery.

PHYSIOLOGY

Total hepatic blood flow (about 1500 mL/min; 30 mL/min per kg body weight) constitutes 25% of the cardiac output, though the liver accounts for only 2.5% of body weight. About 30% of the hepatic volume is blood (12% of total blood volume). Two-thirds of the flow enters through the portal vein and one-third through the hepatic artery. Pressure in the portal vein is normally low (10–15 cm H₂O [7–11 mm Hg]). The liver derives half of its oxygen from hepatic arterial blood and half from portal venous blood.

Blood flow within the liver is uniform, as demonstrated by an even distribution of microspheres injected into the hepatic artery or portal vein. Hepatic blood flow to the liver is regulated by a number of factors. Muscular sphincters at the inlet and outlet of sinusoids represent a major control point and respond to a number of different stimuli, including the autonomic nervous system, circulating hormones, bile salts, and metabolites. The cells lining the hepatic sinusoids (endothelial cells, Kupffer cells, and stellate cells) can also regulate flow to some extent.

Portal venous and hepatic arterial blood becomes pooled after entering the periphery of the hepatic sinusoid (Figure 24–5). Hepatic arterial flow increases or decreases reciprocally with changes in portal flow; however, portal venous

▲ Figure 24–5. Vascular anatomy of the liver lobule.

flow does not increase with reductions in arterial flow. This arterial compensatory response is controlled largely by adenosine, which is released into the space of Mall surrounding the hepatic arterial resistance vessels. High concentrations of adenosine dilate the vessels, which increases flow and washes out the adenosine.

Sudden occlusion of the portal vein results in an immediate 60% rise in hepatic arterial flow. The total flow then gradually returns toward normal. On the other hand, sudden reductions in hepatic arterial supply are not immediately met by significant increases in portal vein flow. In both normal subjects and cirrhotics, total hepatic flow, and portal pressure drop following hepatic arterial occlusion. Arterial collaterals develop, and arterial perfusion is ultimately restored.

It is for this reason that interruption of hepatic arterial flow to the right or left liver generally has little impact on hepatic function. The one notable exception is in the setting of biliary obstruction. Decreased hepatic arterial flow to portions of the liver with impaired biliary drainage carries a high risk of hepatic necrosis. Clinically, this is an important consideration in patients undergoing hepatic arterial embolization of liver tumors and in patients undergoing resection of periampullary tumors, where jaundice is common and dissection within the porta hepatis could potentially put the hepatic artery at risk for injury. On the other hand, portal venous flow plays a critical role in maintaining normal hepatic architecture and function. This point is underscored by the observation that occlusion of the right or left portal venous branches results in profound ipsilateral hepatic atrophy and contralateral hypertrophy. Portal vein occlusion is clinically relevant in a number of disease processes, particularly carcinoma of the hepatic duct confluence (hilar

cholangiocarcinoma), in which portal venous involvement is common and has important therapeutic implications. Additionally, intentional occlusion of a major portal vein branch (usually the right side) is a procedure being used with greater frequency prior to major hepatic resection, primarily when the regenerative capacity of the future liver remnant (that portion of the liver that remains behind after the resection) is questionable because of either size concerns (too small) or underlying parenchymal disease (steatohepatitis, cirrhosis). By causing atrophy of the liver to be resected, and therefore hypertrophy of the future liver remnant, the risk of postoperative hepatic failure may be reduced.

HEPATIC RESECTION

Liver resection is most commonly indicated for primary and secondary malignant tumors and symptomatic benign tumors; less common indications include traumatic injury, infection/abscesses, and living donor transplantation. Removal of as much as 80% of the normal liver can be performed with the expectation that the liver remnant will regenerate sufficiently for the patient to survive. It must be emphasized, however, that such extensive resections should be considered only in patients with normal hepatic function; those with cirrhosis or significant fibrosis or steatosis (fatty infiltration of the liver) are less likely to tolerate a major hepatic resection. Liver function may be impaired for several weeks after an extensive resection, but the extraordinary regenerative capacity of the liver rapidly provides new functioning hepatocytes. Within 24 hours after partial hepatectomy, cell replication becomes active and continues until the original volume of hepatic tissue is restored. Considerable

regeneration occurs within 10 days, and the process is essentially complete by 4-5 weeks. Excised portions of liver are not re-formed; rather, the growth consists of formation of new lobules and expansion of residual lobules. The stimuli for hepatic regeneration are thought to include the following: hepatocyte growth factor, tumor growth factor (TGF)- α , heparin-binding growth factor, hepatopoietin B, and disinhibition by TGF- β_1 (ie, decreased levels of this inhibitor of hepatic growth).

► Preoperative Evaluation

Several different disease-related and patient-related factors must be assessed before deciding to proceed with hepatic resection. Among the most important of these is the preoperative functional status of the liver. Cirrhosis is a relative contraindication for partial hepatectomy because the limited reserve of the residual cirrhotic liver may be insufficient to meet essential metabolic demands, and the cirrhotic liver has a reduced capacity for regeneration. Cirrhosis is a particular concern in patients with hepatocellular carcinoma, which frequently arises in the setting of chronic hepatic parenchymal disease. An increasingly important concern in patients with hepatic colorectal metastases is chemotherapy-induced liver damage, which may also impair regeneration of the liver remnant.

Several tests are available to assess hepatic function prior to operation, none of which is perfect. The Child-Pugh classification is the oldest and most widely employed and remains the most useful assessment. The Child-Pugh system classifies hepatic function on the basis of the amount of ascites, the degree of encephalopathy, albumin and total bilirubin levels, and the prothrombin time (INR) (Table 24-1).

Table 24-1. Child-Pugh classification of functional status in liver diseases.

	1	Points 2	3
Ascites	Absent	Slight to moderate	Tense, refractory
Encephalopathy ^a	None	Grades I-II	Grades III-IV
Serum albumin (g/dL)	> 3.5	3.0-3.5	< 3.0
Serum bilirubin (mg/dL)	< 2.0	2.0-3.0	> 3.0
Prothrombin time (seconds above control)/INR	< 4.0/< 1.7	4.0-6.0/1.7-2.3	> 6.0/> 2.3
Child-Pugh Classification	Scores		
A (low risk)	5-6		
B (moderate)	7-9		
C (high risk)	10-15		

^a Grade I, altered mood; Grade II, inappropriate behavior, somnolence; Grade III, markedly confused, stuporous but arousable; Grade IV, unresponsive.

To convert the values for bilirubin to $\mu\text{mol/L}$, multiply by 17.1.

Originally used to assess mortality related to portosystemic shunts, the Child–Pugh score also predicts mortality in patients with cirrhosis after hepatic resection. In general, only Child–Pugh A and highly selected Child–Pugh B cirrhotics would be candidates for resection. More recently in the United States, to improve allocation of cadaveric liver transplant to cirrhotic patients with the highest risk of death, the Model for End-Stage Liver Disease (MELD) score has been validated. Similar to the Child–Pugh classification, the total bilirubin level, and the INR are accounted for, combined with the serum creatinine level. The MELD score was originally devised to predict mortality of patients awaiting liver transplantation but is also effective for assessing liver function in patients undergoing resection. The indocyanine green clearance test is commonly used in centers outside North America but has not been proven superior to the Child–Pugh scoring system.

► Extent of Hepatic Resection

Hepatic resections are classified as anatomical (based on the segmental liver anatomy) or nonanatomical. Wedge resections, enucleations, and resectional debridement of devitalized tissue are examples of the latter. In general, anatomical resections are preferred because they are associated with lower blood loss and, when performed for malignancy, a lower incidence of positive resection margins.

Major resections must be performed in accordance with the segmental anatomy (Figure 24–2). Major resections (right or left hepatectomy or extended hepatectomy) are commonly performed; however, the segmental anatomy of the liver allows smaller resections or bilateral resections to be performed when necessary and appropriate. For example, in selected situations, a resection of the anterior (segments V and VIII) or posterior (segments VI and VII) sectors may be performed rather than sacrificing the entire right liver. Such parenchymal-sparing resections on one side would then allow a resection of part of the contralateral lobe, if necessary. Sequential, two-stage hepatectomy has also proven to benefit patients in the setting of multiple, bilateral liver metastases of colorectal cancer origin, allowing time for the liver remnant to regenerate and compensate for the second resection.

The terminology and extent of the common types of major resections are in Figure 24–2. The operation entails removal of a lobe or segment with its afferent and efferent vessels while avoiding injury to vessels and bile ducts supplying the remnant tissue.

Most elective hepatic resections can be performed through an abdominal incision, although selected situations (very large right lobe tumors) are probably best performed with a thoracoabdominal approach. Laparoscopic resections are being performed with greater frequency, although the open approach is most common and remains the standard. The best perioperative results are obtained by minimizing

blood, which is accomplished by: (1) achieving vascular inflow and outflow control prior to parenchymal transection; (2) performing careful division of the liver with precise control of intrahepatic vascular structures; and (3) using low central venous pressure anesthesia, which reduces hepatic venous blood loss. Clamping of the portal inflow pedicle (Pringle maneuver) for periods of 10–15 minutes is commonly used to minimize blood loss via intrahepatic arterial and portal venous branches, although hepatic venous bleeding is unaffected.

► Preoperative Portal Vein Embolization

As discussed previously, preoperative portal vein embolization is a technique that can be used to potentially improve the safety of major hepatic resections. By inducing hypertrophy of the future liver remnant prior to operation, the risk of postoperative liver failure is potentially reduced. The risk of such complications increases significantly with resections that leave behind a liver remnant of less than 25% in patients with normal liver or less than 40% in patients with liver disease.

► Postoperative Course

Patients submitted to major resections require close monitoring for the first several postoperative days; however, a prolonged stay in the intensive care unit is unnecessary in most cases. The major concern in the immediate postoperative period is hemorrhage, although in practice, reoperation for bleeding is rarely necessary. Patients without cirrhosis usually exhibit some metabolic changes consistent with mild liver insufficiency, but these quickly normalize, and they are often ready for discharge on the seventh or eighth postoperative day. In the presence of significant hepatic parenchymal disease (ie, cirrhosis, fibrosis, steatosis) or septic complications, postoperative liver function may be significantly impaired.

Many of the postoperative abnormalities can be predicted on the basis of the liver's normal function. The serum bilirubin often increases after major resections but returns to normal as regeneration progresses. A persistent or rising serum bilirubin level should raise concern for a perihepatic fluid collection (biloma) or hepatic failure (especially if other measures of hepatic function are also deteriorating). The serum albumin level usually falls, and the prothrombin time often increases; treatment of the latter with fresh frozen plasma is generally needed only when the INR is markedly elevated (> 2). Some patients may develop ascites, which can be treated with diuretics. Although the liver's glycogen stores are necessarily reduced after a major partial hepatectomy, hypoglycemia is almost never a problem postoperatively; normoglycemia can be easily maintained with 5% dextrose solutions, and profound hypoglycemia should raise concern for liver failure. Serum levels of phosphate,

magnesium, and potassium often decrease during the first several postoperative days and require replacement. The liver enzymes (aspartate aminotransferase [AST], alanine aminotransferase [ALT]) are usually increased in the first few days after operation and then normalize. By contrast, the alkaline phosphatase is often initially normal and then increases and can remain elevated for several days to weeks after surgery.

► Complications

Complications may occur in up to 40% of patients after major liver resection (≥ 3 segments), but many are relatively minor, and the overwhelming majority are readily managed and resolve without sequelae. Liver-related complications are the most frequent; perihepatic fluid collections requiring drainage occur in approximately 10%-15% of patients. Relative hepatic insufficiency (hyperbilirubinemia, ascites, coagulopathy) is common but resolves in most patients as the liver regenerates; however, hepatic failure is distinctly uncommon in high-volume centers. Pulmonary complications are also seen with some frequency, underscoring the need for aggressive pulmonary toilet postoperatively. The most common pulmonary problems are symptomatic pleural effusions or atelectasis; pneumonia is infrequent. Despite the potential complications associated with major liver resection, mortality rates are low, typically on the order of 1%-3% in high-volume centers. Less extensive liver resections (< 3 segments) are associated with even lower morbidity and mortality rates.

DISEASES & DISORDERS OF THE LIVER

HEPATIC TRAUMA

The liver is injured in approximately 5% of all trauma admissions. Based on the mechanism of injury, liver trauma is classified as penetrating or blunt. Penetrating wounds, constituting more than half of cases, are typically due to projectiles (such as bullets or shrapnel) or knives. In civilian practice, most of these tend to be clean wounds that are dangerous because of intra-abdominal bleeding but do not result in much devitalization of liver tissue. In contrast, high-velocity projectiles, commonly associated with military weapons, are associated with greater energy that is transferred to the abdominal viscera and can shatter the parenchyma, even if the projectile does not enter the liver directly.

Blunt trauma can be inflicted by a direct blow to the upper abdomen or lower right rib cage or can follow sudden deceleration, as occurs with a fall from a great height. Most often a consequence of automobile accidents, direct blunt trauma tends to produce explosive bursting wounds or linear lacerations of the hepatic surface, often with considerable parenchymal destruction. The stellate, bursting type of injury tends to affect the posterior and superior aspect of the right liver (segments VI, VII, and VIII) because of its relatively vulnerable location, convex surface, fixed position, and concentration of hepatic mass. Damage to the left liver is much less common than damage to the right. Injuries that involve shearing forces can tear the hepatic veins where they enter the liver substance, producing an exsanguinating retrohepatic injury in an area difficult to surgically expose and repair.

The improvement in image quality and rapidity of execution of CT scans has transformed the initial management of trauma patients over the past few decades. For patients who can be hemodynamically stabilized with initial resuscitation, CT allows staging of the liver injury, in addition to all other structures from the neck to the pelvis. The staging system described in Table 24-2 is used to categorize liver injuries and provide a common language in order to allow comparisons of results of treatment between institutions. Patients who cannot be stabilized must go directly to the operating room.

There are two main management approaches to traumatic liver injury: nonoperative, which can be combined with angiography and selective embolization, or operative. When angiographic embolization is used as adjuvant to nonoperative management, approximately 85% of patient with blunt hepatic trauma can be successfully managed. A major limitation of arterial embolization is its inability to control bleeding from major venous injuries. Penetrating trauma, however, most often requires surgical intervention. The principal surgical goals are to stop bleeding and debride

Table 24–2. Liver injury scale.¹

Grade	Type	Description
I	Hematoma	Subcapsular, nonexpanding, < 10% of liver capsule surface area
	Laceration	Capsular tear, nonbleeding; < 1 cm deep in parenchyma
II	Hematoma	Subcapsular, nonexpanding, 10%-50% surface area; intraparenchymal, nonexpanding, < 2 cm in diameter
	Laceration	Capsular tear, active bleeding; 1-3 cm deep into the parenchyma, < 10 cm long
III	Hematoma	Subcapsular, > 50% surface area or expanding; ruptured subcapsular hematoma with active bleeding; intraparenchymal hematoma > 2 cm or expanding
	Laceration	> 3 cm deep into the parenchyma
IV	Hematoma	Ruptured intraparenchymal hematoma with active bleeding
	Laceration	Parenchymal disruption involving > 50% of hepatic lobe
V	Laceration	Parenchymal disruption involving > 50% of hepatic lobe
	Vascular	Juxtahepatic venous injuries; ie, retrohepatic vena cava or major hepatic veins
VI	Vascular	Hepatic avulsion

¹Increase by one grade when there are two or more injuries to the liver. Grading applied based on best available evidence, whether from x-rays, operative findings, or autopsy findings.

devitalized liver. Because some degree of liver failure is common postoperatively, efforts should be made during each step to maintain adequate oxygenation and perfusion of the liver. Also, when one is debriding liver tissue, care should be taken to avoid injury to the vascular supply of adjacent viable parenchyma.

► Clinical Findings

A. Symptoms and Signs

The clinical manifestations of liver injury are those of hypovolemic shock: hypotension, decreased urinary output, low central venous pressure, and, in some cases, abdominal distention. Patients managed nonoperatively are admitted in a monitored setting and closely followed with serial examinations and hematocrit assessments. Patients who develop peritoneal signs on physical examination or the onset of

hemodynamic instability denote the failure of nonoperative management and mandate surgical intervention.

B. Laboratory Findings

With major injuries, particularly those associated with disruption of hepatic veins, the rate of blood loss is usually so rapid that anemia does not develop. Leukocytosis greater than 15,000/ μ L is common following rupture of the liver from blunt trauma. Polytraumatized patients most often develop acidosis and coagulopathy.

C. Imaging Techniques

Focused abdominal sonography for trauma (FAST) in unstable patients has a sensitivity of 97% for detecting hemoperitoneum larger than 1 L and can direct surgical intervention in patients going directly to surgical management. The exact location of the injury often cannot be reliably identified with FAST. There is no defined role for FAST in stable patients.

High resolution CT scan with intravenous contrast enhancement should be obtained in all stable patients suspected of having a hepatic injury. The CT provides a detailed evaluation of the liver injury and its extent, an estimate of the amount of blood loss, and can demonstrate a contrast blush from the liver parenchyma. The findings are useful for triaging, since minor injuries rarely require surgical treatment, whereas extensive injuries usually do. One must exercise caution, however, in using CT estimates of injury grade, because they correlate poorly (ie, they both understage and overstage) with what is found at surgery. CT scanning is also useful for identifying injuries to other organs, which are not uncommon, particularly in the setting of high velocity blunt trauma.

Angiography is generally not helpful in the acute setting for the diagnosis of liver injury, but may be used as an interventional adjunct in patients who are potential candidates for nonoperative management.

► Treatment

Regardless of the grade of blunt liver injury, the hemodynamic stability of patients dictates whether or not a liver trauma should be managed operatively. In contrast, only highly selected patients with penetrating trauma can be managed nonoperatively. In the absence of injury to the spleen and the kidneys, CT findings most often associated with successful nonoperative management include small hemoperitoneum, contained subcapsular or intrahepatic hematoma, unilobar fracture, absence of devitalized liver, minimal intraperitoneal blood, and absence of injuries to other intra-abdominal organs. Failure rate of the nonoperative approach increases with the grade of the liver injury, reaching one out of four patients with grade V blunt injury. Conversely, it should be kept in mind that low-grade injuries

can bleed significantly. Drop in hematocrit in stable patients should prompt a CT scan to verify that the lesion is stable rather than expanding, and if a blush of intravenous contrast is associated with the liver injury, often bleeding can be addressed by angiographic embolization.

Most patients with CT or clinical evidence of active bleeding or a major injury, however, require prompt exploration. Most minor parenchymal lacerations have stopped bleeding by the time operation is performed. In the absence of active hemorrhage, these wounds should not be sutured. Active bleeding should be managed by clipping or direct suture of identifiable vessels, if possible, rather than by mass ligatures. Subcapsular hematomas often overlie an active bleeding site or parenchyma in need of debridement and should be explored even though the injury appears to be tamponaded and of limited severity. Blunt injuries associated with substantial amounts of parenchymal destruction may be particularly difficult to manage. Rarely, a very severe pulverizing injury requires formal partial hepatectomy.

Temporary occlusion of the hepatic artery and portal vein can be done quickly by placing a vascular clamp around the entire hepatoduodenal ligament (Pringle maneuver). This can be done for periods of 15-20 minutes and reduce the hemorrhage sufficiently to permit more accurate ligation of bleeding vessels. With major hepatic venous injuries, however, a Pringle maneuver has little effect, and precise repair of the injury may not be possible. Absorbable gauze mesh (eg, polyglycolic acid) can sometimes be wrapped around an injured lobe and sutured in a way that maintains pressure and tamponades the bleeding; this is difficult to accomplish without rendering the involved liver ischemic, however, and such an approach is rarely applicable. In some cases, control of arterial hemorrhage requires ligation of the hepatic artery or one of the accessible major branches (ie, right anterior or right posterior sectoral branches) in the hilum.

The most difficult problems involve lacerations of the major hepatic veins behind the liver. With such injuries, temporary clamping of the inflow vessels has no impact on back-bleeding from the inferior vena cava and does not allow adequate inspection and repair of the injured vessels. For persistent bleeding, the abdominal incision can be extended into a median sternotomy to improve exposure. An ancillary technique, which is used only rarely and has been associated with high mortality rates, is to place a tube through the atrial appendage into the inferior vena cava past the origin of the hepatic veins. Appropriately placed ligatures around the supra- and infra-hepatic vena cava combined with the Pringle maneuver permit total isolation of the liver circulation. Resection of the right liver improves exposure of the retrohepatic vena cava but is difficult to perform in the face of massive hemorrhage.

In many cases, when bleeding is difficult to control, and especially when other injuries must be addressed, damage control is the best strategy and involves packing the liver to

achieve hemostasis. The packs are generally left in place for 48-72 hours, during which time the patient remains sedated and intubated in the intensive care unit where adequate resuscitative measures are undertaken to correct hypothermia, acidosis, and coagulopathy. The packs are removed in the operating room; if persistent bleeding is noted, definitive repair of the injury can then be performed in a somewhat more controlled fashion.

The majority of patients who come to operation require little in the way of surgical intervention to control bleeding; drainage of substantial liver lacerations and other injuries is reasonable, since bile leakage can occur. For superficial liver injuries, bleeding can often be controlled with direct compression, topical agents, electrocautery or argon beam coagulation. Suture ligation of bleeding hepatic vessels and debridement of devitalized tissue are indicated in about 30% and 10% of cases, respectively. More extensive procedures are indicated even less often.

Penetrating injuries that also involve the small bowel or colon may result in contamination of perihepatic fluid or devitalized liver tissue, leading to a subhepatic abscess. Placement of drains may help prevent this problem, but a high index of suspicion should be maintained during the postoperative period.

► Postoperative Complications

With present techniques, hemorrhage at laparotomy is rarely uncontrollable except with retrohepatic venous injuries. Patients who rebleed early from the liver wound after initial suture ligation should be treated by reexploration and packing, in most cases; rarely is a major resection required. Angiography and CT scanning may provide useful diagnostic information preoperatively in such patients.

Bile leaks can follow both blunt penetrating liver injuries when the biliary system is disrupted. Most bilomas can be treated with image-guided percutaneous drainage. Endoscopic retrograde cholangiopancreatography may help identify the site of injury and may be therapeutic in some cases, since stents can be deployed in selected bile ducts and sphincterotomy of the sphincter of Oddi can relieve pressure in the biliary system. It should be noted, however, that such maneuvers have not been shown to expedite the resolution of biliary injuries, provided that adequate drainage of the biloma has been achieved.

Subhepatic sepsis develops in about 20% of cases; it is more frequent if a major hepatectomy has been performed. Abscess can occur after blunt trauma, especially with concomitant enteric injuries. Most abscess can be managed with percutaneous drainage and antibiotic therapy.

Hemobilia may be responsible for gastrointestinal bleeding in the postoperative period and can be diagnosed by selective angiography. Treatment consists of embolization through the arteriography catheter.

► Prognosis

The death rate of 10%-15% following hepatic trauma depends largely on the type of injury and the extent of associated injury to other organs. About one-third of patients admitted to the emergency department in shock cannot be saved. Only 1% of penetrating civilian wounds are lethal, whereas a 20% death rate attends blunt trauma. The death rate in blunt hepatic injury is 10% when only the liver is injured. If three major organs are damaged, the death rate is close to 70%. Bleeding causes more than half of deaths associated with liver trauma.

SPONTANEOUS HEPATIC RUPTURE

Spontaneous rupture of the liver is not common. Most cases of ruptured diseased liver are due to hepatic tumors. Approximately 5% of hepatocellular carcinoma can rupture and manifest as hemoperitoneum. Hepatic adenoma larger than 5 cm carries a risk of spontaneous bleeding of approximately 20%-40%.

Many cases of ruptured normal liver occur during or after pregnancy and are related to preeclampsia-eclampsia and/or HELLP syndrome (hemolysis, elevated liver enzymes, low platelet count). Hepatic rupture should be suspected in any pregnant or postpartum patient (especially if hypertensive) who complains of acute discomfort in the upper abdomen.

Spontaneous rupture has also been reported in association with a number of other conditions, including hepatic hemangioma, typhoid fever, malaria, tuberculosis, syphilis, polyarteritis nodosa, and diabetes mellitus. Rupture of the liver in the newborn is related to birth trauma in larger infants after difficult deliveries. The typical progression is intrahepatic hemorrhage expanding to subcapsular hematoma and eventually capsular rupture and free intra-abdominal hemorrhage.

The diagnosis is best made by CT scanning. Angiography and hepatic artery embolization can be quite effective for controlling hemorrhage in the setting of spontaneous rupture. Emergency laparotomy and intraoperative management (as one would for a traumatic liver injury) are reserved for those who fail hepatic artery embolization or are unsuitable for the procedure. Patients who experience hemoperitoneum from spontaneous rupture of hepatocellular carcinoma appear to be at increased risk for peritoneal dissemination of tumor.

PRIMARY LIVER CANCER

Liver malignancy may arise from hepatocytes (hepatocellular carcinoma [HCC], the most common) or biliary epithelial cells (intrahepatic cholangiocarcinoma). Tumors arising from both cell types (mixed hepatocellular carcinoma/cholangiocarcinoma) have also been described. Neonates may also develop a variant of hepatocellular carcinoma called hepatoblastoma because it is morphologically similar to fetal liver and the occasional presence of hematopoiesis. Primary malignancy arising from other liver cell types (endothelial cells, stellate cells, neuroendocrine cells, or lymphocytes) is exceedingly rare.

Primary hepatic cancer is relatively uncommon in the United States, with an estimated 28,720 new cases in 2012. The incidence of HCC has tripled during the past two decades, largely the result of hepatitis C infection outbreak. The 5-year survival rate of patients with HCC remains under 16%, ranking this tumor amongst the 10 leading cause of cancer related death in both men and women in the United States. In Asia and Africa, primary liver cancer is extremely common and in some areas represents the single-most frequent abdominal tumor and the most common cause of cancer-related death. The etiologic factors in these high-risk areas are environmental or cultural, since persons of similar racial background in the United States are at only slightly greater risk than Caucasians.

► Hepatocellular Carcinoma

Chronic hepatitis B and C virus (HBV and HCV) infection is the principal etiologic factor worldwide for HCC. Patients chronically seropositive for HBsAg constitute a high-risk group for development of hepatocellular carcinoma. Hepatitis B virus DNA has been detected integrated into the genome of host hepatocytes and hepatoma cells and has a direct oncogenic effect. Patients with chronic hepatitis B infection may therefore develop hepatocellular carcinoma in the absence of cirrhosis; by contrast, HCC arising in the setting of chronic hepatitis C infection is typically associated with cirrhotic change. Cirrhosis from almost any cause (eg, alcoholism, hemochromatosis, α_1 -antitrypsin deficiency, or primary biliary cirrhosis) is associated with an increased risk of hepatocellular carcinoma, and the great majority of these tumors arise in the setting of chronic underlying liver

disease. With the increase in obesity in the United States, nonalcoholic fatty liver disease (NAFLD) has become the one of the most common causes of chronic liver disease; a subgroup of these patients with nonalcoholic steatohepatitis (NASH) are at high risk of cirrhosis and malignant transformation. Certain fungal metabolites called aflatoxins have been shown experimentally to be capable of producing liver tumors. These substances are present in staple foods (eg, ground nuts and grain) in some parts of Africa where hepatocellular carcinoma has a high incidence.

HCC constitutes about 85%-95% of primary hepatic cancers. Previously, differences in morphology were used to separate tumors into three types: mass-forming type, characterized by a single predominant mass clearly demarcated from the surrounding liver, occasionally with small satellite nodules; nodular type, composed of multiple nodules, often distributed throughout the liver; and a diffuse type, characterized by infiltration of tumor throughout the remaining parenchyma. A number of staging systems for hepatocellular carcinoma are in current use when considering treatment options for patients with HCC: the Barcelona Clinic Liver Cancer (BCLC), Cancer of the Liver Italian Program (CLIP), Okuda, Chinese University Prognostic Index (CUPI), and Japan Integrated Staging (JIS); these classifications differ on their assessment of tumor burden, related symptoms, and underlying liver dysfunction, and most cannot predict the survival in patients with advanced HCC. The 7th edition of the American Joint Commission on Cancer tumor-node-metastasis (TNM) staging system can be used after pathological examination of the resected liver for determining the prognosis of patients after transplantation. About 50% of resectable tumors are surrounded by a fibrous capsule, which develops as a result of compression of adjacent liver stroma. Encapsulated tumors exhibit a lower incidence of tumor microsatellites and venous permeation compared with non-encapsulated tumors, and the finding is a favorable sign. An uncommon variant, fibrolamellar hepatocellular carcinoma, contains numerous fibrous septa and may resemble focal nodular hyperplasia (FNH). Fibrolamellar hepatoma occurs in a younger age group (average 25 years) and is not associated with cirrhosis or hepatitis virus infection.

A large proportion of patients have intrahepatic or extrahepatic metastases at presentation. Multiple intrahepatic tumors can arise as a result of infiltration of the portal venous system with subsequent dissemination of tumor cells. Vascular invasion is more common with larger tumors (> 5 cm). The extrahepatic sites most commonly involved with metastatic disease include the hilar and celiac lymph nodes and the lungs; metastases to bone and brain are less common, and peritoneal disease (ie, carcinomatosis) is distinctly unusual. Major portal or hepatic veins are often invaded by tumor, and venous occlusion may occur as a result.

Microscopically, there is usually little stroma between the malignant cells, and the tumor has a soft consistency.

The tumor may be highly vascularized, a feature that rarely can result in massive intraperitoneal hemorrhage following spontaneous rupture.

► Intrahepatic Cholangiocarcinoma

Cholangiocarcinoma makes up a small fraction of primary liver cancers, although several reports have documented a marked increase in incidence worldwide. Unlike hepatocellular carcinoma, intrahepatic cholangiocarcinoma is less frequently associated with cirrhosis. Primary sclerosing cholangitis is a predisposing condition in a small minority of patients. Widespread infection with liver flukes (*Clonorchis sinensis*) is at least partly responsible for the higher incidence of these tumors in some parts of Asia. Emerging evidence has implicated chronic hepatitis C infection, obesity, diabetes mellitus, chronic liver disease, and cigarette smoking as risk factors for intrahepatic cholangiocarcinoma. In Western centers, the vast majority of intrahepatic cholangiocarcinomas are sporadic. Intrahepatic cholangiocarcinoma generally presents as a large mass within the liver and is therefore clinically distinct from cholangiocarcinoma arising from the extrahepatic biliary tree.

Histologically, these tumors are most often invasive adenocarcinomas, although rare variants have been reported. Intrahepatic or extrahepatic spread of disease is not uncommon by the time the tumor is detected. These tumors infrequently cause symptoms at early stages and therefore often grow to a large size before they become apparent, frequently because of pain. Infrequently, these tumors may contain cells of both cholangiocellular and hepatocellular origin. These mixed tumors are similar to intrahepatic cholangiocarcinoma in that they are infrequently associated with chronic liver disease.

Angiosarcoma of the liver, a rare fatal tumor, has been seen in workers intensively exposed to vinyl chloride for prolonged periods in polymerization plants. Hepatoblastomas are the most common primary hepatic tumors of childhood and is estimated to affect 1 child younger than 15 years in 1 million per year, and approximately 50-70 new cases are reported in the United States yearly.

► Clinical Findings

A. Symptoms and Signs

The diagnosis at early and more treatable stages is often difficult, since symptoms are often absent. Screening and surveillance of high-risk patients (with cirrhosis, chronic hepatitis, etc) with ultrasonography of the liver has been recommended. Patients with more advanced tumors may have epigastric or right upper quadrant pain, which may be associated with referred pain in the right shoulder. Weight loss may be present. Jaundice is rare in patients with small tumors and good liver function; the presence of jaundice

suggests either very advanced cancer or deteriorating liver function or both.

Hepatomegaly or a mass is palpable in many patients. An arterial bruit or a friction rub may be audible over the liver. Intermittent fever may be a presenting feature. Ascites or gastrointestinal bleeding from varices indicates advanced disease, and ascites fluid with blood should always suggest hepatocellular carcinoma. An acute deterioration in a previously well-compensated cirrhotic patient should also raise the suspicion of hepatocellular carcinoma.

The patterns of presentation can thus be extremely variable and may include: (1) pain with or without hepatomegaly; (2) sudden deterioration of the condition of a cirrhotic patient with the onset of hepatic failure, bleeding varices, or ascites; (3) sudden, massive intraperitoneal hemorrhage; (4) acute illness with fever and abdominal pain; (5) symptoms related to distant metastases; and (6) no clinical findings or symptoms.

B. Laboratory Findings

Depending on the disease extent and underlying hepatic function, laboratory values may range from entirely normal to suggestive of impending liver failure. Serum transaminase levels (AST and ALT) and alkaline phosphatase may be increased but are nonspecific and often seen in patients with chronic liver disease without hepatocellular carcinoma. The presence of a moderate to large liver tumor may bring about an increase in the serum alkaline phosphatase in the absence of underlying liver disease. An elevated serum bilirubin is a more ominous finding and reflects some degree of liver dysfunction, either from the underlying chronic liver disease or from a large volume of cancer within the liver. Tumor extension within the portal venous system is not uncommon, and involvement of the right and left portal trunks or the main portal vein may result in jaundice due to compromised portal venous inflow. Less often, jaundice is the result of tumor involvement of the biliary confluence by direct compression or by intrabiliary tumor extension. Other signs of compromised hepatic function include hypoalbuminemia, coagulopathy, and thrombocytopenia. A large number of patients may be positive for HBsAg or HCV antibody; the proportions of each vary somewhat by geography.

C. Liver Imaging

Liver ultrasound, CT scans, and magnetic resonance imaging (MRI) scans demonstrate the principal lesion in nearly all patients. A triple-phase (no contrast, arterial phase, and portal venous phase), contrast-enhanced helical CT scan of the chest, abdomen, and pelvis generally provides the best images of disease extent within the liver and also assesses for extrahepatic spread. Hepatocellular carcinomas are supplied primarily by the hepatic artery, and the vast majority thus enhance on arterial phase more than the adjacent nontu-

morous liver parenchyma (hypervascular). In some cases, the center of the tumor has become necrotic, and only the peripheral areas are hypervascular. Arterial branches supplying the tumor have an irregular appearance compared to the native hepatic artery, and arterial-venous shunting may be seen. Upon venous phase, the arterial contrast typically has washed out, and the HCC bear similar density to the adjacent parenchyma (isodense). In contrast to HCC, cholangiocarcinomas usually appear less vascular than adjacent liver parenchyma, on all phase contrast. As an adjunct to CT, MRI scans with MR angiography or CT angiography may provide more detail regarding vascular involvement and clarify if a tumor is surgically removable.

D. Angiography

Diagnostic angiography was previously used often to assess liver tumors but is now rarely needed for this purpose; it is reserved primarily for treatment (ie, transarterial chemoembolization). Angiography may be equivocal in small HCC, which may be demonstrated with greater certainty by a selective injection of iodized oil (Lipiodol) followed 1-2 weeks later by CT scanning. In a normal liver, the contrast medium is cleared quickly but HCC retains it and remains opacified.

E. Liver Biopsy

The diagnosis can be established by percutaneous core biopsy or aspiration biopsy. Fine-needle aspiration biopsy is associated with an approximately 30% false-negative rate. A negative result therefore does not rule out malignant disease, and a core biopsy should be pursued if the index of suspicion is high. Percutaneous biopsy carries some risk of bleeding, although this is rare in experienced hands; tumor dissemination by seeding resulting from a biopsy can occur in 2%-4%. In patients with cirrhosis, the presence of a hypervascular mass larger than 1 cm with typical imaging features on contrast-enhanced CT or MRI has specificity and predictive positive values of nearly 100% and a biopsy is generally not required in this setting. In other clinical scenario, a diagnostic biopsy is often requested for nonsurgical candidate to guide appropriate liver-directed or systemic treatment.

F. Surveillance

In patients with cirrhosis or chronic hepatitis B, surveillance with biannual liver sonography is recommended since early detection and treatment is the best strategy to achieve long-term survival. The optimal type and timing of imaging studies is the subject of debate, but such programs have proved useful in areas with a high incidence of chronic hepatitis, such as Asia, where a large proportion of patients are now identified with a mass 2 cm in diameter or smaller; other studies in high-risk patients have also proved valuable.

G. Tumor Markers

Alpha fetoprotein (AFP), a glycoprotein normally present only in the fetal circulation, is present in high concentrations in the serum of many patients with hepatocellular carcinoma, testicular tumors, and hepatoblastomas. Increased levels are rarely seen as a product of other tumor types, such as the lung, stomach, pancreas, and biliary tree.

The upper limit of normal in the serum is 20 ng/mL; values above 200 ng/mL are suggestive of HCC, while levels above 400 ng/mL in a cirrhotic patient with a hypervascular liver mass larger than 2 cm in diameter are diagnostic. Levels in the intermediate range are nonspecific and may occur with benign liver diseases, such as cirrhosis and chronic hepatitis, where they represent a manifestation of liver cell proliferation. As imaging methods have improved, the diagnosis of liver cancer is being made earlier, when AFP levels may be normal or only minimally elevated. Additionally, some patients may have normal AFP levels despite the presence of advanced disease. In general, AFP levels correlate with tumor size and vascular invasion, and a number of studies have shown a correlation between high AFP levels and recurrent cancer after resection. AFP levels can also provide a measure of tumor response in patients treated nonoperatively.

► Differential Diagnosis

The clinical picture is often nonspecific, and the presenting symptoms may provide little in the way of diagnostic clues. Primary liver cancer may initially be confused with metastatic cancer arising from other abdominal sites. The presence of cirrhosis and findings consistent with chronic liver disease should make hepatocellular carcinoma the leading diagnosis, and this is often confirmed with further testing. In patients without cirrhosis or normal AFP levels (or both), a hypervascular mass in the liver should raise other diagnostic considerations, such as hepatic adenoma, which can be difficult to distinguish from hepatocellular carcinoma on the basis of imaging alone. In addition, certain types of cancer may give rise to hypervascular liver metastases, including melanoma, neuroendocrine carcinoma, and renal cell carcinoma.

When sudden decompensation develops in a cirrhotic patient, the possibility of HCC must always be considered. In rare instances, HCC is associated with metabolic or endocrine abnormalities such as erythrocytosis, hypercalcemia, hypoglycemic attacks, Cushing syndrome, or virilization.

► Complications

Sudden intra-abdominal hemorrhage may occur from spontaneous bleeding. Obstruction of the portal vein may produce portal hypertension, and obstruction of the hepatic veins may produce the Budd–Chiari syndrome. Liver failure is a common cause of death in these situations.

► Treatment

A. Partial Hepatectomy

Resection is the treatment of choice in selected patients without cirrhosis or in cirrhotics with well-preserved hepatic function. Initial diagnostic laparoscopy, immediately prior to planned laparotomy, may identify previously undetected spread of tumor within the liver or abdominal cavity that would preclude resection; however, with better imaging, the yield of laparoscopy has decreased. The minimal criteria of resectability that must be met are: (1) disease confined to the liver and (2) disease amenable to a complete resection. Multiple tumors in the liver and tumor invasion into major portal or hepatic veins are bad prognostic findings, even if resection is technically feasible; such patients generally are not good candidates for resection. For small and peripherally placed lesions, particularly in cirrhotics, sublobar, segmental resections are preferred if technically feasible. Anatomical segmentectomies are preferred to nonanatomical resections. Larger or more central tumors require more extensive resections. In Western centers, about 25%-30% of patients with hepatocellular carcinoma prove to be candidates for resection; this proportion is over 60% in Japan due largely to widespread surveillance programs.

If gross tumor is left behind or if the margins of resection are involved microscopically, progressive disease is the rule. After a complete resection, the prognosis is best for patients with a solitary, small (< 3 cm), and asymptomatic tumor and well-preserved hepatic function. Several adverse predictors of outcome have been identified, which vary somewhat among studies. However, the presence of vascular invasion (even if microscopic) has been identified in nearly all studies to predict recurrent cancer and poor outcome. Large tumor size (> 5 cm), the presence of satellite tumors, and markedly elevated AFP (> 2000 ng/mL) are also associated with a worse outcome, in part because of their correlation with vascular invasion. Additionally, patients with coexistent hepatocellular disease (ie, cirrhosis) do worse, and this is especially true in the face of significant hepatocellular dysfunction or portal hypertension.

In general, cirrhosis constitutes the major obstacle to resection in patients with hepatocellular carcinoma. Careful patient selection (Child–Pugh A, no portal hypertension) is critical in order to avoid acute liver failure and provide survival benefit to patients. In addition to this immediate perioperative concern, cirrhotic patients have a late risk of death from progression of the underlying liver disease (bleeding esophageal varices or liver failure) and a high rate (> 75%) of new tumors developing in the residual liver. For these reasons, highly selected patients may be better treated with liver transplantation rather than resection.

Overall, the rate of tumor recurrence is approximately 70% at 5 years (although it is higher, as mentioned above, in

patients with cirrhosis). Some patients may be candidates for repeat resection or ablative procedures. The 5-year survival rate varies from approximately 40% to 70%, but is lower for patients with cirrhosis.

After the surgery, patients should be followed by periodic physical examinations and blood work to assess liver function. Imaging studies and AFP measurements (if elevated before resection) at regular intervals may help identify early, localized recurrences that may be amenable to repeat resection or palliative therapy.

For intrahepatic cholangiocarcinoma, resection, when possible, is the treatment of choice.

B. Liver Transplantation

Hepatocellular carcinoma is the only solid neoplasm for which transplantation plays a significant role. Liver transplantation has the advantage of treating not only the malignant disease but also the underlying cirrhosis. Previously, the selection criteria for transplanting hepatoma patients were broad and included patients with very advanced disease. Consequently, 5-year survival rates were less than 40%, too low to justify use of a scarce resource. The lessons learned from this early experience have allowed identification of patients most likely to benefit, specifically those with a single tumor no larger than 5 cm in diameter or up to three tumors with none exceeding 3 cm in diameter and no major vascular invasion. Using these strict criteria (the Milan criteria), 5-year survival rates of 70% can be achieved, a survival benefit similar to transplant patients with advanced cirrhosis but without HCC.

It should be emphasized that the benefit of transplantation is realized only when the waiting time for a new graft is under 6 months. Since waiting times can exceed 12 months in many centers, up to 50% of patients develop cancer progression or otherwise become ineligible. This problem has led a number of centers to adopt living donor transplantation as a means of increasing the donor pool, an approach that remains controversial because of donor-related morbidity and mortality. Another approach to this problem has been to increase the number of MELD points for transplantable liver disease, which effectively places eligible patients higher on the priority list.

A major concern of transplantation in cancer patients has been that the immunosuppressive therapy required to support the graft would remove an important defense mechanism against progression of residual microscopic disease. Indeed, calculated tumor doubling times for lesions in transplanted patients have been shown to be greater compared to patients not on immunosuppressive agents. Despite this possibility and although the logistical problems and expense are enormous, transplantation is a reasonable option in patients with cirrhosis who are not candidates for resection and have limited malignant disease burden, as specified in the selection criteria.

At present, transplantation has no role in patients with intrahepatic cholangiocarcinoma outside the controlled clinical trials, since the results to date have been poor.

C. Liver-Directed Therapy

Liver-directed therapies have been the subject of multiple investigations for the treatment of hepatocellular carcinoma. The effectiveness of these approaches for unresectable intrahepatic cholangiocarcinoma is being evaluated.

D. Ethanol Injection

Percutaneous ablative techniques are a reasonable option in patients with small, unresectable hepatocellular carcinoma, of which ethanol injection is the cheapest, easiest, and least morbid. Using ultrasound or CT guidance, 95% ethanol (5-20 mL) is injected through a 22-gauge needle directly into the tumor. This approach can achieve complete necrosis in 90%-100% of tumors smaller than 2 cm, but its efficacy declines rapidly as the tumor size increases. The patient is followed up and retreatment given for residual or new primary tumors. In one multi-institutional series from Italy, survival 1, 2, and 3 years after treatment for patients with solitary, small tumors was 90%, 80%, and 63%, respectively.

E. Radiofrequency Ablation

Radiofrequency ablation (RFA) is another percutaneous ablative approach, useful for treating selected patients with small tumors who are not candidate for surgery or liver transplantation. RFA has generally supplanted ethanol injection as the percutaneous treatment of choice. Under ultrasound or CT guidance, a needle is used to access the lesion; the needle is attached to a radiofrequency generator that generates thermal energy to bring about tumor destruction. RFA can be used percutaneously, laparoscopically, or at laparotomy.

The goal of RFA is the same as that of ethanol injection: to achieve complete tumor necrosis. The efficacy of RFA is limited by tumor size but may be somewhat greater than ethanol injection in this regard; RFA is less effective for tumors adjacent to major vascular structures. A randomized study comparing the two techniques found no differences in survival, although RFA may offer better local tumor control rates. In carefully selected patients, 5-year survival rates of 30%-40% have been reported. RFA has been compared with resection in early HCC in randomized controlled trials, but results have varied. Generally, RFA appear to be as effective as resection in lesions smaller than 2 cm. Ablation techniques, including RFA, have been studied in the context of controlling disease progression while on the waiting list in patients who are candidates for transplantation with some suggestion of benefit.

Microwave ablation and irreversible electroporation are two emerging ablative techniques that may prove to be alternatives to RFA.

F. Arterial Embolization

Hepatic artery embolization is another ablative technique that is more broadly applicable than RFA or ethanol injection. This approach takes advantage of the fact that primary liver cancers derive disproportionately greater blood supply from the hepatic arterial circulation compared to the surrounding liver. The strategy is to combine selective hepatic arterial injection of cancer chemotherapeutic agents with arterial embolization, the latter to produce tumor necrosis and slow the washout of the drugs. Embolization can be used in patients with much larger tumors than can be effectively treated with percutaneous procedures, and the procedure can be staged to treat bilobar disease. Patients must have adequate liver function; those with Child-Pugh C cirrhosis or thrombosis of the portal vein are not suitable candidates.

A variety of techniques have been used. Embolization is often performed with Gelfoam, which dissolves after a few weeks, but other inert agents are also used and are probably more effective for occluding vessels. Some centers use inert particles without chemotherapy (ie, bland embolization) but most employ a chemotherapeutic component (ie, transarterial chemoembolization or TACE). Doxorubicin, mitomycin, and cisplatin in various combinations are the drugs most often given. Lipiodol, which lodges in the tumor, has occasionally been used as a carrier for the drugs. It remains unclear if the addition of chemotherapeutic agents provides much benefit beyond the necrosis produced by occlusion of the hepatic arterial supply. Many patients require multiple treatments, although the optimal schedule is ill defined. Embolization achieves partial responses in up to 55% of patients. A survival benefit of approximately 10 months has been reported with chemoembolization compared to best supportive care in randomized controlled trials, and 30%-50% of patients are reported to survive at 3 years. Of note, histologic studies of tumors resected shortly after treatment reveal viable neoplastic cells in the tumor capsule, which receives blood from the portal vein as well as the hepatic artery. Recently, a randomized prospective trial showed that the combination of RFA and chemoembolization provided superior disease control rates than either technique alone.

G. Systemic Therapy

Until recently, no systemic treatment was found able to prolong the survival of patients with metastatic hepatocellular carcinoma. The multikinase inhibitor sorafenib, that mainly blocks RAF, VEGF, PDGF, and c-Kit signaling, has however been shown to have antitumor efficacy. In two phase 3, multicenter, randomized, double-blind and placebo-controlled trials, sorafenib improved by 2-3 months the survival of

patients with advanced HCC and compensated liver function. The efficacy of combining sorafenib with other biologic and chemotherapeutic agents is being evaluated, as well as its use in less advanced disease status and in the adjuvant setting in an attempt to lessen or delay cancer recurrence.

Gemcitabine-based chemotherapy, in particular with combination with cisplatin, has shown prolongation of survival in patients with metastatic biliary tract cancer.

METASTATIC NEOPLASMS OF THE LIVER

In Western countries, metastatic cancer is much more common than primary tumors in the liver. Nearly all solid tumors can potentially give rise to liver metastases; primary cancers of the gastrointestinal tract (colon, pancreas,

esophagus, stomach, neuroendocrine), breast, lung, genitourinary system (kidney, adrenal), ovary and uterus, melanoma, and sarcomas account for the overwhelming majority of cases. Spread to the liver may be via the systemic or portal venous circulation. The cirrhotic liver, which often gives rise to primary hepatic tumors, seems to be less susceptible than normal liver to implantation of metastases.

Individual tumor types have characteristic patterns of spread. For example, colorectal cancer spreads to the liver as the first site of metastatic disease in a very high proportion of patients; the lung is the next most common site, but bone, brain, or adrenal metastases are distinctly unusual. By contrast, metastatic lung cancer to the liver typically occurs concomitantly with spread to other sites, with brain, bone, and adrenal among the most common. In general, the vast majority of patients with metastases to the liver also have disease at other sites. A notable exception is colorectal cancer, which in many cases involves the liver only for a prolonged period. In the past, approximately 20% of patients with hepatic metastases had additional tumor deposits in the liver not seen on preoperative imaging studies. As imaging technology has improved, however, this proportion has become increasingly smaller.

► Clinical Findings

A. Symptoms and Signs

The signs and symptoms vary with the clinical scenario, the disease extent within the liver, and the presence or absence of metastatic disease to other sites. Patients with an undiagnosed primary tumor may come to attention because of symptoms caused by the metastatic disease. Weight loss, fatigue, pain, and anorexia are the presenting general complaints in many such patients. Signs of liver failure, such as ascites and jaundice, are uncommon and suggestive of very advanced cancer. Fever without demonstrable infection is present in 15% of cases. By contrast, patients with a known history of cancer undergoing routine surveillance often develop liver metastases that cause no symptoms; in a small proportion of cases, liver metastases are found on studies done for unrelated reasons.

Physical examination is frequently unrevealing. Hepatomegaly or a palpable tumor in the upper abdomen may be present, and either may be tender. Portal hypertension may be manifested by abdominal venous collaterals or splenomegaly. A friction rub is sometimes heard over the liver.

B. Laboratory Findings

Laboratory values may be entirely normal or at most reflect only minor nonspecific changes. Patients with advanced cancer can have anemia and hypoalbuminemia. The alkaline phosphatase is increased in most patients. More significant derangements in liver function occur in patients with a large

volume of liver disease, although this is uncommon at initial presentation. Tumor marker levels (carcinoembryonic antigen [CEA], carbohydrate antigen [CA] 19-9, CA-125) are often elevated, depending on the tumor type, and may be helpful for monitoring treatment.

The diagnosis can be established in most cases by CT-guided or ultrasound-guided percutaneous liver biopsy or fine-needle aspiration for malignant cells.

C. Imaging Studies

The detection of liver metastases relies on CT and/or MRI scans; ultrasonography identifies tumors in the liver and distinguishes solid from cystic lesions but cannot provide the same degree of anatomical detail. MRI provides useful additional information and may help distinguish benign from malignant disease. However, a high-quality triple phase CT scan with intravenous and oral contrast medium provides excellent assessment of disease extent in the liver and elsewhere in the abdomen. In the past, CT portography was superior to ordinary contrast-enhanced CT and was obtained routinely in patients being considered for hepatic resection, but this is no longer the case. Positron emission tomography using 18-fluorodeoxyglucose (FDG-PET) is a commonly used staging study and may help identify extrahepatic disease, a finding that could change the treatment recommendations. During surgery, intraoperative ultrasound is used to assess the liver for disease not appreciated on imaging studies.

► Treatment

For most patients with metastatic liver disease, chemotherapy is the only treatment option, particularly with coexisting metastases outside the liver. Such therapy is usually not curative but rather palliative in most cases. A notable exception is metastatic colorectal cancer, for which resection or other treatments aimed at the liver disease are effective and potentially curative; the recent advent of several active chemotherapeutic agents has further improved the results of treatment. Carefully selected patients with metastases from other primary tumors (sarcoma, breast, ovary, lung, neuroendocrine) may also benefit from resection but represent a small minority of cases.

A. Hepatic Resection

Hepatic resection is most commonly indicated in patients with metastatic colorectal cancer. Of the approximately 130,000 patients diagnosed with colorectal cancer annually in the United States, approximately 50% either have liver metastases at diagnosis or develop liver metastases at some point. In 40% of the latter group, the liver is the only demonstrable site of disease. Hepatic metastases from colorectal cancer thus affect approximately 20,000 patients per year, which is comparable to the annual incidence of pancreatic or esophageal carcinoma.

After a complete resection, the 5-year survival rate has historically been 25%-40%; systemic or regional chemotherapy or both are frequently given after resection and appear to enhance the results of surgery, with more recent series reporting 5-year survival figures of approximately 50%. The presence of extrahepatic metastases and inability to achieve a complete resection are contraindications to resection in most cases. However, as more effective chemotherapeutic options have emerged, the indications for resection have expanded to include selected patients with multiple bilobar tumors and even some with extrahepatic metastatic disease. Extensive use of chemotherapy prior to surgery can cause changes in the liver, particularly steatosis and steatohepatitis, which can impair the liver's normal regenerative response. Caution is therefore needed when considering such patients for major hepatic resections, since operative morbidity and mortality may be increased; preoperative portal vein embolization may reduce the incidence of serious postoperative complications.

The following variables are associated with a worse prognosis after resection: (1) original tumor with involved lymph nodes (stage III or Dukes C); (2) multiple liver lesions; (3) less than 1-year interval between resection of the colon primary and diagnosis of liver disease (disease-free interval); and (4) CEA level higher than 200 ng/mL. Variables that do not influence the outcome include: (1) histologic grade of the tumor; (2) bilateral rather than unilateral disease; (3) site of the primary tumor within the large intestine; and (4) the gender of the patient. The mortality rate for resection of hepatic metastases is 1%-2% in hospitals where this operation is performed frequently.

The liver is the most common site of cancer recurrence after a complete resection. A small proportion of patients with hepatic recurrence may be amenable to a second resection. The use of adjuvant hepatic arterial chemotherapy appears to reduce the risk of intrahepatic recurrence.

The efficacy of liver resection for colorectal cancer has been clearly established and is the most common indication for this procedure. By contrast, for most other tumor types, particularly those arising from the gastrointestinal tract other than the colon or rectum, the benefit of liver resection is much more limited. Rare patients with metastases from renal cell carcinoma, ovarian cancer, adrenocortical carcinoma, or sarcomas appear to derive the most benefit; by contrast, liver resection for metastatic esophageal, gastric, or pancreatic cancer is almost never warranted. In selecting patients with noncolorectal liver metastases for resection, the most important factors are: (1) long disease-free interval; (2) solitary resectable liver tumor; and (3) the absence of extrahepatic metastases.

Neuroendocrine carcinomas (pancreatic islet cell tumors, carcinoids) represent a unique class of tumors that often give rise to liver metastases. Unlike patients with other metastatic tumor types, those with neuroendocrine

tumors often survive for many years. Multiple liver metastases are the rule with this disease, so complete resection is usually not possible. However, debulking liver resections are sometimes indicated to palliate tumor-related pain or hormonal symptoms. Partial hepatectomy is also sometimes worthwhile to extirpate a tumor invading directly from a contiguous organ.

B. Radiofrequency Ablation

RFA has been used to treat metastases to the liver from a variety of tumor types. The indications for this procedure remain ill defined. The best candidates are those with a limited number of small liver lesions with no evidence of extrahepatic cancer.

C. Chemotherapy

In a large proportion of patients with metastatic colorectal cancer, the liver is the only evident site of disease. If the lesions cannot be resected, regional intrahepatic chemotherapy can be given by placing a catheter in the gastroduodenal artery (at its origin with the common hepatic artery) connected to an implantable, subcutaneous infusion pump, which allows the delivery of much higher concentrations of drug to the tumor than is possible with systemic administration. This regimen is generally not used for metastases from other kinds of tumors. The pump is primed with floxuridine, which is delivered by continuous infusion (0.1-0.2 mg/kg/d) for 14-day periods alternating with 14-day rests. Systemic chemotherapy is usually given concomitantly. The discovery of extrahepatic lesions at laparotomy for pump placement is a relative contraindication to proceeding with this approach. Treatment is continued until disease progression or excessive toxicity is seen or, rarely, until the response is complete. Toxicity consists mainly of gastroduodenal erosions (caused by unintentional perfusion of these areas), chemical hepatitis, or chemical sclerosing cholangitis. Survival is related principally to the initial amount of liver involvement by tumor, objective response to treatment (which is seen in about 60% of patients), and extent of prior chemotherapy. The median survival of patients with less than 30% of liver replaced by tumor is 24 months, compared with 10 months if the extent of replacement exceeds 30%. Up to 47% of patients with initially unresectable disease may respond enough to become resectable and potentially benefit from surgery. There is a general perception that hepatic artery infusion therapy improves survival, but the objective evidence is inconclusive.

Hepatic artery infusion chemotherapy may be a useful adjunctive therapy after complete tumor resection or RFA. Studies of this option are under way. Systemic chemotherapy (eg, with fluorouracil, irinotecan, or oxaliplatin) after a complete resection of liver metastases has not been proved to improve survival, although it is often prescribed.

D. Miscellaneous

Hepatic artery ligation or angiographic embolization of the tumor has been of benefit in a few patients with hepatic metastases from specific tumor types, particularly neuroendocrine tumors.

► Prognosis

Survival varies with the site of origin of the primary tumor and the extent of metastatic disease. Patients with extensive hepatic replacement by multiple lesions have a dismal outlook, with a survival measured in months, compared to perhaps 2-3 years for patients with small solitary lesions. The range of treatment options and effective chemotherapeutic agents is greatest for metastatic colorectal cancer compared to most other tumor types, and survival is generally better in this group.

to very large dimensions (giant hemangiomas) and cause abdominal pain or a palpable mass. Most are small to moderate-sized lesions, however; pain is uncommon in tumors smaller than 8-10 cm in diameter.

Rare complications of liver hemangiomas include hemorrhagic shock resulting from spontaneous rupture and the Kasabach-Merritt syndrome, which is usually seen in children and is associated with thrombocytopenia and a consumptive coagulopathy; both of these complications are exceedingly uncommon. Large congenital hemangiomas of the liver may be associated with others in the skin. Large hemangiomas may also give rise to large-volume arteriovenous shunting, resulting in cardiac hypertrophy and congestive heart failure.

Large-bore needle biopsy is hazardous due to bleeding risks; aspiration biopsy with a fine needle is safe but rarely helpful. Fortunately, biopsy is very rarely indicated, since the diagnosis can be made with certainty in most cases by contrast-enhanced CT or MRI scans. The hallmark features of hemangiomas are nodular peripheral enhancement on arterial phase with progressive central enhancement on the more delayed images. MRI is a particularly good study for hemangiomas, which appear very bright on the T2-weighted images, and combined with dynamic intravenous contrast, has a sensitivity and specificity of 98%. Angiography is unnecessary, and nuclear scans lack sufficient sensitivity and specificity.

Irrespective of their size, the only reasons to resect hemangiomas are for symptoms, most commonly pain, or diagnostic uncertainty (rare). Symptomatic hemangiomas should be excised by lobectomy or enucleation. Even large lesions can be safely removed. Radiotherapy or embolization via a catheter in the hepatic artery may be tried in patients who are poor candidates for surgery, but the efficacy of these approaches is limited. The natural history of asymptomatic hemangiomas, whether large or small, is benign. The vast majority of incidentally discovered hemangiomas remain stable in follow-up, do not give rise to symptoms, and therefore do not require resection. Progressive growth of asymptomatic hemangiomas over a relatively short time interval, particularly in young patients, is considered a relative indication for resection.

BENIGN TUMORS & CYSTS OF THE LIVER

► Hemangiomas

Hemangioma is the most common benign hepatic tumor and has an incidence of approximately 7%. Except for the skin and mucous membranes, the liver is the most common site of origin. Women are affected more often than men—in some series, up to 75% of patients are female. Histologically, hepatic hemangiomas are of the cavernous type rather than the capillary type. Most are small, solitary subcapsular growths that are found incidentally during laparotomy or autopsy or on imaging studies. Rarely, hemangiomas grow

► Cysts

A number of different cystic lesions may affect the liver. Simple hepatic cysts, the most common, are unilocular

fluid-filled lesions that generally produce no symptoms. The occasionally large cyst may present as an upper abdominal mass or discomfort. Small, simple cysts may be difficult to diagnose on CT and may be confused for metastatic disease; ultrasound and MRI are better modalities to assess the character of cystic lesions. Many patients have multiple simple cysts, which should not be confused with polycystic liver disease, a progressive condition characterized by cystic replacement of virtually the entire liver. Polycystic liver disease is associated in about half of cases with polycystic renal disease. The possibility of echinococcosis should be considered in patients with cystic liver lesions and the appropriate exposure history, although their radiographic appearance is usually quite distinctive.

Most simple cysts have a serous lining and a smooth, thin wall. Intracystic hemorrhage can occur, which can confuse the radiographic appearance. Solitary cysts lined with cuboidal epithelium are classified as cystadenomas and should be resected, since they are premalignant. Cystadenomas are characterized radiographically as complex, with internal septae, an irregular lining, and papillary projections. Complex, multilocular (septated) cysts (if not echinococcal) are often neoplastic and should be resected. However, cystadenomas and cystadenocarcinomas are rare, while internal hemorrhage into a simple cyst is a more common entity and may have a similar appearance. Nevertheless, complex cysts of the liver must be approached with some caution in order to avoid inappropriate interventions. There are few indications for aspirating hepatic cysts—simple cysts reaccumulate fluid quickly, neoplastic cysts must be excised, and parasitic cysts might rupture and the parasite thus be allowed to spread. It is possible to eliminate small cysts by aspiration of the contents followed by an injection into the lumen of 20-100 mL of absolute alcohol; however, small cysts almost never cause symptoms and generally require no treatment.

Large symptomatic cysts are difficult to eradicate with alcohol injections, and serious superinfection of the cyst cavity may occur. The simplest method of treatment consists of laparoscopic cyst fenestration (wide excision of the cyst wall). A tongue of omentum may be fixed so it lies in the residual cyst cavity as an ancillary measure to prevent the edges from coapting. The operation is curative in nearly all patients.

Multiple, small, simple cysts do not usually require treatment, but large polycystic livers that cause discomfort or are associated with obstructive jaundice can be managed by partial resection or surgically unroofing the cysts on the surface of the liver and creating windows between superficial cysts and adjacent deep cysts. The opened cysts are allowed to drain into the abdominal cavity. The results of surgery for polycystic liver disease are often disappointing, with quick return of symptoms in many patients.

► Hepatic Adenoma

Hepatic adenomas occur predominantly in women of child-bearing age and appear to be related to the use of oral contraceptives. Mestranol-containing compounds have been associated with a disproportionate number of cases, but mestranol has been in use longer than the other agents.

The tumors are soft, yellow-tan, well-circumscribed masses that are usually of moderate size (range of 2-15 cm in diameter). Most of those that cause symptoms are in the 8-15 cm range. Two-thirds of hepatic adenomas are solitary; other benign tumors (such as FNH, see next section) are present in some cases. Transition from benign hepatic adenoma to hepatocellular carcinoma is estimated to occur in 5%, with liver cell dysplasia as an intermediate step. Histologically, hepatic adenomas consist of an encapsulated homogeneous mass of normal-appearing hepatocytes without bile ducts or central veins. Intratumoral hemorrhage or central necrosis may be present.

About half of patients are asymptomatic. Most of those with symptoms present with right upper quadrant pain. Spontaneous hemorrhage into the substance of the tumor with subsequent rupture and intraperitoneal bleeding is a well-known potential complication of adenomas estimated to occur in 20%-40% of untreated cases. The true risk of spontaneous hemorrhage is, however, difficult to know with certainty, since the overall incidence of adenomas is unknown. This risk increases with size, and there appears to be a strong association of acute bleeding episodes from adenoma with pregnancy. Patients with this life-threatening problem present with acute pain or even hemorrhagic shock.

Liver function tests and AFP levels are usually normal or minimally deranged. Adenomas typically appear hypervascular compared to the surrounding liver parenchyma, a feature that is apparent on contrast-enhanced CT or MRI scans or angiography. Adenomas can be difficult to distinguish from FNH, another benign tumor often found in young women. Differences in tumor vascularity may be demonstrated on angiography; however, MRI is probably the best study for differentiating these lesions. Adenomas often cannot be distinguished from well-differentiated hepatocellular carcinoma on imaging studies and even on biopsy specimens. Needle biopsy is generally safe but often inconclusive and is associated with a small risk of bleeding.

The general recommendation is that adenomas should be resected because of the risks of malignant change and spontaneous hemorrhage. Unfortunately, the true likelihood of these events is difficult to estimate, since most series include only treated patients. Lesion measuring less than 5 cm can be observed with serial imaging since the risk of malignant transformation or bleeding at this size appears minimal. Symptomatic and large asymptomatic adenomas clearly should be resected. Emergent resection or hepatic artery embolization should be undertaken in patients with evidence of hemorrhage. Small peripheral lesions may be removed with wedge excisions, but larger tumors require more extensive resections. Small adenomas may regress when oral contraceptive agents are discontinued, and close follow-up with imaging studies is not unreasonable in such cases; however, any change in symptoms or imaging characteristics (growth, hemorrhage) should prompt resection. The possibility that a presumed adenoma is actually a well-differentiated hepatocellular carcinoma or contains a focus of malignancy must always be kept in mind; there is no completely reliable means of making the differentiation other than pathologic analysis of the resected specimen.

Most patients recover without sequelae after surgical removal; recurrence is rare. Oral contraceptives should be proscribed permanently in all cases. Radiotherapy and chemotherapy are of no value, but elective hepatic artery embolization may be helpful in patients who are not surgical candidates. Embolization may be particularly helpful in the very rare patient with multiple hepatic adenomas (hepatic adenomatosis), since resection is usually not possible.

► Focal Nodular Hyperplasia

FNH accounts for the second most common benign liver process after hemangioma. Like hepatic adenoma, FNH is much more common in young women. The average age is about 40 years, but the tumor can occur at any age. Unlike hepatic adenoma, however, the use of oral contraceptive agents does not appear to predispose to the development of FNH, although it has been suggested that these agents may stimulate growth.

Grossly, the tumor is a well-circumscribed, firm, tan, usually subcapsular mass measuring 2-3 cm in diameter. In patients with symptoms, the lesions are much larger, usually around 10 cm. Multiple tumors can occur; 80% are solitary. The gross appearance on cut section is quite characteristic, consisting of a central stellate scar (which is actually an aggregation of blood vessels) with radiating fibrous septa that compartmentalize the lesion into lobules. Histologically, there are nodular aggregations of normal-appearing hepatocytes without central veins or portal triads. Bile duct proliferation is present in the nodules.

Most patients with FNH are asymptomatic. The few with symptoms present with a right upper quadrant discomfort. Unlike hepatic adenomas, these lesions rarely, if ever, bleed, and the natural history of asymptomatic lesions is benign. Very rare patients with diffuse FNH develop portal hypertension.

Hepatic function tests and AFP levels are usually normal. Hepatic scintiscans usually do not show a filling defect but are of little practical value. CT scans demonstrate the tumor and may also show the central stellate scar. The arteriographic pattern is one of hypervascularity. In most cases, the diagnosis of FNH can be made with noninvasive studies, although distinguishing FNH from hepatic adenomas can be difficult, even for experienced radiologists. MRI scanning is the best modality, but the imaging features of both tumors overlap somewhat, and they occur in similar patient populations. Fine-needle aspiration biopsies are generally not helpful.

Symptomatic lesions should be removed, while asymptomatic tumors (the majority) should be left undisturbed, provided that the diagnosis has been made confidently. In the latter circumstance, a period of observation with imaging studies is recommended to ensure stability. Inability to distinguish FNH from adenoma or malignant disease is an indication for resection in some patients. Discontinuation of oral contraceptives probably has no impact. FNH can be reliably identified on examination of frozen sections.

CIRRHOSIS

Hepatic cirrhosis remains a major public health problem worldwide, with an annual mortality of approximately 23,000 per year in the United States alone. The incidence of cirrhosis is increasing, due in large measure to hepatitis C, and at present is the third-most common cause of death in men in the fifth decade of life. Another contributing factor is the epidemic of obesity, which is associated with NAFLD and progression to cirrhosis in many patients.

Alcohol abuse remains the leading cause of cirrhosis in most Western countries. Alcohol exerts direct toxic effects on the liver that are magnified in the presence of protein and other dietary deficiencies that are often present. Even still, cirrhosis develops in a small minority of patients who abuse alcohol. Alcohol induces a specific cytochrome P450 in the

liver (ie, P450 2E1) that participates in its metabolism to acetaldehyde, which has a number of deleterious effects, including antibody formation, decreased DNA repair, enzyme inactivation, and alterations in microtubules, mitochondria, and plasma membranes. Acetaldehyde also promotes glutathione depletion, free radical-mediated toxicity, lipid peroxidation, and hepatic collagen synthesis. Hepatic steatosis and alcoholic hepatitis are stages of alcoholic liver injury that may precede cirrhosis. Alcoholic hyalin, a glycoprotein, accumulates in centrilobular hepatocytes of patients with alcoholic hepatitis. There is some evidence that immunologic responses to alcoholic hyalin may be important in the pathogenesis of cirrhosis.

Regardless of the cause (Table 24–3), collagen deposition in cirrhosis results from increased fibroblastic activity as well as from repair following hepatocellular injury and necrosis. The ultimate result is a liver containing regenerative nodules and connective tissue septa linking portal fields with central canals, which can be graded by severity on pathologic assessment of liver biopsy.

The natural history of cirrhosis is difficult to predict. Once the diagnosis has been established, up to 30% of patients die within a year from hepatic failure or complications of portal hypertension, of which bleeding esophageal varices is the most feared. In newly diagnosed cirrhotics, the chances of dying within the subsequent 2–3 years are influenced by the status of liver function (as reflected by the Child–Pugh classification, [Table 24–1]), the presence of varices, and the portal pressure. A group of cirrhotics

with varices followed by the Boston Interhospital Liver Group experienced a 1-year death rate of 66%. Cirrhotics without varices may benefit substantially by abstaining from alcohol. Bleeding episodes occur in up to 40% of all patients with cirrhosis, and the initial episode of variceal hemorrhage is fatal in 50% or more. At least two-thirds of those who survive their initial hemorrhage bleed again, and the risk of dying from the second is similarly high. It is principally for such patients that portal decompressive procedures are recommended.

Other main complications of cirrhosis include ascites, hepatorenal syndrome with hyponatremia and renal insufficiency, coagulopathy, and encephalopathy. Those processes are mainly managed medically to maintain a state of relative physiological compensation. Liver transplantation for appropriate candidates provides the most effective treatment option associated with prolongation of survival.

PORTAL HYPERTENSION

► Etiology

The major causes of portal hypertension are listed in Table 24–4. In all but a few instances, the basic lesion is increased resistance to portal flow. Those associated with increased resistance can be subclassified according to the site of the block as prehepatic, hepatic, and posthepatic; hepatic causes of portal hypertension are further subclassified as presinusoidal, sinusoidal, and postsinusoidal. Cirrhosis accounts for about 85% of cases of portal hypertension in the United States, most commonly from heavy alcohol use. Postnecrotic cirrhosis is next in frequency, followed by biliary cirrhosis. The other intrahepatic causes of portal hypertension are relatively rare in Western countries, although in some parts of the world, hepatic schistosomiasis constitutes the largest single group. Idiopathic portal hypertension occurs with greater frequency in southern Asia.

After cirrhosis, extrahepatic portal venous thrombosis or occlusion is the most common cause of portal hypertension in the United States. Patients with this condition are generally younger than cirrhotics, and many are children. Posthepatic obstruction due to Budd–Chiari syndrome (BCS) or constrictive pericarditis is rare.

► Pathophysiology

Portal hypertension is defined as a hepatic venous pressure gradient (HVPG) (the difference between portal-vein pressure and hepatic-vein pressure) greater than 5 mm Hg, but usually become clinically significant when this gradient reaches 10 mm Hg. Portal venous pressure normally ranges from 7 to 10 mm Hg. In portal hypertension, portal pressure exceeds 10 mm Hg, averaging around 20 mm Hg and occasionally rising as high as 50–60 mm Hg. With those portal pressures, since the venous pressure in the right atrium averages 5 mm Hg, the HVPG can easily become greater than 5 mm Hg.

Since pressure in the portal venous system is determined by the relationship $\text{Pressure} = \text{Flow} \times \text{Resistance}$, portal hypertension could result either from increased volume of portal blood flow or increased resistance to flow. Portal hypertension can be classified by pathophysiologic processes as summarized in Table 24–4.

In practice, however, the liver has tremendous reserve capacity to accommodate increased blood flow, and portal hypertension solely due to this mechanism is extremely uncommon. Increased flow may contribute to portal

hypertension in patients with arterial-portal venous fistulae (traumatic, congenital). When an arteriovenous fistula occurs, portal hypertension and its clinical manifestations usually do not appear for several months, because sinusoidal capacity is so great that the immediate rise in portal pressure is only moderate. With time, however, sinusoidal sclerosis develops, resistance increases, and portal pressure gradually reaches high levels, leading to the formation of varices.

Nearly all clinically relevant cases of portal hypertension result from increased resistance, in itself due to both structural distortion of the liver vascular architecture by fibrosis and dynamic increases in hepatic vascular tone. In addition to increased vascular resistance in the liver, splanchnic vascular bed resistance decreases, a consequence of local production of vasodilators (eg, nitric oxide) and mesenteric angiogenesis, paradoxically worsening the portal hypertension by increasing the splanchnic blood flow to the liver.

The average portal flow in cirrhotic patients with complications of portal hypertension is nonetheless about 30% of normal, ranging from 0 to 700 mL/min. Hepatic arterial flow is usually reduced by a similar proportion. The range of portal flow rates in different patients may vary greatly; in some, blood in the portal vein moves sluggishly or the direction of flow may even be reversed (hepatofugal) so that the portal vein functions as an outflow tract from the liver. These states of low flow predispose to spontaneous thrombosis of the portal vein, a complication of cirrhosis seen in 16% per year in patients with advanced liver disease. Portal thrombosis usually is associated with acute clinical deterioration and renders the portal vein unsuitable for a shunt to decompress the portal venous system.

Fluctuations in the level of portal hypertension may occur in conjunction with changes in blood volume. This is almost never a problem in patients with a normal liver. However, administration of colloid solutions to a patient with underlying liver disease and a normal or expanded blood volume could theoretically aggravate the clinical manifestations of portal hypertension.

A. Disease-Specific Pathophysiology

In alcoholic liver disease, the abnormal resistance is predominantly hepatic and postsinusoidal, as indicated by the results of wedged hepatic vein pressure studies.* The causes of increased resistance in this disease are thought to be: (1) distortion of the hepatic veins by regenerative nodules and

*A catheter wedged in a tributary of the hepatic vein permits estimation of the pressure in the afferent veins to the sinusoid. The gradient between the wedged pressure and that in the hepatic vein reflects resistance at any point between the wedged position and the periphery of the sinusoid. The current view holds that the site of principal resistance in normal persons is in reasonably large hepatic veins. In cirrhosis, it is probably in the sinusoids as well as the hepatic veins.

(2) fibrosis of perivascular tissue around the hepatic veins and the sinusoids.

Even in the absence of cirrhosis, acute alcoholic hepatitis can raise portal pressure by producing centrilobular swelling and fibrosis. Sinusoidal resistance to flow is also increased by engorgement of adjacent hepatocytes with fat and resultant distortion and narrowing of vascular channels. Documented cases of normalization or reduction in portal pressure have occurred with resolution of the pathologic changes.

Schistosomiasis can produce a unique form of hepatic presinusoidal obstruction to blood flow from deposition of parasite ova in small portal venules. The subsequent chronic inflammatory reaction leads to fibrosis and cirrhosis. Many patients with schistosomiasis are also at risk for chronic hepatitis, which can exacerbate the liver damage.

BCS (hepatic vein thrombosis) results from obstruction of flow through the hepatic veins. The resulting sinusoidal hypertension produces prominent ascites and hepatomegaly. Conditions (veno-occlusive disease, inferior vena cava obstruction by tumor or congenital webs, right-sided heart failure) that reduce flow through the hepatic veins result in a similar clinical picture.

Banti syndrome was defined as liver disease secondary to primary splenic disease and was incorrectly considered as the cause of portal hypertension now known to result from cirrhosis and other hepatic disorders rather than a consequence of such conditions. Portal hypertension from splenomegaly and increased splenic vein flow has been described in patients with hematologic diseases or tropical splenomegaly and apparently normal liver function. This is extremely uncommon, however, and given the great reserve of the liver to handle increases in portal flow, many such patients probably have some component of liver disease. In cirrhosis, the increased splenic blood flow accompanying “congestive” splenomegaly may occasionally be great enough to warrant splenic artery ligation or splenectomy to decrease portal pressure and improve symptoms, but this situation is rare.

B. Development of Portosystemic Collaterals and Varices

The obstacle to flow through the liver promotes expansion of collateral channels between the portal and systemic venous systems. As the pathologic process develops, portal pressure increases until a level of about 40 cm H₂O (30 mm Hg) is reached. At this point, increasing hepatic resistance, even to the point of occlusion of the portal vein, diverts a greater fraction of portal flow through collaterals without significant increments in portal pressure.

The type of portosystemic collaterals that develops depends partly on the cause of the portal hypertension. In extrahepatic portal vein thrombosis (without liver disease), collaterals in the diaphragm and in the hepatocolic, hepato-duodenal, and gastrohepatic ligaments transport blood

into the liver around the occluded vein (hepatopetal). In cirrhosis, collateral vessels circumvent the liver and deliver portal blood directly into the systemic circulation (hepatofugal); these collaterals give rise to esophageal and gastric varices. Other common spontaneous collaterals are through a recanalized umbilical vein to the abdominal wall, from the superior hemorrhoidal vein into the middle and inferior hemorrhoidal veins, and through numerous small veins (of Retzius) connecting the retroperitoneal viscera with the posterior abdominal wall.

Isolated thrombosis of the splenic vein causes localized splenic venous hypertension and gives rise to large collaterals from spleen to gastric fundus (sinistral, or left-sided, portal hypertension). From there, the blood returns to the main portal system through the coronary vein. In this condition, gastric varices are often present without esophageal varices.

Of the many large collaterals that form as a result of portal hypertension, spontaneous bleeding is relatively uncommon except from those at the gastroesophageal junction; spontaneous bleeding from gastric varices can sometimes occur and carries a higher rate of death than gastroesophageal varices. Compared with adjacent areas of the esophagus and stomach, the gastroesophageal junction is especially rich in submucosal veins, which expand disproportionately in patients with portal hypertension. The cause of variceal bleeding is most probably rupture due to sudden increases in hydrostatic pressure. Esophagitis is usually mild or absent.

ACUTELY BLEEDING VARICES

Varices develop in 5%-15% of cirrhotic patients per year. Most patients with cirrhosis develop varices, but only about one-third experience variceal hemorrhage. Each bleeding episode is associated with a mortality rate of up to 25%, and 70% of untreated patients die within a year of the first episode. This high death rate reflects not only the massive hemorrhage but also the frequent presence of severely compromised liver function and other systemic disease that may or may not be related to alcohol abuse. Malnutrition, pulmonary aspiration, infections, and coronary artery disease are frequent coexisting conditions. Additional complicating factors in this patient population include lack of cooperation with treatment and acute alcohol withdrawal, which in its worst manifestation (delirium tremens) adds greatly to the already high mortality rate.

► Clinical Findings

A. Symptoms and Signs

If cirrhosis or varices have been documented on previous examinations, hematemesis would strongly suggest bleeding varices as the cause. Patient with significant hemorrhage present with alteration of mental status, hypotension, and tachycardia, often in hypovolemic shock. It must be emphasized that bleeding from varices cannot be accurately diagnosed on clinical grounds alone even though the history or the appearance of the patient may strongly suggest the presence of cirrhosis or portal hypertension. Most patients with bleeding varices have alcoholic cirrhosis, and the diagnosis may seem obvious in a patient with hepatomegaly, jaundice, and vascular spiders who admits to recent binge drinking. Splenomegaly, the most constant physical finding, is present in 80% of patients with portal hypertension regardless of the cause. Ascites is frequently present. Massive ascites and hepatosplenomegaly in a nonalcoholic would suggest the much less common BCS.

B. Laboratory Findings

Most patients with alcoholic liver disease and acute upper gastrointestinal bleeding have compromised liver function. The bilirubin is usually elevated, and the serum albumin is often below 3 g/dL. The leukocyte count may be elevated. Anemia may be a reflection of chronic alcoholic liver disease or hypersplenism as well as acute hemorrhage. The development of a hepatoma by a cirrhotic may first manifest by hemorrhage from varices; CT scan and marked elevation of the serum α -fetoprotein make the diagnosis. Thrombocytopenia and coagulopathy are common.

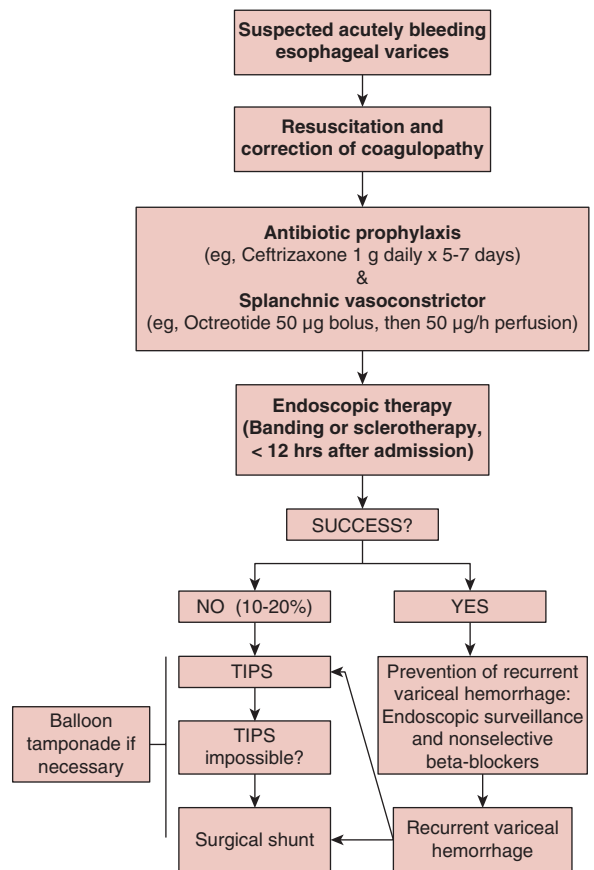

Table 24-5. First line management of acute bleeding from esophageal varices.

1. Medical—vasoconstrictor
Somatostatin analogs
Vasopressin, terlipressin
2. Medical—antibioprophylaxis

Transjugular intrahepatic portosystemic shunt (TIPS)
4. Mechanical
Balloon tamponade (Sengstaken–Blakemore)
5. Surgical
Emergency portosystemic shunts
Esophageal transection and reanastomosis
Esophagogastric devascularization
Suture ligation of varices

► Treatment of Acute Bleeding

The general goal of treatment is to control the bleeding as quickly and reliably as possible using methods with the fewest possible side effects. The methods in use for acute variceal bleeding are listed in Table 24-5 and presented into a current treatment algorithm in Figure 24-6. Over the past decades, improvement in medical, endoscopic, and endovascular technique studied in the setting of randomized control trials has lessened the need for surgical interventions.

The initial management of the patient with massive gastrointestinal hemorrhage is discussed in Chapter 23. Critical initial steps include airway protection, particularly in patients with altered mental status or those with hemodynamic instability, and resuscitation with fluid and blood products. In the cirrhotic patients, correction of coagulopathy and thrombocytopenia should also be initiated early. Patients admitted with variceal hemorrhage are often

▲ Figure 24-6. Algorithm for the management of acute variceal bleeding.

bacteremic as a result of a concomitant infectious process (spontaneous bacterial peritonitis, urinary tract infection, or pneumonia). Clinical trials have shown better outcomes when empiric antibiotic therapy is initiated during an episode of variceal bleed, and usually a third-generation cephalosporin such as ceftriaxone is favored.

Vasoconstrictive drugs which reduce portal pressure (somatostatin and vasopressin analogs) and endoscopic variceal ablation (ligation and sclerotherapy) are the mainstay of initial management. The combined pharmacologic and endoscopic therapy has been shown in single trials and meta-analysis to be more effective in controlling acute bleeding than endoscopic treatment alone. With this initial strategy, control of bleeding can be achieved in 80%-85% of episodes. Endoscopic intervention requires a skilled endoscopist; banding has been shown effective and is considered the treatment of choice, although very profuse bleeding makes ligation a challenge, and sclerotherapy with cyanoacrylate may be useful in this setting if special expertise is available. Balloon tamponade is no longer used routinely but is rather reserved for failure of the pharmacologic/endoscopic therapy for the hemodynamically unstable patients, and when the next line of treatment cannot readily be implemented.

The failure rate of the standard medical therapy for all comers is of 10%-20%, highest in patients with Child-Pugh class C disease, and early rebleeding rate has been reported in up to 30% of patients. Placement of a transjugular intrahepatic portosystemic shunt (TIPS) is currently considered the salvage therapy of choice in this situation. TIPS may not be an option in some cases, for example in face of portal thrombosis, in which situation surgical shunt or devascularization procedures are indicated.

Death rates rise rapidly in patients requiring more than 10 units of blood, and in general, patients still bleeding after 6 units—or those whose bleeding is still unchecked 24 hours after admission—should be considered for portal decompression procedures. Even when the bleeding is brought under control by the initial intervention, the mortality rate remains high (about 35%) as a result of liver failure and other complications.

► Specific Measures

1. Acute endoscopic sclerotherapy or ligation—

Emergency esophagogastroscopey is the most useful procedure for the diagnosis and the treatment of bleeding varices and should be performed as soon as the patient's general condition is stabilized by blood transfusion, correction of coagulopathy, administration of vasoconstrictors, and antibiotics are given. Endotracheal intubation is usually necessary for airway control. Varices appear as three or four large, tortuous submucosal bluish vessels running lon-

gitudinally in the distal esophagus. The bleeding site may be identified, but in some cases the lumen fills with blood so rapidly that the lesion is obscured. Using fiber-optic endoscopy, 13 mL of sclerosant solution is injected into the lumen of each varix, causing it to become thrombosed. Variations in the type of endoscope or sclerosant solution or whether or not the varices are physically compressed appear to have little influence on the outcome. Endoscopy is usually repeated within 48 hours and then once or twice again at weekly intervals, at which time any residual varices are injected.

Sclerotherapy controls acute bleeding in 80%-85% of patients, and rebleeding during the same hospitalization is about half (25% vs. 50%) the rebleeding rate of patients treated with a combination of vasopressin and balloon tamponade. Even though controlled trials show improvement in the control of bleeding with sclerotherapy, the evidence for increased patient survival is conflicting.

A similar effect is achieved by endoscopic ligation of the varices. The varix is lifted with a suction tip, and a small rubber band is slipped around the base. The varix necroses to leave a superficial ulcer. Several controlled trials have reported rubber band ligation to be more effective in controlling long-term bleeding episodes compared to sclerotherapy, although comparisons in the acute setting are limited. Band ligation is associated with fewer complications and fewer procedures are needed for complete eradication and has thus emerged as the initial endoscopic treatment of choice.

2. Somatostatin and analogs—Octreotide (brand name Sandostatin), is an octapeptide that mimics the hormone somatostatin pharmacologically. Purified somatostatin is not available in the United States. Somatostatin infusion reduces portal pressure without any impact on systemic hemodynamics; this effect may be less pronounced for octreotide. Somatostatin has been shown, in a prospective randomized trial, to effectively control acute bleeding, although other studies have had equivocal results. A meta-analysis of all studies using somatostatin or its analogs did show a significant risk reduction in control of hemorrhage. The efficacy of octreotide remains uncertain, but it appears to reduce the rebleeding rate when used in conjunction with endoscopic therapy. It should be emphasized that no study of somatostatin or octreotide has shown improved survival after an acute bleeding episode. Octreotide is given as an initial bolus of 50 µg followed by a continuous infusion of 50 µg/h for 2-5 days.

3. Vasopressin and analogs—Vasopressin and its analog terlipressin (triglycyl lysine vasopressin) lower portal blood flow and portal pressure by directly constricting splanchnic arterioles, thereby reducing inflow. Vasopressin or terlipressin alone controls acute bleeding in about 80%-85% of

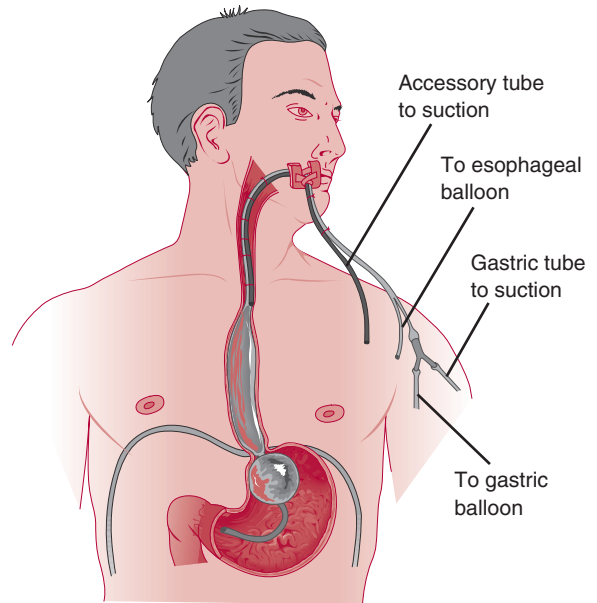

patients, and this rate is increased when combined with endoscopic therapy or balloon tamponade. Cardiac output, oxygen delivery to the tissues, hepatic blood flow, and renal blood flow are also decreased—effects that occasionally produce complications such as myocardial infarction, cardiac arrhythmias, and intestinal necrosis. These unwanted side effects may sometimes be prevented without interfering with the decrease in portal pressure by simultaneous administration of nitroglycerin or isoproterenol. Terlipressin has fewer untoward cardiovascular side effects than vasopressin.

Although the results are somewhat contradictory, controlled trials generally indicate that vasopressin plus nitroglycerin is superior to vasopressin alone and that vasopressin alone is superior to placebo in controlling active variceal bleeding. Survival is not increased, however. In fact, while several vasoactive agents effectively stop acute hemorrhage, only terlipressin has been shown to improve survival after an acute event. Vasopressin is given as a peripheral intravenous infusion (at about 0.4 units/min), which is safer than bolus injections. Nitroglycerin can be given intravenously or sublingually. Terlipressin undergoes gradual conversion to vasopressin in the body and is safe to give by intravenous bolus injection (2 mg intravenously every 6 hours); this drug is, however, not available in the United States.

4. Balloon Tamponade—Tubes designed for tamponade have two balloons that can be inflated in the lumen of the gut to compress bleeding varices. There are three or four lumens in the tube, depending on the type: two are for filling balloons within the stomach and the esophagus, and the third permits aspiration of gastric contents. A fourth lumen in the Minnesota tube is used to aspirate the esophagus orad to the esophageal balloon. The main effect results from traction applied to the tube, which forces the gastric balloon, generally inflated first and with 200 mL of air, to compress the collateral veins at the cardia of the stomach. Inflating the esophageal balloon probably contributes little, since barium x-rays suggest that it does not actually compress the varices (Figure 24-7).

The most common serious complication is aspiration of pharyngeal secretions and pneumonitis. Another serious hazard is the occasional instance of esophageal rupture caused by inflation of the esophageal balloon. The esophageal balloon is therefore infrequently used.

About 75% of actively bleeding patients can be controlled by balloon tamponade, usually applied for 6-12 hours. When bleeding has stopped, the balloons are left inflated for another 24 hours. They are then decompressed, leaving the tube in place. If bleeding does not recur, the tube should be withdrawn. The efficacy of other therapies combined with potential complications associated with balloon catheters have led to a marked reduction in the use of the latter approach, which is now reserved as a salvage treatment or

▲ **Figure 24-7.** Sengstaken–Blakemore tube with both gastric and esophageal balloons inflated.

temporary bridge in patients who fail medical and endoscopic therapy.

5. Transjugular Intrahepatic Portosystemic Shunt—TIPS is a minimally invasive means of creating a portosystemic shunt by creating a direct communication between the portal and hepatic venous systems within the liver parenchyma. A catheter is introduced through the jugular vein and, under radiologic control, positioned in the hepatic vein. From this point, the portal vein is accessed through the liver, the tract is dilated, and the channel is kept open by inserting an expandable metal stent, which is left in place. This technique is of great value in controlling portal hypertension and variceal bleeding and is used most commonly as a salvage therapy to stop acute bleeding for the 10%-20% of patients in whom medical and endoscopic therapy fails. TIPS is also indicated to prevent rebleeding in patients with advanced liver disease at high risk for recurrent variceal bleeding. In this latter category of patients, early use of TIPS has been shown in randomized controlled trial to improve survival. The shunt remains open in most patients for up to a year, at which point intimal overgrowth lead to thrombosis and occlusion in many cases. The use of polytetrafluoroethylene (PTFE)-covered stents now appears to have improved the patency rate.

TIPS should not be regarded as definitive therapy, however, even though the shunt usually remains patent

for many months. Patients with advanced liver disease are the principal candidates for TIPS, proved most useful as a bridge to transplantation. Patients with less severe cirrhosis should generally be considered for beta-blocker therapy and in some cases for surgical devascularization procedure when transplantation is not a suitable option.

6. Surgery—The operative procedures to control active bleeding are emergency portosystemic shunt and variceal ligation or esophageal transection.

A. EMERGENCY PORTACAVAL SHUNT—Although TIPS, when technically feasible, has largely supplanted more invasive surgical shunts as a salvage procedure for variceal bleed, emergency portacaval shunt success has a success rate of 95% in stopping bleeding in this context. The death rate of the operation is not insignificant, generally related to the status of the patient's liver function (eg, Child–Pugh classification; Table 24–1) as well as the rate and amount of bleeding and its effects on cardiac, renal, and pulmonary function. Some patients with advanced liver disease, especially those with severe encephalopathy and ascites, have an extraordinarily poor survival regardless of the treatment. In such patients, surgery is usually not warranted, even in the face of continued bleeding. On the other hand, patients with good liver function usually recover after an emergency shunt. A controlled trial showed that the death rate in acutely bleeding Child–Pugh C patients was insignificantly lower after endoscopic sclerotherapy (44%) than after emergency portacaval shunt (50%).

For active bleeding, a nonselective end-to-side portacaval shunt is most commonly performed (Figure 24–8C). A side-to-side portacaval shunt might be preferable in an acutely bleeding patient with severe ascites (Figure 24–8B), and this approach (or a variant such as an H-mesocaval shunt) would be required for someone with BCS.

The central splenorenal shunt, in which the portal vein is decompressed via the splenic vein into the left renal vein, is more complicated than portacaval shunts and has no specific advantages. Selective shunts, such as the distal splenorenal (Warren) shunt, in which the gastrosplenic collaterals are decompressed via the splenic vein into the left renal vein, leaving the portal vein intact, are usually too time-consuming for use in emergency operations.

Although the risk of variceal rebleeding is low, approximately 40% of patients develop encephalopathy after portacaval surgical shunting. Hepatic insufficiency is accelerated and liver failure is the cause of death in about two-thirds of those who die after an emergency portacaval shunt. Portacaval shunts can also render liver transplantation more difficult. Renal failure, which is often accompanied by ascites, is another potentially lethal problem. Metabolic alkalosis and delirium tremens are not uncommon postoperatively in alcoholics.

B. ESOPHAGEAL TRANSECTION—Varices may be obliterated by firing the end-to-end stapler in the distal esophagus after tucking a full-thickness ring of tissue into the cartridge with a circumferential tie. This procedure has gained popularity in the past decade, and in many surgical units it is considered a last resort therapy when nonsurgical methods fail.

If transection is performed, it must be done as soon as it is recognized that a second attempt at sclerotherapy or band ligation has failed. The results (eg, survival) are better in patients with nonalcoholic cirrhosis. Stapled transection has replaced the older technique of direct suture ligation of the varices. Transection must be viewed as an emergency measure to stop persistent bleeding—not as definitive treatment—since the underlying portal hypertension is not corrected and varices recur months later in many patients.

NONBLEEDING VARICES

Gastroesophageal varices are present in almost half of patients with cirrhosis at the time of diagnosis. Development and growth of esophageal varices each occur at a rate of 7% per year. Patients with varices that have never bled have a 30% chance of bleeding at some point; of those who bleed, 50% die. For patients who do not bleed during the first year after diagnosis of varices, the risk of bleeding subsequently decreases by half and continues to drop thereafter. Patients who have bled once from esophageal varices have a 60%-70% chance of bleeding again, and about two-thirds of repeat bleeding episodes are fatal.

► Evaluation

A. Portal Flow and Pressure Measurements

Measurements of pressure and flow in the splanchnic vasculature have been used for diagnosis and as a guide to therapy and prognosis in portal hypertension. Portal pressure can be measured directly at surgery or preoperatively by any of the following techniques:

1. Wedged hepatic venous pressure (WHVP) accurately reflects free portal pressure when portal hypertension is caused by a postsinusoidal (or sinusoidal) resistance, as in cirrhosis. The portal pressure can be determined with the catheter in the wedged position, corrected by subtracting the free hepatic venous pressure; the HVPG (the pressure gradient from the portal to the hepatic venous systems) can also be determined. This is the most commonly used technique.
2. Direct measurement of splenic pulp pressure is obtained by a percutaneously placed needle.
3. Percutaneous transhepatic catheterization of the intrahepatic branches of the portal vein is the method of choice in patients thought to have presinusoidal block or BCS.

4. Catheterization of the umbilical vein is accomplished through a small incision, and the catheter is threaded into the portal system. With each of these methods, one may also obtain anatomic information by performing angiography through the catheter.

HVPG predicts decompensation and death. Reduction in the HVPG, either spontaneously or after therapy, may help predict the risk of rebleeding in some patients. It has therefore been suggested that HVPG can be used to guide therapy. However, its value currently has been shown primarily in alcoholic liver disease. Also, it is an invasive study that requires special expertise and is not always readily available. Duplex ultrasonography is an accurate noninvasive means of assessing the amount and direction of flow in the portal vein. Preoperatively, duplex ultrasonography is useful to determine patency of the portal vein and direction of flow. Because of spontaneous thrombosis, about 10% of patients with cirrhosis have a portal vein unsuitable for a portacaval shunt. If flow in the portal vein is reversed (hepatofugal), a selective shunt (eg, splenorenal, distal) is not recommended, because it compromises the ability of portal tributaries to serve as an outflow tract for liver blood. Duplex ultrasonography can also be used to follow changes in portal perfusion after shunt operations.

B. Portal Angiography

The portal venous anatomy is often studied preoperatively by angiographic techniques. The objectives are to determine the patency, location, and size of the veins tentatively chosen for a shunt, to demonstrate the presence of varices, and to estimate the degree of prograde portal flow. Some of this information can now be obtained less invasively by duplex ultrasonography. When a splenorenal shunt is contemplated, the left renal vein should be opacified, either by injection of the renal artery or renal vein.

► Treatment

The treatment options consist of expectant management, endoscopic sclerotherapy, nonselective beta-blocker (eg, propranolol, nadolol), portosystemic shunts, devascularization of the esophagogastric junction, and miscellaneous rarely used operations. The treatment of patients with varices that have never bled is usually referred to as prophylactic therapy (eg, prophylactic endoscopic variceal ligation (EVL) or prophylactic propranolol). By convention, procedures performed on patients who have bled previously are referred to as therapeutic (eg, therapeutic shunts).

A. Prophylactic Therapy

Prophylactic therapy is of value, since the mortality rate of variceal bleeding is high (25%), the risk of bleeding in patients with varices is relatively high (30%), and varices can

often be diagnosed before the initial episode of bleeding. In patients who have never had a bleeding episode, the following have been shown to be related to the risk of hemorrhage: Child–Pugh classification, the size of the varices, and the presence of red wale markings (longitudinal dilated venules resembling whip marks) on the varices. This information can be used to identify high-risk patients (up to 65% risk of bleeding within a year) who are most likely to benefit from prophylactic treatment.

In cirrhotic patients without varices, treatment with nonselective beta-blockers is not recommended because they do not prevent the development of varices and are associated with side effects. In patients with low-risk varices (small, no red wale marks, no severe liver dysfunction), nonselective beta-blockers may delay variceal growth and thereby prevent hemorrhage. The alternative is to schedule periodic endoscopic screening for detection of variceal growth, at what time medical treatment can be initiated.

In patients who have never bled but have a high risk (medium to large varices or small varices with red wale markings and/or decompensated cirrhosis), EVL, or nonselective beta-blockers are considered equally adequate, as high-quality randomized controlled trial have concluded to similar survival of patients with either approaches. It has been suggested that beta-blocker therapy should be the first-line treatment, with EVL used in patients who cannot tolerate or have contraindications to beta-blockade. Endoscopic sclerotherapy is no longer routinely used as primary prophylaxis. More recently, low-dose carvediol as shown lower rates of first variceal hemorrhage when compared to EVL (10% vs. 23%), but those results needs to be validated in other trials.

B. Therapy of Patients Who Have Bled Previously

As noted earlier, patients who recover from an episode of variceal bleeding have an approximately 60%-70% chance of bleeding again. Much effort has been expended to ascertain the best treatment for these patients. The methods of greatest interest include nonselective beta-blocker therapy, endoscopic band ligation, and portosystemic shunts.

1. Nonselective beta-blocker therapy—As with patients with esophageal varices who have never bled, nonselective beta-adrenergic blocking agents (propranolol, nadolol) effectively reduce the risk of recurrent bleeding episodes. These agents work by decreasing cardiac output and splanchnic blood flow and consequently portal blood pressure. Chronic propranolol therapy, 20-160 mg twice daily (a dose that reduces resting pulse rate by 25%), decreases by about 40% the frequency of rebleeding from esophageal or gastric varices, deaths from rebleeding, and overall mortality. The benefits are greater in Child–Pugh A and

B than in Child–Pugh C cirrhotics. Beta-blocker therapy has been compared to endoscopic sclerotherapy, with no difference in rebleeding or mortality seen but with higher complications in the sclerotherapy group. On the other hand, randomized controlled trials have shown that the combined use of EVL and nonselective beta blockers could further lower the risk of rebleeding. The addition of nitrate drugs to beta-blocker therapy appears to result in a greater reduction of portal pressure compared to beta-blockade alone. This approach is often favored in patients who are not candidates for EVL. Abstinence from alcohol should always be emphasized and may help prevent further bleeding but may not necessarily decrease the mortality related specifically to variceal hemorrhage, as was previously thought.

2. Endoscopic band ligation—Endoscopic band ligation, as described earlier, is an effective means of preventing recurrent bleeding episodes and has been shown to be superior to sclerotherapy in this regard. Both band ligation and beta-blocker therapy appear to be similarly effective in preventing rebleeding. However, the combination of both therapies has been shown to significantly reduce not only the risk of rebleeding but also the recurrence of varices. Thus, combination therapy appears to be the most effective treatment after an initial bleeding episode.

3. Endoscopic sclerotherapy—The technique of endoscopic sclerotherapy was described earlier in this chapter. Sclerotherapy was previously used routinely to reduce the risk of rebleeding but has been replaced by band ligation.

4. Transjugular intrahepatic portosystemic shunt—The TIPS technique is described in the preceding section. TIPS is effective in preventing rebleeding episodes, more so than either endoscopic or pharmacologic therapy alone. However, this advantage is offset by its higher morbidity and mortality rate from the development of hepatic encephalopathy and liver failure. For this reason, as well as the lack of a clear survival or cost-benefit advantage, TIPS is used mainly to salvage patients who fail endoscopic and/or pharmacologic treatment.

TIPS has generally superseded shunt surgery in most patients who fail first-line therapy. A recent large multicenter randomized trial showed that TIPS and surgical shunts had similar rates of rebleeding, encephalopathy, and mortality in Child–Pugh A and B cirrhotic patients. There was a higher incidence of shunt dysfunction in the TIPS patients, perhaps because of the type of stent used, the first generation not being covered with PTFE. The use of TIPS covered with PTFE has significantly lower occlusion rate. The choice between TIPS and surgical shunts therefore currently depends on expertise, anatomical considerations, and patient's preference.

C. Surgical Approaches

The objective of surgical procedures used to treat portal hypertension is either to obliterate the varices or to reduce blood flow and pressure within the varices (Table 24–6). A third option, liver transplantation, can treat both the underlying liver dysfunction and the portal hypertension.

1. Liver transplantation—Any relatively young patient with cirrhosis who has survived an episode of variceal hemorrhage should be considered a candidate for liver transplantation, since any other form of therapy carries a much higher (about 80%) mortality rate within the subsequent 1–2 years as a result of repeat bleeding or complications of hepatic failure. Obviously, continued alcohol use is a contraindication to transplantation in most patients. The good transplantation candidates, however, should not be

subjected to portosystemic shunts or other procedures if it appears that they will come to transplantation in the near future. In general, Child-Pugh A patients are candidates for portal decompression; Child-Pugh C patients are candidates for a transplant. A TIPS (see previous section) is an excellent way to control bleeding while the patient is being prepared for a transplant.

2. Portosystemic shunts—The advent of TIPS has resulted in a marked decline in the number of shunt operations performed. However, surgical shunts are durable, and good risk patients appear to benefit from these procedures.

Portosystemic shunts can be grouped into those that shunt the entire portal system (total shunts) and those that selectively shunt blood from the gastrosplenic region while preserving the pressure-flow relationships in the rest of the portal bed (selective shunts). All of the shunt operations commonly used today reduce the incidence of rebleeding to less than 10%, compared with about 75% in unshunted patients. Unfortunately, the price of this achievement is an operative mortality rate of 5%–20% (depending on the Child–Pugh classification), further impairment of liver function, and an increase in encephalopathy (greater with total shunts). Therefore, since shunts have these potential drawbacks, clinical trials are needed to pinpoint their place within an overall treatment strategy.

In one well-designed trial, patients who had bled previously were randomized to chronic sclerotherapy or a distal splenorenal shunt (Warren shunt, Figure 24–8F). Patients randomized to chronic sclerotherapy who had recurrent episodes of bleeding during treatment (ie, treatment failures, which amounted to 30% of the sclerotherapy group) were then treated surgically (ie, shunted). The results showed that 2-year survival was better among those originally randomized to sclerotherapy (90%) than among those originally assigned to the shunt group (60%). This trial supports a general treatment plan consisting initially of endoscopic therapy and reserving portosystemic shunts for the patients in whom the former fails to control bleeding adequately (Figure 24–6).

The choice of shunt has been the subject of much debate and several randomized trials. The principal question in recent years has been whether encephalopathy and survival are better with a selective shunt (eg, a distal splenorenal shunt, Figure 24–8F) than with a total shunt (eg, a mesocaval or an end-to-side portacaval shunt, Figure 24–8 C and 24–8 D). The results are conflicting, but in general they support the contention that there is about half as much severe encephalopathy following selective shunts. None of the trials have shown any particular shunt to be associated with longer survival.

3. Severity of hepatic disease and operative risk—The immediate death rate of an elective shunt procedure can be

C. Measures to preserve hepatic blood flow after portacaval shunt

1. Arterialization of portal vein stump

predicted from the patient's hepatic function as reflected by the Child–Pugh classification (Table 24–1). In addition to operative death rate, the figures also correlate with the death rate in the first postshunt year. Thereafter, survival curves of the different risk classes become reasonably parallel.

The severity of histopathologic changes in liver biopsies correlates with the immediate surgical death rate, the most ominous findings being hepatocellular necrosis, polymorphonuclear leukocyte infiltration, and the presence of Mallory bodies. The extent of histologic change also correlates with the more easily obtained data in the Child–Pugh classification (ie, severe changes occur in class C patients), so results of biopsies have no independent predictive value.

A. TYPES OF PORTOSYSTEMIC SHUNTS—Figure 24–8 depicts the various shunts in use currently. Although they differ technically, physiologically there are only three different types: end-to-side, side-to-side, and selective.

1. Total shunts—The end-to-side shunt completely disconnects the liver from the portal system. The portal vein is transected near its bifurcation in the liver hilum and anastomosed to the side of the inferior vena cava. The hepatic stump of the vein is oversewn. Postoperatively, the WHVP (sinusoidal pressure) drops slightly, reflecting the inability of the hepatic artery to compensate fully for the loss of portal inflow. The side-to-side portacaval, mesocaval, mesorenal, and central splenorenal shunts are all physiologically similar, since the shunt preserves continuity between the hepatic limb of the portal vein, the portal system, and the anastomosis. Flow through the hepatic limb of the standard side-to-side shunt is nearly always away from the liver and toward the anastomosis. The extent to which hepatofugal flow is produced by the other types of side-to-side shunts listed previously is not known.

The end-to-side portacaval shunt gives immediate and permanent protection from variceal bleeding and is somewhat easier to perform than a side-to-side portacaval or central splenorenal shunt. Encephalopathy may be slightly more common after side-to-side than end-to-side portacaval shunts. Side-to-side shunts are required in patients with BCS or refractory ascites (when the latter is treated by a portosystemic shunt).

The mesocaval shunt interposes a segment of prosthetic graft or internal jugular vein between the inferior vena cava and the superior mesenteric vein where the latter passes in front of the uncinate process of the pancreas. The mesocaval shunt is particularly useful in the presence of severe scarring in the right upper quadrant or portal vein thrombosis, and in some cases it may be technically easier than a conventional side-to-side portacaval shunt if a side-to-side type of shunt is necessary. In most cases, portal flow to the liver is lost after this shunt. Evidence has been presented, however, that by limiting the diameter of the prosthetic graft to 8 mm

(compared with 12- to 20-mm grafts), prograde flow is preserved in the portal vein, which decreases the incidence of postoperative encephalopathy while still preventing variceal hemorrhage.

2. Selective shunts—Selective shunts lower pressure in the gastroesophageal venous plexus while preserving blood flow through the liver via the portal vein.

The distal splenorenal (Warren) shunt involves anastomosing the distal (splenic) end of the transected splenic vein to the side of the left renal vein, plus ligation of the major collaterals between the remaining portal and isolated gastrosplenic venous system. The latter step involves division of the gastric vein, the right gastroepiploic vein, and the vessels in the splenicocolic ligament. The operation is more difficult and time consuming than conventional shunts and except for the experienced operator is probably too complex for emergency portal decompression. If mobilization of the splenic vein is hazardous, the renal vein may be transected and its caval end joined to the side of the undisturbed splenic vein. The segment of splenic vein between the anastomosis and the portal vein is then ligated. Surprisingly, this seems to have little permanent effect on renal function as long as the remaining tributaries are preserved on the oversewn renal vein stump.

In contrast to total shunts, the Warren shunt does not improve ascites and should not be performed in patients whose ascites has been difficult to control. Preoperative angiography should be performed to determine if the splenic vein and left renal vein are large enough and close enough together for performance of this shunt. Recent pancreatitis may preclude safe dissection of the splenic vein from the undersurface of the pancreas.

Another type of selective shunt (Inokuchi shunt) consists of joining the left gastric vein to the inferior vena cava by a short segment of autogenous saphenous vein. The procedure has not become popular, perhaps because of its technical complexity.

Selective shunts tend to become less selective over several years as new collaterals develop between the high-pressure and low-pressure regions of the portal system. This is accompanied by a gradual decrease in portal pressure (measured by WHVP) and evolution of the procedure into a version of side-to-side total shunt. The enlargement postoperatively of small venous tributaries entering the distal splenic vein from the pancreas suggests that this is the path by which nonselectivity develops. It is possible that this can be avoided by mobilizing the splenic vein all the way to the hilum (dividing these small vessels) before performing the splenorenal anastomosis.

B. CHOICE OF SHUNT—A reasonable approach to shunt selection is as follows.

The distal splenorenal shunt is the first choice for elective portal decompression. If ascites is present or the anatomy is

unfavorable, an end-to-side portacaval shunt is preferred. Side-to-side shunts would be done for patients with severe ascites or BCS. The H-mesocaval and central splenorenal shunts are reserved for special anatomic situations in which the above operations are unsuitable. An end-to-side shunt or H-mesocaval shunt is performed for emergency decompression.

Portacaval and distal splenorenal shunts are often followed by a rise in platelet count in patients with secondary hypersplenism. The response is unpredictable, however, and hypersplenism need not necessarily dictate the type of shunt since it rarely produces clinical manifestations. A central splenorenal shunt, in which splenectomy is performed, should not be considered preferable to other kinds of shunts just because the patient has a low platelet count.

C. RESULTS OF PORTOSYSTEMIC SHUNTS—Over 90% of portosystemic shunts remain patent, and the incidence of recurrent variceal bleeding is less than 10%. The 5-year survival rate after a portacaval shunt for alcoholic liver disease averages 45%. Some degree of encephalopathy develops in 15%-25% of patients. Severe encephalopathy is seen in about 20% of alcoholics following a total shunt; its occurrence is not related to the severity of preshunt encephalopathy.

D. Devascularization Operations

The objective of devascularization is to destroy the venous collaterals that transport blood from the high-pressure portal system into the veins in the submucosa of the esophagus.

The Sugiura-Futugawa procedure initially described in 1973 was done in two stages. The first stage was performed through a thoracotomy and consisted in division of the dilated venous collaterals between esophagus and adjacent structures, transection of the esophagus at the level of the diaphragm, and reanastomosis. The second stage, a laparotomy, was performed immediately after the thoracotomy if the patient was actively bleeding or deferred 4-6 weeks in elective cases. In the second stage of the operation, the upper two-thirds of the stomach was devascularized, and selective vagotomy, pyloroplasty, and splenectomy performed.

More recently, an analogous one-stage operation has been described in many series and performed through laparotomy that consists of splenectomy, devascularization of 8-10 cm of distal esophagus, devascularization of the lesser and greater curvature with ligation of the left gastric and gastroepiploic vessels, transection and end-to-end anastomosis of the lower esophagus 4-5 cm above the gastroesophageal junction (EEA-stapler), pyloroplasty, and insertion of a feeding jejunostomy.

In Eastern and Western series published between 1980 and 1999, the operative mortality ranged from 0% to 36%, up to 80% in Child C patients, the variceal rebleeding rate from 0% to 37%, encephalopathy from 0% to 22%, and esophageal

stenosis ranged from 2% to 37%. For cirrhotic patients with extensive portal thrombosis, for whom portosystemic shunt cannot be performed, devascularization operations can offer a good alternative.

E. Miscellaneous Operations

Attempts have also been made to decrease portal pressure by decreasing splanchnic inflow through splenectomy or splenic artery ligation. Diseases characterized by marked splenomegaly may rarely be associated with portal hypertension as a consequence of increased splenic blood flow, which has been known to reach levels as high as 1000 mL/min. Splenic blood flow may occasionally be increased enough in patients with cirrhosis to contribute significantly to the portal hypertension. However, splenectomy or splenic artery ligation in cirrhosis most often gives only a transient decrease in portal pressure, and over half of patients having these operations bleed again. Some workers have suggested that the absolute size of the splenic artery (a crude index of splenic flow) correlates with the clinical effectiveness of splenic artery ligation, a good result being predictable if the diameter of the artery is 1 cm or greater.

EXTRAHEPATIC PORTAL VENOUS OCCLUSION

Extrahepatic portal vein obstruction is one of many causes of noncirrhotic portal hypertension, the other common cause being noncirrhotic portal fibrosis. These disorders are distinct but appear to share several similar etiological and

pathogenetic features, the most notable of which is the clinical manifestation of portal hypertension in the absence of significant hepatic parenchymal dysfunction.

Idiopathic portal vein thrombosis (in the absence of liver disease) is a relatively common cause of portal hypertension in developing countries but is less prevalent in the West. This diagnosis accounts for most cases of portal hypertension in childhood (80%-90%) and for a smaller proportion of cases in adults. Neonatal septicemia, omphalitis, umbilical vein catheterization for exchange transfusion, and dehydration have all been incriminated as possible causes, but collectively they can be implicated in less than half of cases. The causes of portal vein thrombosis in adults include hepatic tumors, cirrhosis, trauma, pancreatitis, pancreatic pseudocyst, myelofibrosis, thrombotic states (eg, protein C deficiency), and sepsis; in particular, cirrhosis and/or hepatocellular carcinoma need to be considered in adult patients. In adult, systemic anticoagulation result in complete portal vein recanalization in approximately 38.3% of cases and partial recanalization in 15%.

Although clinical manifestations may be delayed until adulthood, 80% of patients with idiopathic portal vein thrombosis present between 1 and 6 years of age with variceal bleeding, although hemorrhage from ectopic varices at other locations in the gastrointestinal tract is not uncommon. About 70% of hemorrhages are preceded by a recent upper respiratory tract infection. Some of these children first come to medical attention because of splenomegaly and pancytopenia. Failure to recognize the underlying problem has occasionally led to splenectomy, with the result that portal decompression using the splenic vein is precluded. Ascites is uncommon except transiently after bleeding. Liver function is either normal or only slightly impaired, which probably accounts for the low incidence of overt encephalopathy. There is an increased frequency of neuropsychiatric problems, which may be a subtle form of encephalopathy.

Portal biliopathy refers to abnormalities of the extrahepatic bile ducts, usually the result of bile duct compression from large, dilated venous collaterals within the porta hepatis. These changes result in marked irregularities of the biliary wall that can progress to strictures and even obstructive jaundice and cholangitis in some cases; secondary biliary cirrhosis has been reported. Biliopathy is commonly seen on imaging studies, but most patients remain free of related symptoms.

Because the patient's general condition and liver function are good, the death rate for sudden massive bleeding is below that for other types of portal hypertension. The diagnosis can be confirmed with cross-sectional imaging or direct mesenteric angiography. WHVP is normal to slightly elevated; liver biopsies are normal or may show mild to moderate periportal fibrosis.

Bleeding episodes in children under age 8 years are usually self-limited and often do not require endoscopic

sclerotherapy, administration of vasopressin, or balloon tamponade. Even if such interventions are necessary, however, the bleeding episodes are self-limited and uncommonly fatal, so emergency operations are rarely necessary.

Thrombosed portal veins are unsuitable for shunt procedures. Cavomesenteric shunts are best for young children, whose vessels are small. In older individuals, treatment should be started with sclerotherapy; if that fails to control the bleeding, a distal splenorenal shunt is preferred. Splenectomy alone has no permanent effect and sacrifices the splenic vein, which might be needed later for a shunt operation. Shunts in small children have a high rate of spontaneous thrombosis and should be avoided, if possible, until approximately 8-10 years of age, when the vessels are of larger caliber. Even still, using precise technique, some surgeons have obtained a high rate of anastomotic patency in the very young. Encephalopathy and hepatic dysfunction many years after a total shunt may be improved if converted to a selective shunt.

Splenectomy alone is never indicated in this disease, either for hypersplenism or in an attempt to reduce portal pressure, because the rebleeding rate is 90% and fatal post-splenectomy sepsis is not uncommon. If it is not possible to construct an adequate shunt, expectant management is the best strategy. Repeated severe bleeding episodes should be treated by transendoscopic sclerosis. Esophagogastrectomy with colonic interposition may be effective but should be considered a last resort.

SPLenic VEIN THROMBOSIS

Isolated thrombosis of the splenic vein is a rare cause of variceal bleeding that can be cured by splenectomy. The splenic venous blood, blocked from its normal route, flows through the short gastric vessels to the gastric fundus and then into the left gastric vein, continuing toward the liver. This phenomenon is called left-sided (or sinistral) portal hypertension. As the blood traverses the stomach, large gastric varices are produced that may rupture and bleed. Characteristically, the collateral pattern does not involve the esophagus, so esophageal varices are uncommon.

The principal causes of this syndrome are pancreatitis, pancreatic pseudocyst, neoplasm, and trauma. The mean incidence of splenic vein thrombosis associated with chronic and acute pancreatitis is estimated at 12.4% and 22.6% respectively, with an overall bleeding rate of 12.3%. Splenomegaly is present in two-thirds of patients. Diagnosis can be made by selective splenic arteriography that opacifies the venous phase, but more commonly nowadays on CT

scan with portal phase imaging. Splenectomy is curative. Many cases of splenic vein thrombosis are unaccompanied by bleeding varices, and in such cases, no therapy is required. Treatment of acute bleeding from gastric varices is generally endoscopic, and endoscopic variceal obturation with tissue glue appears to be superior to band ligation or sclerotherapy.

BUDD-CHIARI SYNDROME

BCS is a rare disorder resulting from obstruction of hepatic venous outflow, which can arise at several different levels, from the small hepatic venous tributaries within the liver parenchyma to the major hepatic venous trunks to the inferior vena cava up to the level of the right atrium. The prevalence of BCS is estimated as 1:100,000, and the largest published series reported on 237 patients treated at four centers in the United States, the Netherlands, and France between 1984 and 2001. Most cases are caused by spontaneous thrombosis of the hepatic veins, often associated with myeloproliferative disorders (polycythemia vera, essential thrombocytosis) or the use of birth control pills. Other common associated conditions include factor V Leiden and factor II gene mutations. Other predisposing factors include protein C and S deficiencies, antiphospholipid syndrome, antithrombin III deficiency, paroxysmal nocturnal hemoglobinuria, Behçet syndrome, and trauma. Some patients present with idiopathic membranous stenosis of the inferior vena cava located between the hepatic veins and right atrium, which is usually associated with secondary thrombosis of the hepatic veins; this condition appears to be more common in Asia than in Western countries. Many patients with BCS are HBsAg-positive, and others have malignancies (eg, hepatocellular carcinoma). Vena caval webs were once thought to be congenital, but more recent evidence suggests that they are the consequence of thrombus formation. Primary BCS originates from within the lumen of the hepatic veins or venules, and occlusion results from thrombosis, webs, or endophlebitis. By contrast, secondary BCS results from extrinsic compression of the venous outflow tract, usually related to a neoplasm or abscess.

Veno-occlusive disease and congestive hepatopathy are two conditions that can cause hepatic venous outflow obstruction, and although the clinical picture of both may be indistinguishable from that of BCS, they differ in the level of obstruction and in predisposing conditions. Veno-occlusive disease is primarily a problem affecting the sinusoids and

terminal venules, while congestive hepatopathy reflects a problem at the level of the heart.

Posthepatic (postsinusoidal) obstruction raises sinusoidal pressure, which is transmitted proximally to cause portal hypertension. Because the parenchyma is relatively free of fibrosis, filtration across the sinusoids and hepatic lymph formation increase greatly, producing marked ascites.

Symptoms usually begin with a mild prodrome consisting of vague right upper quadrant abdominal pain, postprandial bloating, and anorexia. After weeks or months, a more florid picture develops consisting of gross ascites, hepatomegaly, and hepatic failure. At this stage, the AST is usually markedly increased, the serum bilirubin is slightly elevated, and the alkaline phosphatase is inconsistently abnormal.

Except in patients with membranous obstruction of the vena cava, liver scans (CT or MRI) usually demonstrate a marked perfusion abnormality throughout most of the liver except for a small central area representing the caudate lobe, whose venous outflow is spared (it goes directly to the vena cava through multiple small tributaries). CT scans show pooling of intravenous contrast media in the periphery of the liver; patent hepatic veins cannot be seen on ultrasound scans. An enlarged azygos vein may be seen on chest x-rays of patients with caval obstruction. Liver biopsy reveals grossly dilated central veins and sinusoids, pericentral necrosis, and replacement of hepatocytes by red blood cells. Centrilobular fibrosis develops late. The clinical diagnosis should be confirmed by venography, which shows the hepatic veins to be obstructed, usually with a beaklike deformity at their orifice. The inferior vena cava should be opacified to verify its patency, which is a requirement for a successful portacaval shunt. Previously, direct venography was used, but the required information may now be obtained using noninvasive methods, such as CT or MR angiography. The x-rays may show compression of the intrahepatic cava by the congested liver.

Treatment of BCS relies on expert consensus given the low incidence of this disease. Anticoagulation is recommended in the presence of recent or long-standing thrombosis to allow recanalization or to avoid propagation of venous thrombosis. Management of ascites and treatment or prevention of portal hypertension and variceal hemorrhage follows the same algorithms as for cirrhotic patients. Surgical or radiological approaches to relieve sinusoidal pressure have been advocated and are now considered appropriate only for symptomatic patients who do not improve with medical management. In recent years, the development of interventional radiology techniques using thrombolysis and angioplasty has shown possible to insert TIPS in selected patients with recent thrombosis or with short-length stenosis of the IVC or hepatic veins with good outcomes. Portosystemic surgical shunts are considered effective for relieving sinusoidal hypertension with the potential to reverse hepatic necrosis and prevent cirrhosis.

Focal membranous obstruction of the suprahepatic cava may be treated by excision of the lesion with or without the addition of a patch angioplasty. Some cases may be managed nonsurgically by percutaneous transluminal balloon dilation of the stenosis. Occlusion of the inferior vena cava by thrombosis or compression from the liver requires a mesoatrial shunt using a prosthetic vascular graft. Because the incidence of graft thrombosis is relatively high, it may be advisable to perform a second-stage side-to-side portacaval shunt a few months after mesoatrial shunt decompression of the liver in patients with hepatic vein thrombosis whose vena cava was originally blocked by a congested liver. Development of hepatocellular carcinoma is common in patients with membranous obstruction of the vena cava. The postoperative results are excellent in patients without malignant neoplasms.

Liver transplantation is required when medical treatment and portosystemic shunts fail in patients presenting progressive liver failure either from cirrhosis or as part of the acute syndrome. The 1-, 5-, 10-year survival rates with transplantation are of 76%, 71%, and 68%, respectively, and the risk of later hepatocellular carcinoma is eliminated.

ASCITES

Ascites is a common manifestation of chronic liver disease, resulting from sinusoidal hypertension as the specific pathophysiologic abnormality. Ascites in hepatic disease results from (1) increased formation of hepatic lymph (from sinusoidal hypertension), (2) increased formation of splanchnic lymph (from splanchnic vasodilatation), (3) hypoalbuminemia, and (4) salt and water retention by the kidneys. Before therapy is started, paracentesis should be performed and the following examinations made on a sample of ascitic fluid: (1) Culture and leukocyte count—spontaneous bacterial peritonitis is common and may be clinically silent. A white count above 250/ μL is highly suggestive of infection. (2) LDH levels—a ratio of LDH in ascites to serum that exceeds 0.6 suggests the presence of cancer or infection. (3) Serum amylase—a high level suggests pancreatic disease. (4) Albumin—the ratio of serum to ascites albumin concentrations is above 1.1 in liver disease and below 1.1 in malignant ascites. (5) Cytology—this is pertinent only in patients with a cancer diagnosis or a suspicion of cancer.

Nonhepatic ascites can result from congestive heart failure, chylous leak, peritoneal carcinomatosis, infections such as tuberculosis, coccidiomycosis, and chlamydia, and some autoimmune disease involving the connective tissues, such as systemic lupus erythematosus. Treatments of ascites in these contexts depend on the underlying cause and are not discussed in this chapter.

► Medical Treatment

In general, the intensity of medical therapy required to control ascites can be predicted from the pretreatment 24-hour urine Na^+ output as follows: A Na^+ output below 5 mEq/24 h requires strong diuretics; 5-25 mEq/24 h, mild diuretics; and above 25 mEq/24 h, no diuretics. Initial treatment is usually with spironolactone, 200 mg/d. The objective is to stimulate a weight loss of 0.5-0.75 kg/d except in patients with peripheral edema who can mobilize fluid faster. If spironolactone alone is insufficient, another drug such as furosemide should be added. A loop diuretic (eg, furosemide, ethacrynic acid) should be given only in combination with a distally acting diuretic (eg, spironolactone, triamterene). Alternatively, massive ascites may be treated by one or more large volume (eg, 5-L) paracenteses; this is often accompanied by an intravenous infusion of albumin, although the benefits of albumin remain controversial. Caution is required in patients with evidence of renal dysfunction, since aggressive fluid removal can result in renal failure. Close monitoring of serum electrolytes should be done. Because the development of ascites in cirrhosis is a result of renal sodium retention, dietary sodium restriction is a mainstay of treatment. A typical American diet contains 4-6 g of sodium per day. Patients are educated to have a diet of maximum 2 g of sodium per day. Fluid restriction is only indicated in patients with severe hyponatremia, but all should avoid excessive fluid intake.

► Surgical Treatment

A. Portacaval Shunt

A history of ascites that has been easy to control need not influence the choice of shunt operation intended to treat variceal bleeding. When ascites has been severe, however, a side-to-side shunt (eg, side-to-side portacaval, H-mesocaval, central splenorenal) may be considered, because it reduces sinusoidal as well as splanchnic venous pressure. A side-to-side portacaval shunt is rarely indicated just to treat ascites (eg, in patients in whom several LeVeen shunts have thrombosed), although the incidence of severe postoperative encephalopathy is high under these circumstances. TIPS is another effective intervention for refractory ascites, probably a better option than repeated paracentesis in good-risk patients, although there is an associated risk of hepatic encephalopathy.

B. Peritoneal-Jugular Shunt (LeVein Shunt, Denver Shunt)

Refractory ascites can be treated with a LeVein shunt—a subcutaneous Silastic catheter that transports ascitic fluid from the peritoneal cavity to the jugular vein. A small unidirectional valve sensitive to a pressure gradient of 3–5 cm H₂O prevents backflow of blood. A modification called the Denver shunt contains a small chamber that can be used as a pump to clear the line by external pressure. In practice, Denver shunts become blocked more often than LeVein shunts.

In patients with ascites due to cirrhosis, use of a LeVein shunt should be confined to those who fail to respond to high doses of diuretics (eg, 400 mg of spironolactone and 400 mg of furosemide daily) or who repeatedly develop encephalopathy or azotemia during diuretic therapy.

Peritoneovenous shunts may also be used for ascites associated with cancer. The best results occur in patients whose ascitic fluid contains no malignant cells. A LeVein shunt is of benefit in BCS but is ineffective for chylous ascites. Because the incidence of complications and early shunt thrombosis is high, a LeVein shunt is relatively contraindicated if the ascitic fluid is grossly bloody, contains many malignant cells, or has a high protein concentration (> 4.5 g/dL). The incidence of tumor embolization is low (5%).

The ascitic fluid should be cultured a few days before the shunt is inserted. Antibiotic coverage should be given for the procedure. The operation can be done with local anesthesia.

Postoperatively, the patient is outfitted with an abdominal binder and instructed to perform respiratory exercises against mild pressure to increase abdominal pressure and flow through the shunt. Dietary salt should not be restricted. A functioning LeVein shunt alone is unable to fully eliminate the ascites, but it improves symptoms related to distention and renders the patient much more responsive to diuretics. Therefore, furosemide should be administered postoperatively.

An average of 10 kg of weight is lost during the first 10 days after the operation, and eventually the abdomen assumes a normal configuration. Nutrition and serum albumin levels often improve postoperatively. Urinary sodium excretion increases promptly, and renal function may improve in patients with the hepatorenal syndrome. Serious complications and deaths are most common in patients with advanced hepatorenal syndrome or a serum bilirubin level greater than 4 mg/dL. Although some patients eventually bleed from varices following insertion of a LeVein shunt, the shunt itself does not increase the risk of bleeding and actually decreases portal pressure. Thus, a previous episode of variceal bleeding is not a contraindication for this procedure. Disseminated intravascular coagulation (manifested by increased fibrin split products, decreased platelet count, etc) occurs in more than half of cases but is clinically relevant

in only a few. The frequency and severity of disseminated intravascular coagulation may be minimized by emptying most of the ascitic fluid from the abdomen during operation and partially replacing it with Ringer lactate solution. Lethal septicemia may occur if the ascitic fluid is infected at the time the shunt is inserted. In about 10% of cases, the valve becomes thrombosed and must be replaced.

Hydrothorax, usually on the right side, may develop in patients with cirrhosis and ascites. The fluid reaches the chest through a pinhole opening in the membranous portion of the diaphragm, a pathway that can be demonstrated by aspirating the thoracic fluid, injecting technetium ^{99m}Tc colloid into the ascites fluid, and observing rapid accumulation of the label in the chest. Treatment consists of a peritoneovenous shunt and injection of a sclerosing agent into the pleural cavity after it has been tapped dry. If a leak persists, it may be closed surgically by thoracotomy.

HEPATIC ENCEPHALOPATHY

Central nervous system abnormalities may be seen in patients with chronic liver disease and are especially likely after portacaval shunts. Portosystemic encephalopathy, ammonia intoxication, hepatic coma, and meat intoxication are older terms used to refer to this condition. The manifestations range from lethargy to coma—from minor personality changes to psychosis—from asterixis to paraplegia. Hypothermia and hyperventilation may precede coma. The changes may be quite subtle and detectable only with the use of neuropsychological or neurophysiological testing.

▶ Pathogenesis

Hepatic encephalopathy is a reversible metabolic neuropathy that results from the action of chemicals absorbed from the gut on the brain. Increased exposure of the brain to these agents is the result of impaired hepatic metabolism due to cirrhosis or spontaneous or surgically created shunts of portal venous blood around the liver and increased permeability of the blood-brain barrier. The chemical agents responsible for encephalopathy form from the action of colonic bacteria on protein within the gut. Potential aggravating factors include gastrointestinal hemorrhage, constipation, azotemia, hypokalemic alkalosis, infection, excessive dietary protein, and sedatives (Table 24–7). Four main chemical mediators of this syndrome currently attract the most attention.

Table 24–7. Factors contributing to encephalopathy.**A. Increased systemic toxin levels**

1. Extent of portal-systemic venous shunt
2. Depressed liver function
3. Intestinal protein load
4. Intestinal flora
5. Azotemia
6. Constipation

B. Increased sensitivity of the central nervous system

1. Age of patient
2. Hypokalemia
3. Alkalosis
4. Diuretics
5. Sedatives, narcotics, tranquilizers
6. Infection
7. Hypoxia, hypoglycemia, myxedema

Low-grade cerebral edema appears to be a major component of the pathophysiologic process.

A. Amino Acid Neurotransmitters

Gamma-aminobutyric acid (GABA), the principal inhibitory neurotransmitter in the brain, produces a state similar to hepatic encephalopathy when given experimentally. It is normally synthesized in the brain and by bacteria within the colon; GABA in the gastrointestinal tract is normally degraded by the liver and is found in increased levels in the serum of patients with hepatic encephalopathy. The passage of GABA across the blood-brain barrier is increased in hepatic encephalopathy. Experiments also indicate the presence of increased numbers of GABA receptors in encephalopathy and increased GABA-ergic tone, perhaps due to a benzodiazepine receptor agonist ligand on the receptor complex (GABA/benzodiazepine receptor). This has raised the possibility of treating encephalopathy with benzodiazepine antagonists, and the drug flumazenil has shown promise in preliminary trials.

B. Ammonia

Ammonia is produced in the colon by bacteria and is absorbed and transported in portal venous blood to the liver, where it is extracted and converted to glutamine. Ammonia concentrations are elevated in the arterial blood and cerebrospinal fluid of patients with encephalopathy, and experimental administration of ammonia produces central nervous system symptoms.

C. False Neurotransmitters

According to this theory, cerebral neurons become depleted of normal neurotransmitters (norepinephrine and dopamine), which are partially replaced by false neurotransmitters (octopamine and phenylethanolamine). The result is

inhibition of neural function. Serum levels of branched-chain amino acids (leucine, isoleucine, valine) are decreased, and levels of aromatic amino acids (tryptophan, phenylalanine, tyrosine) are elevated in patients with encephalopathy. Because these two classes of amino acids compete for transport across the blood-brain barrier, the aromatic amino acids have increased access to the central nervous system, where they serve as precursors for false neurotransmitters. Trials of therapy with supplements of branched-chain amino acids have given conflicting results.

D. Synergistic Neurotoxins

This theory postulates that ammonia, mercaptans, and fatty acids, none of which accumulate in the brain in amounts capable of producing encephalopathy, have synergistic effects that produce the full-blown syndrome in patients with liver disease.

► Prevention

Encephalopathy is a major side effect of portacaval shunt and is to some extent predictable. Elderly patients are considerably more susceptible. Patients with alcoholic liver disease fare better than those with postnecrotic or cryptogenic cirrhosis, apparently owing to the invariable progression of liver dysfunction in the latter. Good liver function partially protects against encephalopathy. If the liver has adapted to complete or nearly complete diversion of portal blood before operation, a surgical shunt is less apt to depress liver function further. For example, patients with thrombosis of the portal vein (complete diversion and normal liver function) rarely experience encephalopathy after portosystemic shunt. Encephalopathy is less common after a distal splenorenal (Warren) shunt than after other kinds of shunts.

Increased intestinal protein, whether of dietary origin or from intestinal bleeding, aggravates encephalopathy by providing more substrate for intestinal bacteria. Constipation allows more time for bacterial action on colonic contents. Azotemia results in higher concentration of blood urea, which diffuses into the intestine, is converted to ammonia, and is then reabsorbed. Hypokalemia and metabolic alkalosis aggravate encephalopathy by shifting ammonia from extracellular to intracellular sites where the toxic action occurs.

► Laboratory Findings

Arterial ammonia levels are usually high, although encephalopathy can certainly be present with a normal ammonia level. The presence of high levels of glutamine in the cerebrospinal fluid may help distinguish hepatic encephalopathy from other causes of coma. Electroencephalography is more sensitive than clinical evaluation in detecting minor involvement. The changes are nonspecific and consist of slower mean frequencies. Studies performed at different times can be compared to assess the effects of therapy.

► Treatment

Acute encephalopathy is treated by controlling precipitating factors, halting all dietary protein intake, cleansing the bowel with purgatives and enemas, and administering antibiotics (neomycin or ampicillin) or lactulose. Neomycin may be given orally or by gastric tube (two to four times daily) or rectally as an enema (1% solution one or two times daily). At least 1600 kcal of carbohydrate should be provided daily, along with therapeutic amounts of vitamins. Blood volume must be maintained to avoid prerenal azotemia. After the patient responds to initial therapy, dietary protein may be started at 20 g/d and increased by increments of 10-20 g every 2-5 days as tolerated.

Chronic encephalopathy is treated by restriction of dietary protein, avoidance of constipation, and elimination of sedatives, diuretics, and tranquilizers. To avoid protein depletion, protein intake must not be chronically reduced below 50 g/d. Vegetable protein in the diet is tolerated better than animal protein. Lactulose, a disaccharide unaffected by intestinal enzymes, is the drug of choice for long-term control. When given orally (20-30 g three or four times daily), it reaches the colon, where it stimulates bacterial anabolism (which increases ammonia uptake) and inhibits bacterial enzymes (which decreases the generation of nitrogenous toxins). Its effect is independent of colonic pH. A related compound outside the United States, lactitol (β -galactoside sorbitol), is also effective and appears to work faster. As a powder, it is easier to use than liquid lactulose. Intermittent courses of oral neomycin or metronidazole may be given if lactulose therapy and preventive measures are inadequate.

HEPATIC ABSCESS

Hepatic abscesses may be bacterial, parasitic, or fungal in origin. In the United States, pyogenic abscesses are the most common, followed by amebic abscesses (see Chapter 8). Unless otherwise indicated, the remarks in this section refer to bacterial abscesses.

Cases are about evenly divided between those with a single abscess and those with multiple abscesses. About 90% of right lobe abscesses are solitary, while only 10% of left lobe abscesses are solitary.

In most cases, the development of a hepatic abscess follows a suppurative process elsewhere in the body. Many abscesses are due to direct spread from biliary infections such as empyema of the gallbladder or protracted cholangitis. Abdominal infections such as appendicitis or diverticulitis may spread through the portal vein to involve the liver with abscess formation. About 40% of patients have an

underlying malignancy. Other cases develop after generalized sepsis from bacterial endocarditis, renal infection, or pneumonitis. In 25% of cases, no antecedent infection can be documented (cryptogenic abscesses). Rare causes include secondary bacterial infection of an amebic abscess, hydatid cyst, or congenital hepatic cyst.

In most cases, the organism is of enteric origin.

Escherichia coli, *Klebsiella pneumoniae*, bacteroides, enterococci (eg, *Streptococcus faecalis*), anaerobic streptococci (eg, *Peptostreptococcus*), and microaerophilic streptococci are most common. Staphylococci, hemolytic streptococci, or other gram-positive organisms are usually found if the primary infection is bacterial endocarditis or pneumonitis.

► Clinical Findings

A. Symptoms and Signs

When liver abscess develops in the course of another intra-abdominal infection such as diverticulitis, it is accompanied by increasing toxicity, higher fever, jaundice, and a generally deteriorating clinical picture. Right upper quadrant pain and chills may appear.

In other cases, the diagnosis is much less obvious, since the illness develops insidiously in a previously healthy person. In these, the first symptoms are usually malaise and fatigue, followed after several weeks by fever. Epigastric or right upper quadrant pain is present in about half of cases. The pain may be aggravated by motion or may be referred to the right shoulder.

The course of fever is often erratic, and spikes to 40-41°C are common. Chills are present in about 25% of cases. The liver is usually enlarged and may be tender to palpation. If tenderness is severe, the condition may be confused with cholecystitis.

Jaundice is unusual in solitary abscesses unless the patient's condition is worsening. Jaundice is often present in patients with multiple abscesses and primary disease in the biliary tree and in general is a bad prognostic sign.

B. Laboratory Findings

Leukocytosis is present in most cases and is usually over 15,000/ μ L. A small group of patients, usually the most seriously ill, may fail to develop leukocytosis. Anemia is present in most. The average hematocrit is 33%.

Serum bilirubin is usually normal except in patients with multiple abscesses or biliary obstruction or when hepatic failure has supervened. Alkaline phosphatase is often elevated even in the presence of a normal bilirubin.

C. Imaging Studies

X-ray changes present in the right lung in about one-third of cases consist of basilar atelectasis or pleural effusion. The right diaphragm may be elevated and less mobile than the left.

Plain films of the abdomen are usually normal or show only hepatomegaly. In a few patients, an air-fluid level in the region of the liver reveals the presence and location of the abscess. Distortion of the contour of the stomach on upper gastrointestinal series may be seen with large abscesses involving the left lobe.

Ultrasound and CT scans are the most useful diagnostic tests, providing accurate information regarding the presence, size, number, and location of abscesses within the liver. CT scans have the added advantage of being able to demonstrate abscesses or neoplasms elsewhere in the abdomen. The radioisotope liver scintiscan is able to demonstrate most liver abscesses but is nonspecific, gives little other useful information, and is therefore not helpful.

► Differential Diagnosis

In many cases, early findings may be so vague that hepatic abscess is not even considered. The multiple other causes of malaise, weight loss, and anemia would enter into the differential diagnosis. With spiking fevers, one must consider all the causes of fever of unknown origin. Failure to entertain the idea of hepatic abscess and to obtain the necessary scans leads to most errors in diagnosis.

Once imaging tests have demonstrated the abscess, the responsible organisms must be identified. Amebiasis should be considered in cases of a solitary abscess. Compared with amebic abscesses, pyogenic liver abscesses are seen more often in patients older than 50 years and are associated with jaundice, pruritus, sepsis, a palpable mass, and elevated bilirubin and alkaline phosphatase levels. Patients with amebic abscesses more often have been to an endemic area and have abdominal pain and tenderness, diarrhea, hepatomegaly, and positive serologic tests for amebiasis.

► Complications

Intrahepatic spread of infection may create multiple additional abscesses and is responsible for some failures after treatment of an apparently solitary abscess. As the untreated abscess expands, rupture may occur in the pleural or peritoneal cavity, usually with catastrophic results. Septicemia and septic shock are common terminal complications of diffuse hepatic infection. Hepatic failure may develop in addition to uncontrolled sepsis, or it may predominate over signs of infection.

Hemobilia may follow bleeding from the vascular wall into the abscess cavity. In this case, hepatic artery embolization or ligation may be required to control bleeding.

► Treatment

Antibiotics should be started promptly. Initial coverage, before culture results are available, should be adequate for *E coli*, *K pneumoniae*, bacteroides, enterococci, and anaerobic streptococci and consequently would usually include an

aminoglycoside, clindamycin or metronidazole, and ampicillin. The regimen may be modified later according to the results of cultures.

About 80% or more of patients with liver abscesses are adequately treated by drainage catheters inserted percutaneously under ultrasound or CT guidance. Whether the patient has a single abscess or multiple abscesses, this is usually the most appropriate initial therapy. The catheters can be removed in 1-2 weeks after output becomes nonpurulent and scant.

In about 40% of patients, the catheters do not drain well following initial placement and must be repositioned. The principal advantage of percutaneous drainage is lower morbidity compared to open drainage, although not necessarily lower mortality. It is easier to provide thorough drainage surgically, so when difficulties are encountered with percutaneous drainage, laparotomy should be performed promptly. Surgical intervention is more often necessary in cases of multiple, loculated collections or when the abscess cavity contains a large amount of necrotic debris. In such cases, open debridement should be considered early. Likewise, early surgical intervention is indicated for patients who are seriously ill (APACHE II score ≥ 15). Rarely, multiple abscesses are confined to a single lobe and can be cured by lobectomy. Biliary obstruction or other causes of sepsis must also be corrected.

► Prognosis

The overall mortality rate of 15% is more closely related to the underlying disease than to any other factor. The mortality rate is about 40% in patients with malignant disease. Pleural effusion, leukocytosis over 20,000/ μL , hypoalbuminemia, and polymicrobial infection correlate with a poor outcome. In the United States, whether the abscess is solitary or multiple no longer has a major influence on survival, but where benign biliary disease remains a major cause of this disease, multiple hepatic abscesses are associated with a worse prognosis. Death is rare in patients with a cryptogenic liver abscess.

MULTIPLE CHOICE QUESTIONS

- All of the following are true about the blood supply to the liver, except
 - The portal vein is formed by the confluence of the splenic and superior mesenteric veins at the level of the second lumbar vertebra behind the head of the pancreas.

- B. The common hepatic artery arises from the celiac axis, ascends in the hepatoduodenal ligament, and gives rise to the right gastric, gastroduodenal, and proper hepatic arteries.
 - C. In the hepatoduodenal ligament, the portal vein lies dorsal and slightly medial to the common bile duct.
 - D. A replaced right hepatic artery typically arises from the inferior mesenteric artery and courses posteriorly and to the right of the common bile duct within the porta hepatis.
 - E. A replaced left hepatic artery typically arises from the left gastric artery.
2. The Child–Pugh classification of functional status in liver disease does not include
- A. Prothrombin time
 - B. Serum albumin
 - C. Encephalopathy
 - D. Serum sodium
 - E. Serum bilirubin
3. Blunt trauma to the liver
- A. Requires operative management in 85% of patients
 - B. With a laceration 4-cm deep but not affecting the major vasculature is a Grade III lesion
 - C. Is involved in approximately 20% of all trauma admissions
 - D. Is more common in the left liver than the right
 - E. Is best evaluated acutely by MRI to define the ductal anatomy
4. Portal hypertension
- A. In the United States, is most often caused by cirrhosis
 - B. Is defined as a hepatic venous pressure gradient (the difference between portal-vein pressure and hepatic-vein pressure) greater than 25 mm Hg
 - C. Is caused by Budd–Chiari syndrome in about 25% of cases in the United States
 - D. Due to hepatic venous thrombosis causes isolated splenic venous hypertension (sinistral or left-sided portal hypertension)
 - E. Requires operative management in most patients
5. Management of acute bleeding from esophageal varices
- A. Can include transecting and anastomosing the mid-esophagus with an end-to-end stapler
 - B. Should include urgent operation in most patients
 - C. Should include controlling hemorrhage as expeditiously and simply as possible
 - D. Is commonly required in the management of chronic pancreatitis
 - E. Should reserve invasive procedures for patients who have required more than 15 units blood transfusion

Biliary Tract

Gerard M. Doherty, MD

EMBRYOLOGY & ANATOMY

The anlage of the biliary ducts and liver consists of a diverticulum that appears on the ventral aspect of the foregut in 3 mm embryos. The cranial portion becomes the liver; a caudal bud forms the ventral pancreas; and an intermediate bud develops into the gallbladder. Originally hollow, the hepatic diverticulum becomes a solid mass of cells that later recanalizes to form the ducts. The smallest ducts—the bile canaliculi—first appear as a basal network between the primitive hepatocytes that eventually expands throughout the liver (Figure 25-1). Numerous microvilli increase the canalicular surface area. Bile secreted here passes through the interlobular ductules (canals of Hering) and the lobar ducts and then into the hepatic duct in the hilum. In most cases, the common hepatic duct is formed by the union of a single right and left duct, but in 25% of individuals, the anterior and posterior divisions of the right duct join the left duct separately. The origin of the common hepatic duct is close to the liver but always outside its substance. It runs about 4 cm before joining the cystic duct to form the common bile duct. The common duct begins in the hepatoduodenal ligament, passes behind the first portion of the duodenum, and runs in a groove on the posterior surface of the pancreas before entering the duodenum. Its terminal 1 cm is intimately adherent to the duodenal wall. The total length of the common duct is about 9 cm.

In 80%-90% of individuals, the main pancreatic duct joins the common duct to form a common channel about 1-cm long. The intraduodenal segment of the duct is called the hepatopancreatic ampulla, or ampulla of Vater.

The gallbladder is a pear-shaped organ adherent to the undersurface of the liver in a groove separating the right and left lobes. The fundus projects 1-2 cm below the hepatic edge and can often be felt when the cystic or common duct is obstructed. It rarely has a complete peritoneal covering, but when this variation does occur, it predisposes to infarction by torsion. The gallbladder holds about 50 mL of bile when fully

distended. The neck of the gallbladder tapers into the narrow cystic duct, which connects with the common duct. The lumen of the cystic duct contains a thin mucosal septum, the spiral valve of Heister that offers mild resistance to bile flow. In 75% of persons, the cystic duct enters the common duct at an angle. In the remainder, it runs parallel to the hepatic duct or winds around it before joining the common duct (Figure 25-2).

In the hepatoduodenal ligament, the hepatic artery is to the left of the common duct and the portal vein is posterior and medial. The right hepatic artery usually passes behind the hepatic duct and then gives off the cystic artery before entering the right lobe of the liver, but variations are common.

The mucosal epithelium of the bile ducts varies from cuboidal in the ductules to columnar in the main ducts. The gallbladder mucosa is thrown into prominent ridges when the organ is collapsed, and these flatten during distention. The tall columnar cells of the gallbladder mucosa are covered by microvilli on their luminal surface. Wide channels, which play an important role in water and electrolyte absorption, separate the individual cells.

The walls of the bile ducts contain only small amounts of smooth muscle, but the termination of the common duct is enveloped by a complex sphincteric muscle. The gallbladder musculature is composed of interdigitated bundles of longitudinal and spirally arranged fibers.

The biliary tree receives parasympathetic and sympathetic innervation. The former contains motor fibers to the gallbladder and secretory fibers to the ductal epithelium. The afferent fibers in the sympathetic nerves mediate the pain of biliary colic.

PHYSIOLOGY

► Bile Flow

Bile is produced at a rate of 500-1500 mL/d by the hepatocytes and the cells of the ducts. Active secretion of bile salts into the biliary canaliculus is responsible for most of the

▲ **FIGURE 25-1.** Scanning electron photomicrograph of a hepatic plate with adjacent sinusoids and sinusoidal microvilli and a bile canaliculus running in the center of the liver cells. Although their boundaries are indistinct, about four hepatocytes constitute the section of the plate in the middle of the photograph. Occasional red cells are present within the sinusoids. (Reduced from $\times 2000$.) (Courtesy of Dr James Boyer.)

volume of bile and its fluctuations. Na^+ and water follow passively to establish isosmolality and electrical neutrality. Lecithin and cholesterol enter the canaliculus at rates that correlate with variations in bile salt output. Bilirubin and a number of other organic anions—estrogens, sulfobromophthalein, etc—are actively secreted by the hepatocyte by a different transport system from that which handles bile salts.

The columnar cells of the ducts add a fluid rich in HCO_3^- to that produced in the canaliculus. This involves active secretion of Na^+ and HCO_3^- by a cellular pump stimulated by secretin, VIP, and cholecystokinin (CCK). K^+ and water are distributed passively across the ducts (Figure 25-3).

Between meals, bile is stored in the gallbladder, where it is concentrated at rates of up to 20% per hour. Na^+ and either HCO_3^- or Cl^- are actively transported from its lumen during absorption. The changes in composition brought about by concentration are shown in Figure 25-4.

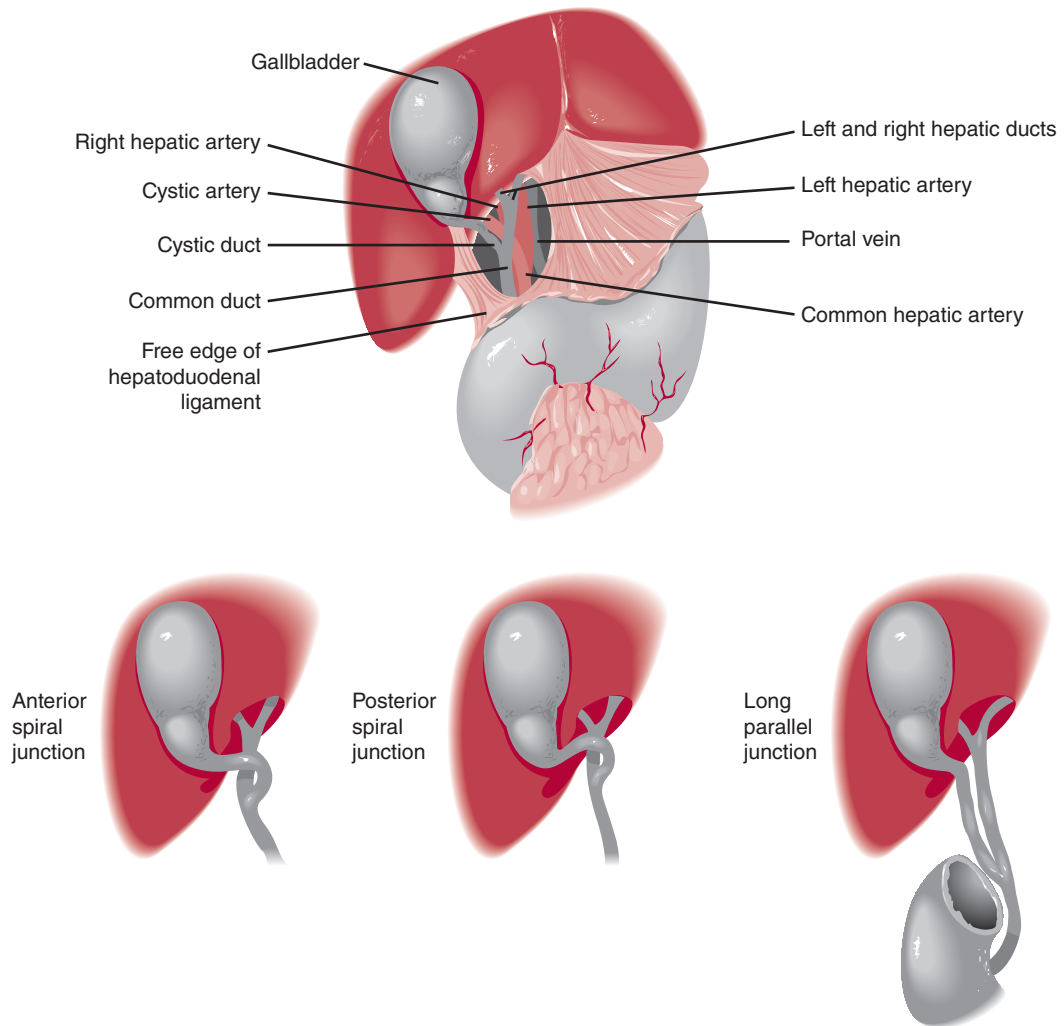

Three factors regulate bile flow: hepatic secretion, gallbladder contraction, and choledochal sphincteric resistance. In the fasting state, pressure in the common bile duct is 5-10 $\text{cm H}_2\text{O}$, and bile produced in the liver is diverted into the gallbladder. After a meal, the gallbladder contracts, the sphincter relaxes, and bile is forced into the duodenum in

squirts as ductal pressure intermittently exceeds sphincteric resistance. During contraction, pressure within the gallbladder reaches 25 $\text{cm H}_2\text{O}$ and that in the common bile duct 15-20 $\text{cm H}_2\text{O}$.

CCK is the major physiologic stimulus for postprandial gallbladder contraction and relaxation of the sphincter, but vagal impulses facilitate its action. CCK is released into the bloodstream from the mucosa of the small bowel by fat or lipolytic products in the lumen. Amino acids and small polypeptides are weaker stimuli, and carbohydrates are ineffective. Bile flow during a meal is augmented by turnover of bile salts in the enterohepatic circulation and stimulation of ductal secretion by secretin, VIP, and CCK. Motilin stimulates episodic partial gallbladder emptying in the interdigestive phase.

► Bile Salts & the Enterohepatic Circulation

Bile salts, lecithin, and cholesterol comprise about 90% of the solids in bile, the remainder consisting of bilirubin, fatty acids, and inorganic salts. Gallbladder bile contains about 10% solids and has a bile salt concentration between 200 and 300 mmol/L (Figure 25-4).

▲ **FIGURE 25-2.** Anatomy of the gallbladder and variations in anatomy.

Bile salts are steroid molecules formed from cholesterol by hepatocytes. The rate of synthesis is under feedback control and can be increased a maximum of about 20-fold. Two primary bile salts—cholate and chenodeoxycholate—are produced by the liver. Before excretion into bile, they are conjugated with either glycine or taurine, which enhances water solubility. Intestinal bacteria alter these compounds to produce the secondary bile salts, deoxycholate and lithocholate. The former is reabsorbed and enters bile, but lithocholate is insoluble and is excreted in the stool. Bile is composed of 40% cholate, 40% chenodeoxycholate, and 20% deoxycholate, conjugated with glycine or taurine in a ratio of 3:1.

The functions of bile salts are: (1) to induce the flow of bile, (2) to transport lipids, and (3) to bind calcium ions in

bile. The importance of the last of these is unknown. Bile acid molecules are amphipathic—that is, they have hydrophilic and hydrophobic poles. In bile, they form multimolecular aggregates called micelles in which the hydrophilic poles become aligned to face the aqueous medium. Water-insoluble lipids, such as cholesterol, can be dissolved within the hydrophobic centers of bile salt micelles. Molecules of lecithin, a water-insoluble but polar lipid, aggregate into hydrated bilayers that form vesicles in bile, and they also become incorporated into bile acid micelles to form mixed micelles. Mixed micelles have an increased lipid-carrying capacity compared with pure bile acid micelles. Cholesterol in bile is transported within the phospholipid vesicles and the bile salt micelles.

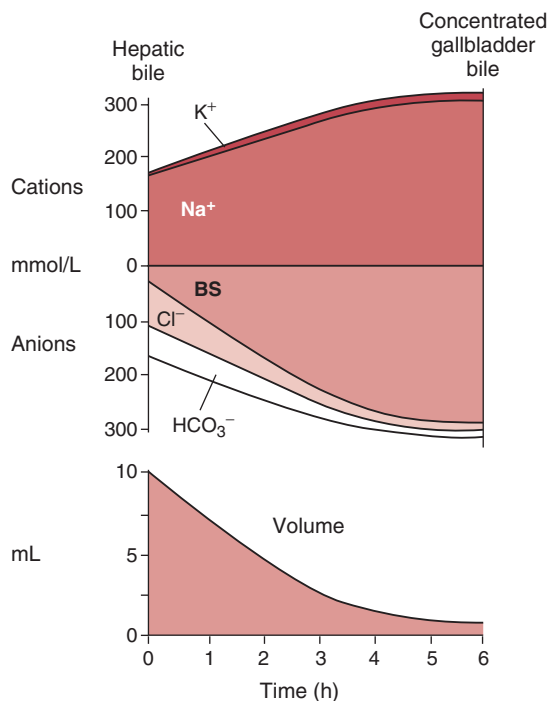

▲ **FIGURE 25-3.** Bile formation. Solid lines into the ductular lumen indicate active transport; dotted lines represent passive diffusion.

Bile salts remain in the intestinal lumen throughout the jejunum, where they participate in fat digestion and absorption (Figure 25-5). Upon reaching the distal small bowel, they are reabsorbed by an active transport system located in the terminal 200 cm of ileum. More than 95% of bile salts arriving from the jejunum are transferred by this process into portal vein blood; the remainder enters the colon, where they are converted to secondary bile salts. The entire bile salt pool of 2.5-4 g circulates twice through the enterohepatic circulation during each meal, and six to eight cycles are made each

day. The normal daily loss of bile salts in the stool amounts to 10%-20% of the pool and is restored by hepatic synthesis.

► Bilirubin

About 250-300 mg of bilirubin is excreted each day in the bile, 75% of it from breakdown of red cells in the reticuloendothelial system and 25% from turnover of hepatic heme and hemoproteins. First, heme is liberated from hemoglobin, and the iron and globin are removed for reuse by the organism.

▲ **FIGURE 25-4.** Changes in gallbladder bile composition with time. (Courtesy of J Dietschy.)

Biliverdin, the first pigment formed from heme, is reduced to unconjugated bilirubin, the indirect-reacting bilirubin of the van den Bergh test. Unconjugated bilirubin is insoluble in water and is transported in plasma bound to albumin.

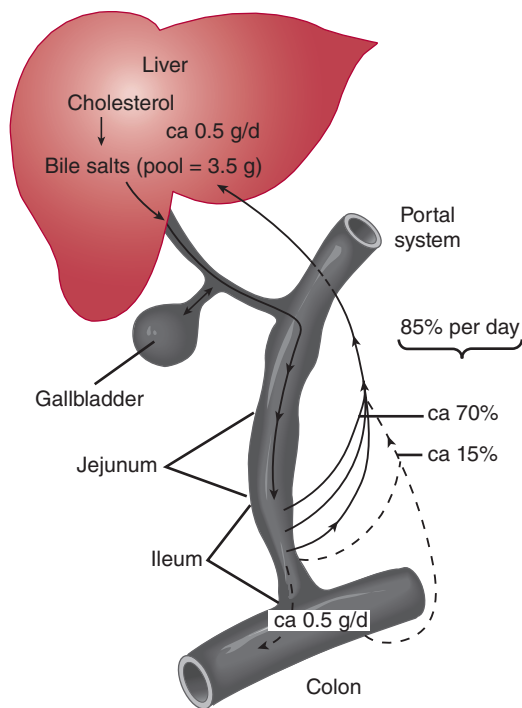

Unconjugated bilirubin is extracted from blood by hepatocytes, where it is conjugated with glucuronic acid to form bilirubin diglucuronide, the water-soluble direct bilirubin. Conjugation is catalyzed by glucuronyl transferase, an enzyme on the endoplasmic reticulum. Bilirubin is transported within the hepatocyte by cytosolic binding proteins, which rapidly deliver the molecule to the canalicular membrane for active secretion into bile. Within bile, conjugated bilirubin is largely transported in association with mixed lipid micelles.

After entering the intestine, bilirubin is reduced by intestinal bacteria to several compounds known as urobilinogens, which are subsequently oxidized and converted to pigmented urobilins. The term urobilinogen is often used to refer to both urobilins and urobilinogens.

DIAGNOSTIC EXAMINATION OF THE BILIARY TREE

► Plain Abdominal Film

The posteroanterior supine view of the abdomen will show gallstones in the 10%-15% of cases when they are radiopaque.

▲ **Figure 25-5.** Enterohepatic circulation of bile salts. (Courtesy of M Tyrer.)

The bile itself sometimes contains sufficient calcium (milk of calcium bile) to be seen. An enlarged gallbladder can occasionally be identified as a soft tissue mass in the right upper quadrant indenting an air-filled hepatic flexure.

In several types of biliary disease, the diagnosis may be suggested by air seen in the bile ducts on a plain film. This usually signifies the presence of a biliary-intestinal fistula (from disease or surgery) but also occurs rarely in severe cholangitis, emphysematous cholecystitis, and biliary ascariasis.

► Percutaneous Transhepatic Cholangiography

Percutaneous transhepatic cholangiography (THC, PTC) is performed by passing a fine needle through the right-lower rib cage and the hepatic parenchyma and into the lumen of a bile duct. Water-soluble contrast material is injected, and x-ray films are taken.

The technical success is related to the degree of dilatation of the intrahepatic bile ducts. THC is especially valuable in demonstrating the biliary anatomy in patients with benign biliary strictures, malignant lesions of the proximal bile duct, or when endoscopic retrograde cholangiopancreatography (ERCP) (see later) has been unsuccessful. Failure of the contrast medium to enter a duct does not prove that obstruction is absent. Virtually all patients should be

premedicated with antibiotics regardless of whether they have cholangitis—septic shock has been produced by sudden inoculation of organisms from bile into the systemic circulation. Otherwise, the contraindications are the same as for percutaneous liver biopsy.

► Endoscopic Retrograde Cholangiopancreatography

ERCP involves cannulating the sphincter of Oddi under direct vision through a side-viewing duodenoscope. It requires special training involving more than familiarity with the use of fiberoptic endoscopes. Usually it is possible to opacify the pancreatic as well as the bile ducts. It is the preferred method of examining the biliary tree in patients with presumed choledocholithiasis or obstructing lesions in the periampullary region, and provides access for therapeutic intervention as well.

► Ultrasound

Ultrasonography is both sensitive and specific in detecting gallbladder stones and dilatation of bile ducts. In the investigation of gallbladder disease, false-positive diagnoses for stones are rare, and false-negative reports owing to small stones or a contracted gallbladder occur in only 5% of patients examined by real time ultrasound. Ultrasound usually misses stones in the common duct.

Dilatation of bile ducts in a jaundiced patient indicates bile duct obstruction, but it is fairly common for the ducts to be normal in the presence of obstruction. When ultrasound shows dilated ducts, THC will nearly always be technically successful.

The ultrasonographer occasionally reports that the gallbladder contains “sludge.” This material is sonographically opaque, does not cast an acoustic shadow, and forms a dependent layer in the gallbladder. On clinical analysis, it is a fine precipitate of calcium bilirubinate. Sludge may accompany gallstone disease or may be a solitary finding. It is observed in a variety of clinical settings, many of which are characterized by gallbladder stasis (eg, prolonged fasting). By itself, sludge is not an indication for cholecystectomy.

► Radionuclide Scan (HIDA Scan)

Technetium 99m-labeled derivatives of iminodiacetic acid (IDA) are excreted in high concentration in bile and produce excellent gamma camera images. Following intravenous injection of the radionuclide, imaging of the bile ducts and gallbladder normally appears within 15-30 minutes and of the intestine within 60 minutes. In patients with acute right upper quadrant pain and tenderness, a good image of the bile duct accompanied by no image of the gallbladder indicates cystic duct obstruction and strongly supports a diagnosis of acute cholecystitis. The test is easy to perform

and is occasionally a useful method of confirming this diagnosis.

JAUNDICE

Jaundice is categorized as prehepatic, hepatic, or posthepatic, depending upon the site of the underlying disease. Hemolysis, the most common cause of prehepatic jaundice, involves increased production of bilirubin. Less common causes of prehepatic jaundice are Gilbert disease and the Crigler–Najjar syndrome.

Hepatic parenchymal jaundice is subdivided into hepatocellular and cholestatic types. The former includes acute viral hepatitis and chronic alcoholic cirrhosis. Some cases of intrahepatic cholestasis may be indistinguishable clinically and biochemically from cholestasis due to bile duct obstruction. Primary biliary cirrhosis, toxic drug jaundice, cholestatic jaundice of pregnancy, and postoperative cholestatic jaundice are the most common forms.

Extrahepatic jaundice most often results from biliary obstruction by a malignant tumor, choledocholithiasis, or biliary stricture. Pancreatic pseudocyst, chronic pancreatitis, sclerosing cholangitis, metastatic cancer, and duodenal diverticulitis are less common causes.

The cause of jaundice can be ascertained in the majority of patients from clinical and laboratory findings alone. In the remainder, THC or ERCP and ultrasound or CT scans will be necessary. The indications for these tests are discussed in later sections.

► History

The age, gender, and parity of the patient and possible deleterious habits should be noted. Most cases of infectious hepatitis occur in patients under age 30 years. A history of drug addiction may suggest serum hepatitis transmitted by shared hypodermic equipment. Chronic alcoholism can usually be documented in patients with cirrhosis, and acute jaundice in alcoholics usually follows a recent binge. Obstructing gallstones or tumors are more common in older people.

Patients with jaundice due to choledocholithiasis may have associated biliary colic, fever, and chills, and may report previous similar attacks. The pain in malignant obstruction is deep-seated and dull and may be affected by changes in position. Pain in the region of the liver is frequently experienced in the early stages of viral hepatitis and acute alcoholic liver injury. The patient with extrahepatic obstruction may report that stools have become lighter in color and the urine dark.

Cholestatic diseases are often accompanied by pruritus—a source of severe discomfort in some cases. Pruritus may precede jaundice, but usually it appears at about the same time. The itching is most severe on the extremities and is aggravated by warm, humid weather. The cause remains obscure; itching does not correlate with bile salt levels in the skin, as was once believed.

► Physical Examination

Hepatomegaly is common in both hepatic and posthepatic jaundice. In some cases, palpation of the liver may suggest cirrhosis or metastatic cancer, but impressions of this kind are unreliable. Secondary stigmata of cirrhosis usually accompany acute alcoholic jaundice; liver palms, spider angiomas, ascites, collateral veins on the abdominal walls, and splenomegaly suggest cirrhosis. A nontender, palpable gallbladder in a jaundiced patient suggests malignant obstruction of the common duct (Courvoisier's sign), but absence of a palpable gallbladder is of little significance in ruling out cancer.

► Laboratory Tests

In hemolytic disease, the increased bilirubin is principally in the unconjugated indirect fraction. Since unconjugated bilirubin is insoluble in water, the jaundice in hemolysis is acholuric. The total bilirubin in hemolysis rarely exceeds 4-5 mg/dL, because the rate of excretion increases as the bilirubin concentration rises, and a plateau is quickly reached. Greater values suggest concomitant hepatic parenchymal disease.

Jaundice due to hepatic parenchymal disease is characterized by elevations of both conjugated and unconjugated serum bilirubin. An increase in the conjugated fraction always signifies disease within the hepatobiliary system. The direct bilirubin predominates in about half of cases of hepatic parenchymal disease.

Both intrahepatic cholestasis and extrahepatic obstruction raise the direct bilirubin fraction, though the indirect fraction also increases somewhat. Since direct bilirubin is water-soluble, bilirubinuria develops. With complete extrahepatic obstruction, the total bilirubin rises to a plateau of 25-30 mg/dL, at which point loss in the urine equals the additional daily production. Higher values suggest concomitant hemolysis or decreased renal function. Obstruction of a single hepatic duct does not usually cause jaundice.

In extrahepatic obstruction caused by neoplasms, the serum bilirubin usually exceeds 10 mg/dL, and the average concentration is about 18 mg/dL. Obstructive jaundice due to common duct stones often produces transient bilirubin increases in the range of 2-4 mg/dL, and the level rarely exceeds 15 mg/dL. Serum bilirubin values in patients with alcoholic cirrhosis and acute viral hepatitis vary widely in relation to the severity of the parenchymal damage.

In extrahepatic obstruction, modest rises of AST levels are common, but levels as high as 1000 units/L are seen (though rarely) in patients with common duct stones and cholangitis. In the latter patients, the high values last for only a few days and are associated with increases in LDH concentrations. In general, AST levels above 1000 units/L suggest viral hepatitis.

Serum alkaline phosphatase comes from three sites: liver, bone, and intestine. In normal subjects, liver and bone contribute about equally, and the intestinal contribution is small.

Hepatic alkaline phosphatase is a product of the epithelial cells of the cholangioles, and increased alkaline phosphatase levels associated with liver disease are the result of increased enzyme production. Alkaline phosphatase levels go up with intrahepatic cholestasis, cholangitis, or extrahepatic obstruction. Since the elevation is from overproduction, it may occur with focal hepatic lesions in the absence of jaundice. For example, a solitary hepatic metastasis or pyogenic abscess in one lobe or a tumor obstructing only one hepatic duct may fail to obstruct enough hepatic parenchyma to cause jaundice but usually is associated with increased alkaline phosphatase. In cholangitis with incomplete extrahepatic obstruction, serum bilirubin levels may be normal or mildly elevated, but serum alkaline phosphatase may be very high.

Bone disease may complicate the interpretation of abnormal alkaline phosphatase levels (Figure 25-6). If one suspects that the increased serum enzyme may be from bone, serum calcium, phosphorus, and 5'-nucleotidase or leucine aminopeptidase levels should be determined. These last two enzymes are also produced by cholangioles and are elevated in cholestasis, but their serum concentrations remain unchanged with bone disease.

Changes in serum protein levels may reflect hepatic parenchymal dysfunction. In cirrhosis, the serum albumin falls and the globulins increase. Serum globulins reach high

▲ **Figure 25-6.** Range of alkaline phosphatase values in various hepatobiliary disorders.

values in some patients with primary biliary cirrhosis. Biliary obstruction generally produces no changes unless secondary biliary cirrhosis has developed.

► Diagnosis

The principal diagnostic objective is to distinguish surgical (obstructive) from nonsurgical jaundice. The history, physical examination, and basic laboratory data allow an accurate diagnosis to be made in most cases without invasive tests (eg, liver biopsy, cholangiograms).

Since most jaundiced patients are not critically ill when first examined, diagnosis and therapy may be conducted in a stepwise fashion, with each test selected according to the information available at that point. Only severe or worsening cholangitis requires urgent intervention. If the jaundice is mild and recent, it often passes within 24-48 hours, at which time an ultrasound scan can be ordered to verify gallstone disease.

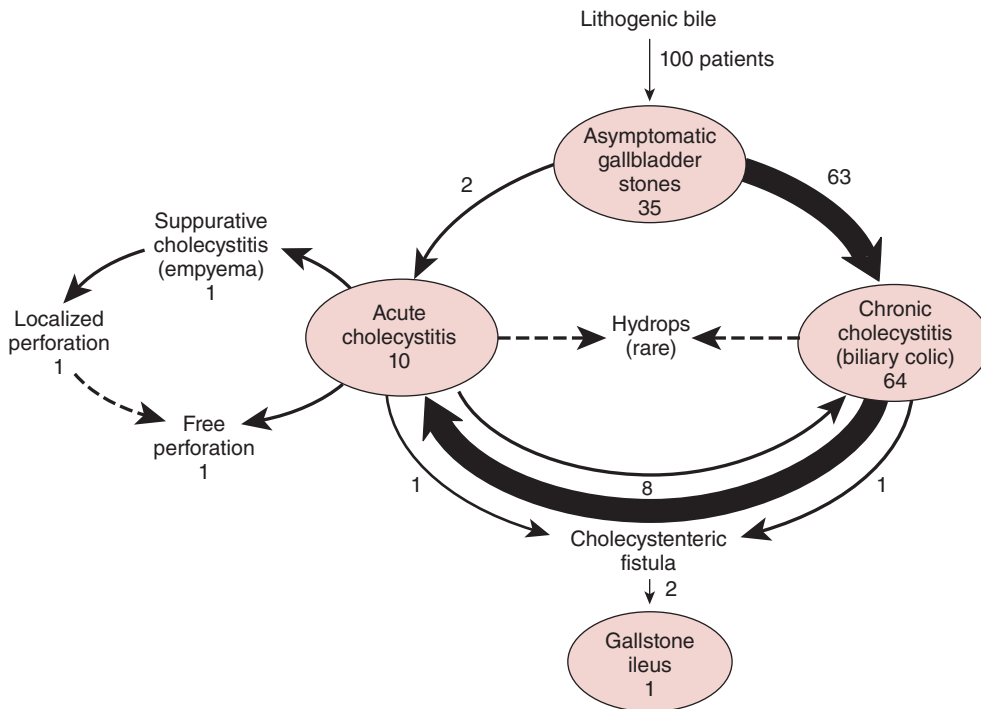

In patients with persistent jaundice, the first test is usually an ultrasound scan, which may show dilated intrahepatic bile ducts (indicating ductal obstruction) or gallbladder stones. The lesion may be further delineated by ERCP or THC. ERCP is preferable when the lower end of the duct is believed to be obstructed (eg, suspected carcinoma of the pancreas or other periampullary tumors). THC is

usually preferred for proximal lesions (eg, biliary stricture, neoplasm of the bifurcation of the hepatic ducts), because it gives better opacification of the ducts proximal to the obstruction and therefore provides more information that can be used in planning surgery. If the clinical presentation suggests neoplastic obstruction, a CT scan could be selected in preference to an ultrasound scan, because CT gives better definition of mass lesions while also demonstrating the presence and general location of bile duct obstruction.

If ultrasound or CT scans suggest biliary obstruction, a decision must be made about whether cholangiograms are indicated. In general, patients with gallstone disease do not require preoperative cholangiograms, whereas cholangiograms would be routine in patients with neoplastic obstruction, benign biliary stricture, or rare or unknown causes of obstructive jaundice.

PATHOGENESIS OF GALLSTONES

More than 20 million people in the United States have gallstones in their gallbladders; about 300,000 operations are performed annually for this disease, and at least 6000 deaths result from its complications or treatment. The incidence of gallstones rises with age, so that between 50 and 65 years of age about 20% of women and 5% of men are affected (Figure 25-7).

▲ Figure 25-7. The natural history of gallbladder stones. The numbers approximate the percentage of patients in each category. Note that most patients with acute cholecystitis have previously had biliary colic.

The gallstones in 75% of patients are composed predominantly (70%-95%) of cholesterol and are called cholesterol stones. The remaining 25% are pigment stones. Regardless of composition, all gallstones give rise to similar clinical sequelae.

► Cholesterol Gallstones

Cholesterol gallstones result from secretion by the liver of bile supersaturated with cholesterol. Influenced by various factors present in bile, the cholesterol precipitates from solution and the newly formed crystals grow to macroscopic stones. Except when the common bile duct is dilated or partially obstructed, the stones in this disease form almost exclusively within the gallbladder. Those found in the ducts usually reach that location after passing through the cystic duct.

The incidence of cholesterol gallstone disease is highest in American Indians, lower in Caucasians, and lowest in blacks, with a twofold gradient from one group to the next. More than 75% of American Indian women over age 40 years are affected. Before puberty, the disease is rare but of equal frequency in both sexes. Thereafter, women are more commonly affected than men until after menopause, when the discrepancy lessens. Hormonal effects are also reflected in the increased incidence of gallstones with multiparity and the increased cholesterol saturation of bile and greater incidence of gallstones following ingestion of oral contraceptives. Obesity is the other major risk factor. The relative risk rises proportionately to the extent of overweight due to a progressively increasing output of cholesterol in bile.

As noted previously, cholesterol is insoluble and in bile must be transported within bile salt micelles and phospholipid (lecithin) vesicles. When the amount of cholesterol in bile exceeds the cholesterol holding capacity, cholesterol crystals begin to precipitate from the phospholipid vesicles.

The secretion of bile salt and cholesterol into bile is linked. Bile salt elutes cholesterol from the hepatocyte membrane during passage into the bile canaliculus. At higher bile salt output levels, the amount of cholesterol relative to bile salt entering bile decreases. This means that during low bile flow (eg, during fasting), bile holding capacity for cholesterol is more saturated than during high bile flow. In fact, almost half of persons in Western cultures have bile supersaturated with cholesterol in the morning after an overnight fast. The bile salt pool in patients with cholesterol gallstone disease is about half the size of that of normal subjects, but this is a result of the gallstone disease (eg, gallstones displace bile in the gallbladder) and not a cause.

The occurrence of cholesterol gallstone disease requires cholesterol supersaturation of bile, but that in itself is not sufficient. Cholesterol in supersaturated bile from individuals without gallstone disease precipitates spontaneously at a much slower rate than does the cholesterol in similar bile

from patients with gallstones. Furthermore, among individuals with supersaturated bile, only those with gallstone disease demonstrate cholesterol crystal formation *in vivo*. These observations are the result of specific bile proteins that either stabilize or destabilize cholesterol-laden phospholipid vesicles. For gallstone formation, the pronucleating factors (eg, immunoglobulin, mucus glycoprotein, fibronectin, orosomucoid) appear to be more important than the antinucleating factors (eg, glycoprotein, apolipoprotein, cytokeratin). Variations in these proteins may be the critical factor determining which of the many individuals with saturated bile develop gallstones.

The fact that gallstones form almost exclusively in the gallbladder even though the composition of hepatic bile is abnormal underscores the important role of the gallbladder in gallstone pathogenesis. This includes concentrating the bile, providing nuclei (eg, small grains of pigment) for crystallization of cholesterol, supplying mucoprotein to paste the stones together, and serving as an area of stasis to allow stone formation and growth.

► Pigment Stones

Pigment stones account for 25% of gallstones in the United States and 60% of those in Japan. Pigment stones are black to dark brown, 2-5 mm in diameter, and amorphous. They are composed of a mixture of calcium bilirubinate, complex bilirubin polymers, bile acids, and other unidentified substances. About 50% are radiopaque, and in the United States they constitute two-thirds of all radiopaque gallstones. The incidence is similar in men and women and in blacks and whites. Pigment stones are rare in American Indians.

Predisposing factors are cirrhosis, bile stasis (eg, a strictured or markedly dilated common duct), and chronic hemolysis. Some patients with pigment stones have increased concentrations of unconjugated bilirubin in their bile. Scanning electron microscopy demonstrates that about 90% of pigment stones are composed of dense mixtures of bacteria and bacterial glycocalyx along with pigment solids. This suggests that bacteria have a primary role in pigment gallstone formation, and it also helps to explain why patients with pigment gallstone disease have sepsis more often than do those with cholesterol gallstone disease. It seems likely that bacterial β -glucuronidase is responsible for deconjugating the soluble bilirubin-digluconide to insoluble unconjugated bilirubin, which subsequently becomes agglomerated by glycocalyx into macroscopic stones.

DISEASES OF THE GALLBLADDER & BILE DUCTS

ASYMPTOMATIC GALLSTONES

Data on the prevalence of gallstones in the United States indicate that only about 30% of people with cholelithiasis

come to surgery. Symptoms of gallstone disease generally do not change in severity. Each year, about 2% of patients with asymptomatic gallstones develop symptoms, usually biliary colic rather than one of the complications of gallstone disease. Patients with chronic biliary colic tend to have symptoms of the same level of severity and frequency. The present practice of operating only on symptomatic patients, leaving the millions without symptoms alone, seems appropriate. A question is often raised about what to advise the asymptomatic patient found to have gallstones during the course of unrelated studies. The presence of either of the following portends a more serious course and should probably serve as a reason for prophylactic cholecystectomy: (1) large stones (> 2 cm in diameter), because they produce acute cholecystitis more often than small stones; and (2) a calcified gallbladder, because it so often is associated with carcinoma. However, most asymptomatic patients have no special features. If coexistent cardiopulmonary or other problems increase the risk of surgery, operation should not be considered. For the average asymptomatic patient, it is not reasonable to make a strong recommendation for cholecystectomy. The tendency, however, is to operate on younger patients and temporize in the elderly.

GALLSTONES & CHRONIC CHOLECYSTITIS (BILIARY COLIC)

ESSENTIALS OF DIAGNOSIS

- ▶ Episodic abdominal pain
- ▶ Dyspepsia
- ▶ Gallstones on cholecystography or ultrasound scan

▶ General Considerations

Chronic cholecystitis is the most common form of symptomatic gallbladder disease and is associated with gallstones in nearly every case. In general, the term cholecystitis is applied whenever gallstones are present regardless of the histologic appearance of the gallbladder. Repeated minor episodes of obstruction of the cystic duct cause intermittent biliary colic and contribute to inflammation and subsequent scar formation. Gallbladders from symptomatic patients with gallstones who have never had an attack of acute cholecystitis are of two types: (1) In some, the mucosa may be slightly flattened, but the wall is thin and unscarred and, except for the stones, appears normal. (2) Others exhibit obvious signs of chronic inflammation, with thickening, cellular infiltration, loss of elasticity, and fibrosis. The clinical history in these two groups cannot always be distinguished, and inflammatory changes may also be found in patients with asymptomatic gallstones.

▶ Clinical Findings

A. Symptoms and Signs

Biliary colic, the most characteristic symptom, is caused by transient gallstone obstruction of the cystic duct. The pain usually begins abruptly and subsides gradually, lasting for a few minutes to several hours. The pain of biliary colic is usually steady—not intermittent, like that of intestinal colic. In some patients, attacks occur postprandially; in others, there is no relationship to meals. The frequency of attacks is quite variable, ranging from nearly continuous trouble to episodes many years apart. Nausea and vomiting may accompany the pain.

Biliary colic is usually felt in the right upper quadrant, but epigastric and left abdominal pain are common, and some patients experience precordial pain. The pain may radiate around the costal margin into the back or may be referred to the region of the scapula. Pain on top of the shoulder is unusual and suggests direct diaphragmatic irritation. In a severe attack, the patient usually curls up in bed, changing position frequently in order to be more comfortable.

During an attack, there may be tenderness in the right upper quadrant, and, rarely, the gallbladder is palpable.

Fatty food intolerance, dyspepsia, indigestion, heartburn, flatulence, nausea, and eructations are other symptoms associated with gallstone disease. Because they are also frequent in the general population, their presence in any given patient may only be incidental to the gallstones.

B. Laboratory Findings

An ultrasound scan of the gallbladder should usually be the first test. Gallstones can be demonstrated in about 95% of cases, and a positive reading for gallstones is almost never in error.

About 2% of patients with gallstone disease have normal ultrasound studies. Therefore, if the clinical suspicion of gallbladder disease is high and these two tests are negative, the patient should be studied by ERCP (to opacify the gallbladder in the search for stones) or duodenal intubation and examination of duodenal bile for cholesterol crystals or bilirubinate granules.

▶ Differential Diagnosis

Gallbladder colic may be strongly suggested by the history, but the clinical impression should always be verified by an ultrasound study. Biliary colic may simulate the pain of duodenal ulcer, hiatal hernia, pancreatitis, and myocardial infarction.

An EKG and a chest x-ray should be obtained to investigate cardiopulmonary disease. It has been suggested that biliary colic may sometimes aggravate cardiac disease, but angina pectoris or an abnormal EKG should rarely be indications for cholecystectomy.

Right-sided radicular pain in the T6-T10 dermatomes may be confused with biliary colic. Osteoarthritic spurs, vertebral lesions, or tumors may be shown on x-rays of the spine or may be suggested by hyperesthesia of the abdominal skin.

An upper gastrointestinal series may be indicated to search for esophageal spasm, hiatal hernia, peptic ulcer, or gastric tumors. In some patients, the irritable colon syndrome may be mistaken for gallbladder discomfort. Carcinoma of the cecum or ascending colon may be overlooked on the assumption that postprandial pain in these conditions is due to gallstones.

► Complications

Chronic cholecystitis predisposes to acute cholecystitis, common duct stones, and adenocarcinoma of the gallbladder. The longer the stones have been present, the higher the incidence of all of these complications. Complications are infrequent, however, and the presence of gallstones is not reason enough for prophylactic cholecystectomy in a person with asymptomatic or mildly symptomatic disease.

► Treatment

A. Medical Treatment

Avoidance of offending foods may be helpful.

1. Dissolution—Cholesterol gallstones in the gallbladder can be dissolved in some cases by chronic treatment with ursodiol, which reduces the cholesterol saturation of bile by inhibiting cholesterol secretion. The resulting undersaturated bile slowly dissolves the solid cholesterol in the gallstones.

Unfortunately, bile salt therapy has marginal efficacy. The gallstones must be small (eg, < 5 mm) and devoid of calcium (ie, nonopaque on CT scans), and the gallbladder must opacify on oral cholecystography (an indication of unobstructed flow of bile between bile duct and gallbladder). About 15% of patients with gallstones are candidates for treatment. Dissolution is achieved within 2 years in about 50% of highly selected patients. Stones recur, however, in 50% of cases within 5 years. In general, dissolution therapy—alone or in conjunction with lithotripsy—is used very rarely except in the prevention of gallstones in susceptible populations, such as following weight loss surgery.

B. Surgical Treatment

Cholecystectomy is indicated in most patients with symptoms. The procedure can be scheduled at the patient's convenience, within weeks or months after diagnosis. Active concurrent disease that increases the risk of surgery should be treated before operation. In some chronically ill patients, surgery should be deferred indefinitely.

Cholecystectomy is most often performed laparoscopically, but when the laparoscopic approach is contraindicated (eg, too many adhesions) or unsuccessful, it may be performed through a laparotomy. The difference consists of 4 fewer days in the hospital and fewer weeks off work when done laparoscopically. Regardless of how it is done, operative cholangiography may be included to evaluate for common duct stones. If stones are found, common duct exploration may be performed (see under choledocholithiasis).

► Prognosis

Serious complications and deaths related to the operation itself are rare. The operative death rate is about 0.1% in patients under age 50 and about 0.5% in patients over age 50. Most deaths occur in patients recognized preoperatively to have increased risks. The operation relieves symptoms in 95% of cases.

ACUTE CHOLECYSTITIS

ESSENTIALS OF DIAGNOSIS

- Acute right upper quadrant pain and tenderness
- Fever and leukocytosis
- Palpable gallbladder in one-third of cases
- Nonopacified gallbladder on radionuclide excretion scan
- Sonographic Murphy sign

► General Considerations

In 80% of cases, acute cholecystitis results from obstruction of the cystic duct by a gallstone impacted in Hartmann's pouch. The gallbladder becomes inflamed and distended, creating abdominal pain and tenderness. The natural history of acute cholecystitis varies, depending on whether the obstruction becomes relieved, the extent of secondary bacterial invasion, the age of the patient, and the presence of other aggravating factors such as diabetes mellitus. Most attacks resolve spontaneously without surgery or other specific therapy, but some progress to abscess formation or free perforation with generalized peritonitis.

The pathologic changes in the gallbladder evolve in a typical pattern. Subserosal edema and hemorrhage and patchy mucosal necrosis are the first changes. Later, PMNs appear. The final stage involves development of fibrosis.

Gangrene and perforation may occur as early as 3 days after onset, but most perforations occur during the second week. In cases that resolve spontaneously, acute inflammation has largely cleared by 4 weeks, but some residual evidence of inflammation may last for several months. About 90% of gallbladders removed during an acute attack show chronic scarring, although many of these patients deny having had any previous symptoms.

The cause of acute cholecystitis is still partially conjectural. Obstruction of the cystic duct is present in most cases, but in experimental animals, cystic duct obstruction does not result in acute cholecystitis unless the gallbladder is filled with concentrated bile or bile saturated with cholesterol. There is also evidence that trauma from gallstones releases phospholipase from the mucosal cells of the gallbladder. This is followed by conversion of lecithin in bile to lysolecithin, which is a toxic compound that may cause more inflammation. Bacteria appear to have a minor role in the early stages of acute cholecystitis, even though most complications of the disease involve suppuration.

About 20% of cases of acute cholecystitis occur in the absence of cholelithiasis (acalculous cholecystitis). Some of these are due to cystic duct obstruction by another process such as a malignant tumor. Rarely, acute acalculous cholecystitis results from cystic artery occlusion or primary bacterial infection by *Escherichia coli*, clostridia, or, occasionally, *Salmonella typhi*. Most cases occur in patients hospitalized with some other illness; acute acalculous cholecystitis is particularly common in trauma victims (civilian or military) and in patients receiving total parenteral nutrition. Small-vessel occlusion occurs early, and unless treatment is given promptly, the disease progresses rapidly to gangrenous cholecystitis and septic complications, at which point the death rate is high.

► Clinical Findings

A. Symptoms and Signs

The first symptom is abdominal pain in the right upper quadrant, sometimes associated with referred pain in the region of the right scapula. In 75% of cases, the patient will have had previous attacks of biliary colic, at first indistinguishable from the present illness. However, in acute cholecystitis, the pain persists and becomes associated with abdominal tenderness. Nausea and vomiting are present in about half of patients, but the vomiting is rarely severe. Mild icterus occurs in 10% of cases. The temperature usually ranges from 38°C to 38.5°C. High fever and chills are uncommon and should suggest the possibility of complications or an incorrect diagnosis.

Right upper quadrant tenderness is present, and in about a third of patients the gallbladder is palpable (often in a position lateral to its normal one). Voluntary guarding during examination may prevent detection of an enlarged

gallbladder. In others, the gallbladder is not enlarged because scarring of the wall restricts distention. If instructed to breathe deeply during palpation in the right subcostal region, the patient experiences accentuated tenderness and sudden inspiratory arrest (Murphy sign).

B. Laboratory Findings

The leukocyte count is usually elevated to 12,000-15,000/mL. Normal counts are common, but if the count goes much above 15,000, one should suspect complications. A mild elevation of the serum bilirubin (in the range of 2-4 mg/dL) is common, presumably owing to secondary inflammation of the common duct by the contiguous gallbladder. Bilirubin values above this range would most likely indicate the associated presence of common duct stones. A mild increase in alkaline phosphatase may accompany the attack. Occasionally, the serum amylase concentration transiently reaches 1000 units/dL or more.

C. Imaging Studies

A plain x-ray of the abdomen may occasionally show an enlarged gallbladder shadow. In 15% of patients, the gallstones contain enough calcium to be seen on the plain film.

Ultrasound scans show gallstones, sludge, and thickening of the gallbladder wall, and the ultrasonographer can determine even better than the clinician whether the point of maximum tenderness is over the gallbladder (ultrasonographic Murphy sign). This last finding is often absent, however, when the gallbladder is gangrenous. Usually, ultrasound is the only test needed to make the diagnosis of acute cholecystitis.

If additional diagnostic information is desirable (eg, if ultrasound is equivocal or negative), a radionuclide excretion scan (eg, HIDA scan) should be performed. This test cannot demonstrate gallstones, but if the gallbladder is imaged, acute cholecystitis is ruled out except in rare cases of acalculous cholecystitis (the test is positive in most cases of acute acalculous cholecystitis). Imaging of the duct but not the gallbladder supports the diagnosis of acute cholecystitis. A few false positives are seen in advanced gallstone disease without acute inflammation and in acute biliary pancreatitis.

► Differential Diagnosis

The differential diagnosis includes other common causes of acute upper abdominal pain and tenderness. An acute peptic ulcer with or without perforation might be suggested by a history of epigastric pain relieved by food or antacids. Most cases of perforated ulcer demonstrate free air under the diaphragm on an x-ray. An emergency upper gastrointestinal series may help.

Acute pancreatitis can be confused with acute cholecystitis, especially if cholecystitis is accompanied by an elevated amylase level. Furthermore, HIDA scans fail to outline the gallbladder

in most cases of acute biliary pancreatitis. Sometimes the two diseases coexist, but pancreatitis should not be accepted as a second diagnosis without specific findings.

Acute appendicitis in patients with a high cecum may closely simulate acute cholecystitis.

Severe right upper quadrant pain with high fever and local tenderness may develop in acute gonococcal perihepatitis (Fitz–Hugh–Curtis syndrome). Clues to the proper diagnosis may be found in tenderness in the adnexa, vaginal discharge that shows gonococci on a Gram-stained smear, and a disparity between the patient's high fever and her general lack of toxicity.

► Complications

The major complications of acute cholecystitis are empyema, gangrene, and perforation.

A. Empyema

In empyema (suppurative cholecystitis), the gallbladder contains frank pus, and the patient becomes more toxic, with high spiking fever (39–40°C, chills, and leukocytosis greater than 15,000/mL. Parenteral antibiotics should be given, and percutaneous cholecystostomy or cholecystectomy should be performed.

B. Perforation

Perforation may take any of three forms: (1) localized perforation with pericholecystic abscess; (2) free perforation with generalized peritonitis; and (3) perforation into an adjacent hollow viscus, with the formation of a fistula. Perforation may occur as early as 3 days after the onset of acute cholecystitis or not until late in the second week. The total incidence of perforation is about 10%.

1. Pericholecystic abscess—Pericholecystic abscess, the most common form of perforation, should be suspected when the signs and symptoms progress, especially when accompanied by the appearance of a palpable mass. The patient often becomes toxic, with fever to 39°C and a leukocyte count above 15,000/mL, but sometimes there is no correlation between the clinical signs and the development of local abscess. Cholecystectomy and drainage of the abscess can be performed safely in many of these patients, but if the patient's condition is unstable, percutaneous cholecystostomy is preferable.

2. Free perforation—Free perforation occurs in only 1%–2% of patients, most often early in the disease when gangrene develops before adhesions wall off the gallbladder. The diagnosis is made preoperatively in less than half of cases. In some patients with localized pain, sudden spread of pain and tenderness to other parts of the abdomen suggests the diagnosis. Whenever it is suspected, free perfora-

tion must be treated by emergency laparotomy. Abdominal paracentesis may be misleading and has proved to be of little diagnostic usefulness. Cholecystectomy should be performed if the patient's condition will permit; otherwise, cholecystostomy is done. The death rate depends partly on whether the cystic duct remains obstructed or the stone becomes dislodged after perforation. The former leads to a purulent peritonitis that is lethal in 20% of cases. In the latter, a true bile peritonitis ensues and over 50% of patients die. The earlier operation is performed, the better the prognosis.

3. Cholecystenteric fistula—If the acutely inflamed gallbladder becomes adherent to adjacent stomach, duodenum, or colon and necrosis develops at the site of one of these adhesions, perforation may occur into the lumen of the gut. The resulting decompression often allows the acute disease to resolve. If the gallbladder stones discharge through the fistula and if they are large enough, they may obstruct the small intestine (gallstone ileus; see below). Rarely, patients vomit gallstones that have entered the stomach through a cholecystogastric fistula. In most patients, the acute attack subsides and the cholecystenteric fistula is clinically unsuspected.

Cholecystenteric fistulas do not usually cause symptoms unless the gallbladder is still partially obstructed by stones or scarring. Neither oral nor intravenous cholangiograms will opacify the gallbladder or the fistula, but the latter may be shown on upper gastrointestinal series, where it must be differentiated from a fistula due to perforated peptic ulcer. Malabsorption and steatorrhea have been reported in isolated cases of cholecystocolonic fistulas. Steatorrhea in this situation could be due either to absence of bile in the proximal bowel following diversion into the colon or, more rarely, to excess bacteria in the upper intestine.

Symptomatic cholecystenteric fistulas should be treated by cholecystectomy and closure of the fistula. The majority is discovered incidentally during cholecystectomy for symptomatic gallbladder disease.

► Treatment

Intravenous fluids should be given to correct dehydration and electrolyte imbalance, and a nasogastric tube should be inserted. For acute cholecystitis of average severity, parenteral cefazolin (2–4 g daily) should be given. Parenteral penicillin (20 million units daily), clindamycin, and an aminoglycoside should be given for severe disease. Single-drug therapy using imipenem is a good alternative.

There are acute options for the treatment of acute cholecystitis. Since the disease resolves with antibiotics and supportive care in about 60% of cases, one approach is to manage the patient expectantly, with a plan to perform elective cholecystectomy after recovery, reserving surgery during the acute attack for those with severe or worsening

disease. This approach is untenable in acute acalculous cholecystitis.

The preferred plan is to perform cholecystectomy in all patients unless there are specific contraindications to operation (eg, serious concomitant disease). Four controlled trials have supported this approach with the following data: (1) the incidence of technical complications is no greater with early surgery; (2) early surgery reduces the total duration of illness by approximately 30 days, length of hospitalization by 5-7 days, and direct medical costs by several thousand dollars; and (3) the death rate is slightly lower with early surgery because of earlier treatment for some patients whose condition would have worsened during expectant management.

The following are the major factors that affect the decision (Figure 25-8): (1) whether the diagnosis is established; (2) the general health of the patient as modified by coexistent disease or the present illness; and (3) signs of local complications of acute cholecystitis. The diagnosis should be clear-cut and the patient optimally prepared; if perforation or empyema is suspected, emergency surgery is indicated.

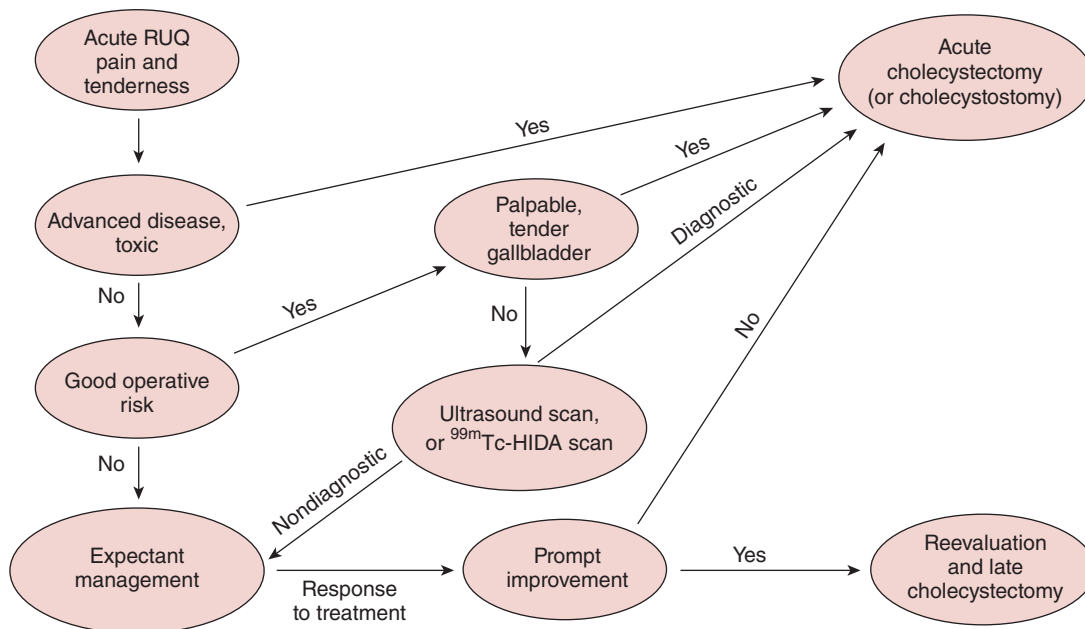

In about 30% of cases, the diagnosis of acute cholecystitis is established but the general condition of the patient is unsatisfactory. If possible, surgery should be postponed in these cases until the ancillary disease is controlled. Expectant management cannot be rigidly adhered to, however, if the manifestations of cholecystitis worsen.

About 10% of patients require emergency treatment. These are generally clinical situations in which the disease

appears to have become complicated or is about to. High fever (39°C), marked leukocytosis (> 15,000/mL), or chills suggest suppurative progression. Acalculous acute cholecystitis should automatically be placed in this category. When the patient's general condition is poor, percutaneous catheter cholecystostomy is the preferable treatment. Patients in better overall health should be treated by cholecystectomy.

The sudden appearance of generalized abdominal pain may indicate free perforation. Appearance of a mass while the patient is under observation may be a sign of local perforation and abscess formation. Changes of this sort are indications for emergency surgery.

Cholecystectomy is the preferable operation in acute cholecystitis, and it can be performed laparoscopically in about 50% of patients. Operative cholangiography should be performed in most cases, and the common bile duct explored if appropriate indications are present (see section on choledocholithiasis). Patients with severe acute cholecystitis who are in poor condition for emergency cholecystectomy should be treated by percutaneous cholecystostomy. Percutaneous cholecystostomy may also be the preferred therapy for acute acalculous cholecystitis. A catheter inserted under ultrasound or CT guidance is allowed to drain the gallbladder of its bile or pus. The resulting decompression controls the acute disease, including any local infection, but the gallstones cannot be removed. Therefore, cholecystectomy should be performed after the patient recovers in order to avoid recurrent attacks. Cholecystectomy is definitive therapy in the patient with acalculous cholecystitis.

▲ Figure 25-8. Scheme for the management of acute cholecystitis.

► Prognosis

The overall death rate of acute cholecystitis is about 5%. Nearly all of the deaths are in patients over age 60 or those with diabetes mellitus. In the older age group, secondary cardiovascular or pulmonary complications contribute substantially to the death rate. Uncontrolled sepsis with peritonitis and intrahepatic abscesses are the most important local conditions responsible for death.

Common duct stones are present in about 15% of patients with acute cholecystitis, and some of the more seriously ill patients have simultaneous cholangitis from biliary obstruction. Acute pancreatitis may also complicate acute cholecystitis, and the combination carries a greater risk.

Patients who develop the suppurative forms of gallbladder disease such as empyema or perforation are less likely to recover. Earlier admission to the hospital and early cholecystectomy reduce the chances of these complications.

Gurusamy KS, Rossi M, Davidson BR. Percutaneous cholecystostomy for high-risk surgical patients with acute calculous cholecystitis. *Cochrane Database Syst Rev* 2013 Aug 12;8:CD007088.

EMPHYSEMATOUS CHOLECYSTITIS

Emphysematous cholecystitis is a rare condition in which bubbles of gas from anaerobic infection appear in the lumen of the gallbladder, its wall, the pericholecystic space, and, on occasion, the bile ducts. Clostridia species are the most commonly implicated organisms, but other gas-forming anaerobes such as *E coli* or anaerobic streptococci may be found. Three times as many men as women are affected, and 20% of patients have diabetes mellitus. In contrast to the usual form of acute cholecystitis, the disease probably is a bacterial infection from the earliest moment. In many cases, the gallbladder contains no stones.

The disease begins with sudden and rapidly progressive right upper quadrant pain. Fever and leukocytosis reach high levels quickly, and the patient is considerably more toxic than is usually the case in acute cholecystitis. On examination, a mass can usually be found in the right upper quadrant.

Plain films of the abdomen show tissue emphysema outlining the gallbladder and, in some cases, an air-fluid level in the lumen. The clinical and x-ray pictures are characteristic enough so that the diagnosis is usually obvious. If the changes on plain films are equivocal, a CT scan may bring them out.

The patient should be treated with high doses of antibiotics effective against clostridia and the other species mentioned above. Emergency surgical treatment should follow the initial resuscitative measures. Cholecystectomy can be safely performed in most cases, but the most critically ill

might fare better with cholecystostomy. The types of complications are the same as in other forms of acute cholecystitis, but illness is more severe and death rates are higher.

GALLSTONE ILEUS

Gallstone ileus is mechanical intestinal obstruction caused by a large gallstone lodged in the lumen. It occurs more often in women, and the average patient age is about 70 years.

► Clinical Findings

A. Symptoms

The patient usually presents with obvious small bowel obstruction, either partial or complete. The obstructing gallstone enters the intestine through a cholecystenteric fistula located in the duodenum, colon, or, rarely, the stomach or jejunum. The gallbladder may contain one or several stones, but stones that cause gallstone ileus are almost always 2.5 cm or more in diameter. The lumen in the proximal bowel will allow most of these large calculi to pass caudally until the ileum is reached. Obstruction of the large intestine may follow passage of a gallstone through a fistula at the hepatic flexure or may occur even after the stone has traversed the entire small bowel.

B. Signs

In most patients, the findings on physical examination are typical of distal small bowel obstruction. Obstruction of the duodenum or jejunum may give a perplexing clinical picture because of the lack of distention. Right upper quadrant tenderness and a mass may be present in some cases, but the distended abdomen may be difficult to examine accurately.

C. Imaging Studies

In addition to dilated small intestine, plain films of the abdomen may show a radiopaque gallstone, and unless one is alert to the possibility of gallstone ileus, the ectopic stone can be a puzzling finding. In about 40% of cases, careful examination of the film will reveal gas in the biliary tree, a manifestation of the cholecystenteric fistula. When the clinical picture is unclear, an upper gastrointestinal series should be obtained, which will demonstrate the cholecystoduodenal fistula and verify intestinal obstruction.

► Treatment

The proper treatment is emergency laparotomy and removal of the obstructing stone through a small enterotomy. The proximal intestine must be carefully inspected for the

presence of a second calculus that might cause a postoperative recurrence. The gallbladder should be left undisturbed at the original operation.

Once the patient has recovered, an elective cholecystectomy should be scheduled if the patient complains of chronic gallbladder symptoms. On this basis, interval cholecystectomy will be required in about 30% of patients. The fistula itself is rarely the source of trouble and closes spontaneously in most patients.

► Prognosis

The death rate from gallstone ileus remains about 20%, largely because of the poor general condition of elderly patients at the time of laparotomy. In many cases, the patient has developed cardiac or pulmonary complications during a preoperative delay when the diagnosis was unclear.

CHOLANGITIS (BACTERIAL CHOLANGITIS)

Bacterial infection of the biliary ducts always signifies biliary obstruction, since in the absence of obstruction even heavy bacterial contamination of the ducts fails to produce symptoms or pathologic changes. The block to flow may be partial or, less commonly, complete. The principal causes are choledocholithiasis, biliary stricture, and neoplasm. Less common causes are chronic pancreatitis, ampullary stenosis, pancreatic pseudocyst, duodenal diverticulum, congenital cyst, and parasitic invasion. Iatrogenic cholangitis may complicate transhepatic or T tube cholangiography. Not all obstructing lesions are followed by cholangitis, however. For example, biliary infection develops in only 15% of patients with neoplastic obstruction. The likelihood of cholangitis is greatest when the obstruction occurs after the duct has acquired a resident bacterial population.

With obstruction, ductal pressure rises, and bacteria proliferate and escape into the systemic circulation via the hepatic sinusoids. Experimentally, the incidence of positive blood cultures with ductal infection is directly proportionate to the absolute height of the pressure in the duct.

The symptoms of cholangitis (sometimes referred to as Charcot's triad) are biliary colic, jaundice, and chills and fever, though a complete triad is present in only 70% of cases. Laboratory findings include leukocytosis and elevated serum bilirubin and alkaline phosphatase levels. The predominant organisms in bile (in approximately decreasing frequency) are *E coli*, *Klebsiella*, *Pseudomonas*, *Enterococci*, and *Proteus*. *Bacteroides fragilis* and other anaerobes (eg, *Clostridium perfringens*) can be detected in about 25% of cases, and their presence correlates with multiple previous biliary operations (often including a biliary enteric anastomosis), severe symptoms, and a high incidence of postoperative suppurative complications. Anaerobes are nearly always seen in the company of aerobes. Two species of bacteria can be cultured

in about 50% of cases. Bacteremia probably occurs in most cases, and blood cultures obtained at the appropriate time contain the same organisms as the bile. Early in an attack, an ultrasound scan will often give useful diagnostic information. Further workup (THC, ERCP, etc) can proceed later after the acute manifestations are brought under control. Cholangiography is dangerous during active cholangitis.

The term suppurative cholangitis has been used for the most severe form of this disease, when manifestations of sepsis overshadow those of hepatobiliary disease. The diagnostic pentad of suppurative cholangitis consists of abdominal pain, jaundice, fever and chills, mental confusion or lethargy, and shock. The diagnosis is often missed because the signs of biliary disease are overlooked.

Most cases of cholangitis can be controlled with intravenous antibiotics. A cephalosporin antibiotic (eg, cefazolin, cefoxitin) is the drug of choice in the average mild to moderately severe case. If disease is severe or progressively worsens, an aminoglycoside plus clindamycin or metronidazole should be added to the regimen.

For patients with severe cholangitis or unremitting cholangitis despite antibiotic therapy, the bile duct must be promptly decompressed. Most cases of severe acute cholangitis are associated with choledocholithiasis, for which the best treatment consists of emergency endoscopic sphincterotomy. In the uncommon case where this is unsuccessful, laparotomy is indicated in order to decompress the bile duct. Cholangitis accompanying neoplastic obstruction may be managed by insertion of a transhepatic drainage catheter into the bile duct. A cholangiogram should not be obtained because the procedure could worsen sepsis.

Urgent intervention (eg, endoscopic sphincterotomy, percutaneous transhepatic drainage, or operative decompression) is required in about 10% of patients with acute cholangitis. The remaining 90% are eventually treated by elective surgery or endoscopic sphincterotomy following antibiotic therapy and a thorough diagnostic evaluation.

CHOLEDOCHOLITHIASIS

ESSENTIALS OF DIAGNOSIS

- Biliary pain
- Jaundice
- Episodic cholangitis
- Stones in gallbladder or previous cholecystectomy

► General Considerations

Approximately 15% of patients with stones in the gallbladder harbor calculi within the bile ducts. Common duct stones are usually accompanied by others in the gallbladder, but in 5% of cases, the gallbladder is empty. The number of duct stones may vary from one to more than 100.

There are two possible origins for common duct stones. The evidence suggests that most cholesterol stones develop within the gallbladder and reach the duct after traversing the cystic duct. These are called secondary stones. Pigment stones may have a similar pedigree or, more often, develop *de novo* within the common duct. These are called primary common duct stones. About 60% of common duct stones are cholesterol stones and 40% are pigment stones. The latter are, on the average, associated with more severe clinical manifestations.

Patients may have one or more of the following principal findings, all of which are caused by obstruction to the flow of bile or pancreatic juice: biliary colic, cholangitis, jaundice, and pancreatitis (Figure 25–9). It seems likely,

however, that as many as 50% of patients with choledocholithiasis remain asymptomatic.

The common duct may dilate to 2–3 cm proximal to an obstructing lesion, and truly huge ducts develop in patients with biliary tumors. In choledocholithiasis or biliary stricture, the inflammatory reaction restricts dilation, so the dilatation is less marked. Dilation of the ductal system within the liver can also be limited by cirrhosis.

Biliary colic is the result of rapid rises in biliary pressure whether the block is in the common duct or neck of the gallbladder. Gradual occlusion of the duct—as in cancer—rarely produces the same kind of pain as gallstone disease.

► Clinical Findings

A. Symptoms

Choledocholithiasis may be asymptomatic or may produce sudden toxic cholangitis, leading to a rapid demise. The seriousness of the disease parallels the degree of obstruction, the length of time it has been present, and the extent of secondary bacterial infection (see Cholangitis, above). Biliary colic, jaundice, or pancreatitis may be isolated findings or may occur in any combination along with signs of infection (cholangitis).

Biliary colic from common duct obstruction cannot be distinguished from that caused by stones in the gallbladder. The pain is felt in the right subcostal region, epigastrium, or even the substernal area. Referred pain to the region of the right scapula is common.

Choledocholithiasis should be strongly suspected if intermittent chills, fever, or jaundice accompanies biliary colic. Some patients notice transient darkening of their urine during an attack even though jaundice is not evident.

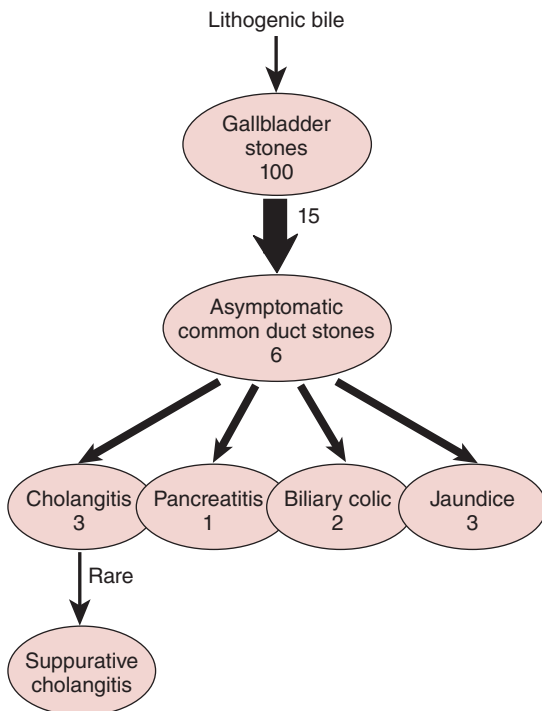

Pruritus is usually the result of persistent long-standing obstruction. The itching is more intense in warm weather when the patient perspires and is usually worse on the extremities than on the trunk. It is much more common with neoplastic obstruction than with gallstone obstruction.

B. Signs

The patient may be icteric and toxic, with high fever and chills, or may appear to be perfectly healthy. A palpable gallbladder is unusual in patients with obstructive jaundice from common duct stone because the obstruction is transient and partial, and scarring of the gallbladder renders it inelastic and nondistensible. Tenderness may be present in the right upper quadrant but is not often as marked as in acute cholecystitis, perforated peptic ulcer, or acute pancreatitis. Tender hepatic enlargement may occur.

C. Laboratory Findings

In cholangitis, leukocytosis of 15,000/mL is usual, and values above 20,000/mL are common. A rise in serum bilirubin

▲ **Figure 25–9.** The natural history of common duct stones. Of every 100 patients with gallbladder stones, 15 will have common duct stones, which will produce the spectrum of syndromes illustrated. Note that the individual syndromes overlap, indicating that they may appear together in various combinations.

often appears within 24 hours after the onset of symptoms. The absolute level usually remains under 10 mg/dL, and most are in the range of 2-4 mg/dL. The direct fraction exceeds the indirect, but the latter becomes elevated in most cases. Bilirubin levels do not ordinarily reach the high values seen in malignant tumors because the obstruction is usually incomplete and transient. In fact, fluctuating jaundice is so characteristic of choledocholithiasis that it fairly reliably differentiates between benign and malignant obstruction.

The serum alkaline phosphatase level usually rises and may be the only chemical abnormality in patients without jaundice. When the obstruction is relieved, the alkaline phosphatase and bilirubin levels should return to normal within 1-2 weeks, with the exception that the former may remain elevated longer if the obstruction was prolonged.

Mild increases in AST and ALT are often seen with extrahepatic obstruction of the ducts; rarely, AST levels transiently reach 1000 units.

D. Imaging Studies

Radiopaque gallstones may be seen on plain abdominal films or CT scans. Ultrasound scans will usually show gallbladder stones and, depending on the degree of obstruction, dilatation of the bile duct. Ultrasound and CT scans are insensitive in the search for stones in the common duct. ERCP is indicated if the patient has had a previous cholecystectomy. If cholecystectomy has not been performed, cholangiography should be part of operative management. Some clinicians choose preoperative ERCP for patients scheduled for cholecystectomy in order to clear the common bile duct. If ERCP is not technically successful, the surgeon will be forced to convert to open common bile duct exploration to clear the duct of stones.

Bilirubin values above 10 mg/dL are so uncommon in choledocholithiasis that when this finding is present, cholangiography should be performed to rule out the possibility of neoplastic obstruction.

► Differential Diagnosis

The workup should consider the same possibilities in differential diagnosis as for cholecystitis.

Serum amylase levels above 500 units/dL can result from acute pancreatitis, acute cholecystitis, or choledocholithiasis. Other manifestations of pancreatic disease should be documented before an unqualified diagnosis of pancreatitis is accepted.

Alcoholic cirrhosis or acute alcoholic hepatitis may present with jaundice, right upper quadrant tenderness, and leukocytosis. The differentiation from cholangitis may be impossible from clinical data. A history of a recent binge suggests acute liver disease. A percutaneous liver biopsy may be specific.

Intrahepatic cholestasis from drugs, pregnancy, chronic active hepatitis, or primary biliary cirrhosis may be difficult

to distinguish from extrahepatic obstruction. ERCP would be appropriate to make the distinction, particularly if other studies (eg, ultrasound scan) failed to provide evidence of gallstone disease. If jaundice has persisted for 4-6 weeks, a mechanical cause is probable. Since most patients improve during this interval, persistent jaundice should never be assumed to be the result of parenchymal disease unless a normal cholangiogram rules out obstruction of the major ducts.

Intermittent jaundice and cholangitis after cholecystectomy are compatible with biliary stricture, and the distinction requires ERCP.

Biliary tumors usually produce intense jaundice without biliary colic or fever, and once it begins, the jaundice rarely remits.

► Complications

Long-standing ductal infection can produce intrahepatic abscesses. Hepatic failure or secondary biliary cirrhosis may develop in unrelieved obstruction of long duration. Since the obstruction is usually incomplete and intermittent, cirrhosis develops only after several years in untreated disease. Acute pancreatitis, a fairly common complication of calculous biliary disease, is discussed in Chapter 26. Rarely, a stone in the common duct may erode through the ampulla, resulting in gallstone ileus. Hemorrhage (hemobilia) is also a rare complication.

► Treatment

Patients with acute cholangitis should be treated with systemic antibiotics and other measures as described in the preceding section; this usually controls the attack within 24-48 hours. If the patient's condition worsens or if marked improvement is not observed within 2-4 days, endoscopic sphincterotomy or surgery and common bile duct exploration should be performed.

The typical patient presents with mild cholangitis and evidence on ultrasound scans of gallbladder stones. Laparoscopic cholecystectomy is indicated and, depending on the experience of the surgeon, laparoscopic exploration of the common duct if an operative cholangiogram or laparoscopic ultrasound demonstrates the expected common duct stones. Laparoscopic common duct exploration is usually accomplished through the cystic duct (which may have to be dilated), but when the common duct is enlarged (> 1.5 cm), it may be accomplished through a choledochotomy incision, just as in open surgery. Eventually, nearly all cases of common duct stones should be manageable by laparoscopic techniques, but at this stage the requisite laparoscopic skills are not available in most hospitals. If the surgeon thinks the common duct stones cannot be removed laparoscopically, it is probably best to remove the gallbladder laparoscopically and the common duct stones by endoscopic sphincterotomy. If the stones cannot be removed by sphincterotomy, a second (open) operation may be necessary.

There is also a lack of consensus regarding the importance of operative cholangiography or ultrasound during cholecystectomy when there are no clues suggesting stones in the duct. In such cases the chances of finding a stone are only 3%-5%, and some consider the effort unwarranted. On the other hand, operative cholangiograms also provide confirmation of the biliary anatomy, which contributes to avoidance of bile duct injuries, and the natural history of the few overlooked stones is worrisome. Therefore, we side with those who perform operative cholangiography liberally in such cases.

When the common duct is explored through the cystic duct and gallstones are removed, the cystic duct must be ligated, but a drainage catheter is not usually left within the common duct. When the common duct is explored through a choledochotomy (either during a laparoscopic or open operation), a T tube is usually left in the duct, and cholangiograms are taken a week or so postoperatively. Any residual stones discovered on these postoperative x-rays can be extracted 4-6 weeks later through the T tube tract.

Patients with common duct stones who have had a previous cholecystectomy are best treated by endoscopic sphincterotomy. Using a side-viewing duodenoscope, the ampulla is cannulated, and a 1-cm incision is made in the sphincter with an electrocautery wire. The opening created in the sphincter permits stones to pass from the duct into the duodenum. Endoscopic sphincterotomy is unlikely to be successful in patients with large stones (eg, > 2 cm), and it is contraindicated in the presence of stenosis of the bile duct proximal to the sphincter. Laparotomy and common duct exploration are required in a few cases.

Stones in the intrahepatic branches of the bile duct can usually be removed without difficulty during common duct exploration. In some cases, however, one or more of the intrahepatic ducts have become packed with stones, and the associated chronic inflammation has produced stenosis of the duct near its junction with the common hepatic duct. It is often impossible in these cases to clear the duct of stones, and if the disease involves only one lobe (usually the left lobe), hepatic lobectomy is indicated.

POSTCHOLECYSTECTOMY SYNDROME

This term has been used to signify the heterogeneous group of disorders affecting patients who continue to complain of symptoms after cholecystectomy. It is not really a syndrome, and the term is confusing.

The usual reason for incomplete relief after cholecystectomy is that the preoperative diagnosis of chronic cholecystitis was incorrect. The only symptom entirely characteristic of chronic cholecystitis is biliary colic. When a calculous gallbladder is removed in the hope that the patient will gain relief from dyspepsia, fatty food intolerance, belching, etc, the operation may leave the symptoms unchanged.

The presenting symptom may be dyspepsia or pain. An organic cause for the symptoms is more likely to be

discovered in patients with severe episodic pain than in those with other complaints. Abnormal liver function studies, jaundice, and cholangitis are other manifestations that indicate residual biliary disease. Patients with suspicious findings should be studied by ERCP or THC. Choledocholithiasis, biliary stricture, and chronic pancreatitis are the most common causes of symptoms. Occasionally, there is sufficient evidence to implicate sphincter of Oddi dysmotility as a cause of pain. Relief of pain may follow endoscopic sphincterotomy. Stenosis of the hepatobiliary ampulla, a long cystic duct remnant, and neuromas have been blamed for continued symptoms.

CARCINOMA OF THE GALLBLADDER

Carcinoma of the gallbladder is an uncommon neoplasm that occurs in elderly patients. It is associated with gallstones in 70% of cases, and the risk of malignant degeneration correlates with the length of time gallstones have been present. The tumor is twice as common in women as in men, as one would expect from the association with gallstones.

Most primary tumors of the gallbladder are adenocarcinomas that appear histologically to be scirrhous (60%), papillary (25%), or mucoid (15%). Dissemination of the tumor occurs early by direct invasion of the liver and hilar structures and by metastases to the common duct lymph nodes, liver, and lungs. In an occasional case, where carcinoma is an incidental finding after cholecystectomy for gallstone disease, the tumor is confined to the gallbladder as a carcinoma in situ or an early invasive lesion. Most invasive carcinomas, however, have spread by the time of surgery, and spread is virtually certain if the tumor has progressed to the point where it causes symptoms.

► Clinical Findings

A. Symptoms and Signs

The most common presenting complaint is of right upper quadrant pain similar to previous episodes of biliary colic but more persistent. Obstruction of the cystic duct by tumor sometimes initiates an attack of acute cholecystitis. Other cases present with obstructive jaundice and, occasionally, cholangitis due to secondary involvement of the common duct.

Examination usually reveals a mass in the region of the gallbladder, which may not be recognized as a neoplasm if the patient has acute cholecystitis. If cholangitis is the principal symptom, a palpable gallbladder would be an unusual finding with choledocholithiasis alone and should suggest gallbladder carcinoma.

B. Imaging Studies

CT and ultrasound scans may demonstrate the extent of disease, but more often they show only gallstones.

The correct diagnosis is made preoperatively in only 10% of cases.

► Complications

Obstruction of the common duct may produce multiple intrahepatic abscesses. Abscesses in or next to the tumor-laden gallbladder are frequent.

► Prevention

The incidence of gallbladder cancer has decreased in recent years as the frequency of cholecystectomy has increased. It has been estimated that one case of gallbladder cancer is prevented for every 100 cholecystectomies performed for gallstone disease.

► Treatment

If a localized carcinoma of the gallbladder is recognized at laparotomy, cholecystectomy should be performed along with en bloc wedge resection of an adjacent 3-5 cm of normal liver and dissection of the lymph nodes in the hepatoduodenal ligament. If a small invasive carcinoma overlooked during cholecystectomy for gallstone disease is later discovered by the pathologist, reoperation is indicated to perform a wedge resection of the liver bed plus regional lymphadenectomy. Some surgeons also recommend that the common duct be included routinely (ie, even in the absence of gross invasion) in the lymph node dissection for any lesion that involves the full thickness of the gallbladder wall. In the few cases when cancer has not penetrated the muscularis mucosae, cholecystectomy alone should suffice. More extensive hepatectomies (eg, right lobectomy) are not worthwhile. Lesions that invade the bile duct and produce jaundice should be resected if possible. When not, a stent should be inserted endoscopically or percutaneously. There is little that surgery can offer in cases with hepatic metastases or more distant spread.

► Prognosis

Radiotherapy and chemotherapy are not effective palliative measures. About 85% of patients are dead within a year after diagnosis.

The 10% of patients who presently survive more than 5 years consist of those whose carcinoma was an incidental finding during cholecystectomy for symptomatic gallstone disease and those in whom an aggressive resection has removed all gross tumor.

Wu LM, Jiang XX, Gu HY, et al. Endoscopic ultrasound-guided fine-needle aspiration biopsy in the evaluation of bile duct strictures and gallbladder masses: a systematic review and meta-analysis. *Eur J Gastroenterol Hepatol* 2011 Feb;23(2):113-120.

MALIGNANT TUMORS OF THE BILE DUCT

ESSENTIALS OF DIAGNOSIS

- Intense cholestatic jaundice and pruritus
- Anorexia and dull right upper quadrant pain
- Dilated intrahepatic bile ducts on ultrasound or CT scan
- Focal stricture on transhepatic or retrograde endoscopic cholangiogram

► General Considerations

Primary bile duct tumors are not more common in patients with cholelithiasis, and men and women are affected with equal frequency. Tumors appear at an average age of 60 years but may appear at any time between 20 and 80 years of age. More young people have been seen with this disease in recent years. Ulcerative colitis is a common associated condition, and in occasional cases bile duct cancer develops in a patient with ulcerative colitis who has been known to have sclerosing cholangitis for several years. Chronic parasitic infestation of the bile ducts in the Orient may be responsible for the greater incidence of bile duct tumors in that area.

Most malignant biliary tumors are adenocarcinomas located in the hepatic or common bile duct. The histologic pattern varies from typical adenocarcinoma to tumors composed principally of fibrous stroma and few cells. The acellular tumors may be mistaken for benign strictures or sclerosing cholangitis if adequate biopsies are not obtained. About 10% are bulky papillary tumors, which tend to be less invasive and less apt to metastasize.

At presentation, metastases are uncommon, but the tumor has often grown into the portal vein or hepatic artery.

► Clinical Findings

A. Symptoms and Signs

The illness presents with gradual onset of jaundice or pruritus. Chills, fever, and biliary colic are usually absent, and except for a deep discomfort in the right upper quadrant the patient feels well. Bilirubinuria is present from the start, and light-colored stools are usual. Anorexia and weight loss develop insidiously with time.

Icterus is the most obvious physical finding. If the tumor is located in the common duct, the gallbladder may distend and become palpable in the right upper quadrant. The tumor itself is never palpable. Patients with tumors of the hepatic duct do not develop palpable gallbladders. Hepatomegaly is common. If obstruction is unrelieved, the liver may eventually become cirrhotic, and splenomegaly, ascites, or bleeding varices become secondary manifestations.

B. Laboratory Findings

Since the duct is often completely obstructed, the serum bilirubin is usually over 15 mg/dL. Serum alkaline phosphatase is also increased. Fever and leukocytosis are not common, since the bile is sterile in most cases. The stool may contain occult blood, but this is more common with tumors of the pancreas or hepatopancreatic ampulla than those of the bile ducts.

C. Imaging Studies

Ultrasound or CT scans usually detect dilated intrahepatic bile ducts. THC or ERCP clearly depicts the lesion, and both are indicated in most cases. THC is of greater value, since it better demonstrates the ductal anatomy on the hepatic side of the lesion. With tumors involving the bifurcation of the common hepatic duct (Klatskin tumors), it is important to determine the proximal extent of the lesion (ie, whether the first branches of the lobar ducts are also involved). ERCP is of value with proximal tumors because if it shows concomitant obstruction of the cystic duct, the diagnosis will most often prove to be gallbladder cancer invading the common duct (not a primary common duct neoplasm). The typical pattern with distal bile duct cancers consists of stenosis of the bile duct with sparing of the pancreatic duct. Adjacent stenoses of both ducts (the double-duct sign) indicate primary cancer of the pancreas. MR cholangiopancreatography may be useful if high-quality studies are available.

Occasionally, bile samples obtained at the time of THC will show malignant cells on cytologic study, but this is not a particularly useful test since the diagnosis of cancer must be presumed from the cholangiographic findings and a negative cytologic study is unreliable. Angiography may suggest invasion of the portal vein or encasement of the hepatic artery. False positives may occur, however.

► Differential Diagnosis

The differential diagnosis must consider other causes of extrahepatic and intrahepatic cholestatic jaundice. Choledocholithiasis is characterized by episodes of partial obstruction, pain, and cholangitis, which contrast with the unremitting jaundice of malignant obstruction. Bilirubin concentrations rarely surpass 15 mg/dL and are usually below 10 mg/dL in gallstone obstruction, whereas bilirubin levels almost always exceed 10 mg/dL and are usually above 15 mg/dL in neoplastic obstruction. A rapid rise of the bilirubin level to above 15 mg/dL in a patient with sclerosing cholangitis should suggest superimposed neoplasm. Dilatation of the gallbladder may occur with tumors of the distal common duct but is rare with calculous obstruction.

The combination of an enlarged gallbladder with obstructive jaundice is usually recognized as being due to tumor. If the gallbladder cannot be felt, primary biliary cirrhosis, drug-induced jaundice, chronic active hepatitis, metastatic

hepatic cancer, and common duct stone must be ruled out. In general, any patient with cholestatic jaundice of more than 2 weeks' duration whose diagnosis is uncertain should be studied by THC or ERCP. The finding of focal bile duct stenosis in the absence of previous biliary surgery is almost pathognomonic of neoplasm.

► Treatment

Patients without evidence of metastases or other signs of advanced cancer (eg, ascites) are candidates for laparotomy. The 30% of patients who do not qualify may be treated by insertion of a tube stent into the bile duct transhepatically under radiologic control or from the duodenum under endoscopic control. The tube is positioned so that holes above and below the tumor reestablish flow of bile into the duodenum. If both lobar ducts are blocked by a tumor at the bifurcation of the common hepatic duct, it is usually necessary to place a transhepatic tube into only one lobar duct. If the lesion blocks the takeoff of the segmental ducts, stents are rarely beneficial.

Laparotomy is indicated in most cases, however, with the objective of removing the tumor. Preoperative decompression of the bile duct with a percutaneous catheter to relieve jaundice does not lower the incidence of postoperative complications. At operation, which may be immediately preceded by diagnostic laparoscopy, the extent of the tumor should be determined by external examination of the bile duct and the adjacent portal vein and hepatic artery.

Tumors of the distal common duct should be treated by radical pancreaticoduodenectomy (Whipple procedure) if it appears that all tumor would be removed. Secondary involvement of the portal vein is the usual reason for unresectability of tumors in this location. Mid-common duct or low-hepatic duct tumors should also be removed if possible. If the tumor cannot be excised, bile flow should be reestablished into the intestine by a cholecystojejunostomy or Roux-en-Y choledochojejunostomy. The choice is based on technical considerations.

Tumors at the hilum of the liver should be resected if possible and a Roux-en-Y hepaticojejunostomy performed. The anastomosis is usually between hilum and bowel rather than between individual bile ducts and bowel. A curative operation nearly always requires resection of either the right or the left lobe of the liver and, in all cases, the caudate lobe. Extension into the lobar and segmental ducts and secondary involvement of the hepatic artery and portal vein are the most common reasons for inability to resect the tumor. Subtotal resections offer little in the way of palliation.

Postoperative radiotherapy is commonly recommended.

► Prognosis

The average patient with adenocarcinoma of the bile duct survives less than a year. The overall 5-year survival rate is 15%. Following a thorough radical operation, 5-year survival

is about 40%. Biliary cirrhosis, intrahepatic infection, and general debility with terminal pneumonitis are the usual causes of death. Palliative resections and stents may improve the length and quality of survival in this disease even though surgical cure is uncommon. Limited experience with liver transplantation for this disease has been discouraging; tumor has recurred postoperatively in most patients.

BENIGN TUMORS & PSEUDOTUMORS OF THE GALLBLADDER

Various unrelated lesions appear on ultrasound as projections from the gallbladder wall. The differentiation from gallstones is based upon observing whether a shift in position of the projections follows changes in posture of the patient, since stones are not fixed. Cancer should be suspected in any polypoid lesion that exceeds 1 cm in diameter.

► Polyps

Most of these are not true neoplasms but cholesterol polyps, a local form of cholesterosis. Histologically, they consist of a cluster of lipid-filled macrophages in the submucosa. They easily become detached from the wall when the gallbladder is handled at surgery. It is not known whether cholesterol polyps are important in the genesis of gallstones. Some patients experience gallbladder pain, but whether this is related to the presence of the polyps *per se* or is a manifestation of functional gallbladder disease has not been established.

Inflammatory polyps have also been reported, but they are quite rare.

► Adenomyomatosis

On cholecystography, this entity presents as a slight intraluminal convexity that is often marked by central umbilication. It is usually found in the fundus but may occur elsewhere. It is unclear whether adenomyomatosis is an acquired degenerative lesion or a developmental abnormality (ie, hamartoma). The following synonyms for this lesion appear in the literature: adenomatous hyperplasia, cholecystitis glandularis proliferans, and diverticulosis of the gallbladder. Although the condition is probably asymptomatic in many cases, adenomyomatosis can cause abdominal pain. Cholecystectomy should be performed in such patients.

► Adenomas

These appear as pedunculated adenomatous polyps, true neoplasms that may be papillary or nonpapillary histologically. In a few cases they have been found in association with carcinoma *in situ* of the gallbladder.

BENIGN TUMORS OF THE BILE DUCTS

Benign papillomas and adenomas may arise from the ductal epithelium. Only 90 cases have been reported to date. The neoplastic propensity of the ductal epithelium is widespread, so the tumors are often multiple, and recurrence is common after excision. The affected duct must be radically excised for permanent cure to result.

BILE DUCT INJURIES & STRICTURES

ESSENTIALS OF DIAGNOSIS

- Episodic cholangitis
- Previous biliary surgery
- Transhepatic cholangiogram often diagnostic

► General Considerations

Benign biliary injuries and strictures are caused by surgical trauma in about 95% of cases. The remainder result from external abdominal trauma or, rarely, from erosion of the duct by a gallstone. Prevention of injury to the duct depends on a combination of technical skill, experience, and a thorough knowledge of the normal anatomy and its variations in the hilum of the liver. The number of bile duct injuries has risen sharply in the past few years along with the shift from open to laparoscopic cholecystectomy.

The most common lesion consists of excision of a segment of the common duct as a result of mistaking it for the cystic duct. Partial transection, occlusion with metal clips, injury to the right hepatic duct, and leakage from the cystic duct are other examples. A full discussion of how these injuries occur and how they can be prevented is beyond the scope of this text.

A clean incision of the duct without additional damage is best managed by opening the abdomen and suturing the incision with fine absorbable suture material.

► Clinical Findings

A. Symptoms

Manifestations of injury to the duct may or may not be evident in the postoperative period. Following laparoscopic surgery, bile ascites, manifested by abdominal distention, bloating, and pain plus mild jaundice, is the usual

presentation, since the duct is usually open to the abdomen. The symptoms are relatively mild and may for a time mimic ileus until a worsening picture requires further investigation.

Injuries following open cholecystectomy more often present with intermittent cholangitis or jaundice as a consequence of a biliary stricture. The first clear-cut symptoms may not be evident for weeks or months after surgery.

B. Signs

Findings are not distinctive. Bile ascites produces abdominal distention and ileus and, rarely, true bile peritonitis with toxicity. The right upper quadrant may be tender but usually is not. Jaundice is usually present during an attack of cholangitis.

C. Laboratory Findings

The serum alkaline phosphatase concentration is elevated in cases of stricture. The serum bilirubin fluctuates in relation to symptoms but usually remains well below 10 mg/dL.

Blood cultures are usually positive during acute cholangitis.

D. Imaging Studies

Bile ascites can be suspected on ultrasound or CT scan. Fluid should be aspirated, and if it is bile, the diagnosis is clear. THC and ERCP are necessary to depict the anatomy. After laparoscopic cholecystectomy, the most common pattern is a blocked (by a metal clip) lower duct and an upper duct draining freely into the abdomen. With a stricture, the findings most often consist of focal narrowing of the common hepatic duct within 2 cm of the bifurcation and mild to moderate dilatation of the intrahepatic ducts.

► Differential Diagnosis

Cholelithiasis is the condition that most often must be differentiated from biliary stricture because the clinical and laboratory findings can be identical. A history of trauma to the duct would point toward stricture as the more likely diagnosis. The final distinction must often await radiologic or surgical findings. THC or ERCP should be definitive.

Other causes of cholestatic jaundice may have to be ruled out in some cases.

► Complications

Complications develop quickly if the leak is not controlled. Bile peritonitis and abscesses may form. With stricture, persistent cholangitis may progress to multiple intrahepatic abscesses and a septic death.

► Treatment

Bile duct injuries should be surgically repaired in all but a few patients who are likely to improve with a nonoperative

approach. Excision of the damaged duct and Roux-en-Y hepaticojejunostomy is indicated for most acute and chronic injuries. The entire biliary tree must be outlined by cholangiograms preoperatively. The key to success is the thoroughness of the dissection and the ability ultimately to suture healthy duct to healthy bowel. This, in turn, depends on the experience of the surgeon with this particular operation.

When a definitive repair is technically impossible, the stricture may be dilated with a transhepatic balloon-tipped catheter. This is particularly applicable to patients with portal hypertension, whose hepatic hilum contains numerous venous collaterals that make operation hazardous.

► Prognosis

The death rate from biliary injuries is about 5%, and severe illness is frequent. If the stricture is not repaired, episodic cholangitis and secondary liver disease are inevitable.

Surgical correction of the stricture should be successful in about 90% of cases. Experience at centers with a special interest in this problem indicates that good results can be obtained even if several previous attempts did not relieve the obstruction. There is essentially no place for liver transplantation in this disease.

UNCOMMON CAUSES OF BILE DUCT OBSTRUCTION

► Congenital Choledochal Cysts

About 30% of congenital choledochal cysts produce their first symptoms in adults, usually presenting with jaundice, cholangitis, and a right upper quadrant mass. Diagnosis can be made by THC or ERCP. The optimal surgical procedure is excision of the cyst and construction of a Roux-en-Y hepaticojejunostomy. If this is not technically possible or if the patient’s condition will not permit a prolonged operation, the cyst should be emptied of precipitated biliary sludge and a cystenteric anastomosis constructed. Congenital cysts of the biliary tree have a high incidence of malignant degeneration, which is another argument for excision rather than drainage.

► Caroli’s Disease

Caroli’s disease, another form of congenital cystic disease, consists of saccular intrahepatic dilatation of the ducts. In some cases, the biliary abnormality is an isolated finding, but more often it is associated with congenital hepatic fibrosis and medullary sponge kidney. The latter patients often present in childhood or as young adults with complications

of portal hypertension. Others have cholangitis and obstructive jaundice as initial manifestations. There is no definitive surgical solution to the problem except in rare cases with isolated involvement of one hepatic lobe, where lobectomy is curative. Intermittent antibiotic therapy for cholangitis is the usual regimen.

► Hemobilia

Hemobilia presents with the triad of biliary colic, obstructive jaundice, and occult or gross intestinal bleeding. Most cases in Western cultures follow several weeks after hepatic trauma with bleeding from an intrahepatic branch of the hepatic artery into a duct. It is seen with less frequency now, because the general principles of management of hepatic trauma are better understood. In the Orient, hemobilia usually follows ductal parasitism (*Ascaris lumbricoides*) or Oriental cholangiohepatitis. Other causes are hepatic neoplasms, rupture of a hepatic artery aneurysm, hepatic abscess, and choledocholithiasis. The diagnosis may be suspected from a technetium 99m-labeled red blood cell scan, but an arteriogram is usually required for diagnosis and planning of therapy. Sometimes the bleeding can be stopped by embolizing the lesion with stainless steel coils, Gelfoam, or autologous blood clot infused through a catheter selectively positioned in the hepatic artery. If this is unsuccessful, either direct ligation of the bleeding point in the liver or proximal ligation of an upstream branch of the hepatic artery in the hilum is required.

► Pancreatitis

Pancreatitis can cause obstruction of the intrapancreatic portion of the bile duct by inflammatory swelling, encasement with scar, or compression by a pseudocyst. The patient may present with painless jaundice or cholangitis. Occasionally, a distended gallbladder can be felt on abdominal examination. Differentiation from choledocholithiasis and secondary acute pancreatitis depends on biliary x-rays or surgical exploration if the jaundice persists. Jaundice due to inflammation alone rarely lasts more than 2 weeks; persistent jaundice following an attack of acute pancreatitis suggests the development of a pseudocyst, underlying chronic pancreatitis with obstruction by fibrosis, or even an obstructing neoplasm.

Biliary obstruction from chronic pancreatitis may have few or no clinical manifestations. Jaundice is usually present, but the average peak bilirubin level is only 4-5 mg/dL. Some patients with functionally significant stenosis have persistently elevated alkaline phosphatase levels as the only abnormality; when surgical decompression of the bile duct is not performed, these patients often develop secondary biliary cirrhosis within a year or so. Diagnosis of stricture is made by ERCP, which shows a long stenosis of the intrapancreatic portion of the duct, proximal dilatation,

and either a gradual or abrupt tapering of the lumen at the pancreatic border, occasionally accompanied by ductal angulation. If cholangiograms show stenosis and if alkaline phosphatase or bilirubin levels remain more than twice normal for longer than 2 months, the stenosis is functionally significant and unlikely to resolve and requires surgical correction. Choledochoduodenostomy is done in most cases. Cholecystoduodenostomy is unreliable because the cystic duct is often too narrow to provide continued biliary decompression.

Patients with obstructive jaundice and pseudocyst usually respond to surgical drainage of the pseudocyst. However, occasionally they do not respond, because chronic scarring—not the cyst—is the cause of obstruction. Procedures to drain both the bile duct and the pseudocyst are indicated if operative cholangiograms demonstrate persistent bile duct obstruction after the cyst has been decompressed.

► Ampullary Dysfunction & Stenosis

Stenosis of the hepatopancreatic ampulla (ampullary stenosis) has been implicated as a cause of pain and other manifestations of ampullary obstruction and is often considered as a cause of postcholecystectomy complaints. Some cases are idiopathic, whereas others may be the result of trauma from gallstones. If the patient has secondary manifestations of biliary obstruction (eg, jaundice, increased alkaline phosphatase concentration, and cholangitis) in the absence of gallstones or some other obstructing lesion, and cholangiography shows dilatation of the common duct, ampullary stenosis is a plausible explanation. However, the diagnosis is more often proposed as a reason for upper abdominal pain without these more objective findings. Ampullary dysfunction is postulated in these cases.

Sphincter of Oddi dysfunction may be the cause of biliary-like pain and is often considered in patients who remain uncomfortable after cholecystectomy. The pathogenesis of the symptoms is thought to be similar to that of esophageal dysmotility and the irritable bowel syndrome. The patients typically experience severe, intermittent upper abdominal pain that lasts for 1-3 hours, sometimes following a meal.

Residual gallstone and pancreatic disease must first be ruled out. Ampullary dysfunction can then be diagnosed by sphincter of Oddi manometry. Patients are placed in one of three groups depending on the presence of three objective manifestations of biliary obstruction: abnormal liver function tests, prolonged (> 45 minutes) common bile duct emptying of contrast media after ERCP; and a common duct greater than 12 mm in diameter. Patients in group I have all three findings; patients in group II have one or two findings; and patients in group III have none of the findings. Group I patients are thought to have enough evidence of disease that sphincterotomy should be performed without manometry. Group I patients have abnormal motility so rarely that they

should not be considered further for sphincterotomy. Thus, motility studies are most often of value in determining which of the group II patients will improve after sphincterotomy.

The abnormalities sought on the motility studies include an elevated (> 40 mm Hg) basal sphincter pressure and a paradoxical rise in sphincter pressure in response to CCK. The former is most reliable. About 50% of group II patients have elevated sphincter pressures, and these are the ones who benefit from sphincterotomy.

A scintigraphic test may be just as accurate. The patient is given a bolus of CCK followed by ^{99m}Tc-DISIDA. Gamma camera images of the liver and bile duct are obtained for 60 minutes. A scoring system (score: 0-12) is based on the rate of passage of the imaging agent past various relevant points (eg, appearance and clearance through the liver, bile duct, and bowel). The normal range is 0-5; abnormal is 6-12.

Sphincter of Oddi dysfunction is an uncommon explanation for abdominal pain, and it is appropriate to remain skeptical unless the objective findings of biliary obstruction are clear-cut. In well-selected cases, however, endoscopic sphincterotomy is beneficial.

Heetun ZS, Zeb F, Cullen G, Courtney G, Aftab AR. Biliary sphincter of Oddi dysfunction: response rates after ERCP and sphincterotomy in a 5-year ERCP series and proposal for new practical guidelines. *Eur J Gastroenterol Hepatol* 2011;23(4):327-333.

► Duodenal Diverticula

Duodenal diverticula usually arise on the medial aspect of the duodenum within 2 cm of the orifice of the bile duct, and in some individuals the duct empties directly into a diverticulum. Even in the latter circumstance, duodenal diverticula are usually innocuous. Occasionally, distortion of the duct entrance or obstruction by enterolith formation in the diverticulum produces symptoms. Either choledochoduodenostomy or Roux-en-Y choledochojejunostomy is usually a safer method of reestablishing biliary drainage than attempts to excise the diverticulum and reimplant the duct.

► Ascariasis

When the worms invade the duct from the duodenum, ascariasis can produce symptoms of ductal obstruction. Air may sometimes be seen within the ducts on plain films. Antibiotics should be used until cholangitis is controlled, and anthelmintic therapy (mebendazole, albendazole, or pyrantel pamoate) should then be given. The acute symptoms usually subside with antibiotics, but if they do not, endoscopic sphincterotomy should be performed and attempts made to extricate the worms. If this is unsuccessful and the patient remains acutely ill, the duct should be emptied surgically.

► Recurrent Pyogenic Cholangitis (Oriental Cholangiohepatitis)

Oriental cholangiohepatitis is a type of chronic recurrent cholangitis prevalent in coastal areas from Japan to Southeast Asia. In Hong Kong it is the third most common indication for emergency laparotomy and the most frequent type of biliary disease. The disease is currently thought to result from chronic portal bacteremia, with portal phlebitis antedating the biliary disease. *E coli* causes secondary infection of the bile ducts, which initiates pigment stone formation within the ducts.

Biliary obstruction from the stones gives rise to recurrent cholangitis, which, unlike gallstone disease in Western countries, may be unaccompanied by gallbladder stones. The gallbladder is usually distended during an attack and may contain pus.

Chronic recurrent infection often leads to biliary strictures and hepatic abscess formation. The strictures are usually located in the intrahepatic bile ducts, and for some unknown reason the left lobe of the liver is more severely involved. Intrahepatic gallstones are common, and their surgical removal may be difficult or impossible. Acute abdominal pain, chills, and high fever are usually present, and jaundice develops in about half of cases. Right upper quadrant tenderness is usually marked, and in about 80% of cases the gallbladder is palpable. ERCP or THC is the best way to study the biliary tree and can help in determining the need for surgery and the type of procedure.

Systemic antibiotics should be given for acute cholangitis. Surgical treatment consists of cholecystectomy, common duct exploration, and removal of stones. Sphincteroplasty should also be performed to allow any residual or recurrent stones to escape from the duct. A Roux-en-Y choledochojejunostomy is indicated for patients with strictures, markedly dilated ducts (eg, > 3 cm), or recurrent disease after a previous sphincteroplasty. The results of surgery are good in 80% of patients. Chronic intrahepatic stones and infection, which often involve only one lobe, may require hepatic lobectomy.

Although many patients are cured, prolonged illness from repeated infection is almost unavoidable once strictures have appeared or the intrahepatic ducts have become packed with stones.

► Sclerosing Cholangitis

Sclerosing cholangitis is a rare chronic disease of unknown cause characterized by nonbacterial inflammatory narrowing of the bile ducts. About 60% of cases occur in patients with ulcerative colitis, and sclerosing cholangitis develops in about 5% of patients with that disorder. Other less commonly associated conditions are thyroiditis, retroperitoneal fibrosis, and mediastinal fibrosis. The disease chiefly affects men 20-50 years of age. In most cases, the entire biliary tree is affected by the inflammatory process, which causes

irregular partial obliteration of the lumen of the ducts. The narrowing may be confined, however, to the intrahepatic or extrahepatic ducts, though it is almost never so short as to resemble a posttraumatic or focal malignant stricture. The woody-hard duct walls contain increased collagen and lymphoid elements and are thickened at the expense of the lumen.

The clinical onset usually consists of the gradual appearance of mild jaundice and pruritus. Symptoms of bacterial cholangitis (eg, fever and chills) are uncommon in the absence of previous biliary surgery. Laboratory findings are typical of cholestasis. The total serum bilirubin averages about 4 mg/dL and rarely exceeds 10 mg/dL. ERCP is usually diagnostic, demonstrating ductal stenoses and irregularity, which often gives a beaded appearance. Liver biopsy may show pericholangitis and bile stasis, but the changes are nonspecific.

The complications of sclerosing cholangitis include gallstone disease and adenocarcinoma of the bile duct. The latter is most common in patients with ulcerative colitis. Furthermore, patients with ulcerative colitis and sclerosing cholangitis appear to be at greater risk for colonic mucosal dysplasia and colon cancer than those with ulcerative colitis not associated with sclerosing cholangitis.

Ursodiol (ursodeoxycholic acid), 10 mg/kg/d, improves liver function tests and symptoms. Cholestyramine will give relief from pruritus. Percutaneous transhepatic balloon dilatation can be of value to treat dominant strictures. In cases where the disease is largely confined to the distal extrahepatic duct and the proximal ducts are dilated, a Roux-en-Y hepaticojejunostomy may be indicated. For patients with severe intrahepatic involvement, hepatic transplantation should be considered.

The natural history of sclerosing cholangitis is one of chronicity and unpredictable severity. Some patients seem to obtain nearly complete remission after treatment, but this is not common. Bacterial cholangitis may develop after operation if adequate drainage has not been established. In these cases, antibiotics will be required at intervals. Most patients experience the gradual evolution of secondary biliary cirrhosis after many years of mild to moderate jaundice and pruritus. Liver transplantation is indicated when the disease becomes advanced. The results are good.

MULTIPLE CHOICE QUESTIONS

- All of the following are current useful imaging modalities for the biliary tree and gallbladder, except
 - Abdominal ultrasound
 - Endoscopic retrograde cholangiopancreatography
 - Abdominal CT scan
 - Oral cholecystography
 - Transhepatic cholangiography
- Serum alkaline phosphatase can come from
 - Lung
 - Muscle
 - Skin
 - Intestine
 - Red blood cells
- Gallstones
 - Are symptomatic in greater than 50% of people
 - Are nearly always present in people with chronic cholecystitis
 - In the gallbladder are not detected by ultrasound in about 50% of cases (false negative)
 - Are usually detectable by ultrasound if present in the common bile duct
 - Are comprised of bile pigment in the majority of cases in the United States
- Acute cholecystitis can be commonly confused with each of the following, except
 - Diverticulitis
 - Pancreatitis
 - Peptic ulcer disease
 - Acute appendicitis
 - Fitz-Hugh-Curtis syndrome
- Management of acute cholangitis
 - Typically requires emergent operation
 - Should not include antibiotics until bile cultures are pending
 - Should usually include draining the biliary tree
 - Is commonly required in the management of chronic pancreatitis
 - Should reserve invasive procedures for patients who have required more than 3 days of antibiotics

Pancreas

Gerard M. Doherty, MD

EMBRYOLOGY

The pancreas appears in the fourth week of fetal life from the caudal part of the foregut as dorsal and ventral pancreatic buds. Both anlagen rotate to the right and fuse near the point of origin of the ventral pancreas. Later, as the duodenum rotates, the pancreas shifts to the left. In the adult, only the caudal portion of the head and the uncinata process are derived from the ventral pancreas. The cranial part of the head and all of the body and tail are derived from the dorsal pancreas. Most of the dorsal pancreatic duct joins with the duct of the ventral pancreas to form the main pancreatic duct (duct of Wirsung); a small part persists as the accessory duct (duct of Santorini). In 5%-10% of people, the ventral and dorsal pancreatic ducts do not fuse, and most regions of the pancreas drain through the duct of Santorini and the orifice of the minor papilla. In this case, only the small ventral pancreas drains with the common bile duct through the papilla of Vater.

ANATOMY

The pancreas is a thin elliptic organ that lies within the retroperitoneum in the upper abdomen (Figures 26-1 and 26-2). In the adult, it is 12-15 cm long and weighs 70-100 g. The gland can be divided into three portions—head, body, and tail. The head of the pancreas is intimately adherent to the medial portion of the duodenum and lies in front of the inferior vena cava and superior mesenteric vessels. A small tongue of tissue called the uncinata process lies behind the superior mesenteric vessels as they emerge from the retroperitoneum. Anteriorly, the stomach and the first portion of the duodenum lie partly in front of the pancreas. The common bile duct passes through a posterior groove in the head of the pancreas adjacent to the duodenum. The body of the pancreas is in contact posteriorly with the aorta, the left crus of the diaphragm, the left adrenal gland, and the left kidney. The tail of the pancreas lies in the hilum of the spleen. The main pancreatic duct (the duct of Wirsung) courses along

the gland from the tail to the head and joins the common bile duct just before entering the duodenum at the ampulla of Vater. The accessory pancreatic duct (the duct of Santorini) enters the duodenum 2-2.5 cm proximal to the ampulla of Vater (Figure 26-1).

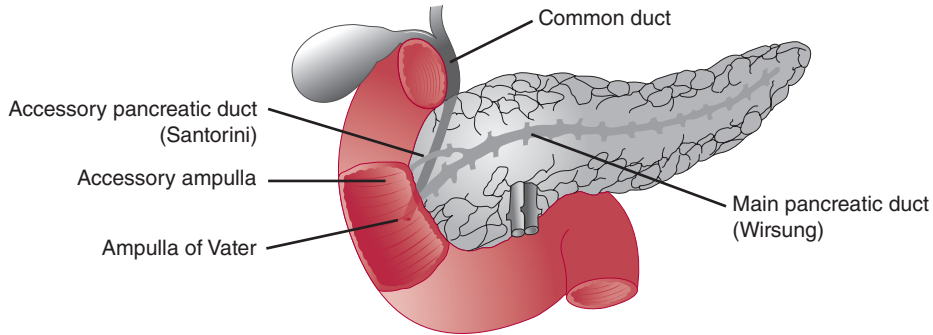

The blood supply of the pancreas is derived from branches of the celiac and superior mesenteric arteries (Figure 26-2). The superior pancreaticoduodenal artery arises from the gastroduodenal artery, runs parallel to the duodenum, and eventually meets the inferior pancreaticoduodenal artery, a branch of the superior mesenteric artery, to form an arcade. The splenic artery provides tributaries that supply the body and tail of the pancreas. The main branches are termed the dorsal pancreatic, pancreatica magna, and caudal pancreatic arteries. The venous supply of the gland parallels the arterial supply. Lymphatic drainage is into the peripancreatic nodes located along the veins.

The innervation of the pancreas is derived from the vagal and splanchnic nerves. The efferent fibers pass through the celiac plexus from the celiac branch of the right vagal nerve to terminate in ganglia located in the interlobular septa of the pancreas. Postganglionic fibers from these synapses innervate the acini, the islets, and the ducts. The visceral afferent fibers from the pancreas also travel in the vagal and splanchnic nerves, but those that mediate pain are confined to the latter. Sympathetic fibers to the pancreas pass from the splanchnic nerves through the celiac plexus and innervate the pancreatic vasculature.

PHYSIOLOGY

▶ Exocrine Function

The external secretion of the pancreas consists of a clear, alkaline (pH 7.0-8.3) solution of 1-2 L/d containing digestive enzymes. Secretion is stimulated by the hormones secretin and cholecystokinin (CCK) and by parasympathetic vagal discharge. Secretin and CCK are synthesized, stored, and

▲ **Figure 26-1.** Anatomic configuration of pancreatic ductal system. Courtesy of W Silen.

released from duodenal mucosal cells in response to specific stimuli. Acid in the lumen of the duodenum causes the release of secretin, and luminal digestion products of fat and protein cause the release of CCK.

The water and electrolyte secretion is formed by the centroacinar and intercalated duct cells principally in response to secretin stimulation. The secretion is modified by exchange processes and active secretion in the ductal collecting system. The cations sodium and potassium are present in the same concentrations as in plasma. The anions bicarbonate and chloride vary in concentration according to the rate of secretion: with increasing rate of secretion, the bicarbonate concentration increases and chloride concentration falls, so that the sum of the two is the same throughout the secretory range. Pancreatic juice helps neutralize gastric

acid in the duodenum and adjusts luminal pH to the level that gives optimal activity of pancreatic enzymes.

Pancreatic enzymes are synthesized, stored (as zymogen granules), and released by the acinar cells of the gland, principally in response to CCK and vagal stimulation. Pancreatic enzymes are proteolytic, lipolytic, and amylolytic. Lipase and amylase are stored and secreted in active forms. The proteolytic enzymes are secreted as inactive precursors and are activated by the duodenal enzyme enterokinase. Other enzymes secreted by the pancreas include ribonucleases and phospholipase A. Phospholipase A is secreted as an inactive proenzyme activated in the duodenum by trypsin. It catalyzes the conversion of biliary lecithin to lysolecithin.

Turnover of protein in the pancreas exceeds that of any other organ in the body. Intravenously injected amino acids

▲ **Figure 26-2.** Arterial supply and venous drainage of the pancreas. Courtesy of W Silen.

are incorporated into enzyme protein and may appear in the pancreatic juice within 1 hour. Three mechanisms prevent autodigestion of the pancreas by its proteolytic enzymes: (1) the enzymes are stored in acinar cells as zymogen granules, where they are separated from other cell proteins; (2) the enzymes are secreted in an inactive form; and (3) inhibitors of proteolytic enzymes are present in pancreatic juice and pancreatic tissue.

► Endocrine Function

The function of the endocrine pancreas is to facilitate storage of foodstuffs by release of insulin after a meal and to provide a mechanism for their mobilization by release of glucagon during periods of fasting. Insulin and glucagon, as well as pancreatic polypeptide and somatostatin, are produced by the islets of Langerhans.

Insulin, a polypeptide (MW 5734) consisting of 51 amino acid residues, is formed in the beta cells of the pancreas via the precursor proinsulin. Insulin secretion is stimulated by rising or high serum concentrations of metabolic substrates such as glucose, amino acids, and perhaps short-chain fatty acids. The major normal stimulus for insulin release appears to be glucose. The release and synthesis of insulin are stimulated by activation of specific glucoreceptors located on the surface membrane of the beta cell. Insulin release is also stimulated by calcium, glucagon, secretin, CCK, vasoactive intestinal polypeptide (VIP), and gastrin, all of which sensitize the receptors on the beta cell to glucose. Epinephrine, tolbutamide, and chlorpropamide release insulin by acting on the adenylyl cyclase system.

Glucagon, a polypeptide (MW 3485) consisting of 29 amino acid residues, is formed in the α cells of the pancreas. The release of glucagon is stimulated by a low blood glucose concentration, amino acids, catecholamines, sympathetic nervous discharge, and CCK. It is suppressed by hyperglycemia and insulin.

The principal functions of insulin are to stimulate anabolic reactions involving carbohydrates, fats, proteins, and nucleic acids. Insulin decreases glycogenolysis, lipolysis, proteolysis, gluconeogenesis, ureagenesis, and ketogenesis. Glucagon stimulates glycogenolysis from the liver and proteolysis and lipolysis in adipose tissue as well as in the liver. With the increase in lipolysis, there is an increase in ketogenesis and gluconeogenesis. Glucagon increases cAMP in the liver, heart, skeletal muscle, and adipose tissue. The short-term regulation of gluconeogenesis depends on the balance between insulin and glucagon. Studies on insulin and glucagon suggest that the hormones exert their effects via receptors on the cell membrane. Before entering the systemic circulation, blood draining from the islets of Langerhans perfuses the pancreatic acini, and this exposure to high levels of hormones is thought to influence acinar function.

ANNULAR PANCREAS

Annular pancreas is a rare congenital condition in which a ring of pancreatic tissue from the head of the pancreas surrounds the descending duodenum. The abnormality usually presents in infancy as duodenal obstruction with postprandial vomiting. There is bile in the vomitus if the constriction is distal to the entrance of the common bile duct. X-rays show a dilated stomach and proximal duodenum (double bubble sign) and little or no air in the rest of the small bowel.

After correction of fluid and electrolyte imbalance, the obstructed segment should be bypassed by a duodenojejunostomy or other similar procedure. No attempt should be made to resect the obstructing pancreas, because a pancreatic fistula or acute pancreatitis often develops postoperatively.

Occasionally, annular pancreas will present in adult life with similar symptoms.

PANCREATITIS

Pancreatitis is a common nonbacterial inflammatory disease caused by activation, interstitial liberation, and autodigestion of the pancreas by its own enzymes. The process may or may not be accompanied by permanent morphologic and functional changes in the gland. Much is known about the causes of pancreatitis, but despite the accumulation of much experimental data, understanding of the pathogenesis of this disorder is still incomplete.

In acute pancreatitis, there is sudden upper abdominal pain, nausea and vomiting, and elevated serum amylase. Chronic pancreatitis is characterized by chronic pain, pancreatic calcification on x-ray, and exocrine (steatorrhea) or endocrine (diabetes mellitus) insufficiency. Attacks of acute pancreatitis often occur in patients with chronic pancreatitis. *Acute relapsing pancreatitis* is defined as multiple attacks of pancreatitis without permanent pancreatic scarring, a picture most often associated with biliary pancreatitis. The unsatisfactory term chronic relapsing pancreatitis, denoting recurrent acute attacks superimposed on chronic pancreatitis, will not be used in this chapter. Alcoholic pancreatitis often behaves in this way. The term subacute pancreatitis has also been used by some to denote the minor acute attacks that typically appear late in alcoholic pancreatitis.

► Etiology

Most cases of pancreatitis are caused by gallstone disease or alcoholism; a few result from hypercalcemia, trauma, hyperlipidemia, and genetic predisposition; and the remainder are idiopathic. Important differences exist in the manifestations and natural history of the disease as produced by these various factors.

A. Biliary Pancreatitis

About 40% of cases of pancreatitis are associated with gallstone disease, which, if untreated, usually gives rise to additional acute attacks. For unknown reasons, even repeated attacks of acute biliary pancreatitis seldom produce chronic pancreatitis. Eradication of the biliary disease nearly always prevents recurrent pancreatitis. The etiologic mechanism most likely consists of transient obstruction of the ampulla of Vater and pancreatic duct by a gallstone. Cholelithiasis is found in only 25% of cases, but because over 90% of patients excrete a gallstone in feces passed within 10 days after an acute attack, it is assumed that most attacks are caused by a gallstone or biliary sludge traversing the common duct and ampulla of Vater. Other possible steps in pathogenesis initiated by passage of the gallstone are discussed below.

B. Alcoholic Pancreatitis

In the United States, alcoholism accounts for about 40% of cases of pancreatitis. Characteristically, the patients have been heavy users of hard liquor or wine; the condition is relatively infrequent in countries where beer is the most popular alcoholic beverage. Most commonly, 6 years or more of alcoholic excess precede the initial attack of pancreatitis, and even with the first clinical manifestations, signs of chronic pancreatitis can be detected if the gland is examined microscopically. Thus, alcoholic pancreatitis is often considered to be synonymous with chronic pancreatitis no matter what the clinical findings.

Acute administration of alcohol stimulates pancreatic secretion and induces spasm in the sphincter of Oddi. This has been compared to experiments that produce acute pancreatitis by combining partial ductal obstruction and secretory stimulation. If the patient can be persuaded to stop drinking, acute attacks may be prevented, but parenchymal damage continues to occur owing to persistent ductal obstruction and fibrosis.

C. Hypercalcemia

Hyperparathyroidism and other disorders accompanied by hypercalcemia are occasionally complicated by acute pancreatitis. With time, chronic pancreatitis and ductal calculi appear. The increased calcium concentrations in pancreatic juice that result from hypercalcemia may prematurely activate proteases. They may also facilitate precipitation of calculi in the ducts.

D. Hyperlipidemia

In some patients—especially alcoholics—hyperlipidemia appears transiently during an acute attack of pancreatitis; in others with primary hyperlipidemia (especially those

associated with elevated chylomicrons and very low density lipoproteins), pancreatitis seems to be a direct consequence of the metabolic abnormality. Hyperlipidemia during an acute attack of pancreatitis is usually associated with normal serum amylase levels, because the lipid interferes with the chemical determination for amylase; urinary output of amylase may still be high. One should inspect the serum of every patient with acute abdominal pain, because if it is lactescent, pancreatitis will almost always be the correct diagnosis. If a primary lipid abnormality is present, dietary control reduces the chances of additional attacks of pancreatitis as well as other complications.

E. Familial Pancreatitis

In this condition, attacks of abdominal pain usually begin in childhood. Some affected families also have aminoaciduria, but this is not a universal finding. Diabetes mellitus and steatorrhea are uncommon. Chronic calcific pancreatitis develops eventually in most patients, and many patients become candidates for operation for chronic pain. Pancreatic carcinoma is more frequent in patients with familial pancreatitis.

F. Protein Deficiency

In certain populations where dietary protein intake is markedly deficient, the incidence of chronic pancreatitis is high. The reason for this association is obscure, especially in view of the observation that pancreatitis afflicts alcoholics with higher dietary protein and fat intake than those who consume less protein and fat.

G. Postoperative (Iatrogenic) Pancreatitis

Most cases of postoperative pancreatitis follow common bile duct exploration, especially if sphincterotomy was performed. Two practices, now largely abandoned, were often responsible: (1) use of a common duct T tube with a long arm passing through the sphincter of Oddi and (2) dilation of the sphincter to 5-7 mm during common duct exploration. Operations on the pancreas, including pancreatic biopsy, are another cause. A few cases follow gastric surgery or even operations remote from the pancreas. Pancreatitis is particularly common after cardiac surgery with cardiopulmonary bypass, where the risk factors are preoperative renal failure, valve surgery, postoperative hypotension, and (particularly) the perioperative administration of calcium chloride (> 800 mg calcium chloride per square meter of body surface area). Pancreatitis may also complicate endoscopic retrograde pancreatography or endoscopic sphincterotomy.

Rarely, pancreatitis follows Billroth II gastrectomy, owing to acute obstruction of the afferent loop and reflux of duodenal secretions under high pressure into the pancreatic ducts. The condition has been recreated experimentally in dogs (Pfeffer loop preparation).

H. Drug-Induced Pancreatitis

Drugs are probably responsible for more cases of acute pancreatitis than is generally suspected. The most commonly incriminated drugs are corticosteroids, estrogen-containing contraceptives, azathioprine, thiazide diuretics, and tetracyclines. Pancreatitis associated with use of estrogens is usually the result of drug-induced hypertriglyceridemia. The mechanisms involved in the case of other drugs are unknown.

I. Obstructive Pancreatitis

Chronic partial obstruction of the pancreatic duct may be congenital or may follow healing after injury or inflammation. Over time, the parenchyma drained by the obstructed duct is replaced by fibrous tissue, and chronic pancreatitis develops. Sometimes there are episodes of acute pancreatitis as well.

Pancreas divisum may predispose to a kind of obstructive pancreatitis. If this anomaly is present and further narrowing of the opening of the minor papilla occurs (eg, by an inflammatory process), the orifice may be inadequate to handle the flow of pancreatic juice. The diagnosis of pancreas divisum may be made by endoscopic retrograde cholangio-pancreatography (ERCP). If a patient with the anomaly is found to have documented episodes of acute pancreatitis and no other cause is found, it is reasonable to assume that the anomaly is the cause.

Surgical sphincteroplasty of the minor papilla or the insertion of a stent has been proposed as treatment, but results have been suboptimal. This may be due to the presence of irreversible parenchymal changes and the persistence of chronic inflammation. In patients with obvious changes of chronic pancreatitis, surgical treatment should consist of pancreatic resection or drainage.

J. Idiopathic Pancreatitis and Miscellaneous Causes

In about 15% of patients, representing the third largest group after biliary and alcoholic pancreatitis, there is no identifiable cause of the condition. If investigated in greater than usual detail (eg, duodenal drainage examination for cholesterol crystals), many of these patients will be found to have gallstones or biliary sludge undetectable by ultrasound scans. Recent data have linked mutations of the cystic fibrosis gene to idiopathic pancreatitis.

Viral infections and scorpion stings may cause pancreatitis.

► Pathogenesis

The concept that pancreatitis is due to enzymatic digestion of the gland is supported by the finding of proteolytic enzymes in ascitic fluid and increased amounts of phospholipase A and lysolecithins in pancreatic tissue from patients with acute pancreatitis. Experimentally, pancreatitis can be created readily

if activated enzymes are injected into the pancreatic ducts under pressure. Trypsin has not been found in excessive amounts in pancreatic tissue from affected humans, possibly because of inactivation by trypsin inhibitors. Nevertheless, although the available evidence is inconclusive, the autodigestion theory is almost universally accepted. Other proposed factors are vascular insufficiency, lymphatic congestion, and activation of the kallikrein-kinin system.

For many years, trypsin and other proteases were held to be the principal injurious agents, but recent evidence has emphasized phospholipase A, lipase, and elastase as perhaps of greater importance. Trypsin ordinarily does not attack living cells, and even when trypsin is forced into the interstitial spaces, the resulting pancreatitis does not include coagulation necrosis, which is so prominent in human pancreatitis.

Phospholipase A, in the presence of small amounts of bile salts, attacks free phospholipids (eg, lecithin) and those bound in cellular membranes to produce extremely potent lyso-compounds. Lysolecithin, which would result from the action of phospholipase A on biliary lecithin, or phospholipase A itself, plus bile salts, is capable of producing severe necrotizing pancreatitis. Trypsin is important in this scheme, because small amounts are needed to activate phospholipase A from its inactive precursor.

Elastase, which is both elastolytic and proteolytic, is secreted in an inactive form. Because it can digest the walls of blood vessels, elastase has been thought to be important in the pathogenesis of hemorrhagic pancreatitis.

If autodigestion is the final common pathway in pancreatitis, earlier steps must account for the presence of active enzymes and their reaction products in the ducts and their escape into the interstitium. The following are the most popular theories that attempt to link the known etiologic factors with autodigestion.

A. Obstruction-Secretion

In animals, ligation of the pancreatic duct generally produces mild edema of the pancreas that resolves within a week. Thereafter, atrophy of the secretory apparatus occurs. On the other hand, partial or intermittent ductal obstruction, which more closely mimics what seems to happen in humans, can produce frank pancreatitis if the gland is simultaneously stimulated to secrete. The major shortcoming of these experiments has been the difficulty encountered in attempting to cause severe pancreatitis in this way. However, since the human pancreas manufactures ten times as much phospholipase A as does the dog or rat pancreas, the consequences of obstruction in humans conceivably could be more serious.

B. Common Channel Theory

Flow between the biliary and pancreatic ducts requires a common channel connecting these two systems with

the duodenum. Although these ducts converge in 90% of humans, only 10% have a common channel long enough to permit biliary-pancreatic reflux if the ampulla contained a gallstone. Experimentally, pancreatitis produced by pancreatic duct obstruction alone is similar in severity to pancreatitis following obstruction of a common channel, so biliary reflux is discounted as an etiologic factor in this disease.

C. Duodenal Reflux

The above theories do not explain activation of pancreatic enzymes, a process that normally takes place through the action of enterokinase in the duodenum. In experimental animals, if the segment of duodenum into which the pancreatic duct empties is surgically converted to a closed loop, reflux of duodenal juice initiates severe pancreatitis (Pfeffer loop). Pancreatitis associated with acute afferent loop obstruction after Billroth II gastrectomy is probably the result of similar factors. Other than in this specific example, there is no direct evidence for duodenal reflux in the pathogenesis of pancreatitis in humans.

D. Back Diffusion Across the Pancreatic Duct

Just as the gastric mucosa must serve as a barrier to maintain high concentrations of acid, so must the epithelium of the pancreatic duct prevent diffusion of luminal enzymes into the pancreatic parenchyma. Experiments in cats have shown that the barrier function of the pancreatic duct is vulnerable to several injurious agents, including alcohol and bile acids. Furthermore, the effects of alcohol can occur even after oral ingestion, because alcohol is secreted in the pancreatic juice. Injury to the barrier renders the duct permeable to molecules as large as MW 20,000, and enzymes from the lumen may be able to enter the gland and produce pancreatitis.

Some studies have shown that a very early event in several forms of experimental pancreatitis, including that due to pancreatic duct obstruction, consists of zymogen activation within acinar cells by lysosomal hydrolases (eg, cathepsin B). This may represent the long-sought unifying explanation. Other factors must be postulated, however, to account for the variations in severity of the disease. In biliary pancreatitis, transient obstruction of the ampulla of Vater by a gallstone is most likely the first event. Alcoholic pancreatitis probably has several causes, including partial ductal obstruction, secretory stimulation, acute effects on the ductal barrier, and toxic actions of alcohol on parenchymal cells.

E. Systemic Manifestations

Severe acute pancreatitis may be complicated by multiple organ failure, principally respiratory insufficiency (acute respiratory distress syndrome), myocardial depression, renal insufficiency, and gastric stress ulceration. The pathogenesis

of these complications is similar in many respects to that of multiple organ failure in sepsis, and in fact, sepsis due to pancreatic abscess formation is a contributing factor in some of the most severe cases of acute pancreatitis. During acute pancreatitis, pancreatic proteases, bacterial endotoxins, and other active agents are liberated into the systemic circulation. The endotoxin probably originates from bacteria that translocate through an abnormally permeable intestinal mucosa. Within the circulation, the proteases and the endotoxin activate the complement system (especially C5) and kinins. Complement activation leads to granulocyte aggregation and accumulation of aggregates in the pulmonary capillaries. The granulocytes release neutrophil elastase, superoxide anion, hydrogen peroxide, and hydroxide radicals, which in concert with bradykinin exert local toxic effects on the pulmonary epithelium that result in increased permeability. Arachidonate metabolites (eg, PGE₂, PGI₂, leukotriene B₄) may also be involved in some way. Analogous events are thought to occur in other organs.

1. Acute Pancreatitis

ESSENTIALS OF DIAGNOSIS

- ▶ Abrupt onset of epigastric pain, frequently with back pain
- ▶ Nausea and vomiting
- ▶ Elevated serum or urinary amylase
- ▶ Cholelithiasis or alcoholism (many patients)

▶ General Considerations

While edematous and hemorrhagic pancreatitis are manifestations of the same pathologic processes and the general principles of treatment are the same, hemorrhagic pancreatitis has more complications and a higher death rate. In edematous pancreatitis, the glandular tissue and surrounding retroperitoneal structures are engorged with interstitial fluid, and the pancreas is infiltrated with inflammatory cells that surround small foci of parenchymal necrosis. Hemorrhagic pancreatitis is characterized by bleeding into the parenchyma and surrounding retroperitoneal structures and extensive

pancreatic necrosis. In both forms, the peritoneal surfaces may be studded with small calcifications representing areas of fat necrosis.

► Clinical Findings

A. Symptoms and Signs

The acute attack frequently begins with severe epigastric pain that radiates through to the back. The pain is unremitting and usually associated with vomiting and retching. In severe cases, the patient may collapse from shock.

Depending on the severity of the disease, there may be profound dehydration, tachycardia, and postural hypotension. Myocardial function is depressed in severe pancreatitis, presumably because of circulating factors that affect cardiac performance. Examination of the abdomen reveals decreased or absent bowel sounds and tenderness that may be generalized but more often is localized to the epigastrium. Temperature is usually normal or slightly elevated in uncomplicated pancreatitis. Clinical evidence of pleural effusion may be present, especially on the left. If an abdominal mass is found, it probably represents a swollen pancreas (phlegmon) or, later in the illness, a pseudocyst or abscess. In 1%-2% of patients, bluish discoloration is present in the flank (Grey Turner sign) or periumbilical area (Cullen sign), indicating hemorrhagic pancreatitis with dissection of blood retroperitoneally into these areas.

B. Laboratory Findings

The hematocrit may be elevated as a consequence of dehydration or low as a result of abdominal blood loss in hemorrhagic pancreatitis. There is usually a moderate leukocytosis, but total white blood cell counts over 12,000/mL are unusual in the absence of suppurative complications. Liver function studies are usually normal, but there may be a mild elevation of the serum bilirubin concentration (usually < 2 mg/dL).

The serum amylase concentration rises to more than three times normal within 6 hours after the onset of an acute episode and generally remains elevated for several days. Values in excess of 1000 IU/dL occur early in the attack in 95% of patients with biliary pancreatitis and 85% of patients with acute alcoholic pancreatitis. Those with the most severe disease are more apt to have amylase levels below 1000 IU/dL.

Elevated serum lipase is detectable early and for several days after the acute attack. Since the lipase level tends to be higher in alcoholic pancreatitis and the amylase level higher in gallstone pancreatitis, the lipase/amylase ratio has been suggested as a means to help distinguishing the two.

Elevated amylase levels may occur in other acute abdominal conditions, such as gangrenous cholecystitis, small bowel obstruction, mesenteric infarction, and perforated ulcer, though levels rarely exceed 500 IU/dL. Episodes of acute

pancreatitis may occur without rises in serum amylase; this is the rule if hyperlipidemia is present. Furthermore, high levels may return to normal before blood is drawn.

The methods most commonly used for measuring amylase in the serum detect pancreatic amylase, salivary amylase, and macroamylase. However, hyperamylasemia is sometimes present in patients with abdominal pain when the elevated amylase levels consist entirely of salivary amylase or macroamylase and the pancreas is not inflamed.

In severe pancreatitis, the serum calcium concentration may fall as a result of calcium being complexed with fatty acids (liberated from retroperitoneal fat by lipase) and impaired reabsorption from bone owing to the action of calcitonin (liberated by high levels of glucagon). Relative hypoparathyroidism and hypoalbuminemia have also been implicated.

C. Imaging Studies

In about two-thirds of cases, a plain abdominal film is abnormal. The most frequent finding is isolated dilation of a segment of gut (sentinel loop) consisting of jejunum, transverse colon, or duodenum adjacent to the pancreas. Gas distending the right colon that abruptly stops in the mid or left transverse colon (colon cutoff sign) is due to colonic spasm adjacent to the pancreatic inflammation. Both of these findings are relatively nonspecific. Glandular calcification may be evident, signifying chronic pancreatitis. An upper gastrointestinal series may show a widened duodenal loop, swollen ampulla of Vater, and, occasionally, evidence of gastric irritability. Chest films may reveal pleural effusion on the left side. Occasionally, radiopaque gallstones will be apparent on plain x-rays.

Ultrasound study may demonstrate gallstones early in the attack and may be used as a baseline for sequential examinations of the pancreas.

A CT scan of the pancreas using intravenous contrast media should be obtained for one of three reasons: (1) diagnostic uncertainty, (2) confirmation/evaluation of severity based upon other markers or clinical suspicion, or (3) evaluation in the setting of clinical deterioration or failure to respond to therapy. The radiologic findings may be consistent with any of the following: relatively normal appearing pancreas, pancreatic phlegmon, pancreatic phlegmon with extension of the inflammatory process to adjacent extrapancreatic spaces, pancreatic necrosis, or pancreatic pseudocyst, or abscess formation.

Several weeks after the pancreatitis has subsided, ERCP may be of value in patients with a tentative diagnosis of idiopathic pancreatitis (ie, those who have no history of alcoholism and no evidence of gallstones on ultrasound and oral cholecystogram). This examination demonstrates gallstones or changes of chronic pancreatitis in about 40% of such patients.

► Differential Diagnosis

To some extent, acute pancreatitis is a diagnosis of exclusion, for other acute upper abdominal conditions such as acute cholecystitis, penetrating or perforated duodenal ulcer, high small bowel obstruction, acute appendicitis, and mesenteric infarction must always be seriously considered. In most cases, the distinction is possible on the basis of the clinical picture, laboratory findings, and CT scans. The critical point is that the diseases with which acute pancreatitis is most likely to be confused are often lethal if not treated surgically.

Chronic hyperamylasemia occurs rarely without any relation to pancreatic disease. Some cases are associated with renal failure, chronic sialadenitis, salivary tumors, ovarian tumors, or liver disease, but often there is no explanation. Analysis of serum amylase isoenzymes is the only way to determine whether the amylase originates from salivary glands or pancreas. Macroamylasemia is a chronic hyperamylasemia in which normal amylase (usually salivary) is bound to a large serum glycoprotein or immunoglobulin molecule and is therefore not excreted into urine. The diagnosis rests on the combination of hyperamylasemia and low urinary amylase. Macroamylasemia has been found in patients with other diseases such as malabsorption, alcoholism, and cancer. Many patients have abdominal pain, but the relationship of the pain and the macroamylasemia is uncertain.

► Complications

The principal complications of acute pancreatitis are abscess and pseudocyst formation. These are discussed in separate sections. Gastrointestinal bleeding may occur from adjacent inflamed stomach or duodenum, ruptured pseudocyst, or peptic ulcer. Intraperitoneal bleeding may occur spontaneously from the celiac or splenic artery or from the spleen following acute splenic vein thrombosis. Involvement of the transverse colon or duodenum by the inflammatory process may result in partial obstruction, hemorrhage, necrosis, or fistula formation.

Early identification of patients at greatest risk of complications allows them to be managed more aggressively, which appears to decrease the mortality rate. The criteria of severity that have been found to be reliable are based either on the systemic manifestations of the disease as reflected in the clinical and laboratory findings or on the local changes in the pancreas as reflected by the findings on CT scan. Ranson used the former approach to develop the staging criteria listed in Table 26-1. Just the single finding of fluid sequestration (ie, fluid administered minus urine output) exceeding 2 L/d for more than 2 days is a reasonably accurate dividing line between severe (life-threatening) and mild-to-moderate disease. The local changes in the pancreas as shown on CT scans may be even more revealing. The presence of any of the following indicates a high risk of local infection in the pancreatic bed: involvement of extrapancreatic spaces in the inflammatory

Table 26-1. Ranson criteria of severity of acute pancreatitis.¹

Criteria Present Initially

Age > 55 years
White blood cell count > 16,000/ μ L
Blood glucose > 200 mg/dL
SERUM LDH > 350 IU/L
AST (SGOT) > 250 IU/dL

Criteria Developing During First 24 Hours

Hematocrit fall > 10%
BUN rise > 8 mg/dL
Serum Ca^{2+} < 8 mg/dL
Arterial PO_2 < 60 mm Hg
Base deficit > 4 meq/L
Estimated fluid sequestration > 600 mL

¹Morbidity and mortality rates correlate with the number of criteria present. Mortality rates correlate as follows: 0–2 criteria present = 2%; 3 or 4 = 15%; 5 or 6 = 40%; 7 or 8 = 100%.

process, pancreatic necrosis (areas in the pancreas that do not enhance with intravenous contrast media), and early signs of abscess formation (eg, gas bubbles in the tissue).

► Treatment

A. Medical Treatment

The goals of medical therapy are reduction of pancreatic secretory stimuli and correction of fluid and electrolyte derangements.

1. Gastric suction—Oral intake is withheld. A nasogastric tube is often inserted to aspirate gastric secretions, although the latter has no specific therapeutic effect. Oral feeding should be resumed only after the patient appears much improved, appetite has returned, and serum amylase levels have dropped to normal. Premature resumption of eating may result in exacerbation of disease.

2. Fluid replacement—Patients with acute pancreatitis sequester fluid in the retroperitoneum and bowel, and large volumes of intravenous fluids are necessary to maintain circulating blood volume and renal function. In severe hemorrhagic pancreatitis, blood transfusions may also be required. The adequacy of fluid replacement is the single most important aspect of medical therapy. In fact, undertreatment with fluids may actually contribute to the progression of pancreatitis. Fluid replacement may be judged most accurately by monitoring the volume and concentration of the urine.

3. Antibiotics—Antibiotics are not useful in mild cases of acute pancreatitis. However, some studies have shown benefit of antibiotics that penetrate pancreatic tissue for patients with severe pancreatitis. Imipenem is the most commonly

used antibiotic, though its use is not universally supported even in patients with severe disease. Antibiotics should also be used for treatment of specific operative complications.

4. Calcium and magnesium—In severe attacks of acute pancreatitis, hypocalcemia may require parenteral calcium replacement in amounts determined by serial calcium measurements. Recognition of hypocalcemia is important because it may produce cardiac dysrhythmias. Hypomagnesemia is also common, especially in alcoholics, and magnesium should also be replaced as indicated by serum levels.

5. Oxygen—Hypoxemia severe enough to require therapy develops in about 30% of patients with acute pancreatitis. It is often insidious, without clinical or x-ray signs, and out of proportion to the severity of the pancreatitis. The most pronounced examples accompany severe pancreatitis, often in association with hypocalcemia. The basic lesion, a form of adult respiratory distress syndrome, is poorly understood. Pulmonary changes include decreased vital capacity and an oxygen diffusion defect.

Hypoxemia must be suspected in every patient, and oxygen saturation should be monitored periodically or continuously for the first few hospital days. An occasional patient requires endotracheal intubation and mechanical ventilation. Diuretics may be useful in decreasing lung water and improving arterial oxygen saturation.

6. Nutrition—Enteral feeding should be used to support nutritional goals during the acute episode. Total parenteral nutrition avoids pancreatic stimulation and should be used for nutritional support only if enteral feeding is not practical for 5 or more days. Neither form of nutrition directly affects recovery of the pancreas.

7. Other drugs—Octreotide, H₂ receptor blockers, anticholinergic drugs, glucagon, and aprotinin have shown no beneficial effects in controlled trials.

B. Endoscopic Sphincterotomy

Biliary pancreatitis is caused by a gallstone becoming lodged in the ampulla of Vater. In most cases, the stone passes into the intestine but occasionally it becomes impacted in the ampulla, which results in more severe disease. Less than 10% of cases of biliary pancreatitis are severe (ie, three or more Ranson criteria), but in severe cases, endoscopic sphincterotomy performed within 72 hours of the onset of the disease has been shown to decrease the incidence of concomitant biliary sepsis and lower the mortality rate from the pancreatitis.

C. Surgical Treatment

Surgery is generally contraindicated in uncomplicated acute pancreatitis. However, when the diagnosis is uncertain

in a patient with severe abdominal pain, diagnostic laparoscopy or laparotomy is not thought to aggravate pancreatitis.

When operative evaluation has been performed for diagnosis and mild to moderate pancreatitis is found, cholecystectomy should be performed if gallstones are present, but the pancreas should be left undisturbed. Although some surgeons place drains and irrigating catheters in the region of the pancreas, we prefer to keep foreign bodies out of this area.

The diagnosis of biliary pancreatitis can usually be suspected on the basis of ultrasound studies of the gallbladder early in the acute attack. Cholecystectomy should be performed on these patients during hospitalization for the acute attack soon after the attack resolves. A longer delay (even a few weeks) is associated with a high incidence (80%) of recurrent pancreatitis. Since life-threatening attacks are uncommon in gallstone pancreatitis, operation or endoscopic therapy early in an attack is rarely justified. However, when the attack is especially severe, elective cholecystectomy should be deferred up to several months to allow complete recovery from pancreatitis.

It is currently thought that debridement of dead peripancreatic tissue, which is often (40% of cases) colonized by bacteria, reduces the mortality rate of acute severe necrotizing pancreatitis. Historical controls place the mortality rate at 50%-80% in the absence of operative treatment and 10%-40% among patients subjected to necrosectomy. The diagnosis of necrotizing pancreatitis is suspected from the clinical findings; patients treated surgically have three or more Ranson criteria and average about 4½ criteria. Contrast-enhanced CT scans obtained early in the course of the disease are studied for the presence of nonenhancing areas, which indicate lack of vascular perfusion and reflect the presence of necrotic peripancreatic fat or pancreatic parenchyma. Percutaneous needle aspiration of these areas is used to detect the presence of bacterial colonization. A distinction is made between these cases of “infected necrotizing pancreatitis” and “pancreatic abscess,” which may appear later in the course of the disease. Patients with infected necrotizing pancreatitis and severe clinical findings benefit most from surgical therapy, but laparotomy may be undertaken just because of a deteriorating condition in patients with necrotizing pancreatitis in the absence of bacterial colonization. At surgery, all peripancreatic spaces are opened and any necrotic tissue is removed by gentle blunt dissection. This can be accomplished with less invasive videoscopic techniques. Other than CT evidence of necrotic tissue with or without infection, there are presently no other criteria in general use that call for pancreatic surgery in patients with severe pancreatitis.

Surgery for complications of acute pancreatitis, such as abscess, pseudocyst, and pancreatic ascites, is discussed below.

► Prognosis

The death rate associated with acute pancreatitis is about 10%, and nearly all deaths occur in a first attack and among patients with three or more Ranson criteria of severity. Respiratory insufficiency and hypocalcemia indicate a poor prognosis. The death rate associated with severe necrotizing pancreatitis is 50% or more, but surgical therapy lowers the figure to about 20%. Persistent fever or hyperamylasemia 3 weeks or longer after an attack of pancreatitis usually indicates the presence of a pancreatic abscess or pseudocyst.

2. Pancreatic Pseudocyst

ESSENTIALS OF DIAGNOSIS

- Epigastric mass and pain
- Mild fever and leukocytosis
- Persistent serum amylase elevation
- Pancreatic cyst demonstrated by ultrasound or CT scan

► General Considerations

Pancreatic pseudocysts are encapsulated collections of fluid with high enzyme concentrations that arise from the pancreas. They are usually located either within or adjacent to the pancreas in the lesser sac. The walls of a pseudocyst are formed by inflammatory fibrosis of the peritoneal, mesenteric, and serosal membranes, which limits spread of the pancreatic juice as the lesion develops. The term pseudocyst denotes absence of an epithelial lining, whereas true cysts are lined by epithelium.

Two different processes are involved in the pathogenesis of pancreatic pseudocysts. Many occur as complications of severe acute pancreatitis, where extravasation of pancreatic juice and glandular necrosis form a sterile pocket of fluid that is not reabsorbed as inflammation subsides. Superinfection of such collections leads to pancreatic abscess

instead of pseudocyst. In other patients, usually alcoholics or trauma victims, pseudocysts appear without preceding acute pancreatitis. The mechanism in these cases consists of ductal obstruction and formation of a retention cyst that loses its epithelial lining as it grows beyond the confines of the gland. In posttraumatic pseudocyst, symptoms usually do not appear until several weeks after the injury. Some are iatrogenic, eg, occurring during splenectomy; others follow an external blow to the abdomen.

Pseudocysts develop in about 2% of cases of acute pancreatitis. The cysts are single in 85% of cases and multiple in the remainder.

► Clinical Findings

A. Symptoms and Signs

A pseudocyst should be suspected when a patient with acute pancreatitis fails to recover after a week of treatment or when, after improving for a time, symptoms return. Since it is now fairly routine to obtain a CT scan early in an attack of severe acute pancreatitis, the early stages of pseudocyst formation are often demonstrated radiographically before specific clinical findings appear. The first clinical manifestation is usually a palpable tender mass in the epigastrium, consisting of a swollen pancreas and contiguous viscera (a phlegmon). With time, the mass may subside, but if it persists it most likely represents a pseudocyst.

In other cases, the pseudocyst develops insidiously without an obvious attack of acute pancreatitis.

Regardless of the type of prodromal phase, pain is the most common finding. Fever, weight loss, tenderness, and a palpable mass are present in about half of patients. A few have jaundice, a manifestation of obstruction of the intrapancreatic segment of the bile duct.

B. Laboratory Findings

An elevated serum amylase and leukocytosis are present in about half of patients. When present, elevated bilirubin levels reflect biliary obstruction. Of those patients with acute pancreatitis whose serum amylase remains elevated for as long as 3 weeks, about half will have a pseudocyst.

C. Imaging Studies

CT scan (Figure 26–3) is the diagnostic study of choice. The size and shape of the cyst and its relationship to other viscera can be seen. Acute pseudocysts are often irregular in shape; chronic pseudocysts are most often circular or nearly so. An enlarged pancreatic duct may be demonstrated in patients with chronic pancreatitis. A dilated common bile duct would suggest biliary obstruction, either from the cyst or from underlying chronic pancreatitis.

The gallbladder should be studied by ultrasound to look for stones, especially in patients with acute pancreatitis.

▲ **Figure 26-3.** CT scan of a large pancreatic pseudocyst impinging on the posterior wall of the stomach. The large arrow indicates the pseudocyst; the smaller area indicates the stomach. **A** : More cephalad in the abdomen, the pseudocyst abuts the stomach and liver. **B** : More caudad in the abdomen, the pseudocyst is immediately posterior to the gastric antrum. The stomach is compressed against the anterior wall of the abdomen, and the duodenum is stretched over the pseudocyst, causing early satiety. A cyst in this location is usually best drained into the stomach.

Although ultrasound can also demonstrate pseudocysts, the amount of important detail obtained is limited compared to CT scan, and consequently the role of ultrasound is mainly to follow changes in size of an acute pseudocyst already imaged by CT scan, so the amount of x-ray exposure can be minimized.

MRCP and/or ERCP should be performed if there is concern about significant abnormalities of the bile or pancreatic duct as suggested by CT scans or the results of liver function tests. Either duct may be dilated and in need of surgical drainage in conjunction with drainage of the pseudocyst. ERCP usually opacifies the pseudocyst as well, but the information is not usually of major value in planning treatment, so ERCP is not obtained routinely.

An upper gastrointestinal series will often reveal a mass in the lesser sac that distorts the stomach or duodenum, but this is not particularly useful information. The principal indication for an upper gastrointestinal series is to search for a site of gastric or duodenal obstruction in patients who are vomiting.

With wide use of sensitive imaging studies in the diagnosis of pancreatic disease, small asymptomatic pseudocysts are often demonstrated. The natural history of these subclinical lesions is benign, and there is no indication for prophylactic surgical treatment.

► Differential Diagnosis

Pancreatic pseudocysts must be distinguished from pancreatic abscess and acute pancreatic phlegmon. Patients with an abscess exhibit signs of infection.

Rarely, patients with pseudocyst present with weight loss, jaundice, and a nontender palpable gallbladder and are first thought to have pancreatic carcinoma. CT scans show

that the lesion is fluid-filled, which suggests the correct diagnosis.

Neoplastic cysts—either cystadenoma or cystadenocarcinoma—account for about 5% of all cases of cystic pancreatic masses and may be indistinguishable preoperatively from pseudocyst. The correct diagnosis can be made from the gross appearance supplemented by a biopsy obtained at operation.

► Complications

A. Infection

Infection is a rare complication resulting in high fever, chills, and leukocytosis. Drainage is required as soon as the diagnosis is suspected. Some lesions can be drained externally via a catheter placed percutaneously using ultrasound guidance. Internal drainage of infected pseudocysts adherent to the stomach can be achieved surgically by cystogastrostomy; otherwise, drainage should be external, because the suture line of a Roux-en-Y cystojejunostomy may not heal.

B. Rupture

Sudden perforation into the free peritoneal cavity produces severe chemical peritonitis, with abdominal rigidity and severe pain. Rapid enlargement of the pseudocyst is sometimes noted before it ruptures. The treatment is emergency surgery with irrigation of the peritoneal cavity and a drainage procedure for the pseudocyst. The wall of a ruptured pseudocyst is usually too flimsy to hold sutures securely, so most ruptured cysts must be drained externally. Rupture of a pseudocyst occurs in less than 5% of cases, and even with prompt treatment it may be fatal.

C. Hemorrhage

Bleeding may occur into the cyst cavity or an adjacent viscus into which the cyst has eroded. Intracystic bleeding may present as an enlarging abdominal mass with anemia resulting from blood loss. If the cyst has eroded into the stomach, there may be hematemesis, melena, and blood in the nasogastric aspirate. The rapidity of the blood loss often produces hemorrhagic shock, which may preclude arteriography. If time permits, however, emergency arteriography should be performed to delineate the site of bleeding, which is usually a false aneurysm of an artery in the cyst wall, and to embolize it if possible. If embolization successfully occludes the bleeding vessel, several weeks should elapse to ensure that bleeding will not recur, and at that point the pseudocyst should be drained surgically in the same fashion as a nonbleeding pseudocyst. If the bleeding cannot be stopped by embolization, emergency surgery should be performed. Usually all that can be done is to open the cyst and suture ligate the bleeding vessel in the cyst wall, followed by external or internal drainage of the cyst. Sometimes it is possible to excise the cyst, which is desirable because doing so more certainly avoids the risk of recurrent hemorrhage.

► Treatment

The principal indications for treating pancreatic pseudocysts are to improve symptoms and to prevent complications. Recent data indicate that the natural history of these lesions is more benign than previously thought—that in the absence of symptoms or radiographic evidence of enlargement (and irrespective of cyst size), expectant management is not unreasonable, and that a few untreated cysts resolve spontaneously even after being stable for months. Expectant management is especially important in the first 6-12 weeks of existence of cysts that have arisen during an attack of acute pancreatitis. The chances of spontaneous resolution are about 40%; catheter drainage at this stage is meddlesome; and internal drainage of the cyst by surgery may be difficult or even impossible. Thereafter, for cysts greater than 5 cm, treatment is usually recommended over expectant management (in the absence of contraindications, such as serious concomitant disease), because most cysts can be promptly eliminated by percutaneous catheter drainage or surgical drainage into the stomach or intestine. This obviates the need for prolonged follow-up with repeated ultrasound or CT scans and avoids the risks, albeit low, of complications. Patients who present with a symptomatic pseudocyst and no history of recent acute pancreatitis may be treated without the 6- to 12-week delay, because their cyst wall is tough (mature) enough to hold sutures and allow an anastomosis with the gut. Jaundice in a patient with a pseudocyst is usually caused by pressure from the cyst on the bile duct. Draining the pseudocyst usually relieves the obstruction, but an operative cholangiogram should be obtained to make sure.

A. Excision

Excision is the most definitive treatment but is usually confined to chronic pseudocysts in the tail of the gland. This approach is recommended especially for cysts that follow trauma, where the head and body of the gland are normal. Most cysts should be drained either externally or internally into the gut.

B. External Drainage

External drainage is best for critically ill patients or when the cyst wall has not matured sufficiently for anastomosis to other organs. A large tube is sewn into the cyst lumen, and its end is brought out through the abdominal wall. External drainage is complicated in a third of patients by a pancreatic fistula that sometimes requires surgical drainage but on the average closes spontaneously in several months. The incidence of recurrent pseudocyst is about four times greater after external drainage than after drainage into the gut.

C. Internal Drainage

The preferred method of treatment is internal drainage, where the cyst is anastomosed to a Roux-en-Y limb of jejunum (cystojejunostomy), to the posterior wall of the stomach (cystogastrostomy), or to the duodenum (cystoduodenostomy). The interior of the cyst should be inspected for evidence of a tumor and biopsy performed as appropriate. Cystogastrostomy is preferable for cysts behind and densely adherent to the stomach. This may well be done laparoscopically in the future. To accomplish free, dependent drainage, Roux-en-Y cystojejunostomy provides better drainage of cysts in various other locations. Cystoduodenostomy is indicated for cysts deep within the head of the gland and adjacent to the medial wall of the duodenum—lesions that would be difficult to drain by any other technique. The procedure consists of making a lateral duodenotomy, opening into the cyst through the medial wall of the duodenum, and then closing the lateral duodenotomy. Following internal drainage, the cyst cavity becomes obliterated within a few weeks. Even after cystogastrostomy, an unrestricted diet can be allowed within a week after surgery, and x-rays taken at this time usually show only a small residual cyst cavity.

D. Nonsurgical Drainage

External drainage can be established by a percutaneous catheter placed into the cyst under radiographic or ultrasound control. This is the preferred method for infected pseudocysts. In some centers, it is also used for the majority of uncomplicated pseudocysts as the primary mode of therapy. About two-thirds of cysts so treated are permanently eradicated. It may also be useful to shrink a truly huge

pseudocyst (eg, one that occupies half of the abdominal cavity), because it is technically difficult to obtain adequate internal drainage of these lesions into the gut. Occasionally, a sterile cyst may become infected when a narrow catheter is inserted into it. This is more likely when the cyst lumen contains debris that is not drained effectively by this technique. Chronic external pancreatic fistula is a potential complication of this method.

Two other drainage techniques have been tried: (1) passing a catheter percutaneously through the anterior abdominal wall, the anterior wall of the stomach, and through the posterior stomach into the cyst. After several weeks, the catheter is removed, and a chronic tract remains from cyst to gastric lumen. (2) Using a fiberoptic gastroscope to make a small incision through the back wall of the stomach into the cyst.

► Prognosis

The recurrence rate for pancreatic pseudocyst is about 10%, and recurrence is more frequent after treatment by external drainage. Serious postoperative hemorrhage from the cyst occurs rarely—most often after cystogastrostomy. In most cases, however, surgical treatment of pseudocysts is uncomplicated and definitively solves the immediate problem. Many patients later experience chronic pain as a manifestation of underlying chronic pancreatitis.

3. Pancreatic Abscess

Pancreatic abscess, which complicates about 5% of cases of acute pancreatitis, is invariably fatal if it is not treated surgically. It tends to develop in severe cases accompanied by hypovolemic shock and pancreatic necrosis and is an especially frequent complication of postoperative pancreatitis. Abscess formation follows secondary bacterial contamination of necrotic pancreatic debris and hemorrhagic exudate. The organisms may spread to the pancreas hematogenously as well as directly through the wall of the transverse colon. It is unknown whether prophylactic antibiotics given early in the course of severe acute pancreatitis decrease the incidence of abscess.

► Clinical Findings

An abscess should be suspected when a patient with severe acute pancreatitis fails to improve and develops rising fever or when symptoms return after a period of recovery. In

most cases, there is improvement for a while before signs of infection appear 2-4 weeks after the attack began. Epigastric pain and tenderness and a palpable tender mass are clues to diagnosis. In many cases, the findings are not especially striking—ie, the temperature is only modestly elevated and the patient does not appear septic. Vomiting or jaundice may be present, but in some cases fever and leukocytosis are the only findings. The serum amylase may be elevated but usually is normal. Characteristically, the serum albumin is below 2.5 g/dL and the alkaline phosphatase is elevated. Pleural fluid and diaphragmatic paralysis may be evident on chest x-rays. An upper gastrointestinal series may show deformity of the stomach or duodenum by a mass, but it usually does not, and the changes are nonspecific in any case. Diagnostic CT scans will usually indicate the presence of a fluid collection in the area of the pancreas. Gas in the collection on plain films or CT scans is virtually diagnostic. Percutaneous CT scan-guided aspiration may be used to aid in diagnosis and obtain a specimen for Gram stain and culture.

In general, the diagnosis is difficult, treatment is often instituted late, illness is severe, and death rates are high.

► Treatment

The infected collection must be drained. Percutaneous catheter drainage may be helpful as a first step in order to decrease toxicity or to obtain a specimen for culture. In some cases, catheter drainage will prove to be definitive, but most often the infected retroperitoneal space is honeycombed and contains necrotic debris that cannot pass through the catheter, so surgical debridement is necessary. It is best to consider catheter drainage as a preparatory step for surgery rather than a curative treatment, for that is the usual relationship. Otherwise, there may be a tendency to delay surgery for too long as futile efforts are repeatedly made to manipulate the catheters into better positions. In fact, the two measures—surgical debridement and catheter drainage—are complementary.

Preoperatively, the patient should be given broad-spectrum antibiotics, since the organisms are usually a mixed flora, most often *Escherichia coli*, *Bacteroides*, *Staphylococcus*, *Klebsiella*, *Proteus*, *Candida albicans*, etc. Necrotic debris should be removed and external drainage instituted.

Postoperative hemorrhage (immediate or delayed) from the abscess cavity occurs occasionally.

► Prognosis

The death rate is about 20%, a consequence of the severity of the condition, incomplete surgical drainage, and the inability in some cases to make the diagnosis.

4. Pancreatic Ascites & Pancreatic Pleural Effusion

Pancreatic ascites consists of accumulated pancreatic fluid in the abdomen without peritonitis or severe pain. Since many of these patients are alcoholic, they are often thought at first to have cirrhotic ascites. The syndrome is most often due to chronic leakage of a pseudocyst, but a few cases are due to disruption of a pancreatic duct. The principal causative factors are alcoholic pancreatitis in adults and traumatic pancreatitis in children. Marked recent weight loss is a major clinical manifestation, and unresponsiveness of the ascites to diuretics is an additional diagnostic clue. The ascitic fluid, which ranges in appearance from straw-colored to blood-tinged, contains elevated protein (> 2.9 g/dL) and amylase levels. Once this condition is suspected, definitive diagnosis is based on chemical analysis of the ascitic fluid and endoscopic retrograde pancreatography. The latter procedure frequently demonstrates the point of fluid leak and allows a rational surgical approach if operation is required.

Initial therapy should consist of a period of intravenous hyperalimentation and somatostatin. This often cures the problem. If considerable improvement has not occurred within 2-3 weeks, surgery should be performed. A preoperative ERCP is essential to demonstrate the site of the leak. If it is not entirely obvious from the films taken during ERCP, a CT scan should be performed immediately afterward, while contrast media is still in the pancreatic duct. The greater sensitivity of the CT scan will be enough to reveal the tiny trickle from the pancreatic duct into the abdomen. The operation involves suturing a Roux-en-Y limb of jejunum to the site of the leak on the surface of the pancreas or a pancreatic pseudocyst. With appropriate therapy, the outlook is excellent. The death rate is low in patients treated before debilitation becomes severe.

Chronic pleural effusions of pancreatic origin represent a variant in which the pancreatic fistula drains into the chest. The diagnosis is made by measuring high concentrations of amylase (usually > 3000 IU/dL) in the fluid. A CT scan of the pancreas and retrograde pancreatogram should be obtained. Medical therapy consists of draining the fluid with a chest tube, somatostatin, and total parenteral nutrition. If after several weeks the fistula persists or if it recurs after the tube has been removed, the source of the leak on the pancreas should either be drained into a Roux-en-Y limb of jejunum or excised as part of a distal pancreatectomy.

5. Chronic Pancreatitis

ESSENTIALS OF DIAGNOSIS

- ▶ Persistent or recurrent abdominal pain
- ▶ Pancreatic calcification on x-ray in 50%
- ▶ Pancreatic insufficiency in 30%; malabsorption and diabetes mellitus
- ▶ Most often due to alcoholism

▶ General Considerations

Chronic alcoholism causes most cases of chronic pancreatitis, but a few are due to gallstones, hypercalcemia, hyperlipidemia, duct obstruction from any cause, or inherited predisposition (familial pancreatitis). Direct trauma to the gland, either from an external blow or from surgical injury, can produce chronic pancreatitis if a ductal stricture develops during the healing process. In such cases, disease is often localized to the segment of gland drained by the obstructed duct. Although gallstone disease may cause repeated attacks of acute pancreatitis, this uncommonly leads to chronic pancreatitis.

Pressure within the duct is increased in patients with chronic pancreatitis (about 40 cm H₂O) compared with normal subjects (about 15 cm H₂O). This is a result of increased viscosity of pancreatic juice, partial obstruction by calculi, and impaired distensibility of the gland because of diffuse fibrosis. Sphincteric pressure remains in the normal range. The increased pressure causes dilation of the duct in the patient whose pancreas has not yet become fixed by scarring. It may also impair nutrient blood flow, causing further functional damage. Pathologic changes in the gland include destruction of parenchyma, fibrosis, dedifferentiation of acini, calculi, and ductal dilation.

▶ Clinical Findings

A. Symptoms and Signs

Chronic pancreatitis may be asymptomatic, or it may produce abdominal pain, malabsorption, diabetes mellitus, or (usually) all three manifestations. The pain is typically felt deep in the upper abdomen and radiating through to the back, and it waxes and wanes from day to day. Early in the course of the disease, the pain may be episodic, lasting for days to weeks and then vanishing for several months before returning again. Attacks of acute pancreatitis may occur, superimposed on the pattern of chronic pain. Many patients become addicted to the narcotics prescribed for pain.

B. Laboratory Findings

Abnormal laboratory findings may result from: (1) pancreatic inflammation, (2) pancreatic exocrine insufficiency, (3) diabetes mellitus, (4) bile duct obstruction, or (5) other complications such as pseudocyst formation or splenic vein thrombosis.

1. Amylase—In acute exacerbations, serum and urinary amylase levels may be elevated, but most often they are not, perhaps because pancreatic fibrosis has destroyed so much of the enzyme-forming capacity of the parenchyma.

2. Tests of exocrine pancreatic function—The secretin and CCK stimulation tests are the most sensitive tests to detect exocrine malfunction but are difficult to perform.

3. Diabetes mellitus—About 75% of patients with calcific pancreatitis and 30% of those with noncalcific pancreatitis have insulin-dependent diabetes. Most of the rest have either abnormal glucose tolerance curves or abnormally low serum insulin levels after a test meal. The margin of reserve is such that partial pancreatectomy is quite likely to convert a patient who does not require insulin into one who does require it postoperatively.

4. Biliary obstruction—Elevated bilirubin or alkaline phosphatase levels may result from fibrotic entrapment of the lower end of the bile duct. The differential diagnosis of biliary obstruction in these patients must consider acute pancreatic inflammation, pseudocyst, or pancreatic neoplasm.

5. Miscellaneous—Splenic vein thrombosis may produce secondary hypersplenism or gastric varices.

A. Imaging Studies

MRCP or endoscopic retrograde pancreatography is helpful in establishing the diagnosis of chronic pancreatitis, in ruling out pancreatic pseudocyst and neoplasm, and in preoperative planning for patients thought to be candidates for surgery. The typical findings are ductal stones and irregularity, with dilation and stenoses and, occasionally, ductal occlusion. The discovery of small, unsuspected pseudocysts is common. Retrograde cholangiography should be performed simultaneously to determine whether the common bile duct is narrowed by the pancreatitis, to determine whether biliary calculi are present, and to aid the surgeon in avoiding injury to the bile duct during operation.

► Complications

The principal complications of chronic pancreatitis are pancreatic pseudocyst, biliary obstruction, duodenal

obstruction, malnutrition, and diabetes mellitus. Adenocarcinoma of the pancreas occurs with greater frequency in patients with familial chronic pancreatitis than in the general population.

► Treatment

Medical Treatment

Malabsorption and steatorrhea are managed with support and measures. Controlled trials have shown that administering pancreatic enzymes has little effect on the pain.

Patients with chronic pancreatitis should be urged to discontinue the use of alcohol. Abstinence from alcohol will reduce chronic or episodic pain in more than half of cases even though damage to the pancreas is irreversible. Psychiatric treatment may be beneficial. Diabetes in these patients usually requires insulin.

B. Surgical Treatment

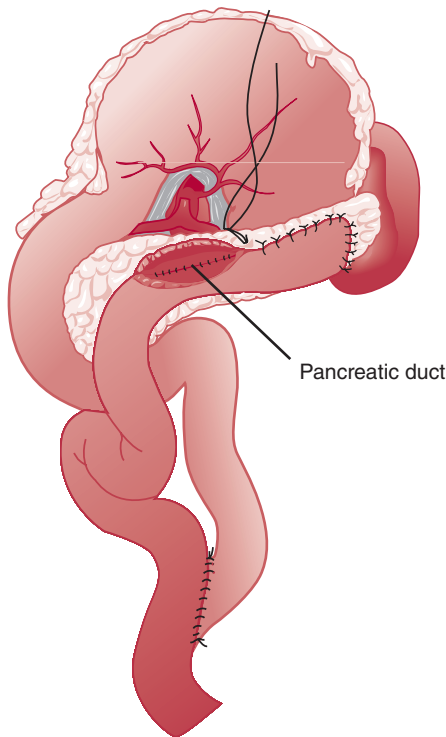

Surgical therapy is principally of value to relieve chronic intractable pain. It is essential that every effort be made to eliminate alcohol abuse. The best surgical candidates are those whose pain persists after alcohol has been abandoned.

Surgical treatment in most cases involves a procedure that facilitates drainage of the pancreatic duct or resects diseased pancreas or that serves both purposes. The choice of operation can usually be made preoperatively based on the findings of a retrograde pancreatogram and CT scans. Coincidental bile duct obstruction is common and should be treated by simultaneous choledochoduodenostomy.

1. Drainage procedures—A dilated ductal system reflects obstruction, and when dilation is present, procedures to improve ductal drainage usually relieve pain. Calcific alcoholic pancreatitis most often falls into this category.

The usual finding is an irregular, widely dilated duct (1-2 cm in diameter) with points of stenosis (“chain of lakes” appearance) and ductal calculi. For such patients, a longitudinal pancreaticojejunostomy (Puestow procedure) is appropriate (Figure 26-4). The duct is opened anteriorly from the tail into the head of the gland and anastomosed side-to-side to a Roux-en-Y segment of proximal jejunum. Pain improves postoperatively in about 80% of patients, but improvement of pancreatic insufficiency is uncommon. This procedure, however, has a low rate of success when the pancreatic duct is narrow (ie, < 8 mm).

Sphincteroplasty and distal (caudal) pancreaticojejunostomy (DuVal procedure) are other drainage techniques that were used more often in the past. The latter is only of historical interest, but surgical sphincteroplasty plus extraction of pancreatic ductal calculi continues in use, more

▲ **Figure 26–4.** Longitudinal pancreaticojejunostomy (Puestow) for chronic pancreatitis.

often now through endoscopic access to the pancreatic duct.

2. Pancreatectomy—In the absence of a dilated duct, pancreatectomy is the best procedure, and the extent of resection can often be determined from a CT scan and pancreatogram. In patients with small ducts, the most severe disease is usually located in the head of the gland, and pancreaticoduodenectomy (Whipple procedure) is the operation of choice. A variant of this procedure involves resection of the head of the gland while preserving the duodenum. A Roux-en-Y limb of jejunum is anastomosed to both cut surfaces of the pancreas. If the duct is also dilated in the body and tail, resection of the head can also be combined with longitudinal pancreaticojejunostomy in that part of the gland. Pain relief is satisfactory in about 80% of patients treated by these operations. Total pancreatectomy is indicated when a previous pancreaticoduodenectomy or distal pancreatectomy has failed to give satisfactory pain relief. The reported results are contradictory; pain relief has been excellent in reports from the United Kingdom but less than excellent in reports from the United States. Difficulties in controlling diabetes mellitus occur in 30%-40% of patients who have had total pancreatectomy and

are responsible for occasional deaths. For this reason, total pancreatectomy is contraindicated in unreformed alcoholics. For chronic alcoholic pancreatitis, resections from the left of the gland—eg, distal subtotal pancreatectomy—are much less successful than resections of the head and are rarely performed nowadays. The most common indication is chronic focal posttraumatic pancreatitis, in which the head may be normal.

3. Celiac plexus block—Celiac plexus block may be used in an attempt to obtain pain relief before proceeding with a major pancreatic resection in small duct pancreatitis.

► Prognosis

Longitudinal pancreaticojejunostomy relieves pain in about 80% of patients with a dilated duct. Weight gain is common but less predictable. The results of pancreaticoduodenectomy are good in 80% of patients, but removal of the distal pancreas is less successful. Total pancreatectomy, which is principally reserved for failures of other operations, gives satisfying relief in 30%-90% of patients depending on the series. The reasons for these widely differing results are not known. Celiac plexus block is of lasting benefit to no more than 30% of patients. In some patients, pain subsides with advancing pancreatic insufficiency.

Except in advanced cases with continuous pain, alcoholics who can be persuaded to stop drinking often experience relief from pain and recurrent attacks of pancreatitis. In familial pancreatitis, the progress of the disease is inexorable, and many of these patients require surgery. The results of longitudinal pancreaticojejunostomy are excellent in familial pancreatitis. Narcotic addiction, diabetes, and malnutrition are serious problems in many patients.

PANCREATIC INSUFFICIENCY (STEATORRHEA; MALABSORPTION)

Pancreatic exocrine insufficiency may follow pancreatectomy or pancreatic disease, especially chronic pancreatitis. Many patients with varying degrees of pancreatic insufficiency have no symptoms and require no treatment, whereas others may benefit greatly from a rational medical regimen.

Malabsorption and steatorrhea do not appear until more than 90% of pancreatic exocrine function is lost; with 2%-10% of normal function, steatorrhea is mild to moderate; with less than 2% of normal function, steatorrhea is severe. On a diet containing 100 g of fat/d, normal subjects excrete 5-7 g/d, and the efficiency of assimilation is similar over a wide range of fat intake. Total pancreatectomy causes about 70% fat malabsorption. If the pancreatic remnant is normal, subtotal resections may have little effect on absorption.

Pancreatic insufficiency affects fat absorption more than that of protein or carbohydrate, because protein digestion is aided by gastric pepsin and carbohydrate digestion by salivary and intestinal amylase. Malabsorption of vitamins is rarely a significant problem. Water-soluble B vitamins are absorbed throughout the small intestine, and fat-soluble vitamins, although dependent on micellar solubilization by bile salts, do not require pancreatic enzymes for absorption. Vitamin B₁₂ malabsorption has been detected in some patients with pancreatic insufficiency, but it is rarely a clinical problem, and vitamin B₁₂ replacement is unnecessary.

Thus, the principal problem in otherwise uncomplicated pancreatic insufficiency is fat malabsorption and accompanying caloric malnutrition.

▶ Tests of Pancreatic Exocrine Function

A. Secretin or Cholecystokinin Test

Pancreatic juice is obtained by peroral duodenal intubation, and the response to an intravenous injection of secretin or CCK is measured. The results vary, depending on the dose and preparation of hormone used. Both tests (using purified hormones or the synthetic octapeptide of CCK) seem to be reliable. Pancreatic fluid should normally have a bicarbonate concentration greater than 80 mEq/L and bicarbonate output above 15 mEq/30 min.

B. Pancreolauryl Test

Fluorescein dilaurate is given orally with breakfast, and urinary fluorescein excretion is measured. Release and absorption of fluorescein depend on the action of pancreatic esterase. The test is relatively specific, but considerable exocrine insufficiency is required for a positive result. It is currently the most widely used test of exocrine function because it is inexpensive and easy to do.

C. PABA Excretion (Bentiromide) Test

The patient ingests 1 g of the synthetic peptide bentiromide (Bz-Ty-PABA), and urinary excretion of aromatic amines (PABA) is measured. Cleavage of the peptide to liberate PABA depends on intraluminal chymotrypsin activity. Patients with chronic pancreatitis excrete about 50% of the normal amount of PABA.

D. Fecal Fat Balance Test

The patient ingests a diet containing 75-100 g fat each day for 5 days. The amounts of dietary fat should be measured and should be the same each day. Excretion of less than 7% of ingested fat is normal. Clinically significant steatorrhea is present when fat malabsorption exceeds about 25%. Total pancreatectomy results in about 70% fat malabsorption.

Examination of a stool specimen for fat globules (obviously much simpler than the fat balance test) is specific and relatively sensitive for fat malabsorption.

▶ Treatment

The diet should aim for 3000-6000 kcal/d, emphasizing carbohydrate (400 g or more) and protein (100-150 g). Patients with steatorrhea may or may not have diarrhea, and dietary restriction of fat is important mainly to control diarrhea. Patients with diarrhea may be restricted to 50 g of fat and the amount increased until diarrhea appears. Permissible fat intake averages 100 g/d distributed equally among four meals.

Pancrelipase replacement may be accomplished with pancreatic extracts containing 30,000-50,000 units of lipase distributed throughout each of four daily meals. Lesser amounts are much less effective; an hourly dosage regimen probably has no advantages.

If enzymes alone do not improve the malabsorption enough, the problem is probably due to destruction of lipase by gastric acid. This can be largely alleviated by adding an H₂ receptor blocking agent to the enzyme regimen. A preparation of enzymes as enteric-coated microspheres (Pancrease) is less vulnerable to low pH and may be more effective in refractory cases.

Medium-chain triglycerides (MCT), which can be obtained as a powder or an oil, may be used as a caloric supplement. This product is more rapidly hydrolyzed and the fatty acids more readily absorbed than are long-chain triglycerides, which make up 98% of the fat in a normal diet. Unfortunately, MCT oil is relatively unpalatable and is frequently associated with nausea and vomiting, bloating, and diarrhea, which limit patient acceptance.

ADENOCARCINOMA OF THE PANCREAS

An estimated 46,420 patients will develop pancreatic cancer in the United States in 2014, and 39,590 will die of the disease. These nearly equal numbers illustrate the dismal prognosis generally associated with pancreatic carcinoma. The death rate per 100,000 people has been basically unchanged since the mid 1960s at about 10/100,000 for men and 27/100,000 for women. After tumors of the lung, prostate and colon, pancreatic carcinoma is the fourth leading cause of death due to cancer in men, and trails lung, breast and colon in women. Factors associated with an increased risk of

pancreatic cancer are cigarette smoking, dietary consumption of meat (especially fried meat) and fat, previous gastrectomy (> 20 years earlier), and race.

The peak incidence is in the fifth and sixth decades. In two-thirds of cases, the tumor is located in the head of the gland; the remainder occurs in the body or tail. Ductal adenocarcinoma, mainly of a poorly differentiated cell pattern, accounts for 80% of the cancers; the remainder is islet cell tumors and cystadenocarcinomas, tumors that are discussed later in this chapter. Pancreatic adenocarcinoma is characterized by early local extension to contiguous structures and metastases to regional lymph nodes and the liver. Pulmonary, peritoneal, and distant nodal metastases occur later.

► Clinical Findings

A. Symptoms and Signs

1. Carcinoma of the head of the pancreas—About 75% of patients with carcinoma of the head of the pancreas present with weight loss, obstructive jaundice, and deep-seated abdominal pain. Back pain occurs in 25% of patients and is associated with a worse prognosis. In general, smaller tumors confined to the pancreas are associated with less pain. Weight loss averages about 20 lb (44 kg). Hepatomegaly is present in half of patients but does not necessarily indicate spread to the liver. A palpable mass, which is found in 20%, nearly always signifies surgical incurability. Jaundice is unrelenting in most patients but fluctuates in about 10%. Cholangitis occurs in only 10% of patients with bile duct obstruction. A palpable nontender gallbladder in a jaundiced patient suggests neoplastic obstruction of the common duct (Courvoisier sign), most often due to pancreatic cancer; this finding is present in about half of cases. Jaundice is often accompanied by pruritus, especially of the hands and feet.

2. Carcinoma of the body and tail of the pancreas—Since carcinomas of the body and tail of the pancreas are remote from the bile duct, less than 10% of patients are jaundiced. The presenting complaints are weight loss and pain, which sometimes occurs in excruciating paroxysms. In the few patients with jaundice or hepatomegaly, metastatic involvement has usually occurred. Migratory thrombophlebitis develops in 10% of cases. Once considered relatively specific as a clue to pancreatic cancer, this complication is now known to affect patients with other types of malignant disease.

The diagnosis of pancreatic carcinoma can be extremely difficult. The typical patient who presents with abdominal pain, weight loss, and obstructive jaundice rarely presents a problem, but those with just weight loss, vague abdominal pain, and nondiagnostic x-rays are occasionally labeled psychoneurotics until the existence of cancer becomes

obvious. If back pain predominates, orthopedic or neurosurgical causes may be sought at first. One characteristic feature is the tendency for the patient to seek relief of pain by assuming a sitting position with the spine flexed. Recumbency, on the other hand, aggravates the discomfort and sometimes makes sleeping in bed impossible. Sudden onset of diabetes mellitus is an early manifestation in 25% of patients.

B. Laboratory Findings

Elevated alkaline phosphatase and bilirubin levels reflect either common duct obstruction or hepatic metastases. The bilirubin level with neoplastic obstruction averages 18 mg/dL, much higher than that generally seen with benign disease of the bile ducts. Only rarely are serum aminotransferase levels markedly elevated. Repeated examination of stool specimens for occult blood gives a positive reaction in many cases.

Serum levels of the tumor marker CA 19-9 are elevated in most patients with pancreatic cancer, but the sensitivity in resectable (< 4 cm) lesions is too low (50%) for this to serve as a screening tool. Elevated levels also occur with other gastrointestinal cancers. The greatest usefulness of CA 19-9 measurements may be in following the results of treatments. After complete resection of a tumor, elevated levels drop to normal, but they rise again with recurrence.

C. Imaging Studies

Nearly all patients should have a CT scan.

1. CT scan—CT scans show a pancreatic mass in 95% of cases, usually with a central zone of diminished attenuation, and in over 90% of patients with a mass there are signs of extension beyond the boundaries of the pancreas. The upstream pancreatic duct is noted to be dilated in 70% of patients, and the bile duct is dilated in 60% (principally in those with jaundice). The presence of both bile duct and pancreatic duct dilation is strong evidence for pancreatic cancer even in the absence of a mass. Findings suggesting unresectability include local tumor extension (eg, behind the pancreas; into the liver hilum), contiguous organ invasion (eg, duodenum, stomach), distant metastases, involvement of the superior mesenteric or portal vessels, or ascites. In general, size of the mass is only loosely related to resectability. CT scans using modern dynamic scanning techniques are as accurate as angiography in assessing vascular involvement.

2. ERCP—In patients with a typical clinical history and a pancreatic mass on CT, ERCP is unnecessary. In the absence of a mass, an ERCP is indicated. It is the most sensitive test (95%) for detecting pancreatic cancer, though specificity in differentiating between cancer and pancreatitis is low. Consequently, a pancreatogram should be obtained early in

cases where the existence of a pancreatic lesion is suspected but unproved. The findings consist of stenosis or obstruction of the pancreatic duct. Adjacent lesions of the bile duct and pancreatic duct (double-duct sign) are highly suggestive of neoplastic disease, especially if the biliary involvement is focal. Although ERCP is useful to distinguish between the various kinds of periampullary tumors, that information rarely alters management.

1. Upper gastrointestinal series—An upper gastrointestinal series is not sensitive in detecting pancreatic cancer, but it provides information about patency of the duodenum that may be useful in deciding whether a gastrojejunostomy will have to be performed. The classic findings consist of widening of the duodenal sweep, narrowing of the lumen, and the “reversed-3 sign,” named for the duodenal configuration.

2. Other studies—Angiography has not proved reliable in detecting or staging pancreatic neoplasms, and ultrasound is a poor second to CT scans for imaging.

D. Aspiration Biopsy

Percutaneous aspiration biopsy of pancreatic mass lesions is positive in 85% of malignant tumors. The procedure is relatively safe, but there is a risk of spreading a localized (resectable) tumor, so it is contraindicated in patients who are candidates for surgery. Percutaneous aspiration biopsy is principally of value to verify a presumptive diagnosis of adenocarcinoma of the pancreas in patients with radiographic evidence of unresectability. In these cases, cytologic proof is important, for treatment decisions should not be made solely on the basis of the indirect evidence provided by CT scans and other imaging tests. There is too great a risk of misdiagnosing something unusual, such as a retroperitoneal lymphoma or sarcoma, and administering inappropriate treatment.

► Differential Diagnosis

The other periampullary neoplasms—carcinoma of the ampulla of Vater, distal common bile duct, or duodenum—may also present with pain, weight loss, obstructive jaundice, and a palpable gallbladder. Preoperative cholangiography and gastrointestinal x-rays may suggest the correct diagnosis, but laparotomy is sometimes required.

► Complications

Obstruction of the splenic vein by tumor may cause splenomegaly and segmental portal hypertension with bleeding gastric or esophageal varices.

► Treatment

Pancreatic resection for pancreatic cancer is appropriate only if all gross tumor can be removed with a standard

resection. The lesion is considered resectable if the following areas are free of tumor: (1) the hepatic artery near the origin of the gastroduodenal artery; (2) the superior mesenteric artery where it courses under the body of the pancreas; and (3) the liver and regional lymph nodes. Since the pancreas is so close to the portal vein and the superior mesenteric vessels, these structures may be involved early. About 20% of cancers of the head of the pancreas can be resected, but because of local and distant spread, this is rarely possible for lesions of the body and tail.

A histologic diagnosis can usually be made at operation by aspiration biopsy. With small lesions of the head of the gland, it may be difficult to obtain a specimen for histologic diagnosis because much of the palpable mass may consist of inflamed pancreatic tissue. Occasionally, histologic diagnosis is impossible, and clinical decisions must rest on indirect evidence.

For curable lesions of the head, pancreaticoduodenectomy (Whipple procedure) is required (Figure 26–5). This involves resection of the common bile duct, the gallbladder, the duodenum, and the pancreas to the mid body. There is an increasing tendency to preserve the antrum and pylorus. Involvement of a short (< 1.5 cm) segment of the portal vein is not a contraindication to a curative resection. This is managed by a partial or circumferential resection of the affected area.

When the procedure is performed by surgeons who do it frequently, the operative mortality rate is less than 5%. When it is performed by less experienced surgeons, the mortality rate is as high as 20%-30%. Postoperative deaths are due to complications such as pancreatic and biliary fistulas, hemorrhage, and infection.

For unresectable lesions, cholecystojejunostomy or choledochojejunostomy provides relief of jaundice and pruritus. A cholangiogram should be obtained to verify patency between the cystic and common bile ducts unless it is grossly obvious. Percutaneous or endoscopically placed biliary stents may also provide effective palliation and are preferable to surgical biliary decompression if the lesion is known to be unresectable. Gastrojejunostomy is required if the tumor blocks the duodenum. If laparotomy has been performed, gastrojejunostomy should be considered regardless of the presence of duodenal obstruction, because with time this often develops before other life-threatening complications.

Laparoscopy is a useful first step in patients scheduled for a possible Whipple procedure. If metastases are seen that militate against a curative resection, laparoscopic gastrojejunostomy or cholecystojejunostomy (or both) can be performed. If not, one should proceed with the laparotomy. About 15% of patients thought to have localized disease from preoperative studies are found to be unresectable at laparoscopy.

▲ **Figure 26-5.** Pancreaticoduodenectomy (Whipple procedure). **A** : Preoperative anatomic relationships showing a tumor in the head of the pancreas. **B**: Postoperative reconstruction showing pancreatic, biliary, and gastric anastomoses. A cholecystectomy and bilateral truncal vagotomy are also part of the procedure. In many cases, the distal stomach and pylorus can be preserved, and vagotomy is then unnecessary.

Gemcitabine-based chemotherapy has clear benefits in patients with metastatic disease. Its utility in combination with radiation therapy and as adjuvant therapy is being defined.

► Prognosis

The mean survival following palliative therapy is 7 months. Following a Whipple procedure, survival averages about 18 months. Factors associated with tumor recurrence and shorter survival include lymph node involvement, tumor size over 2.5 cm, blood vessel invasion, and amount of blood transfused. If tumor cells extend to the margins of the resected specimen, long-term survival is rare. If the margins are clear, about 20% of patients live more than 5 years. Overall 5-year survival is about 10%, but only 60% of these patients are actually free of tumor.

CYSTIC NEOPLASMS

Cystic neoplasms of the pancreas usually present with abdominal pain, a mass, or jaundice and are diagnosed from the findings on CT scans.

Cystadenomas can be classified as serous or mucinous. Serous cystadenomas, which are usually microcystic adenomas, are well-circumscribed lesions consisting of multiple small cysts ranging in size from microscopic to about 2 cm. The cut surface has the appearance of a sponge. The multicystic nature of the lesion is usually—but not always—evident on CT scans, which may also show a few calcifications. The epithelium, which is flat to cuboidal, has no malignant potential. Treatment usually entails excision, but in the rare case where this is too hazardous, the lesion may be left in place with the knowledge that complications are rare. An occasional serous cystadenoma will consist of one or more large cysts (ie, macrocystic).

Mucinous cystadenomas (macrocytic adenomas), which are much more common in women than in men, are unilocular or, more often, multilocular lesions that have a smooth lining with papillary projections. The septate appearance on CT scans is characteristic. The cystic spaces measure 2-20 cm in diameter and contain mucus. The lining consists of tall columnar and goblet cells, which are often arranged in a papillary pattern. In time, most mucinous cystadenomas will evolve into cystadenocarcinomas, so total excision is the required treatment.

Cystadenocarcinomas invariably present as a focus of malignancy within an existing mucinous cystadenoma. The tumors are often quite large (eg, 10-20 cm) at the time of diagnosis. Metastases occur in about 25% of cases. Complete excision results in a 5-year survival rate of 70%.

An uncommon lesion, referred to as solid and papillary or papillary-cystic neoplasm of the pancreas, occurs almost exclusively in young women (under age 25 years). The tumor is usually large. It may be locally invasive, but metastases are uncommon, and cure is to be expected after resection.

ADENOMA & ADENOCARCINOMA OF THE AMPULLA OF VATER

Adenoma and adenocarcinoma of the ampulla of Vater account for about 10% of neoplasms that obstruct the distal bile duct. One-third are adenomas and two-thirds adenocarcinomas. Since a remnant of benign adenoma can be found in a majority of adenocarcinomas, it is suspected that malignant change in an adenoma gives rise to most carcinomas. The presenting symptom is most often jaundice or occasionally gastrointestinal bleeding. Weight loss and pain are more common with carcinoma than with adenoma, but the differences are not great enough to allow a distinction to be made on this basis alone.

CT and ultrasound scans reveal dilation of the biliary tree and pancreatic duct. Gallstones are an incidental finding in 20% of patients, and when common duct stones are present, they may incorrectly be held responsible for the biliary obstruction. ERCP can be an important diagnostic study. In 75% of cases, tumor is visible on duodenoscopy as an exophytic papillary lesion, an ulcerated tumor, or an infiltrating mass. An adequate biopsy usually can be obtained of these lesions. In 25% of cases, there is no intraduodenal growth, and endoscopic sphincterotomy is necessary to display the tumor. It is best to wait 10-14 days to biopsy these tumors because of transient artifacts that result from the sphincterotomy. ERCP also demonstrates dilation of the biliary and pancreatic ducts. It has become common to perform a sphincterotomy whenever possible, not only to facilitate performance of a biopsy but also to decompress the biliary tree and allow jaundice to subside in anticipation of subsequent surgical therapy. The value of this step has not been established.

Although some adenomas have been successfully treated by snare excision or, preferably, by neodymium:YAG laser destruction, local resection, or pancreaticoduodenectomy is preferable because of the significant chance that an invasive carcinoma will be undertreated at a time that it is curable. These nonsurgical methods should be reserved for patients who are poor candidates for resection.

Treatment of adenocarcinoma consists of pancreaticoduodenectomy as for pancreatic carcinoma. The operative mortality rate is less than 5%, and the 5-year survival rate is about 50%. The presence of metastases in resectable peripancreatic lymph nodes is not a contraindication to pancreaticoduodenectomy, for the 5-year survival rate under these circumstances is still a respectable 25%. Local excision is an alternative for noninfiltrating papillary adenocarcinomas in patients who are too poor a risk for pancreaticoduodenectomy, but this operation is not as successful as pancreaticoduodenectomy. Endoscopic sphincterotomy alone or with retrograde stent placement (the combination is usually required) is indicated when there is definite evidence (eg, hepatic metastases) that the tumor is incurable. Survival averages less than a year with this approach, however.

PANCREATIC ISLET CELL TUMORS

Islet cell tumors may be functioning (ie, hormone-producing) or nonfunctioning, malignant or nonmalignant. More than half are functioning; less than half are malignant. Insulinoma, the most common functioning islet cell neoplasm, arises from beta cells and produces insulin and symptoms of hypoglycemia. Tumors of the δ or α_1 cells produce gastrin and the Zollinger-Ellison syndrome. α_2 cell neoplasms may produce excess glucagon and hyperglycemia. Non-beta islet cell tumors may secrete serotonin, ACTH, MSH, and kinins (and evoke the carcinoid syndrome). Some produce pancreatic cholera, a severe diarrheal illness.

1. Nonfunctioning Islet Cell Tumors

Most of these lesions are malignant tumors of the head of the gland, which present with abdominal and back pain, weight loss, and, in many cases, a palpable abdominal mass. Jaundice is encountered occasionally. CT scans reveal a pancreatic mass, and angiography typically shows it to be hypervascular. The histologic pattern on biopsy specimens is diagnostic of islet cell tumor, but whether or not the lesion is malignant rests on evidence of invasiveness or metastases, not the appearance of the cells. Immunohistochemical staining of the tissue is positive for chromogranin and neuron-specific enolase (markers of APUD tumors). Metastases are present at the time of diagnosis in 80% of patients. Resection of all gross tumor (eg, by a Whipple procedure), the preferred treatment, is possible in less than half of patients because of local extension or distant metastases. A

combination of streptozocin and doxorubicin is the most effective chemotherapeutic regimen. The 5-year disease-free survival rate is about 15%.

Oberstein PE, Remotti H, Saif MW, Libutti SK. Pancreatic neuroendocrine tumors: entering a new era. *JOP* 2012;13(2):169-173.

2. Insulinoma

Insulinomas have been reported in all age groups. About 75% are solitary and benign. About 10% are malignant, and metastases are usually evident at the time of diagnosis. The remaining 15% are manifestations of multifocal pancreatic disease—either adenomatosis, nesidioblastosis, or islet cell hyperplasia.

The symptoms (related to cerebral glucose deprivation) are bizarre behavior, memory lapse, or unconsciousness. Patients may be mistakenly treated for psychiatric illness. There may be profuse sympathetic discharge, with palpitations, sweating, and tremulousness. Hypoglycemic episodes are usually precipitated by fasting and are relieved by food, so weight gain is common. The classic diagnostic criteria (Whipple triad) are present in most cases: (1) hypoglycemic symptoms produced by fasting, (2) blood glucose below 50 mg/dL during symptomatic episodes, and (3) relief of symptoms by intravenous administration of glucose.

The most useful diagnostic test and the only one indicated in all but a few patients is demonstration of fasting hypoglycemia in the presence of inappropriately high levels of insulin. The patient is fasted, and blood samples are obtained every 6 hours for glucose and insulin measurements. The fast is continued until hypoglycemia or symptoms appear or for a maximum of 72 hours (some investigators truncate the test at 48 hours). Although insulin levels are not always elevated in patients with insulinoma, they will be high relative to the blood glucose concentration. A ratio of plasma insulin to serum glucose greater than 0.3 is diagnostic. Ratios should be calculated before and during the fast. Proinsulin, which constitutes more than 25% of total insulin (the upper limit of normal) in about 85% of patients with insulinomas, should also be measured. Proinsulin levels greater than 40% suggest a malignant islet cell tumor.

Drugs that release insulin (tolbutamide, glucagon, leucine, arginine, calcium) were used in the past as provocative tests. No provocative tests are currently used.

Localization of the tumor is important but may be difficult. In about 10% of cases, the tumor is so small or located so deeply that it is difficult or impossible to find at laparotomy. High-resolution CT and MR scans are successful in demonstrating about 40% of tumors. Endoscopic ultrasound

examination of the pancreas may be able to show a much higher percentage. The most important examination is intraoperative ultrasound, which can identify a pancreatic tumor in nearly all cases. It is more sensitive than any preoperative test.

In patients who have had previous resection or significant upper abdominal surgery, exploration with intraoperative ultrasound may be difficult. Invasive preoperative testing may then be useful. Angiography gives a yield of about 50%. Transhepatic portal venous sampling has proved an accurate preoperative localizing method, demonstrating the position in the pancreas in about 95% of lesions. However, this test is time-consuming and somewhat invasive, involving entering the portal vein with a catheter passed percutaneously through the liver and testing blood at various sites within the portal, superior mesenteric, and splenic veins for insulin levels. The point where insulin concentrations rise sharply indicates the site of the tumor. An alternative invasive localizing test uses arteriography with selective calcium infusion into arteries supplying the pancreas. Blood samples from the hepatic veins reveal an increase in insulin level when calcium is infused into an artery supplying the tumor.

► Differential Diagnosis

Fasting hypoglycemia may be a manifestation of some non-pancreatic, nonislet cell tumors. Clinically, the condition is identical to that resulting from insulinoma, but the cause is rarely secretion of insulin by the tumors, as serum insulin levels are normal. Most nonislet cell tumors associated with hypoglycemia are large and readily detected on physical examination. The majority are of mesenchymal origin (eg, hemangiopericytoma, fibrosarcoma, leiomyosarcoma) and are located in the abdomen or thorax, but hepatoma, adrenocortical carcinoma, and a variety of other lesions may also produce hypoglycemia. The principal means by which these tumors produce hypoglycemia are the following: (1) secretion by the tumor of insulin-like growth factor II (IGF-II), an insulin-like peptide that normally mediates the effects of growth hormone; and (2) inhibition of glycogenolysis or gluconeogenesis. Rapid utilization of glucose by the tumor, replacement of liver tissue by metastases, and secretion of insulin are other postulated mechanisms that are probably uncommon.

Surreptitious self-administration of insulin is seen occasionally, most often in an individual with access to insulin on the job. If insulin injections have been given for as long as 2 months, insulin antibodies will be detectable in the patient's serum. Circulating C peptide levels are normal in these patients but elevated in most patients with insulinoma. Sulfonyleurea ingestion can be detected by measuring the drug in plasma.

► Treatment

Surgery should be done promptly, because with repeated hypoglycemic attacks, permanent cerebral damage occurs and the patient becomes progressively more obese. Moreover, the tumor may be malignant. Medical treatment is reserved for surgically incurable lesions.

A. Medical Treatment

Diazoxide is administered to suppress insulin release. For incurable islet cell carcinomas, streptozocin is the best chemotherapeutic agent. Sixty percent of patients live up to 2 additional years. Toxicity is considerable; streptozocin is not recommended as a routine adjunct to surgical therapy.

B. Surgical Treatment

At operation, the entire pancreas must be palpated carefully because the tumors are usually small and difficult to find. The gland should also be examined intraoperatively with ultrasound, which may be able to locate a tumor that cannot be felt, or to demonstrate signs of invasion (ie, irregular borders) that indicate malignancy—something that cannot be detected by palpation. When the tumor is found, it may be enucleated if it is superficial or resected as part of a partial pancreatectomy if it is deep-seated or invasive. Insulinomas in the head of the gland can nearly always be enucleated.

Tumors that can be localized preoperatively, and that are placed in favorable anatomic locations, can sometimes be resected using a laparoscopic approach. The same principles of local, complete resection should be followed. Laparoscopic ultrasound is often useful to guide this exploration.

In the past, the tumor could not be detected in about 5% of cases by these methods. The traditional recommendation was to resect the distal half of the pancreas and have the pathologist slice the specimen into thin sections and look for the tumor. If the tumor was found, the operation was concluded; if it was not found, additional pancreas would be resected until an 80% distal pancreatectomy had been performed. Since the tumors are evenly distributed, this strategy is 80% successful in removing the tumor. Intraoperative monitoring of blood glucose is often done as a means of determining if the tumor has been excised, but it is unreliable. With the use of operative ultrasound scanning, however, no more than 1%-2% of insulinomas remain occult, and blind distal pancreatectomy is rarely even considered.

Patients with insulinoma associated with MEN-1 usually have multiple (average of three) lesions. Because persistence of the disease is much more likely in this condition following the standard surgical approach, the operation recommended

here is distal pancreatectomy plus enucleation of any lesions found in the head of the gland.

For islet cell hyperplasia, nesidioblastosis, or multiple benign adenomas, distal subtotal pancreatectomy usually decreases insulin levels enough that medical management is simplified. For islet cell carcinomas, resection of both primary and metastatic lesions is warranted if technically feasible.

Patients with sporadic insulinomas lead a normal life after the tumor has been removed. The outcome is less predictable in patients with MEN-1, who may have several insulin-producing tumors.

Kulke MH et al. National Comprehensive Cancer Networks. Neuroendocrine tumors. *J Natl Compr Canc Netw* 2012;10(6):724-64.

3. Pancreatic Cholera (WDHA Syndrome: Watery Diarrhea, Hypokalemia, & Achlorhydria)

Most cases of pancreatic cholera are caused by a non-beta islet cell tumor of the pancreas that secretes VIP and peptide histidine isoleucine. The syndrome is characterized by profuse watery diarrhea, massive fecal loss of potassium, low serum potassium, and extreme weakness. Gastric acid secretion is usually low or absent even after stimulation with betazole or pentagastrin. Stool volume averages about 5 L/d during acute episodes and contains over 300 mEq of potassium (20 times normal). Severe metabolic acidosis frequently results from loss of bicarbonate in the stool. Many patients are hypercalcemic, possibly from secretion by the tumor of a parathyroid hormone-like substance. Abnormal glucose tolerance may result from hypokalemia and altered sensitivity to insulin. Patients who complain of severe diarrhea must be studied carefully for other causes before the diagnosis of WDHA syndrome is entertained seriously. Chronic laxative abuse is a frequent explanation.

CT scan is the best initial imaging test; somatostatin receptor scintigraphy is also very useful for localization. Approximately 80% of the tumors are solitary, located in the body or tail, and can be removed easily. About half of the lesions are malignant, and three-fourths of those have metastasized by the time of exploration. Even if all of the tumor cannot be removed, resection of most of it alleviates symptoms in about 40% of patients even though the average survival is only 1 year. Streptozocin has produced remissions in several cases, but nephrotoxicity may limit its effectiveness. Treatment with long-acting somatostatin analogues decreases VIP levels, controls diarrhea, and may even reduce tumor size. The effect persists indefinitely in most patients, but in a few it is transient.

Kulke MH et al. National Comprehensive Cancer Networks. Neuroendocrine tumors. *J Natl Compr Canc Netw* 2012;10(6):724-764.

4. Glucagonoma

Glucagonoma syndrome is characterized by migratory necrolytic dermatitis (usually involving the legs and perineum), weight loss, stomatitis, hypoaminoacidemia, anemia, and mild to moderate diabetes mellitus. Scotomas and changes in visual acuity have been reported in some cases. The age range is 20-70 years, and the condition is more common in women. The diagnosis may be suspected from the distinctive skin lesion; in fact, the presence of a prominent rash in a patient with diabetes mellitus should be enough to raise suspicions. Glucagonoma should also be suspected in any patient with new onset of diabetes after the age of 60. Confirmation of the diagnosis depends on measuring elevated serum glucagon levels. CT scans demonstrate the tumor and sites of spread. Angiography is not essential but reveals a hypervascular lesion.

Glucagonomas arise from $\{a\}_2$ cells in the pancreatic islets. Most are large at the time of diagnosis. About 25% are benign and confined to the pancreas. The remainder has metastasized by the time of diagnosis, most often to the liver, lymph nodes, adrenal gland, or vertebrae. A few cases have been the result of islet cell hyperplasia.

Severe malnutrition should be corrected preoperatively with a period of total parenteral nutrition and treatment with somatostatin analogues. Surgical removal of the primary lesion and resectable secondaries is indicated if technically feasible. If the tumor is confined to the pancreas, cure is possible. Even if it is not possible to remove all the tumor deposits, considerable palliation may result from subtotal removal, so surgery is indicated in almost every case. Low-dose heparin therapy should be administered pre- and postoperatively because of a high risk of deep venous thrombosis and pulmonary embolism. Streptozocin and dacarbazine are the most effective chemotherapeutic agents for unresectable lesions. Somatostatin therapy normalizes serum glucagon and amino acid levels, clears the rash, and promotes weight gain. The clinical course generally parallels changes in serum levels of glucagon in response to therapy.

Kulke MH et al. National Comprehensive Cancer Networks. Neuroendocrine tumors. *J Natl Compr Canc Netw* 2012;10(6):724-764.

5. Somatostatinoma

Somatostatinomas are characterized by diabetes mellitus (usually mild), diarrhea and malabsorption, and dilation

of the gallbladder (usually with cholelithiasis). Serum calcitonin and IgM concentrations may be elevated. The syndrome results from secretion of somatostatin by an islet cell tumor of the pancreas, half of which are malignant and accompanied by hepatic metastases. The lesion is usually large and readily demonstrated by CT scan. The diagnosis may be made by recognizing the clinical syndrome and measuring increased concentrations of somatostatin in the serum. Often, however, the somatostatin syndrome is unsuspected until histologic evidence of metastatic islet cell carcinoma has been obtained. When the disease is localized, resection is able to cure about 50% of cases. Enucleation is inappropriate for these tumors. Chemotherapy with streptozocin, dacarbazine, or doxorubicin is the best treatment for unresectable tumors. Small somatostatin-rich tumors of the duodenum or ampulla of Vater have also been reported, but none of these lesions have been associated with high serum levels of somatostatin or the clinical syndrome.

Kulke MH et al. National Comprehensive Cancer Networks. Neuroendocrine tumors. *J Natl Compr Canc Netw* 2012;10(6):724-764.

MULTIPLE CHOICE QUESTIONS

- All of the following are true about the anatomy of the pancreas, except
 - The head is adherent to the medial duodenum.
 - The body is in contact posteriorly with the left crus of the diaphragm and the left adrenal gland.
 - The common bile duct passes through a groove in the posterior aspect of the head.
 - The uncinat process lies anterior to the superior mesenteric artery.
 - The main pancreatic duct is also known as the duct of Wirsung.
- Serum amylase can come from
 - Lung
 - Muscle
 - Skin
 - Parotid gland
 - Red blood cells
- Acute pancreatitis
 - Is usually caused by acute cholecystitis
 - Can be complicated by pancreatic abscess
 - Causes inflammation of the pancreas that is usually not discernible by CT scan

- D. Is associated with common bile duct stones in more than 80% of patients
 - E. Progresses to chronic pancreatitis in about 40% of those affected
4. Pancreatic adenocarcinoma
- A. Is unresectable at the time of diagnosis in most people
 - B. Is smaller at diagnosis, on average, for tumors in the tail of the pancreas than those in the head
 - C. Can be resected by pancreaticoduodenectomy for those tumors limited to the tail
 - D. Has a similar prognosis as malignant pancreatic neuroendocrine tumor
 - E. Should generally be managed by operative enucleation
5. Management of insulinoma
- A. Typically requires emergent operation
 - B. Should not include preoperative imaging
 - C. Should usually include resection of the primary tumor
 - D. Is commonly required in the management of chronic pancreatitis
 - E. Is a palliative approach to an incurable problem for most people

Spleen

27

Gerard M. Doherty, MD

ANATOMY

The spleen is a dark purplish, highly vascular, coffee bean-shaped organ of mesodermal origin situated in the left upper quadrant of the abdomen at the level of the eighth to eleventh ribs between the fundus of the stomach, the diaphragm, the splenic flexure of the colon, and the left kidney (Figure 27–1). The adult spleen weighs 100-150 g, measures about $12 \times 7 \times 4$ cm, and usually cannot be palpated. It is attached to adjacent viscera, the abdominal wall, and the diaphragm by peritoneal folds or “ligaments.” The gastrosplenic ligament carries the short gastric vessels. The other ligaments are avascular except in patients with portal hypertension or myelofibrosis.

The splenic capsule consists of peritoneum overlying a 1- to 2-mm fibroelastic layer that contains a few smooth muscle cells. The fibroelastic layer sends into the pulp numerous fibrous bands (trabeculae) that form the framework of the spleen. Corrosion cast studies demonstrate that the spleen consists of specific segments based on arterial supply numbering between two and six separated by an avascular plane.

The splenic artery enters the hilum of the spleen, branches into the trabecular arteries, and then branches into the central arteries that course through the surrounding white pulp and send radial branches to the peripheral marginal zone and the more distant red pulp. The white pulp consists of lymphatic tissue including T cells adjacent to the central artery (periarteriolar lymphoid sheets [PALS]), with a surrounding area containing lymphoid follicles rich in B cells interspersed with dendritic and reticular cells important in antigen presentation. The vascular spaces of the marginal zone between the red and white pulp channel blood into the splenic Billroth cords and out to the associated sinuses. The red pulp vascular structures have a noncontiguous basement membrane that filters cells such as senescent erythrocytes into the macrophage-lined sinuses.

Accessory spleens (spleniculi) are seen in 10%-15% of the normal population and are located primarily in the gastrosplenic, gastrocolic, and lienorenal ligaments, but they can also be found throughout the peritoneal cavity in the omentum, bowel mesentery, and pelvis. Accessory spleens probably result from a failure of infusion of splenic embryologic tissues. Ordinarily of no significance, they may play a role in recurrence of certain hematologic disorders for which splenectomy is performed. Removal of accessory spleens may lead to remission of disease in these patients. Accessory spleens are more difficult to identify with laparoscopic procedures, but the use of a hand port has allowed identification and resection of accessory spleens with a minimally invasive approach. Patients who fail to respond to initial splenectomy should undergo scanning with technetium 99m-labeled red cells or indium 111-labeled platelets to identify potential sites of missed accessory spleens and can be identified intraoperatively with a hand-held gamma counter.

Ectopic spleen (wandering spleen) is an unusual condition in which a long splenic pedicle allows the spleen to move within the peritoneum. It often resides in the lower abdomen or pelvis, where even a normal-sized spleen can be felt as a mass. The condition is 13 times more common in women than in men. Diagnostic radionuclide scan can diagnose the mass as a spleen. Acute torsion of the pedicle occurs occasionally, necessitating emergency splenectomy, and elective removal of wandering spleens in the pelvis is recommended.

PHYSIOLOGY

The spleen has a dual function as a secondary lymphoid organ important in host immunity, and as a large filter for blood removing senescent erythrocytes and recycling iron. The anatomy of the spleen provides an ideal environment for these two functions with the immune activity in the white pulp and the hematologic function in the red pulp.

▲ **Figure 27-1.** Normal anatomic relations of the spleen.

The spleen receives 5% of the total cardiac output, or approximately 150-300 mL/min, such that each red cell averages 1000 passes through the spleen each day. Normal blood cells pass rapidly through the spleen, while abnormal and senescent cells are slowed and entrapped. As they travel through the hypoxic, acidotic, glucose-deprived splenic cords and sinuses of the red pulp, senescent erythrocytes pass into the vascular spaces and are phagocytosed by macrophages in a process called “culling.” Part of the membrane of erythrocytes can be removed through the gaps between endothelial cells lining the vascular spaces in a similar process called pitting. In the presence of splenomegaly and other disease states, the flow patterns of the spleen become more circuitous as the red pulp volume expands, so that even normal cells may be trapped.

The spleen is considered to be a secondary organ of the immune system and represents the largest single collection of lymphoid tissue in the body. The white pulp of the spleen contains the various cellular components needed to generate an immune response, with structural and functional relationships similar to those of lymph nodes. Lymphocytes and circulating antigen-presenting cells enter the white pulp via the marginal zone capillaries and traverse the T cell-rich PALS before passing through bridging channels into the red pulp. Primary follicles or germinal centers with secondary follicles at the periphery of the white pulp are sites of B cell expansion and immunoglobulin production. Blood passing through the spleen is exposed to all the key cellular components necessary for both humoral and cellular immune responses. Tissue macrophages in the spleen are key components of generating an immune response particularly

in encapsulated organs. Moreover, the concentration of macrophages in the red pulp vascular spaces facilitates opsonization of particles coated with IgG and plays an important role in the filtration and removal of senescent erythrocytes, the autoimmune hematologic diseases as well as explaining the increased risk of sepsis that follows splenectomy in children under 2 years of age. Even in adults, splenectomy leads to a slight but definite reduction in immune function.

Normally, about 30% of the total platelet pool is sequestered in the spleen. Splenomegaly typically involves expansion of the red pulp, which increases this sequestration to between 80% and 95% of the platelet cell mass. Storage of erythrocytes and granulocytes in the spleen is limited in humans, but newly formed reticulocytes released from the bone marrow concentrate in the spleen to undergo a maturational process.

Scandella JT et al. Form follows function: lymphoid tissue micro-architecture in antimicrobial immune defence. *Nature Reviews Immunology* 2008;8:764-775.

OPERATIVE INDICATIONS FOR SPLENECTOMY

To better describe and understand operative indications in surgery of the spleen, one could categorize the indications for splenectomy or procedures of the spleen into eight general areas:

1. **Hypersplenism** is characterized by diffuse enlargement of the spleen by neoplastic disorders, hematopoietic disorders of the bone marrow, and metabolic or storage disorders. These various disease processes result in diffuse enlargement of the spleen and amplify the normal function of elimination of circulating blood cells resulting in general pancytopenia. Erythrocytes and platelets are most commonly affected. Hypersplenism also may cause symptoms of early satiety due to the splenic size.
2. **Autoimmune/erythrocyte disorders** Specific cytopenias are related either to antibodies targeting platelets, erythrocytes, or neutrophils. A second category of diseases relates to intrinsic structural changes within the erythrocyte that lead to a shortened red blood cell half-life with accelerated splenic clearance. There is nothing intrinsically wrong with the spleen, and splenic size is typically normal.
3. Trauma or injury to the spleen.
4. **Vascular diseases** Splenic vein thrombosis and splenic artery aneurysm may require splenectomy for treatment.
5. Cysts, abscesses, and primary splenic tumors are mass lesions of the spleen. This would include treatment of simple cysts, echinococcal cysts, splenic abscess, and various benign neoplasms including hamartomas,

hemangiomas, lymphangiomas, and rare malignant lesions.

6. **Diagnostic procedures** This category of splenectomy occurs when the spleen is removed primarily to make a clinical diagnosis when none is available. A subcategory of this would be staging laparotomy for Hodgkin disease, which has all but been eliminated based on alternative imaging techniques and current treatment regimens.
7. **Iatrogenic splenectomy** Splenectomy that is performed due to an incidental injury to the spleen during surgery within the general abdominal cavity or specifically, the left upper quadrant, can be categorized as iatrogenic splenectomy. This category is likely underreported and may be considered a subcategory of trauma.
8. **Incidental splenectomy** The spleen may be removed as part of a standard operation to remove the distal pancreas most commonly, and also for gastric cancers, left-sided renal cell carcinomas, adrenal cancers, and retroperitoneal sarcomas in the left upper quadrant. The spleen is removed in these instances due to direct tumor extension, vascular involvement, or the need for excision of splenic hilum lymph nodes.

With the increase in splenic preservation for trauma, many institutional series list medical conditions as the most indications for splenectomy. Most recent series report 40%-50% for hematologic conditions, 35%-40% for trauma, and 20%-30% for neoplastic disease. Within the category, idiopathic thrombocytopenia purpura has the highest incidence of splenectomy. Each of these categories of disease will be discussed including the etiology and pathophysiology of the disorder, the specific indications for splenectomy, alternative treatments, and the results of splenectomy.

Musallam KM et al. Postoperative outcomes after laparoscopic splenectomy compared with open splenectomy. *Ann Surg* 2013;257(6):1116-1123.

HYPERSPLENISM

In the past, the term hypersplenism or increased splenic function has been used to denote the syndrome characterized by splenic enlargement, deficiency of one or more blood cell lines, normal or hyperplastic cellularity of deficient cell lines in the marrow, and increased turnover of affected cells. Increased understanding of the pathophysiology of specific disorders has shown that hypersplenism is not synonymous with splenomegaly. Some disorders in which there

is spleen-dependent destruction of blood elements do not manifest all features of hypersplenism. For example, splenomegaly is rarely a feature of immune thrombocytopenic purpura, and splenectomy is not always curative. Conversely, other conditions that enlarge the spleen may not result in destruction or sequestration of blood elements with resultant cytopenias. In disorders with known pathogenesis, the trend has been to classify them as separate disease entities rather than as hypersplenic conditions.

The defects in hypersplenism are exaggerations of normal splenic functions primarily associated with the red pulp. The principal cause of cytopenias in hypersplenism is increased sequestration and destruction of blood cells in the spleen, which is hypertrophied or increased in volume in a variety of diseases. Etiologic factors include: (1) neoplastic infiltration, (2) disease of the bone marrow in which the spleen becomes a site of extramedullary hematopoiesis, or (3) metabolic/genetic disorders such as Gaucher disease. The hyperplastic spleen is not selective in its hyperfunction in most of these disorders. The splenomegaly can lead to an increased turnover in erythrocytes and platelets, with a lesser effect on leukocytes. For example, about 60% of patients with cirrhosis develop splenomegaly and 15% develop hypersplenism. The hypersplenism of cirrhosis is seldom of clinical significance; the anemia and thrombocytopenia are usually mild and rarely are indications for splenectomy.

► Clinical Findings

A. Symptoms and Signs

The clinical findings depend largely on the underlying disorder or are secondary to the depletion of circulating blood elements caused by the hypersplenism (Table 27-1). Manifestations of hypersplenism usually develop gradually, and the diagnosis often follows a routine physical or laboratory examination. Some patients experience left upper quadrant fullness, discomfort (can be severe), or early satiety. Others have hematemesis due to gastroesophageal varices.

Table 27-1. Disorders associated with secondary hypersplenism.

Congestive splenomegaly (cirrhosis, portal or splenic vein obstruction)
Neoplasm (leukemia, metastatic carcinoma)
Inflammatory disease (sarcoid, lupus erythematosus, Felty syndrome)
Acute infections with splenomegaly
Chronic infection (tuberculosis, brucellosis, malaria)
Storage diseases (Gaucher disease, Letterer-Siwe disease, amyloidosis)
Chronic hemolytic diseases (spherocytosis, thalassemia, glucose-6-phosphate dehydrogenase deficiency, elliptocytosis)
Myeloproliferative disorders (myelofibrosis with myeloid metaplasia)

Purpura, bruising, and diffuse mucous membrane bleeding are unusual symptoms despite the presence of thrombocytopenia. Anemia may produce significant fatigue that may be the chief complaint in this patient population. Recurrent infections may be seen in patients with severe leukopenia.

B. Laboratory Findings

Patients with primary hypersplenism usually exhibit pancytopenia of moderate degree and generalized marrow hyperplasia. Anemia is most prominent, reflecting the destruction of erythrocytes in the hypertrophied red pulp of the spleen. Thrombocytopenia occurs due to sequestration of platelets but also possibly due to increased turnover. In most cases more immature cell types such as reticulocytes are present, reflecting the overactivity of the bone marrow to compensate for the pancytopenias. One exception is myeloid metaplasia, in which dysfunction of the bone marrow is the primary defect.

C. Evaluation of Splenic Size

Before it becomes palpable, an enlarged spleen may cause dullness to percussion above the left costal margin. Splenomegaly is manifested on supine x-rays of the abdomen by medial displacement of the stomach and downward displacement of the transverse colon and splenic flexure. CT scan is useful for differentiating the spleen from other abdominal masses and for demonstrating splenic enlargement or intrasplenic lesions. Some of the largest massive spleens (spleen weight > 1500 g) occur in these types of disease. Finding the edge of the spleen below the iliac crest and crossing the abdominal midline are frequently seen.

► Differential Diagnosis

Leukemia and lymphoma are diagnosed by marrow aspiration, lymph node biopsy, and examination of the peripheral blood (white count and differential). In hereditary spherocytosis there are spherocytes, osmotic fragility is increased, and platelets and white cells are normal. The hemoglobinopathies with splenomegaly are differentiated on the basis of hemoglobin electrophoresis or the demonstration of an unstable hemoglobin level. Thalassemia major becomes apparent in early childhood, and the blood smear morphology is characteristic. In myelofibrosis, the bone marrow shows proliferation of fibroblasts and replacement of normal elements. In idiopathic thrombocytopenic purpura (ITP), the spleen is normal or only slightly enlarged. In aplastic anemia, the spleen is not enlarged and the marrow is fatty.

► Treatment & Prognosis

The course, response to treatment, and prognosis of the hypersplenic syndromes differ widely depending on the

underlying disease and its response to treatment and will be discussed for each particular disorder below. The indications for splenectomy are given in Table 27–2.

Splenectomy may decrease transfusion requirements, decrease the incidence and number of infections, prevent hemorrhage, and reduce pain. The course of congestive splenomegaly due to portal hypertension depends upon the degree of venous obstruction and liver damage. The hypersplenism is rarely a major problem and is almost always overshadowed by variceal bleeding or liver dysfunction.

Table 27–2. Indications for splenectomy.

Splenectomy Always Indicated

- Primary splenic tumor (rare)
- Hereditary spherocytosis (congenital hemolytic anemia)

Splenectomy Usually Indicated

- Primary hypersplenism
- Chronic immune thrombocytopenic purpura
- Splenic vein thrombosis causing gastric varices
- Splenic abscess (rare)

Splenectomy Sometimes Indicated

- Splenic injury
- Autoimmune hemolytic disease
- Elliptocytosis with hemolysis
- Nonspherocytic congenital hemolytic anemias
- Hodgkin disease (for staging)
- Thrombotic thrombocytopenic purpura
- Idiopathic myelofibrosis
- Splenic artery aneurysm
- Wiscott–Aldrich syndrome
- Gaucher disease
- Mastocytosis-aggressive disease

Splenectomy Rarely Indicated

- Chronic leukemia
- Splenic lymphoma
- Macroglobulinemia
- Thalassemia major
- Sickle cell anemia
- Congestive splenomegaly and hypersplenism due to portal hypertension
- Felty syndrome
- Hairy cell leukemia
- Chédiak–Higashi syndrome
- Sarcoidosis

Splenectomy Not Indicated

- Asymptomatic hypersplenism
- Splenomegaly with infection
- Splenomegaly associated with elevated IgM
- Hereditary hemolytic anemia of moderate degree
- Acute leukemia
- Agranulocytosis

NEOPLASTIC DISEASES

Neoplastic diseases in which splenectomy may play a role in the management of hypersplenism include chronic lymphocytic leukemia (CLL), hairy cell leukemia, and non-Hodgkin lymphoma. Lymphoma is discussed in detail in Chapter 44. Related neoplastic disorders of idiopathic myelofibrosis and mastocytosis are also discussed as precursors or variants of neoplastic diseases in which splenectomy are occasionally indicated.

1. Chronic Lymphocytic Leukemia

CLL is a low-grade neoplasm of B cell lineage characterized by accumulations of populations of lymphocytes that are mature morphologically but functionally incompetent. In the United States, CLL occurs as 25%-30% of all leukemias with mean age at diagnosis of 72. The clinical manifestations and natural history are variable, but initially the disease tends to be indolent. In more advanced stages, splenomegaly, which is frequently massive, is a common characteristic of CLL. Most symptoms related to the spleen are from thrombocytopenia and anemia due to secondary hypersplenism (80%-90% of splenic symptoms). Ten to 20% of patients may have symptoms primarily related to pressure from the size of the enlarged spleen.

Other causes of cytopenia in CLL relate to decreased cellular production from the bone marrow. Bone marrow failure can be due to replacement with leukemic cells or to depletion of the bone marrow as a toxic effect of prior anti-tumor chemotherapy.

Splenectomy in patients with CLL corrects thrombocytopenia in 70%-85% of cases, neutropenia in 60%-70%, and anemia in 50%-60% of cases. The median duration of benefit for both platelets and red cell populations is well over 1 year. Patients with smaller spleens preoperatively, lower preoperative platelet counts, and extensive prior chemotherapy are less likely to respond to splenectomy. However, a positive bone marrow aspirate for leukemic cells is not a contraindication to splenectomy in CLL. Patients who do not have a good performance status should not undergo splenectomy, since patients in terminal stages have unacceptable operative morbidity.

2. Hairy Cell Leukemia

Hairy cell leukemia is a low-grade lymphoproliferative disorder with characteristic “hairy cells”—ie, B lymphocytes with irregular cytoplasmic protrusions positive for tartrate reaction acid phosphatase—which infiltrate the bone marrow and spleen. Patients are typically male, and onset of the disease is in the fifth or sixth decade of life. Symptoms relate to pancytopenia, with anemia requiring transfusions; and to neutropenia, characterized by increased susceptibility to infections and increased bleeding tendencies. Some patients may have symptoms from splenomegaly, which is present in

80% of patients at the time of diagnosis of hairy cell leukemia. The cytopenias are due to a combination of bone marrow replacement and secondary hypersplenism.

The standard therapy for hairy cell leukemia between 1960 and 1995 was splenectomy, but recent advances in pharmacotherapy have superseded this surgical approach. First-line therapy is now treatment with purine nucleoside analogues primarily cladribine, with a complete response rate of 80%-90%. It has never been shown that splenectomy offers survival benefit in this indolent disease, and the operation should be reserved for palliation of splenomegaly in patients who have failed treatment with cladribine and second line agent rituximab and alpha interferon.

3. Myelodysplastic Syndrome

Myelodysplastic syndromes are a heterogeneous group of clinical hematopoietic stem cell disorders manifested by pancytopenias, and dysplasia of the bone marrow. Pathologic changes include extensive bone marrow fibrosis, extramedullary hematopoiesis in the spleen and liver, and a leuko-erythroblastic blood reaction that may evolve into acute myeloid leukemia over time.

The bone marrow is usually almost completely replaced by fibrous tissue, although in some cases it is hyperplastic and fibrosis is minimal. Extramedullary hematopoiesis develops mainly in the spleen, liver, and long bones. Symptoms are attributable to anemia (weakness, fatigue, dyspnea) and to splenomegaly (abdominal fullness and pain, which may be severe). Pain over the spleen from splenic infarcts is common. Spontaneous bleeding, fatigue, secondary infection, bone pain, and a hypermetabolic state are frequent. Portal hypertension develops in some cases as a result of fibrosis of the liver, greatly increased splenic blood flow, or both.

Hepatomegaly is present in 75% of cases and splenomegaly with a firm and irregular spleen in all cases. Striking changes in the peripheral blood are referable to the combination of extramedullary hematopoiesis and hypersplenism. Patients are uniformly anemic, and red cells vary greatly in size and shape, many of them distorted and fragmented. The white count is usually high (20,000-50,000/mL). The platelet count may be elevated, but values less than 100,000/mL are seen in 30% of cases due to secondary hypersplenism. Bone marrow aspirates frequently result in a dry tap because marrow is replaced with fibrosis. It was once incorrectly thought that the spleen performed a crucial function of extramedullary hematopoiesis in this disease and that splenectomy could be lethal. In fact, many patients with myeloid metaplasia feel better if the massive spleen is removed, and their hypersplenism is often corrected.

About 30% of patients are asymptomatic at the time of initial diagnosis and require no therapy. When cytopenias and splenomegaly produce symptoms, treatment is primarily supportive using transfusions, androgenic steroids,

antimetabolites, and hematopoietic growth factors are indicated. Newer therapies include treatment with immunomodulatory drugs such as thalidomide or antibodies to VEGF and TNF. A subset of patients with myeloid metaplasia has a component of autoimmune hemolytic anemia, and in this group of patients immunosuppressive therapy may be beneficial. Splenectomy is indicated in the following situations: (1) major hemolysis unresponsive to medical management, (2) severe symptoms of massive splenomegaly with mass effect of the spleen, (3) life-threatening thrombocytopenia, and (4) portal hypertension with variceal hemorrhage. This is one of the rare occasions when portal hypertension may be cured by splenectomy.

Splenectomy in myeloid metaplasia is associated with a 7%-10% death rate and frequent complications often related to postsplenectomy hepatic morbidity. Splenectomy best relieves symptoms of splenomegaly and portal hypertension, but only about 75% of patients get relief from anemia and thrombocytopenia. Younger patients with normal platelet counts and symptoms are the best candidates for splenectomy in idiopathic myelofibrosis.

4. Systemic Mast Cell Disease

Systemic mast cell disease, or mastocytosis, is a rare condition characterized by mast cell infiltration of a number of tissues, including the spleen. There are two types: indolent and aggressive. In indolent systemic mast cell disease, there is no need for consideration of splenectomy. The aggressive type is associated with hematologic diseases with characteristics of lymphoma. Splenomegaly may occur, with the predominant symptoms resulting from thrombocytopenia due to hypersplenism. In this subgroup of patients with aggressive disease, splenectomy improves platelet counts and is associated with longer median survival time than for patients with aggressive disease who do not undergo splenectomy, although systemic therapy including alpha interferon has been shown to be effective.

METABOLIC DISORDERS

Metabolic disorders amenable to splenectomy are rare inherited diseases that include as a component splenic enlargement due to the pathologic deposition of material within the spleen. In Gaucher disease, excess sphingolipid is deposited in the spleen. In sarcoidosis, the spleen becomes involved with non-caseating granulomas as can be seen in lymph nodes. Inherited disorders also include disease in which there is a specific immunologic target with associated destruction in the spleen.

1. Gaucher Disease

Gaucher disease is an autosomal recessive disorder characterized by a deficiency in beta-glucosidase, a lysosomal enzyme that degrades the sphingolipid glucocerebroside.

There is an increased incidence of this disorder in Ashkenazi Jews. Three types of this disease exist, and the one amenable to splenectomy is type I, or the adult type. Pathologically, Gaucher disease results in lipid accumulation within the white pulp of the spleen, the liver, or the bone marrow. Predominant symptoms relate to massive splenomegaly from either the direct effects of the size of the spleen or secondary to cytopenias from hypersplenism.

► Treatment & Prognosis

Treatment by total splenectomy alleviates the symptoms but results in accelerated hepatic and bone disease as well as a significant increased risk of postsplenectomy infections. Treatment with partial or subtotal splenectomy has been studied over the past 10 years for both adults and children with Gaucher disease. Removing most of the spleen corrects the symptoms of splenomegaly, but leaving a splenic remnant provides a site for further deposition of lipid that protects the liver and bone. The major problem with partial splenectomy is the eventual recurrence and enlargement of the splenic remnant accompanied by recurrent symptoms. As with hereditary spherocytosis, there is an increase incidence of pigmented gallstones occurring in up to two-thirds of female patients and one-third of male patients. The goal of subtotal splenectomy in Gaucher disease is to leave a small fragment approximately the size of the fist of the patient. Replacement therapy with recombinant glucocerebrosidase enzyme has recently become available, but the cost of chronic treatment is prohibitive.

2. Wiskott–Aldrich Syndrome

Wiskott–Aldrich syndrome is an X-linked disease characterized by thrombocytopenia, combined B and T cell immunodeficiency, eczema, and a propensity to develop malignancies. Thrombocytopenia is the major feature of this rare disorder, with most patients presenting with bloody diarrhea, epistaxis, and petechiae at a young age. Platelet counts typically range between 20,000/mL and 40,000/mL, and the platelets that are present are between one-fourth and one-half of normal size. The spleen sequesters and destroys platelets in this disease, releasing “microplatelets” back into the circulation. The genetic defect in this disorder may be related to an abnormal adhesion molecule affecting immune as well as platelet cell-to-cell interaction.

► Treatment & Prognosis

Splenectomy in Wiskott–Aldrich syndrome was at one time withheld, since the postoperative course was characterized by severe and fatal infections due to the underlying immune defect of this disorder combined with loss of the immune function of the spleen. However, splenectomy does

normalize platelet shape, size, and numbers, and the use of prophylactic antibiotics after splenectomy has significantly increased survival rates. The optimal treatment of Wiskott-Aldrich syndrome is an HLA-matched sibling bone marrow transplantation. However, splenectomy with antibiotics results in better survival than an unmatched bone marrow transplantation. Patients who do not undergo bone marrow transplantation or splenectomy typically do not survive past the age of 5 years.

3. Chédiak–Higashi Syndrome

Chédiak–Higashi syndrome is a rare autosomal recessive disease characterized by immunodeficiency that increases the susceptibility to bacterial and viral infections and is manifested by recurrent fever, nystagmus, and photophobia. Most patients experience widespread infiltration of tissues with histiocytes similar to a lymphoma. Secondary hepatosplenomegaly with lymphadenopathy, leukopenia, and bleeding complications occur in the accelerated phase of Chédiak–Higashi syndrome. Standard treatment includes chemotherapy, steroids, and ascorbic acid, but these patients have a poor prognosis. Splenectomy has been used in the accelerated phase with beneficial results.

4. Sarcoidosis

Sarcoidosis is a granulomatous disease of unknown origin that can involve virtually any organ or area of the body. Pulmonary disease is most common, but autopsy studies have shown that the spleen is the second most common site, with enlargement by noncaseating granulomas in 50%–60% of patients. However, most patients do not have massive splenomegaly. When this does occur, patients can have significant cytopenias related to hypersplenism as well as the constitutional symptoms and hypercalcemia of sarcoidosis. In this subgroup of patients, splenectomy is indicated as a potential curative procedure for each of these symptoms.

ERYTHROCYTE DISORDERS

In this category of diseases there is generally no intrinsic abnormality of the spleen, as opposed to hypersplenism, in which the spleen is primarily infiltrated by neoplasia or storage products and causes cytopenias due to increased volume of splenic tissue. In the autoimmune disorders, there is a humoral antibody response against proteins on circulating blood cells, resulting in depletion primarily within the spleen. Disorders involving platelets, erythrocytes, and neutrophils are listed in decreasing order of incidence. Erythrocyte disorders are genetic defects in structural components or hemoglobin that increase the clearance of red cells in the spleen, causing a significant decrease in erythrocyte half-life.

1. Hereditary Spherocytosis

ESSENTIALS OF DIAGNOSIS

- ▶ Malaise, abdominal discomfort.
- ▶ Jaundice, anemia, splenomegaly.
- ▶ Spherocytosis, increased osmotic fragility of red cells, negative Coombs test.

▶ General Considerations

Hereditary spherocytosis (congenital hemolytic jaundice, familial hemolytic anemia), the most common congenital hemolytic anemia (affecting 1:5000 individuals), is transmitted as an autosomal dominant trait. It is caused by a variety of genetic defects related to abnormal cellular structural proteins, primarily ankyrin band 3, alpha and beta spectrum and protein 4-2 all, which alter binding of the cytoskeleton to the cellular membrane, causing a decreased cellular plasticity with membrane loss. The normal shape of the erythrocyte is changed from a biconcave disk into a sphere, and the decreased membrane-to-cell volume ratio causes a lack of deformability that delays passage through the channels of the splenic red pulp. Significant cell destruction occurs only in the presence of the spleen. Hemolysis is largely relieved by splenectomy.

The condition is seen in all races but is more frequent in whites than in blacks. When discovered early in infancy, it may resemble hemolytic disease of the newborn due to ABO incompatibility. In occasional instances the diagnosis is not made until later in adult life, but it is usually discovered in the first three decades.

▶ Clinical Findings

A. Symptoms and Signs

The principal manifestations are splenomegaly, mild to moderate anemia, and jaundice. The patient may complain of easy fatigability. The spleen is almost always enlarged and may cause fullness and discomfort in the left upper quadrant. However, most patients are diagnosed during a family survey at a time when they are asymptomatic.

Periodic exacerbations of hemolysis can occur. The rare hypoplastic crises, which often follow acute viral illnesses, may be associated with profound anemia, headache, nausea, abdominal pain, pancytopenia, and hypoactive marrow.

B. Laboratory Findings

The red cell count and hemoglobin are moderately reduced. Some of the asymptomatic patients detected by family surveys have normal red cell counts when first seen. The red

cells are usually normocytic, but microcytosis may occur. Macrocytosis may present during periods of marked reticulocytosis. Spherocytes in varying numbers, sizes, and shapes are seen on a Wright-stained smear. The reticulocyte count is increased to 5%-20%.

The indirect serum bilirubin and stool urobilinogen are usually elevated, and serum haptoglobin is usually decreased to absent. The Coombs test is negative. Osmotic fragility is increased; hemolysis of 5%-10% of cells may be observed at saline concentrations of 0.6%. A more accurate reflector of fragility is the cryohemolysis test, which has a sensitivity and specificity of almost 95% for spherocytosis. Occasionally, the osmotic fragility is normal but the incubated fragility test (defibrinated blood incubated at 37°C for 24 hours) will show increased hemolysis. Autohemolysis of defibrinated blood incubated under sterile conditions for 48 hours is usually greatly increased (10%-20%, compared to a normal value of < 5%). The addition of 10% glucose before incubation will decrease the abnormal osmotic fragility and autohemolysis. Infusion of the patient's own blood labeled with ⁵¹Cr shows a greatly shortened red cell life span and sequestration in the spleen. Normal red cells labeled with ⁵¹Cr have a normal life span when transfused into a spherocytotic patient, indicating that splenic function is normal.

► Differential Diagnosis

At present there is no pathognomonic test for hereditary spherocytosis. Spherocytes in large numbers may occur in autoimmune hemolytic anemias, in which osmotic fragility and autohemolysis may be increased but are usually not improved by incubation with glucose. The positive Coombs test, negative family history, and sharply reduced survival of normal donor red cells are diagnostic of autoimmune hemolysis. Spherocytes are also seen in hemoglobin C disease, in some alcoholics, and in some severe burns.

► Complications

Pigment gallstones occur in about 85% of adults with spherocytosis but are uncommon under age 10. On the other hand, gallstones in a child should suggest congenital spherocytosis.

Chronic leg ulcers unrelated to varicosities are a rare complication but, when present, will heal only after the spleen is removed.

► Treatment

Splenectomy is the sole treatment for hereditary spherocytosis and is indicated even when the anemia is fully compensated and the patient is asymptomatic. The longer the hemolytic process persists, the greater the potential risk of complications such as hypoplastic crises and cholelithiasis. At operation, the gallbladder should be inspected

for stones and accessory spleens should be sought. When there is associated cholelithiasis, cholecystectomy should be performed along with the splenectomy. Unless the clinical manifestations are severe, splenectomy should be delayed in children until age 6 to avoid the risk of increased infection due to loss of reticuloendothelial function. For children under age 5 with severe disease and high transfusion requirements, a partial (80%) splenectomy may correct symptoms while maintaining the normal immune functions of the spleen.

► Prognosis

Splenectomy cures the anemia and jaundice in all patients. The membrane abnormality, spherocytosis, and increased osmotic fragility persist, but red cell life span becomes almost normal. An overlooked accessory spleen is an occasional cause of failure of splenectomy. The presence of Howell-Jolly bodies in red cells makes the presence of accessory spleens unlikely.

Perrotta S. Hereditary spherocytosis. *Lancet* 2008;372:1411-1426.

2. Hereditary Elliptocytosis

This autosomal dominant genetic disorder, also known as ovalocytosis, is usually of little clinical significance. Normally, up to 15% oval or elliptic red blood cells can be seen on a peripheral blood smear. In elliptocytosis, at least 25% and up to 90% of circulating erythrocytes are elliptic. As with hereditary spherocytosis, this disease is due to a variety of genetic defects in cytoskeletal proteins such as spectrin. The predominant abnormality is that this structural protein exists as a dimer instead of a tetramer, leading to change in the erythrocyte's shape, decreased plasticity, and a shortened life span of the cell.

Most affected individuals are asymptomatic; about 10% have clinical manifestations consisting of moderate anemia, slight jaundice, and a palpable spleen.

Symptomatic patients should have splenectomy, and cholecystectomy if gallstones are present. The red cell defect persists after splenectomy, but the hemolysis and anemia are cured.

Gallagher PG. Abnormalities of the erythrocyte membrane. *Pediatr Clin North Am* 2013;60(6):1349-1362.

3. Hereditary Nonspherocytic Hemolytic Anemia

This is a heterogeneous group of rare hemolytic anemias caused by inherited intrinsic red cell defects that lead to oxidative hemolysis. Included in the group are pyruvate

kinase deficiency and glucose 6-phosphate dehydrogenase (G6PD) deficiency. They are usually manifested in early childhood with anemia, jaundice, reticulocytosis, erythroid hyperplasia of the marrow, and normal osmotic fragility. As with other hemolytic anemias, there may be associated cholelithiasis.

Multiple blood transfusions are often required. Splenectomy, while not curative, may ameliorate some of these conditions, especially pyruvate kinase deficiency. In G6PD deficiency, splenectomy is not beneficial, and treatment consists of avoidance of dietary oxidants.

4. Thalassemia Major (Mediterranean Anemia; Cooley Anemia)

In the most common form of this autosomal dominant disorder, a structural defect in the β -globin chain causes excess α chains to precipitate on the inner surface of the membrane of the erythrocyte and produces abnormal red cells (eg, target cells). Heterozygotes usually have mild anemia (thalassemia minor); however, starting early in infancy, homozygotes have severe chronic anemia accompanied by jaundice, hepatosplenomegaly (often massive), retarded body growth, and enlargement of the head. The peripheral blood smear reveals target cells, nucleated red cells, and a hypochromic microcytic anemia. Gallstones are present in about 25% of patients. A characteristic feature is the persistence of fetal hemoglobin (Hb F).

Since the anemia of thalassemia is due to both increased destruction of red cells and decreased hemoglobin production, splenectomy does not cure the anemia, as in spherocytosis, but it may reduce transfusion requirements by removing an enlarged, uncomfortable spleen. Treatment is by iron chelation and transfusion.

AUTOIMMUNE DISORDERS

The production of IgG autoantibodies specific for cell membrane proteins on erythrocytes causes autoimmune hemolytic anemia; on platelets, it causes ITP and may cause neutropenia in Felty syndrome. Macrophages express Fc receptors for IgG, and antibody-coated cells that pass through the splenic sinuses of the red pulp come into contact with these phagocytic cells. Furthermore, the microenvironment of the red pulp with slow flow of blood with a high cellular content through circuitous spaces facilitates opsonization of cells in the spleen. Production of autoantibodies in the white pulp germinal centers may also enhance cellular destruction, particularly in ITP. Understanding this pathophysiologic mechanism is important, since autoimmune hemolytic anemia caused by IgM autoantibodies (ie, cold agglutinin hemolytic anemia) does not respond to splenectomy because macrophages do not have Fc receptors for IgM. This mechanism also explains why treatment

with high-dose intravenous immune globulin is beneficial in these diseases because it blocks the macrophage Fc receptor.

1. Acquired Hemolytic Anemia

ESSENTIALS OF DIAGNOSIS

- ▶ Fatigue, pallor, jaundice.
- ▶ Splenomegaly.
- ▶ Persistent anemia and reticulocytosis.

▶ General Considerations

The autoimmune hemolytic anemias have also been classified according to the optimal temperature at which autoantibodies react with the red cell surface (warm or cold antibodies). This classification is particularly useful, since patients with cold antibodies will not benefit from splenectomy but those with warm antibodies may.

Although hemolysis without demonstrable antibody (Coombs test-negative) may occur in uremia, cirrhosis of the liver, cancer, and certain infections, in most cases the red cell membranes are coated with either immunoglobulin or complement (Coombs test-positive). The antibody in IgG autoimmune hemolytic anemia is specifically directed against the Rh locus on the erythrocyte. Initiation of this disease is either idiopathic (40%-50%) or secondary to drug exposure, connective tissue disorders, or lymphoproliferative disorders. Hemolytic anemia due to cold antibodies is less common and always a secondary immune response. Cold agglutinin hemolytic anemia is due typically to an IgM directed against the I red cell antigen, and hemolysis occurs intravascularly by complement fixation and not within the spleen making splenectomy not beneficial in the setting of cold antibodies.

About 20% of cases of secondary immune hemolytic anemia are due to drug use, and hemolysis is usually mediated by warm antibodies. Penicillin, quinidine, hydralazine, and methyldopa have been most commonly implicated in this syndrome (Table 27-3).

Table 27-3. Disorders associated with immune hemolysis.

Immune drug reaction (penicillin, quinidine, hydralazine, methyldopa, cimetidine)
Collagen vascular disease (lupus erythematosus, rheumatoid arthritis)
Tumors (lymphoma, myeloma, leukemia, dermoid cysts, ovarian teratoma)
Infection (<i>Mycoplasma</i> , malaria, syphilis, viremia)

► Clinical Findings

A. Symptoms and Signs

Autoimmune hemolytic anemia may be encountered at any age but is most common after age 50; it occurs twice as often in women. The onset is usually acute, consisting of anemia, mild jaundice, and sometimes fever. The spleen is palpably enlarged in over 50% of patients, and pigment gallstones are present in about 25%. Rarely, a sudden severe onset produces hemoglobinuria, renal tubular necrosis, and a 40%-50% death rate.

B. Laboratory Findings

Hemolytic anemia is diagnosed by demonstrating a normocytic normochromic anemia, reticulocytosis (over 10%), erythroid hyperplasia of the marrow, and elevation of serum indirect bilirubin. Stool urobilinogen may be greatly increased, but there is no bile in the urine. Serum haptoglobin is usually low or absent. The direct Coombs test is positive because the red cells are coated with immunoglobulins or complement (or both).

► Treatment

Associated diseases must be carefully sought and appropriately treated. For drug-induced secondary hemolytic anemia, further exposure to the offending agent must be terminated. Corticosteroids produce a remission in about 75% of patients, but only 25% of remissions are permanent. Transfusion should be avoided if possible, since cross-matching may be extremely difficult, requiring washed red cells and saline-active antisera. Rituximab is an effective second line therapy now producing durable responses 40% of steroid resistant cases.

Splenectomy is indicated for patients with warm-antibody hemolysis who fail to respond to 4-6 weeks of high-dose corticosteroid therapy, for patients who relapse after an initial response when steroids are withdrawn, and for patients in whom steroid therapy is contraindicated (eg, those with active pulmonary tuberculosis). Patients who require chronic high-dose steroid therapy should also be considered for splenectomy, since the risks of long-term steroid administration are substantial.

Splenectomy is effective because it removes the principal site of red cell destruction. Occasionally, splenectomy identifies the presence of an underlying disorder such as lymphoma. About half of patients who fail to respond to splenectomy will respond to azathioprine or cyclophosphamide. Plasmapheresis has been employed as salvage therapy in patients with refractory hemolytic anemia.

► Prognosis

Relapses may occur after splenectomy but are less frequent if the initial response was good. The ultimate

prognosis in the secondary cases depends upon the underlying disorder.

2. Immune Thrombocytopenic Purpura (Idiopathic Thrombocytopenic Purpura)

ESSENTIALS OF DIAGNOSIS

- Petechiae, ecchymoses, epistaxis, and easy bruising.
- No splenomegaly.
- Decreased platelet count, prolonged bleeding time, poor clot retraction, normal coagulation time.

► General Considerations

Immune thrombocytopenic purpura is a hemorrhagic syndrome with diverse causes that can occur in an acute or chronic form and is characterized by marked reduction in the number of circulating platelets, abundant megakaryocytes in the bone marrow, and a shortened platelet life span. It may be idiopathic or secondary to a lymphoproliferative disorder, drugs or toxins, bacterial or viral infection (especially in children), systemic lupus erythematosus, or other conditions. Although responses to corticosteroids and to splenectomy in these patients are comparable to the responses observed in other patients with immune thrombocytopenic purpura, splenectomy should be reserved for those with signs of blood loss, since surgical complications are high and survival may be short. However, due to the incidence of ITP, this disease is typically the most common indication for splenectomy in most institutional series.

The pathogenesis of both primary and secondary disorders involves a circulating antiplatelet IgG autoantibody usually directed against a membrane protein which is the fibrinogen receptor (glycoprotein IIb/IIIa). In this disorder, the spleen is primarily the site of platelet destruction and may also be a significant source of autoantibody production. Splenomegaly, present in only 2% of cases, is usually a manifestation of another underlying disease such as lymphoma or lupus erythematosus. Five to 15% of HIV-positive patients have thrombocytopenia independent of the immunologic state of their disease that is clinically indistinguishable from typical chronic ITP. The precise pathophysiologic mechanism in relation to HIV infection is not known.

► Clinical Findings

A. Symptoms and Signs

The onset may be acute, with ecchymoses or showers of petechiae, and may be accompanied by bleeding gums, vaginal bleeding, gastrointestinal bleeding, and hematuria. Central nervous system bleeding occurs in 3% of patients. The acute form is most common in children, usually occurring before 8 years of age, and often begins 1-3 weeks after a viral upper respiratory illness.

The chronic form, which may start at any age, is more common in women. It characteristically has an insidious onset, often with a long history of easy bruisability and menorrhagia. Showers of petechiae may occur, especially over pressure areas. Cyclic remissions and exacerbations may continue for several years.

B. Laboratory Findings

The platelet count is moderately to severely decreased (always below 100,000/mL), and platelets may be absent from the peripheral blood smear. Although white and red cell counts are usually normal, iron deficiency anemia may be present as a result of bleeding. The bone marrow shows increased numbers of large megakaryocytes without platelet budding.

The bleeding time is prolonged, capillary fragility (Rumpel-Leede test) greatly increased, and clot retraction poor. Partial thromboplastin time, prothrombin time, and coagulation time are normal. Specific determinations of antiplatelet antibody titers can now be routinely assessed to aid in diagnosis. Reduced red cell or platelet survival can be measured by labeling the patient's cells with ⁵¹Cr or the platelets with indium-111 and measuring the rate of disappearance of radioactivity from the blood. The spleen's role in producing the anemia or thrombocytopenia can be determined by measuring the ratio of radioactivity that accumulates in the liver and spleen during destruction of the tagged cells; a spleen/liver ratio greater than 2:1 indicates significant splenic pooling and suggests that splenectomy would be beneficial.

► Differential Diagnosis

Other causes of nonimmunologic thrombocytopenia must be ruled out, such as leukemia, aplastic anemia, and macroglobulinemia. Thrombocytopenia and purpura may be caused by ineffective thrombocytopoiesis (eg, pernicious anemia, preleukemic states) or by nonimmune platelet destruction (eg, septicemia, disseminated intravascular coagulation, or other causes of hypersplenism).

► Treatment

Treatment of immune thrombocytopenic purpura depends on the age of the patient, the severity of the disease, the

duration of the thrombocytopenia, and the clinical variant. Secondary immune thrombocytopenias are best managed by treating the underlying primary disorder (eg, if it is drug-induced, the drug should be stopped).

Patients with mild or no symptoms need no specific therapy but should avoid contact sports, elective surgery, and all unessential medications. Corticosteroids are indicated in patients with moderate to severe purpura of short duration. Usually, 60 mg of prednisone (or equivalent) is required daily; this is continued until the platelet count returns to normal and then is gradually tapered after 4-6 weeks. Corticosteroids produce a response in 70%-80%, but sustained remissions in only 20% of adults. Second line therapy with Rituximab improves platelet counts in 30%-40% of patients and sustained complete response in 10%-20%. New agents to stimulate platelet production such as thrombopoietin (TPO) against AMG531 and eltrombopag are being studied as third line medical therapies.

Splenectomy is the most effective form of therapy and is indicated for patients who do not respond to corticosteroids, for those who relapse after an initial remission on steroids, and for steroid-dependent patients. Corticosteroid therapy is not necessary in the immediate preoperative period unless bleeding is severe or the patient was receiving steroids before the operation. If indicated, platelet transfusions are given intraoperatively only after ligation of the splenic artery or removal of the spleen, since platelets from earlier transfusion would be rapidly sequestered in the spleen. For temporary treatment of the thrombocytopenia, intravenous immunoglobulin is effective.

Splenectomy produces a sustained remission in about 68% of patients. As with corticosteroids, success rates are better with acute than chronic immune thrombocytopenic purpura. Two factors associated with better outcomes are shorter duration of disease and younger age. The platelet count usually rises promptly following splenectomy (eg, it may double in 24 hours) and reaches a peak after 1-2 weeks. If the platelet count remains elevated after 2 months, the patient can be considered cured. When corticosteroids and splenectomy have failed, immunosuppressive drugs (azathioprine, vincristine) achieve remission in 25% of cases.

The benefit of splenectomy for HIV-associated ITP has been less clear. The risk of infection and the overall shortened survival in this population argue against splenectomy. However, in HIV patients without AIDS, clinically significant thrombocytopenia responds completely in 70% and there is partial improvement in 20% following splenectomy. Splenectomy does not appear to alter the overall natural history of HIV infection.

► Prognosis

Acute immune thrombocytopenic purpura in children under age 16 has an excellent prognosis; approximately 80% of patients have a complete and permanent spontaneous

remission. This occurs rarely in adults. Splenectomy is successful in about 80% of patients, but more often in idiopathic cases than in those secondary to another disorder. The proportion of patients undergoing splenectomy for ITP has decreased due to medical treatment other than steroids that have efficacy, although the incidence of chronic TP has increased. Agents to stimulate TPO may have significant benefit for patients who have no improvement in platelet count after splenectomy.

3. Felty's Syndrome

Approximately 1% of patients with rheumatoid arthritis have splenomegaly and neutropenia—a triad known as Felty's syndrome. High levels of IgG have been identified on the surface of neutrophils with evidence of increased of granulopoiesis in the bone marrow. Pathologic analysis of the spleen in Felty's syndrome patients shows a larger proportionate increase in the white pulp as opposed to most conditions of splenomegaly. There is evidence of excess accumulation of neutrophils in both the T cell zone of the white pulp as well as the cord and sinuses of the red pulp.

Patients with severe neutropenia have clinical symptoms of recurring infections in Felty syndrome. Symptomatic patients who have evidence of IgG on the surface of neutrophils should be considered for splenectomy. Neutropenia will improve in 60%-70% of these patients, but relapse of neutropenia as well as recurrent infections in the presence of normal neutrophil counts may occur, and these untoward events have dampened enthusiasm for splenectomy in this disease.

4. Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura is a rare disease with a pentad of clinical features: (1) fever, (2) thrombocytopenic purpura, (3) hemolytic anemia, (4) neurologic

manifestations, and (5) renal failure. The cause is unknown, but autoimmunity to endothelial cells or a primary platelet defect has been implicated, and its occurrence in patients with AIDS has been reported. It is most common between ages 10 and 40 years.

The thrombocytopenia is probably due to a shortened platelet life span. The microangiopathic hemolytic anemia is produced by passage of red cells over damaged small blood vessels containing fibrin strands. Rigid red cells are trapped and fragmented in the spleen, whereas those that escape the spleen may be more vulnerable to damage and destruction in the abnormal microvasculature. The anemia is often severe, and it may be aggravated by hemorrhage secondary to thrombocytopenia. Hepatomegaly and splenomegaly occur in 35% of cases.

► Treatment & Prognosis

Until recently, there was no effective therapy for this disorder, and mortality rates as high as 95% were reported. Most patients died of renal failure or cerebral bleeding. Plasmapheresis with plasma exchange has recently emerged as an effective form of treatment that is superior to simple plasma infusion with complete response rate of 55%-65%. Plasma exchange failure can be salvaged with splenectomy with 60% having a substantial response and a 20%-30% relapse rate.

VASCULAR DISORDERS OF THE SPLEEN

Vascular disease of the spleen treated by splenectomy can occur both with the arterial inflow and the venous outflow. The most common disease is splenic vein thrombosis; this can be treated in a straightforward manner by splenectomy. Splenic artery aneurysms are one of the most common sites of visceral aneurysms and may require splenectomy (discussed in Chapter 34).

1. Splenic Vein Thrombosis

► Etiology

Thrombosis of the splenic vein can occur as an isolated event not due to any pathologic findings in the spleen but due to diseases that impact on the splenic vein as it travels along the superior border of the pancreas. The most common cause is acute or chronic pancreatitis or a pseudocyst of the body/tail of the pancreas, with the general inflammatory reaction in the pancreas resulting in thrombosis of the splenic vein in 20% of patients. Inflammation from a posterior gastric ulcer is another cause. Direct extension of carcinoma of the pancreas or stomach into the lesser sac may cause splenic vein thrombosis, but the diagnosis is generally not subtle because of other manifestations of these malignancies. Idiopathic retroperitoneal fibrosis may be an alternative cause of splenic vein thrombosis.

Splenic vein thrombosis presents as upper gastrointestinal hemorrhage due to isolated gastric varices. With occlusion of the splenic vein, outflow of blood from the spleen is diverted into the short gastric veins as the remaining collateral vessels. These veins dilate and become varices primarily in the fundus of the stomach, resulting in bleeding in 15%-20% of patients.

► Diagnosis

Splenic vein thrombosis is suspected when there are isolated varices of the stomach particularly in the proximal greater curvature without any esophageal varices. Since there is no portal hypertension, there are no associated signs or symptoms of cirrhosis. Definitive diagnosis is made by confirming that there is no blood flow in the main splenic vein. Invasive venography is no longer needed because this diagnosis can be confirmed by CT or MRI scans with contrast material or by high-resolution ultrasound. CT or MRI is preferred because the splenic vein may be hidden from ultrasound by bowel gas and CT or MRI allows characterization of the surrounding structures (pancreas, stomach) to assess for causative pathology.

► Treatment & Prognosis

Splenectomy is curative in patients with splenic vein thrombosis. All of the symptoms relate to increased splenic blood flow through collateral vessels; eliminating that blood flow is curative. If a splenic vein thrombosis is diagnosed—even if the patients have not had an episode of upper gastrointestinal hemorrhage—an elective or prophylactic splenectomy is indicated if the patients are otherwise healthy. In patients with portal vein thrombosis, the magnitude of the disease and associated problems is greatly amplified, and splenectomy is almost never indicated because it is not curative.

Agarwal AK et al. Significance of splenic vein thrombosis in chronic pancreatitis. *Am J Surg* 2008;196:149-154.

2. Cysts & Tumors of the Spleen

Parasitic cysts are almost always echinococcal (see Chapter 8). They may be asymptomatic, but usually the patient notices splenomegaly. Calcification of the cyst wall may be seen on x-ray. Eosinophilia may be found, and serologic tests may confirm the diagnosis. The treatment of choice is splenectomy.

Other cysts are dermoid, epidermoid, endothelial, and pseudocysts. The latter are thought to be late results of infarction or trauma. Splenectomy may be indicated to exclude tumor; however, partial splenectomy or observation has been advocated.

The rare primary tumors of the spleen include lymphoma, sarcoma, hemangioma, and hamartoma. Hamartomas may be confused grossly with splenic lymphoma at laparotomy.

These lesions are usually asymptomatic until splenomegaly causes abdominal discomfort or a palpable mass. The benign vascular tumors of the spleen (angiomas) can produce hypersplenism. Spontaneous rupture with massive hemorrhage can occur. Splenectomy is indicated if the tumor appears to be limited to the spleen. Inflammatory pseudotumors are benign lesions composed of a mixture of inflammatory cells and a granulomatous reaction that can occur in a variety of organs, including the spleen. Constitutional symptoms of lethargy, weight loss, and fatigue occur and can be alleviated by splenectomy.

The spleen is a common site for metastases in advanced cancers, especially of the lung and breast, and melanoma. Splenic metastases are common autopsy findings but are rarely clinically significant.

INFECTIONS OF THE SPLEEN (SPLENIC ABSCESS)

Splenic abscesses are uncommon but are important because the death rate ranges between 40% and 100%. They may be caused by hematogenous seeding of the spleen with bacteria from remote sepsis such as endocarditis, by direct spread of infection from adjacent structures, or by splenic trauma resulting in a secondarily infected splenic hematoma. Splenic abscess is a complication of intravenous drug abuse. In 80% of cases, one or more abscesses exist in organs other than the spleen, and the splenic abscess develops as a terminal manifestation of uncontrolled sepsis in other organs. Enteric organisms are found in over two-thirds of splenic abscesses, with staphylococci and nonenteric streptococci comprising the majority of the remainder. In some patients, unexplained sepsis, progressive splenic enlargement, and abdominal pain are the presenting manifestations. The spleen may not be palpable, because of left upper quadrant tenderness and guarding. A left pleural effusion combined with unexplained leukocytosis in a septic patient suggests a splenic abscess. The finding of gas in the spleen on plain abdominal x-ray is pathognomonic of splenic abscess, but CT scan is the optimal way to define and diagnose a splenic abscess.

Most splenic abscesses remain localized, periodically seeding the bloodstream with bacteria, but spontaneous rupture and peritonitis may occur. Splenectomy is essential for cure if sepsis is localized to the spleen. Percutaneous drainage of large, solitary juxtacapsular abscesses may occasionally be feasible but is associated with an extremely high mortality rate and should be reserved for patients unable to withstand an operation.

DIAGNOSTIC SPLENECTOMY

One indication for splenectomy is for diagnosis in an otherwise asymptomatic patient. Splenectomy may be needed to make a diagnosis when an asymptomatic mass lesion is seen within the spleen on CT scan, ultrasound, or MRI scan for

which a definitive diagnosis cannot be made radiographically. Another example is when a patient has either a palpable spleen on physical examination or an enlarged spleen by scan, and otherwise has no clear diagnostic disorder.

► Splenic Mass Lesions

For the patients who have an isolated splenic mass, 60% turned out to be malignant lesions and 40% turned out to be benign lesions. Most malignant lesions are lymphoma; next most common is metastatic carcinomas, including some in which the primary diagnosis had not been made previously. In patients with benign lesions, more than half were cysts, and there were also splenic hamartomas and splenic hemangiomas.

In diagnosing an isolated splenic mass, most of these lesions can be diagnosed by doing a fine-needle aspiration biopsy. Certain lesions—such as the cystic lesions or hemangioma—would have classic appearance on gadolinium-enhanced MRI scan, and these scans are another imaging modality that could be utilized to sort out mass lesions without tissue biopsy. PET scans will reliably identify high grade lymphoma and metastatic tumors but may miss low-grade or mantle-zone lymphoma. The risk of bleeding is significant in patients with hemangiomas. These benign tumors of endothelial cells can be definitively diagnosed with gadolinium-enhanced MRI, and this imaging test is optimal for characterizing an isolated splenic mass.

► Splenomegaly Without a Diagnosis

The second diagnostic indication for splenectomy is unexplained splenomegaly. Most of these enlarged spleens will be shown to have lymphoma. The minority will have benign diagnoses including benign lymphoid proliferation, benign vascular lesions, and granulomatous disease, as well as splenic infarction and hemorrhage. The role of the fine-needle aspiration and other percutaneous biopsies for nondiagnosed splenomegaly is quite limited with no distinct mass to biopsy; there would be very low yield in terms of being able to make that diagnosis by that form of biopsy.

► Staging Laparotomy for Hodgkin Disease

Another type of diagnostic procedure would be a staging laparotomy for Hodgkin disease. Discussion of this procedure is more of a historical note because it has limited use in today's current practice in treating this form of lymphoma.

A standard practice for pathologic staging between 1960 and 1990 was performance of a staging laparotomy in most patients with Hodgkin disease. The reason for performing this invasive procedure was based on reports that laparotomy altered the clinical stage of disease in approximately 35% of patients. There are several reasons why the incidence of performing staging laparotomy has decreased over the

past 10-15 years. The primary reason is that it does not alter treatment of Hodgkin disease based on results of recent clinical series. Since systemic chemotherapy treats the whole patient, accurate pathologic staging makes no impact on the treatment outcome or treatment decisions.

IATROGENIC SPLENECTOMY

Procedures in which mobilization of the left upper quadrant is done (such as reflection of the spleen and pancreas medially to expose retroperitoneal tissue, left adrenalectomy, and left nephrectomy) put the spleen at risk for injury during the dissection. Simple mobilization of the splenic flexure of the colon can lead to bleeding from the inferior pole of the spleen that may be difficult to control. The ligaments that go directly from the omentum to the capsule of the spleen may be the most common cause of iatrogenic splenic trauma, as it is a common practice to aggressively retract the omentum as needed for exposure. If there are direct branches that sometimes may be sizable from the omentum to the splenic capsule, this could lead to capsular disruption and troublesome bleeding. A national database on antireflux procedures of 86,411 patients reported an incidence of iatrogenic splenectomy of 2.3%, which translates into 1987 iatrogenic splenectomies for that indication alone over a 6-year period. An outcome study for colon cancer of 42,000 reported iatrogenic splenectomy in less than 1% of all patients but 6% of colon cancers at the splenic flexure. Splenectomy had a significant increase in length of stay and a 40% increase in morbidity.

A recent series listed 73 iatrogenic splenectomies over a 10-year period, or an average of 7 per year. This comprised 8.1% of all splenectomies performed during that time interval. There are probably several times that number of minor or moderate injuries to the spleen during unrelated operations in which the spleen was not removed but was repaired or salvaged. Just as in trauma to the spleen, the techniques of splenorraphy can be employed to preserve the spleen. A recent report indicates that use of a mesh wrap splenorraphy even in the setting of bowel surgery does not lead to an increased incidence of infection. For minor capsular disruption, the use of the argon beam coagulator for surface cautery is a helpful technique.

The primary teaching point regarding iatrogenic injuries is that the best way to preserve the spleen is to not damage it in the first place. This requires caution in mobilizing tissue in and around the spleen as well as visual inspection of the attachments of the spleen prior to blunt mobilization. Whenever possible, the spleen should be attempted to be preserved to decrease the risk of postsplenectomy sepsis.

Masoomi H, Carmichael JC, Mills S, et al. Predictive factors of splenic injury in colorectal surgery: data from the Nationwide Inpatient Sample, 2006-2008. *Arch Surg* 2012;147(4):324-329.

INCIDENTAL SPLENECTOMY

In a recent large series evaluating reasons for splenectomy from tertiary institutions, the single most common indication for splenectomy was as an incidental procedure on operations on an adjacent organ. In these situations, the spleen needs to be removed either for completeness of resection or because of division of the splenic vasculature. The actual primary treatments of those various disease entities in adjacent organs are subjects of multiple other chapters within this textbook, but a few comments need to be made regarding the reasons for splenectomy and whether splenic preservation procedures are possible.

One common indication for an incidental splenectomy is to remove tumors located in the distal pancreas. For decades, it was standard practice to remove the spleen when removing the body and tail of the pancreas because the splenic vein is intimately associated with the distal pancreas. Because of the interest in splenic preservation due to the incidence of post-splenectomy infection, operations have been developed to remove the distal pancreas without removing the spleen. The more technically challenging operation is a distal pancreatectomy with preservation of the splenic artery and vein. A second spleen-preserving distal pancreatectomy involves ligation of the splenic artery and vein but preservation of short gastric vessels and utilizing those vessels as collateral inflow and outflow to maintain splenic viability. Removal of the distal pancreas with splenic preservation has also been recently reported as a laparoscopic procedure. For patients with tumors that mandate removal of the lymph nodes of the splenic hilum or with direct association of the tumor with splenic parenchyma, certainly it is more appropriate to do an operation based on neoplastic principles and perform a distal pancreatectomy/splenectomy. In other indications, if the anatomy is appropriate and the completeness of tumor resection is not compromised, splenic preservation is certainly possible.

Additional procedures in which it is common to perform a splenectomy include proximal gastric cancers. The importance of complete nodal dissection in long-term results in gastric resections has been debated for several decades. Level X lymph nodes are located in the splenic hilum, and for 20%-25% of proximal gastric cancers these nodes will have metastatic cancer mandating removal. A randomized trial showed increased morbidity with a splenectomy and a marginal improvement in survival. Other tumors of the left upper quadrant and retroperitoneum may require splenectomy, including large renal cell carcinomas, left adrenal tumors, and retroperitoneal sarcomas that may infiltrate upward into the spleen. Although the asplenic state does make patients susceptible to infections (see Hyposplenism above), the spleen should be viewed as an expendable organ if necessary to accomplish complete resection of malignancies, and there should be no

hesitation to remove the spleen in these situations to do an appropriate cancer operation.

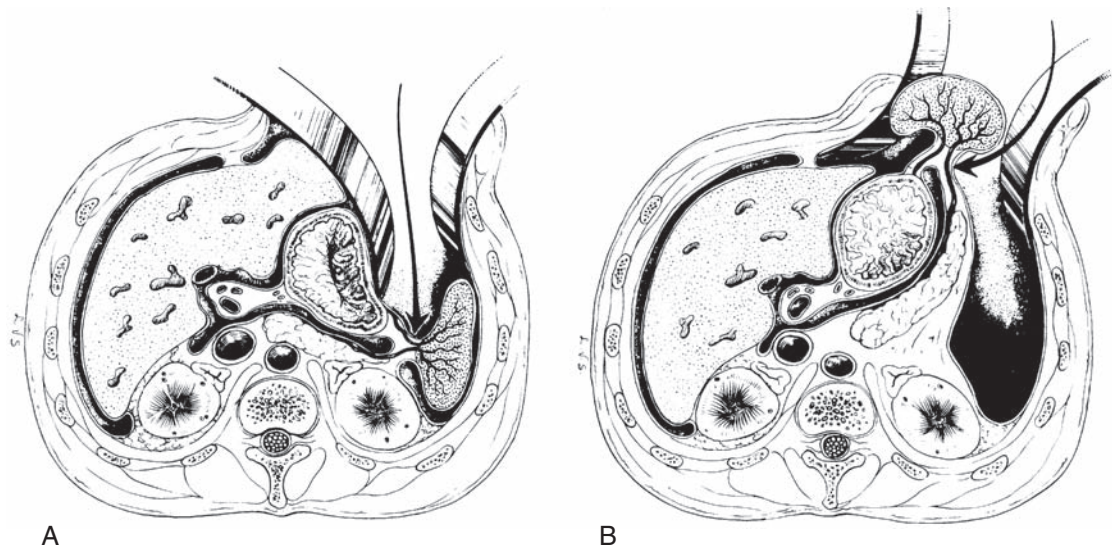

SPLEENOSIS (SPLENIC AUTOTRANSPLANTATION)

In splenosis, multiple small implants of splenic tissue grow in scattered areas on the peritoneal surfaces throughout the abdomen. They arise from dissemination and autotransplantation of splenic fragments following traumatic rupture of the spleen. Splenic implants or intentional autotransplants are capable of cell culling, and some immunologic function appears to be exhibited in cases of intentional autotransplantation. Aggressive attempts at surgical excision are not warranted. Splenosis is usually an incidental finding discovered much later during laparotomy for an unrelated problem. However, the implants stimulate formation of adhesions and may be a cause of intestinal obstruction. They must be distinguished from peritoneal nodules of metastatic carcinoma and from accessory spleens. Histologically, they differ from accessory spleens by the absence of elastic or smooth muscle fibers in the delicate capsule.

SPLENECTOMY

Preoperative preparation of patients undergoing elective splenectomy should correct coagulation abnormalities and deficits in red cell mass, treat infections, and control immune reactions. Because platelets are removed so rapidly from the circulation, they usually are not given for thrombocytopenia until after the splenic artery has been ligated. Antibodies in the patient's serum may complicate cross-matching of blood. Many patients with autoimmune disorders require corticosteroid coverage in the perioperative period. For emergency splenectomy, hypovolemia should be corrected by whole blood transfusions. For elective cases, prophylactic vaccination with a polyvalent pneumococcal vaccine that protects against a common encapsulated offending organism in postsplenectomy infection is recommended. Elective splenectomy is now most commonly performed as a laparoscopic procedure. This reduces the recovery period and is significantly better tolerated by most patients.

Details of surgical technique are not within the scope of this text, but it should be noted that there are two approaches to open splenectomy (Figure 27-2). In one, which is of value chiefly in traumatic rupture of the spleen, the organ is immediately mobilized and the splenic artery is secured from behind as it enters the hilum. In the other, which is of vital importance in the removal of massively enlarged spleens, the organ is left *in situ*. The gastrocolic ligament is opened, and the splenic artery is ligated as it courses along the upper edge of the pancreas. This permits blood to leave the spleen through the splenic vein while all

▲ **Figure 27-2.** **A:** Anterior approach to splenic artery. **B:** Mobilization of spleen with posterior exposure of splenic artery.

other attachments (ie, the short gastric vessels and colic attachments) are divided before the spleen is delivered. This method permits the removal of massively enlarged vascular spleens with practically no loss of blood.

Splenorrhaphy is operative repair of the spleen following trauma. The principles of splenorrhaphy are to debride the devitalized tissue and to attempt to approximate the normal contour of the spleen with capsular sutures or external wraps of material. Partial splenic resections may be performed for trauma or for disease states in which splenic debulking is indicated but may be unsuccessful with a higher immediate complication rate. Partial splenectomy for Gaucher disease, large cysts, or benign tumors has been reported using automatic stapling devices as well as microwave coagulators. On the other hand, for autoimmune disorders, it is absolutely essential for cure to remove the spleen completely including excision of accessory spleens. There may be some benefit to obtaining a preoperative nuclear scan and intraoperative identification with a handheld gamma counter.

Massive splenomegaly is defined as a spleen weight of greater than 1500 g or 8 to 10 times the normal size. Disease processes leading to massive splenomegaly include lymphoma, leukemia, and metabolic storage diseases. The morbidity and mortality rates of splenectomy for massive splenomegaly are increased primarily as a result of the risk of severe and rapid intraoperative blood loss. The operative approach in these cases is initial ligation of the splenic artery through the lesser sac at the superior border of the

pancreas. Next, ligation of the short gastric vessels along the greater curvature all the way to the gastroesophageal junction is performed, allowing the stomach and left lobe of the liver to be retracted away from the spleen. Only after decreasing the splenic arterial inflow by the above maneuvers should mobilization of the lateral and superior attachments be performed, leading to removal of the massive spleen.

Laparoscopic splenectomy is now the standard of care in most major centers with high volumes of splenic surgery. Virtually any indication for elective splenectomy qualifies for a laparoscopic approach, including patients with severe thrombocytopenia, patients with massive splenomegaly, patients needing partial splenectomy, and for the removal of accessory spleens and the wandering spleen. Contraindications to laparoscopic splenectomy include portal hypertension and severe co-morbid disease. With improved techniques, laparoscopic partial splenectomy has now been reported for focal mass lesions and hereditary hematologic diseases.

Laparoscopic splenectomy is performed typically using four ports. Midline ports for the cannula as well as for retraction of the stomach away from the splenic hilum are placed. Left subcostal ports are used as operating sites for dissection of the splenic hilum. An angled laparoscope is required for visualization of the superior and lateral attachments of the spleen. Vessels are divided with clips, sutures, or stapling devices. Precise exposure of the hilum with gentle upward traction on the spleen to stretch and expose the vessels is

preferred to blind stapling of the hilum. Clinical conditions such as ITP and hereditary spherocytosis are the most common indications for laparoscopic splenectomy as the spleen is of normal size. Search via the laparoscope for accessory spleens is important in these procedures for a successful outcome, and this may be facilitated by the use of a hand port for palpation.

HEMATOLOGIC EFFECTS OF SPLENECTOMY

Absence of the spleen in a normal adult usually has few clinical consequences. Red cell count and indices do not change, but red cells with cytoplasmic inclusions may appear, eg, Heinz bodies, Howell–Jolly bodies, and siderocytes. Granulocytosis occurs immediately after splenectomy but is replaced in several weeks by lymphocytosis and monocytosis. Platelets are usually increased, occasionally markedly so, and may stay at levels of 400,000–500,000/mL for over a year. Even more striking thrombocytosis (eg, 200,000–300,000/mL) may develop after splenectomy for hemolytic anemia. A platelet count of over a million is not an indication for anticoagulants, but antiplatelet agents such as aspirin may help prevent thrombosis.

Davies JM et al. British Committee for Standards in Haematology. Review of guidelines for the prevention and treatment of infection in patients with an absent or dysfunctional spleen. *Br J Haematol* 2011;155(3):308–317.

POSTSPLENECTOMY SEPSIS & OTHER POSTSPLENECTOMY PROBLEMS

Complications related to splenectomy per se are relatively few, with atelectasis, pancreatitis, and postoperative hemorrhage being the most common. If splenectomy is done for thrombocytopenia, secondary bleeding may occur even though the platelet count usually rises promptly. Platelet transfusions should be given if primary hemostasis is abnormal (ie, oozing occurs) and the platelet count remains low. Thromboembolic complications may be more common following splenectomy, but this complication does not correlate with the degree of thrombocytosis. The risk of portal vein thrombosis is 3% and occurs most commonly after splenectomy for massive spleens hemolytic anemia and not after trauma or splenectomy for thrombocytopenia. Symptoms include fever, abdominal pain, diarrhea, and abnormal liver function tests. Treatment consists of anticoagulation plus antibiotics.

Individuals are more susceptible to fulminant bacteremia after splenectomy and have been reported between 1 week and greater than 20 years after splenectomy. This is a result of the following changes that occur after

splenectomy: (1) decreased clearance of bacteria from the blood, (2) decreased levels of IgM, and (3) decreased opsonic activity. The risk is greatest in young children, especially in the first 2 years after surgery (80% of cases) and when the disorder for which splenectomy was required was a disease of the reticuloendothelial system. In general, the younger the patient undergoing splenectomy and the more severe the underlying condition, the greater the risk for developing overwhelming postsplenectomy infection. There is a low but significant risk of infection even in otherwise normal adults following splenectomy. Most of these infections occur after the first year, and nearly half occur more than 5 years after splenectomy. Lethal sepsis is very rare in adults. There is a distinct clinical syndrome: mild, nonspecific symptoms are followed by high fever and shock from sepsis, which may rapidly lead to death. *Streptococcus pneumoniae*, *Haemophilus influenzae*, and meningococci are the most common pathogens. Disseminated intravascular coagulation is a common complication. Awareness of this fatal complication has led to efforts to avoid splenectomy or to perform partial splenectomy or splenic repair for ruptured spleens (analogous to surgical management of liver trauma) to maintain adequate splenic function. Splenic autotransplantation may also achieve partial restoration of splenic function after splenectomy.

The risk of fatal sepsis is less after splenectomy for trauma than for hematologic disorders, probably due to splenic autotransplantation. Prophylactic vaccination against pneumococcal sepsis should be used in all surgically or functionally asplenic patients. Since splenic function may be important in the immune response to vaccine, early administration of polyvalent pneumococcal vaccine (Pneumovax) is advisable. The vaccine provides protection in adults and older children for 4–5 years, after which revaccination is advisable. Since the vaccine is only effective against about 80% of organisms, some authorities have recommended a 2-year course, treatment until age 16, or lifelong prophylaxis with penicillin following splenectomy. Others have advocated use of ampicillin to provide coverage for *Haemophilus influenzae* as well as pneumococci. Antibiotic prophylaxis is essential in children under 2 years of age and should be continued until at least age 6. In general, splenectomy should be deferred until age 6 unless the hematologic problem is especially severe.

MULTIPLE CHOICE QUESTIONS

1. Which of the following is true about the spleen?
 - A. The red pulp of the spleen is normally a significant contributor to red blood cell hematopoiesis.
 - B. The spleen's venous drainage is evenly divided between the splenic vein and direct branches of the left renal vein.
 - C. The outer capsule of the spleen is a continuous sheet of smooth muscle.
 - D. The gastrosplenic ligament carries the short gastric vessels.
 - E. Normally 80% of the platelet cell mass is sequestered in the spleen.
2. Indications for splenectomy can include
 - A. Vascular disease
 - B. Splenomegaly associated with infection
 - C. Hereditary spherocytosis
 - D. Both A and C
 - E. A, B, and C
3. Postsplenectomy sepsis
 - A. Only occurs within 1 year of operation
 - B. Is at greatest risk in young children
 - C. Is associated with residual accessory splenules
 - D. Is more often lethal in adults than children
 - E. Is more common after splenectomy for trauma than for other indications

Appendix

28

Elliot C. Pennington, MD
Peter A. Burke, MD

ANATOMY & PHYSIOLOGY

In infants, the appendix is a conical diverticulum at the apex of the cecum, but with differential growth and distention of the cecum, the appendix ultimately arises on the left and dorsally approximately 2.5 cm below the ileocecal valve. The taeniae of the colon converge at the base of the appendix, an arrangement that helps in locating this structure at operation. The appendix is freely mobile in the majority and is fixed retroceally in 16% of adults.

The appendix in children is characterized by a large concentration of lymphoid follicles that appear 2 weeks after birth and number about 200 or more at age 15 years. Thereafter, progressive atrophy of lymphoid tissue proceeds with fibrosis of the wall and partial or total obliteration of the lumen. If the appendix has a physiologic function, it is probably related to the presence of lymphoid follicles.

ACUTE APPENDICITIS

► General Considerations

Approximately 7% of people in Western countries have appendicitis at some time during their lives. With more than 250,000 appendectomies for acute appendicitis performed annually in the United States, it is the most common surgical emergency encountered by the general surgeon and accounts for about 1% of all surgical operations.

Obstruction of the proximal lumen by fibrous bands, lymphoid hyperplasia, fecaliths, calculi, or parasites has long been considered to be the major cause of acute appendicitis. A fecalith or calculus is found in only 10% of acutely inflamed appendices. Though evidence of temporal and geographic clustering of cases has suggested a primary infectious etiology this remains to be proven.

As appendicitis progresses, the blood supply is impaired by bacterial infection in the wall and distention of the lumen; gangrene and perforation occur at about 24 hours, though

the timing is highly variable. Gangrene implies microscopic perforation, bacterial contamination of the peritoneum, and peritonitis. This process may be effectively localized by adhesions from nearby viscera.

► Clinical Findings

Acute appendicitis may simulate almost any other acute abdominal illness, and in turn may be mimicked by a variety of conditions. Progression of symptoms and signs is the rule—in contrast to the fluctuating course of some other diseases.

A. Signs and Symptoms

Typically, the illness begins with vague midabdominal or periumbilical discomfort followed by nausea, anorexia, and indigestion. The pain is continuous but not severe, with occasional mild cramping. The patient may feel constipated or may vomit. Importantly, within several hours of the onset of symptoms the pain shifts to the right-lower quadrant, becoming localized and causing discomfort on moving, walking, or coughing.

Physical examination shows localized tenderness to palpation and perhaps slight muscular guarding. Rebound or percussion tenderness (the latter provides the same information more humanely) may be elicited in the right-lower quadrant. Rectal and pelvic examinations are likely to be negative; if positive, these more often point to another etiology. The temperature is only slightly elevated in the absence of perforation. Administration of narcotic pain medications does not affect the accuracy of the physical examination.

A common misconception is that inflammation of a retrocecal appendix produces an atypical syndrome. This is incorrect; the clinical findings in this situation are the same as for ordinary (antececal) appendicitis. Acute appendicitis may mimic other surgical diseases if the appendix is located outside the right-lower quadrant (ie, sigmoid diverticulitis,

acute cholecystitis, or a perforated ulcer). Even when the cecum is normally situated, however, a long appendix may reach to other parts of the abdomen.

Three general points are worth remembering: (1) people with early (nonperforated) appendicitis often do not appear ill. Finding localized tenderness over the McBurney point is the cornerstone of diagnosis. (2) A rule that will help considerably with atypical cases is never to place appendicitis lower than second in the differential diagnosis of acute abdominal pain in a previously healthy person. (3) Patients with appendicitis most commonly have a history of generalized abdominal that over time becomes focused in the right-lower quadrant.

B. Laboratory Findings

The average leukocyte count is 15,000/ μ L, and 90% of patients have counts over 10,000/ μ L. In three-fourths of patients, the differential white count shows more than 75% neutrophils. It must be emphasized, however, that 1 patient in 10 with acute appendicitis has a normal leukocyte count, and many have normal differential cell counts. Appendicitis in HIV-positive patients, while up to three times more common, produces the same syndrome as in healthy adults but the white blood cell count is usually normal.

Urinalysis is typically normal, but a few leukocytes and erythrocytes and occasionally even gross hematuria may be noted, particularly in retrocecal or pelvic appendicitis.

C. Imaging Studies

On plain radiographs localized air-fluid levels, localized ileus, or increased soft tissue density in the right-lower quadrant is present in 50% of patients with early acute appendicitis. Less common findings are a calculus, an altered right psoas shadow, an abnormal right flank stripe, or free peritoneal air (from perforated appendicitis). In general, the findings on plain films rarely aid in diagnosis.

A CT examination of the abdomen may be of help in diagnosis. An enlarged appendix with wall thickening, enhancement, or periappendiceal fat stranding is the most useful CT findings of acute appendicitis. Other findings may be present, including focal cecal thickening, appendicoliths, extraluminal or intramural air, and pericecal phlegmon, but are less reliable. Oral contrast administration is not. CT scans are of greatest value in patients with less than typical clinical and laboratory findings, where a positive study would be an indication for appendectomy. In young adults, low-dose CT is noninferior to standard-dose CT. In the face of typical time course of disease, right-lower quadrant pain and tenderness plus signs of inflammation (eg, fever, leukocytosis), a CT scan would be superfluous and, if negative, even misleading. Ultrasound imaging is generally less reliable than CT, though may become more reliable when done using a combined transabdominal and transvaginal

approach. When appendicitis is accompanied by a right-lower quadrant mass, an ultrasound or CT scan should be obtained to differentiate between a periappendiceal phlegmon and an abscess or tumor.

D. Appendicitis During Pregnancy

Appendicitis is the most common nonobstetric surgical disease of the abdomen during pregnancy affecting between 1 in 1400 and 1 in 6600 live births, with cases equally distributed through all three trimesters. By far the most common presentation is right-lower quadrant pain, tenderness, and leukocytosis—the classic syndrome—but the enlarged uterus occasionally will have pushed the appendix into the right-upper quadrant, which gives rise to pain in this location. Some symptoms, such as nausea and vomiting, occur in normal pregnancy, which may obscure accurate diagnosis. Fever is less common than with appendicitis in the absence of pregnancy. The main problem is to recognize appendicitis and perform appendectomy promptly. Both CT and MRI are highly sensitive and specific for the diagnosis of acute appendicitis during pregnancy. Delay in operation runs a higher than usual risk of perforation and diffuse peritonitis, because the omentum is less available to wall off the infection. The mother is in greater jeopardy of serious abdominal infection, and the fetus is more vulnerable to premature labor with complications. Laparoscopic appendectomy is well tolerated by the mother and fetus, but the frequency of technical complications is higher than with the open approach. Appendectomy during pregnancy is often followed by preterm labor but rarely by preterm delivery. Early appendectomy in pregnancy has decreased the maternal death rate to under 0.5% and the fetal death rate to less than 10%. Appendectomy in general does not increase a woman's risk for infertility later in life.

► Diagnosis & Differential Diagnosis

The clinical diagnosis of appendicitis rests on a combination of localized pain and tenderness accompanied by signs of inflammation, such as fever, leukocytosis, and elevated C-reactive protein levels. Migration of pain from the periumbilical area to the right-lower quadrant is also diagnostically significant. In the absence of signs of inflammation the diagnosis is less certain, and in this situation a CT scan may be of value. The best strategy in equivocal cases is to observe the patient for a period of 6 hours or more. During this time, patients with appendicitis experience increasing pain and signs of inflammation, while those without appendicitis generally improve. False-positive diagnoses often involve cases where the surgeon has accorded more significance to the patient's pain than to the presence or absence of inflammatory signs. Over the past 20 years, the overall false-positive rate for the diagnosis of appendicitis has dropped from 15% to 10% without an accompanying rise in the number

of perforations. Thus, diagnostic accuracy appears to be improving. Some patients experience chronic appendicitis, which involves pain lasting 3 weeks or more, and typically includes an acute illness in the recent past compatible with acute appendicitis that was managed nonoperatively.

The diagnosis of acute appendicitis may be difficult in patients at the extremities of age, and it is in these groups that diagnosis is most often delayed. Infants display only lethargy, irritability, and anorexia in the early stages, but may develop vomiting, fever, and pain as the disease progresses. The elderly may not display any classic symptoms, even though the course of appendicitis is more virulent in this age group.

The highest incidence of false-positive diagnosis (20%) is in women between ages 20 and 40 and is attributable to gynecologic conditions such as pelvic inflammatory disease. Compared with appendicitis, pelvic inflammatory disease is more often associated with bilateral lower quadrant tenderness, left adnexal tenderness, onset of illness within 5 days of the last menstrual period, and a history that does not include nausea and vomiting.

Clinical scoring systems can be effective in the diagnosis of acute appendicitis. For example, the Alvarado Score, which uses both physical examination (anorexia, migration of pain, nausea, right-lower quadrant tenderness, rebound pain, and elevated temperature) and laboratory findings (leukocytosis, shift of WBC count to the left) has excellent negative predictive value, with a sensitivity of 99%.

► Complications

The complications of acute appendicitis include perforation, peritonitis, abscess, and pylephlebitis.

A. Perforation

Perforation follows the natural history of acute appendicitis, and most likely appears because of delay in seeking treatment. Perforation is accompanied by more severe pain and higher fever (average, 38.3°C) than in simple appendicitis. It is unusual for the acutely inflamed appendix to perforate within the first 12 hours. Appendicitis has progressed to perforation by the time of appendectomy in about 50% of patients under age 10 or over age 50. Perforation in young women increases the subsequent risk of tubal infertility about fourfold.

B. Peritonitis

Localized peritonitis results from microscopic perforation of a gangrenous appendix, while spreading or generalized peritonitis usually implies gross perforation into the free peritoneal cavity. Increasing tenderness and rigidity, abdominal distention, and adynamic ileus are obvious in these patients. High fever and severe toxicity mark progression of this catastrophic illness.

C. Appendiceal Abscess

Localized perforation occurs when the periappendiceal infection becomes walled off by omentum and adjacent viscera. Clinical presentation consists of the usual findings in appendicitis, and may include a right-lower quadrant mass. An ultrasound or CT scan should be performed; if an abscess is found, it is best treated by percutaneous imaging-guided aspiration. Opinion differs about how small abscesses and phlegmons should be handled. Some surgeons prefer a regimen consisting of antibiotics and expectant management followed by elective appendectomy 6 weeks later, so as to avoid spreading the localized infection and the need for a more extensive operation. This strategy is associated with lower rates of overall complications, abscess formation, bowel obstruction, and reoperation. Other surgeons recommend immediate appendectomy, which some believe shortens the duration of illness.

When an unsuspected abscess is encountered during appendectomy, it is usually best to proceed and remove the appendix. If the abscess is large and further dissection would be hazardous, drainage alone is appropriate.

Appendicitis recurs in only 10% of patients whose initial treatment consisted of antibiotics with or without drainage of an abscess. Therefore, when the presence of ancillary conditions increases the risks of surgery, interval appendectomy may be postponed unless symptoms recur.

D. Pylephlebitis

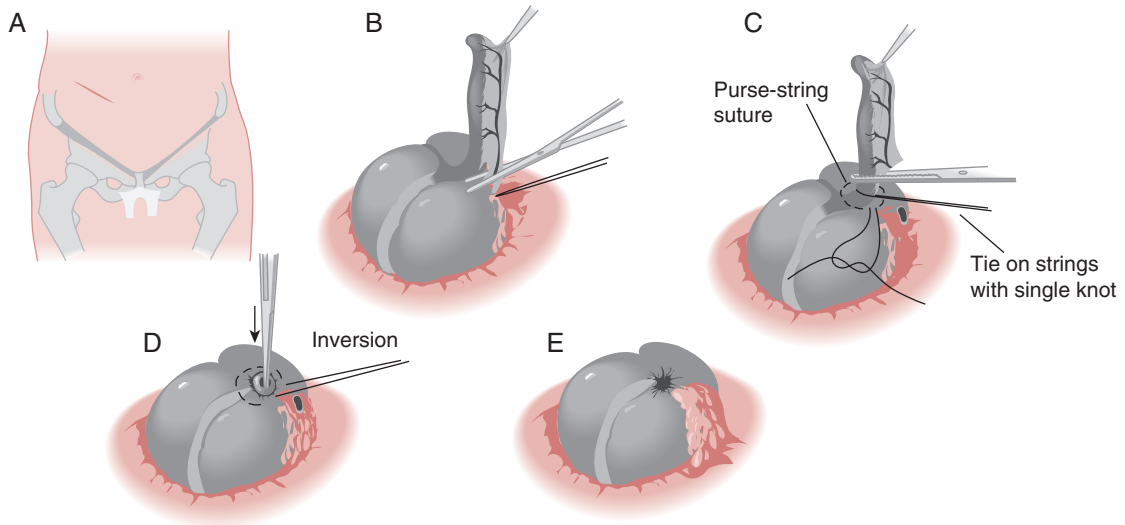

Pylephlebitis is suppurative thrombophlebitis of the portal venous system. Chills, high fever, low-grade jaundice, and, later, hepatic abscesses are the hallmarks of this grave but fortunately rare condition, which affects less than 1% of patients. Prompt surgery and antibiotic therapy is indicated.

► Prevention

There is no effective prevention strategy for appendicitis. In the past it was common to perform an incidental appendectomy in young people during the course of an abdominal operation for another illness—as long as the exposure was adequate and there were no specific contraindications. The declining lifetime risk of appendicitis now calls this practice into question. A related question concerns the appropriate course when a laparoscopy is performed for presumptive appendicitis and the appendix looks normal. There is no consensus on these cases, with some surgeons preferring to remove the appendix and some electing to leave it in place. In children, it is not necessary to remove the appendix after an incidentally diagnosed appendicolith.

► Treatment

With few exceptions, the treatment of appendicitis is surgical (ie, appendectomy). The operation can be done open

▲ **Figure 28-1.** Technique of open appendectomy. **A:** Incision. **B:** After delivery of the tip of the cecum, the mesoappendix is divided. **C:** The base is clamped and ligated with a simple throw of the knot. The next step—inversion of the stump—is optional. **D:** A clamp is placed to hold the knot during inversion with a purse-string suture of fine silk. **E:** The loosely tied inner knot on the stump assures that there is no closed space for the development of a stump abscess.

(Figure 28-1) or laparoscopically. A laparoscopic approach is desirable when the preoperative diagnosis is uncertain. In select patients, outpatient laparoscopic appendectomy may be possible.

Prophylactic antibiotics are indicated preoperatively with a single-drug regimen, usually a cephalosporin. Culturing abdominal fluid is not indicated even when the appendix has perforated, as the organisms obtained are the typical fecal flora. Abdominal drains are called for only to treat established abscesses.

If a patient with appendicitis cannot be taken to a modern surgical facility for care, treatment should consist of antibiotics alone. The complication-free success rate of this approach is above 93%, though acute appendicitis may recur in this population. Success rates of greater than 60% have been reported at 1 year.

A. Laparoscopic Versus Open Appendectomy

The laparoscopic approach to appendectomy was first described by Kurt Semm in 1983. There has been much debate over the appropriate role of laparoscopy in the treatment of appendicitis since that initial report, with an increasing majority of cases in this country performed laparoscopically. In one large study, patients treated laparoscopically had lower overall morbidity (except organ space surgical site infections in patients with complicated appendicitis), but similar serious morbidity, mortality, and length

of stay. Generally, patients undergoing laparoscopic appendectomy have less postoperative pain and a shorter length of stay by 1 day. However, laparoscopic appendectomy may be associated with increased overall hospital costs and longer operative times. Conversion rates from laparoscopic to open approach range from 0% to 27%, and should be based on surgeon experience, judgment, and ability to safely perform the procedure. Currently most patients in the United States undergo laparoscopic treatment, and this approach is safe for both uncomplicated and complicated appendicitis. In select patients, the appendix can be removed using a single-port technique.

B. Outcomes

Although a death rate of zero is theoretically attainable in acute appendicitis, deaths still occur, some of which are avoidable. The mortality rate in simple acute appendicitis is approximately 0.1% and has not changed significantly since 1930. Progress in preoperative and postoperative care has reduced mortality from perforation to about 5%. Nonetheless, postoperative infections still occur in 30% of cases of gangrenous or perforated appendicitis. While the cases may be more technically challenging, obese patients have similar rates of complication, length of stay, and readmission. The substantial increase in tubal infertility that follows perforation in young women is avoidable by early appendectomy. If the entirety of the appendix is not

removed, stump appendicitis can occur in the residual appendix.

C. Controversies

Many controversies exist regarding the treatment of acute appendicitis. Some surgeons routinely irrigate all four quadrants in all appendectomies, while others do not. Irrigation has been shown to reduce postoperative abscess rates in perforated appendicitis only. There is emerging evidence that antibiotics alone may be a preferable initial treatment of uncomplicated acute appendicitis. While it is clear that postoperative antibiotics are not beneficial for nonperforated appendicitis after appendectomy, no consensus exists on the drug regimen or duration of antibiotics for perforated disease.

TUMORS OF THE APPENDIX

Benign tumors, including carcinoids, were found in 4.6% of 71,000 human appendix specimens examined microscopically, typically as incidental findings.

► Malignant Tumors

Primary malignant tumors were found in 1.4% of appendices in the same large series. Carcinoid and neuroendocrine tumors comprise the majority of appendiceal cancers, and the appendix is the commonest location of carcinoid tumors of the gastrointestinal tract. Carcinoid tumors of the appendix are most commonly found at the tip and are usually benign, but tumors over 2 cm in diameter may exhibit malignant behavior. About half of these tumors are discovered during an appendectomy for acute appendicitis, with the remainder identified incidentally. Lesions less than 2 cm in diameter invade the appendiceal wall in 25% of cases, but only 3% metastasize to lymph nodes. Hepatic metastases and the carcinoid syndrome are truly rare. Appendectomy alone is adequate treatment unless the lymph nodes are visibly involved, the tumor is more than 2 cm in diameter, mucinous elements are present in the tumor (adenocarcinoid), or the mesoappendix or base of the cecum is invaded; in these cases, right hemicolectomy is recommended. The recurrence rate after surgical treatment is near zero.

Colonic adenocarcinoma can arise in the appendix and spread rapidly to regional lymph nodes or implant on other peritoneal surfaces. Most patients present with advanced disease. Adenocarcinoma is virtually never diagnosed preoperatively, and about half of cases present as acute

appendicitis. Right hemicolectomy should be performed if disease is localized to the appendix and/or regional lymph nodes. The 5-year survival rate is 60% after right hemicolectomy and only 20% after appendectomy alone, but the latter group includes patients with distant metastases at diagnosis.

► **Mucocele and Pseudomyxoma Peritonei**

An appendiceal mucocele is a cystic, dilated appendix filled with mucin. Simple mucocele is not a neoplasm and results from chronic obstruction of the proximal lumen, usually by fibrous tissue. Rarely, mucocele is caused by a neoplasm—cystadenoma, or adenocarcinoma grade 1 in the older terminology, now often called a mucinous appendix neoplasm (MAN). This lesion may arise de novo or (perhaps) in a preceding simple mucocele. Appendectomy is adequate treatment in either case. If a MAN ruptures, it can lead to a condition known as pseudomyxoma peritonei, characterized by diffuse mucin production throughout the peritoneal cavity, with variable amounts of tumor cellularity. Patients can be treated with either simple appendectomy or right hemicolectomy.

MULTIPLE CHOICE QUESTIONS

- All of the following are true about the appendix, except
 - The appendix in children is characterized by a large concentration of lymphoid follicles that appear 2 weeks after birth and number about 200 or more at age 15 years.
 - The taeniae of the colon converge at the base of the appendix.
 - A fecalith or calculus is found in only 10% of acutely inflamed appendices.
 - The appendix is fixed retroceally in 65% of adults.
 - Acute appendicitis may simulate almost any other acute abdominal illness.
- Helpful tests in the diagnosis of acute appendicitis include
 - Abdominal CT
 - Transvaginal ultrasound
 - Encephalopathy
 - A, B, and C
 - A and C
- Primary malignant tumors of the appendix
 - Should prompt right colectomy in nearly all patients
 - Are most commonly neuroendocrine (carcinoid) tumors
 - Is the most common etiology of appendicitis
 - Usually presents due to liver metastases
 - Are usually found at the base of the appendix

Small Bowel

29

Marco E. Allaix, MD
Mukta Krane, MD
Alessandro Fichera, MD

ANATOMY

► Gross Anatomy

The small intestine is the portion of the alimentary tract extending from the pylorus to the ileocecal valve and it consists of three segments—the duodenum, the jejunum (upper two-fifths), and the ileum (lower three-fifths). The anatomy, physiology, and pathology of the duodenum are discussed in Chapter 23.

The jejunum begins at the ligament of Treitz. The jejunum and ileum are suspended on a mobile mesentery covered by a visceral peritoneal lining that extends onto the external surface of the bowel to form the serosa. There is no sharp demarcation between the jejunum and the ileum; as the intestine proceeds distally, the lumen narrows, the mesenteric vascular arcades become more complex, and the circular mucosal folds become shorter and fewer.

The mesentery contains fat, blood vessels, lymphatic channels and nodes, and nerves. The jejunum and ileum are supplied by the superior mesenteric artery (SMA). Branches within the mesentery anastomose to form arcades, and small straight arteries from these arcades enter the mesenteric border of the gut. Venous blood is drained through the superior mesenteric vein (SMV), which then joins the splenic vein behind the pancreas to form the portal vein.

Lymphatic drainage is abundant. Elliptical, lymphoid aggregates (Peyer's patches) are present in the submucosa on the antimesenteric border along the distal ileum, and smaller follicles are evident throughout the remainder of the small intestine. Regional lymph nodes follow vascular arcades and drain toward the cisterna chyli.

The nerve supply for the small bowel is both sympathetic (fibers from the greater and lesser splanchnic nerves) and parasympathetic (from the right vagus nerve). Although both types of autonomic nerves contain efferent and afferent fibers, only the sympathetic afferents appear to mediate intestinal pain.

► Microscopic Anatomy

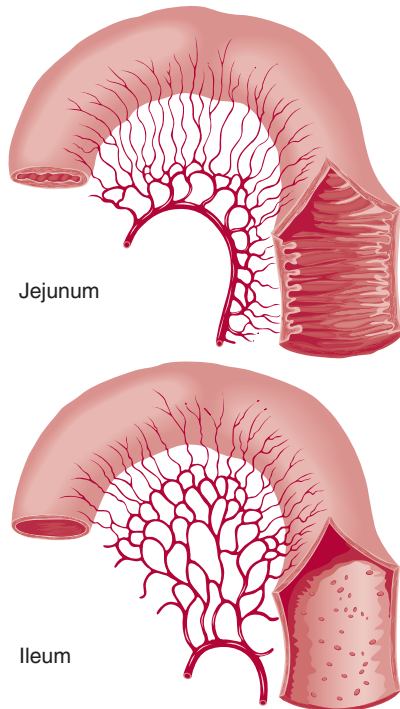

The wall of the small intestine consists of four layers—mucosa (innermost), submucosa, muscularis, and serosa (outermost).

The *mucosa* is characterized by circular folds about 10 mm high, named *valvulae conniventes*, that are taller and more numerous in the proximal jejunum and project into the lumen (Figure 29–1). These folds, combined with the presence of villi on the surface of the *valvulae conniventes*, increase the absorptive surface area about eight times. There are approximately 20–40 villi/mm². They are about 0.5–1 mm long and their walls are made up of epithelial cells with tiny projections named microvilli. The epithelial cells enclose a central axis that contains an arteriole surrounded by blood and lymphatic capillaries, known as a *lacteal*, and fibers from the muscularis mucosae. The microvilli (1 μm in height) amplify the potential absorptive surface area up to 200–500 m² (Figure 29–2).

The mucosa is microscopically subdivided into three different layers: (1) the muscularis mucosae, the outermost, consists of a thin sheet of smooth muscle cells; (2) the lamina propria consists of connective tissue that extends from the base of the crypts up into the intestinal villi; and (3) the epithelium which is the innermost layer.

Intestinal epithelium is composed of multiple cell types that rest on a thin basement membrane overlying the lamina propria. There are two major compartments to the intestinal epithelium, the crypt and the villus, each with distinct function and cellular composition. The crypt is populated by cells that are predominantly secretory and which derive from a pluripotent stem cell located above the base of the crypts of Lieberkühn. Paneth cells stay at the base of the crypts; their function is still unknown but may be secretory, as resembling zymogen-secreting cells of the pancreas.

Most of the crypt cells are undifferentiated; some mature into mucus-secreting goblet cells and enteroendocrine

▲ **Figure 29-1.** Blood supply and luminal surface of the small bowel. The arterial arcades of the small intestine increase in number from one or two in the proximal jejunum to four or five in the distal ileum, a finding that helps to distinguish proximal from distal bowel at operation. Plicae circulares are more prominent in the jejunum.

cells, but the majority become absorptive enterocytes. Enteroendocrine cells include enterochromaffin cells (the most common), N cells that contain neurotensin, L cells (glucagon), and motilin and cholecystokinin (CCK) containing cells. Finally, M cells and T lymphocytes play a major role in mucosal cell-mediated immunity.

The villus compartment is nonproliferative. Factors that affect enterocyte differentiation include growth factors, hormones, matrix proteins, and luminal nutrients. The life span of enterocytes is 3–6 days.

The *submucosa* is a dense connective tissue layer populated by different cell types, including fibroblasts, mast cells, lymphocytes, macrophages, eosinophils, and plasma cells. It contains blood vessels, lymphatics, and nerves. Meissner's submucosal neural plexus interconnects with neural elements from Auerbach's plexus. The submucosa is the strongest layer of small bowel wall. The *muscularis* consists of two layers of smooth muscle, a thicker inner circular layer and a thinner outer longitudinal layer. Specialized intercellular junctional structures called *gap junctions* electrically couple

▲ **Figure 29-2.** Schematic representation of villi and crypts of Lieberkühn.

adjacent smooth muscle cells and allow efficient propagation of peristalsis. Ganglion cells and nerve fibers of Auerbach's myenteric plexus interdigitate between layers and communicate with smaller neural elements between cells. The *serosa* consists of a single layer of flattened mesothelial cells that covers the small bowel.

PHYSIOLOGY

► Motility

Intestinal motility consists of propulsion of luminal contents (peristalsis) combined with mixing action through segmentation. These functions are accomplished by both the outer longitudinal and inner circular muscle layers of the intestinal wall, mainly under the direct control of the myoenteric nervous plexus. The submucosal nervous plexus is primarily involved in the regulation of secretion and absorption. The extrinsic sympathetic input is excitatory and the peptidergic input likely inhibitory. Intestinal motility is also under positive control by local hormones such as motilin and CCK. Smooth muscles of the small intestine undergo spontaneous oscillations of membrane potentials, known as pacesetter potentials, with progressively decreasing frequency from the duodenum to the ileum. The frequency of pacesetter

potentials for the entire small intestine is determined by the duodenum, where they originate. A nerve-related cell type known as the interstitial cell of Cajal appears to play a key role in the generation of pacemaker activity. Small bowel motility varies with the fasted and fed state. During the interdigestive or fasting period, a cyclical pattern of motor activity consisting of three phases is observed. Phase I is resting and lasts for about 80% of the cycle. Phase II, about 15%, consists of random contractions of moderate amplitude. Phase III, about 5%, is a series of brief high pressure waves. This three-phase cycle results in a pattern called the migrating motor complex, which is abolished by ingestion of food. In the fed state, the pattern of contraction is more frequent and consistent over time. Rather than beginning from a proximal site and propagating distally, contractions begin at all levels along the small bowel and spread distally.

► Barrier Function

The intestinal epithelium selectively limits the permeation of potentially harmful luminal substances. The anatomical barrier is the intercellular junction complex, a three-level structure that forms a circumferential seal between adjacent cells: the tight junction faces the lumen, the intermediate junction lies deep to the tight junction, and the desmosome is the innermost element of this complex. Several pathological conditions can alter the barrier function. Certain bacterial toxins, such as *Clostridium difficile*, directly perturb the barrier function through disruption of cytoskeletal-junctional interactions, and various cytokines and proinflammatory mediators can also modulate intestinal permeability.

► Digestion & Absorption

Digestion begins in the stomach with the action of gastric acid and pepsin. In the proximal duodenum, ingested food is broken down by pancreatic enzymes such as trypsin, elastase, chymotrypsin, and carboxypeptidases. The activity of intestinal hydrolases and oligopeptidases then accomplishes terminal protein and carbohydrate digestion, and the resulting monosaccharides, amino acids, or di- and tripeptides then serve as substrates for Na^+ - or H^+ -coupled transporters in the apical membrane of absorptive enterocytes. Fat digestion and absorption occur in the proximal small bowel, where pancreatic lipase partially hydrolyzes triglycerides into two fatty acids and a monoglyceride. These substances are solubilized by bile salts to form micelles that diffuse into enterocytes releasing fatty acid and monoglyceride. Triglycerides are transported intracellularly and incorporated along with cellular protein, phospholipid, and cholesterol to form chylomicrons. They then exit the cell to be absorbed by the lymphatic system. Bile salts are reabsorbed into the enterohepatic circulation in the distal ileum by an ileal Na^+ -coupled bile acid transporter.

The small bowel receives about 1-1.5 L/day of ingested fluids and about 8 L of salivary, gastric, and pancreaticobiliary secretions. Most of this fluid is reabsorbed before reaching the colon. Water movement is driven by the active transcellular absorption of Na^+ and Cl^- and by absorption of nutrients such as glucose and amino acids. The energy for many of these processes derives from the activity of a Na^+ - K^+ ATPase, that maintains the low Na^+ internal environment that drives uptake via coupled ion exchangers (Na^+/H^+ and $\text{Cl}^-/\text{HCO}_3^-$) and Na^+ -coupled nutrient transporters.

► Secretion

Intestinal crypt cells secrete an isotonic fluid through the active transcellular transport of Cl^- . This process lubricates the mucosal surface and facilitates the luminal extrusion of other secrete substances. Diarrhea results when secretion exceeds intestinal absorptive capacity.

► Immune Function

The mucosal immune system is extremely important in defense against toxic and pathogenic threats from the luminal environment. The lamina propria contains numerous immune cells including plasma cells, mast cells, and lymphocytes that produce both immunoglobulins and cytokine mediators.

Plasma cells produce IgA in response to food antigens and microbes. IgA and IgM are secreted into the lumen by a mechanism that involves transcytosis through epithelial cells after binding to the polymeric immunoglobulin receptor on the basolateral membrane. Secretory IgA prevents microbial pathogens from penetrating the epithelial layer. IgA-antigen interactions also occur within the intraepithelial and subepithelial compartments. Intestinal epithelial cells themselves may also contribute to the immune function of the bowel. These cells express major histocompatibility class I and class II molecules on their surface and may function as weak antigen-presenting cells. The epithelial cell layer may transmit important immunoregulatory signals to the underlying lymphocytic population.

Specialized cells known as M cells are found overlying Peyer's patches and act as the major portal of entry for foreign bodies. Specialized membrane invaginations in these cells create a pocket in which lymphocytes and macrophages gather. Luminal substances are immediately delivered to these antigen-presenting cells, and this information is directly conveyed to the underlying follicles. Intraepithelial lymphocytes (IEL) are specialized T cells that reside in the paracellular space between absorptive enterocytes. The precise role of IELs is still uncertain, but they may mediate cross-talk between epithelial cells and the underlying immune and nonimmune cells of the lamina propria. Within the lamina propria and submucosa, mature T cells, B cells, and macrophages carry out traditional cell-mediated

immune response including phagocytosis, cell killing, and cytokine secretion. Mucosal and connective tissue mast cells produce numerous mediators that contribute to overall immune response and modulate the many functions of the epithelial cells.

► Neuroendocrine Function

The small bowel is a rich source of regulatory peptides that control various aspects of gut function. These substances, released in response to luminal or neural stimuli, exert their biological actions either at distant sites or locally.

Secretin is a 27-amino-acid peptide released by enteroendocrine cells in the proximal small bowel in response to luminal acidification, bile salts, and fat. Its major function is to stimulate pancreatic ductal alkaline secretion. Secretin inhibits gastric acid secretion, and gastrointestinal motility. In addition, it stimulates bile flow by stimulating fluid secretion from cholangiocytes. Other members of the secretin family that share substantial sequence homology and interact with similar receptors include vasoactive intestinal polypeptide (VIP), glucagon, gastric inhibitory polypeptide (GIP), and enteroglucagon. Enteroglucagon and glucagon-like peptides are secreted by neuroendocrine cells in the colon and small bowel and may play an important role in gut adaptation and glucose homeostasis.

CCK is released by specialized enteroendocrine cells in response to luminal amino acids and medium- to long-chain fatty acids. CCK release is inhibited by intraluminal trypsin and bile salts. Two major targets of CCK are the gallbladder and the sphincter of Oddi, where it causes coordinated contraction and relaxation, respectively, to enhance luminal mixing of bile with ingested food. Furthermore, CCK stimulates pancreatic enzyme secretion and cell growth in intestinal mucosa and the pancreas, insulin release and intestinal motility.

Somatostatin is a 14-amino-acid peptide that exerts a wide variety of inhibitory functions in the gastrointestinal tract. It is released from specialized enteroendocrine cells and it acts in paracrine fashion to inhibit intestinal, gastric, and pancreatico-biliary secretion and cell growth. Synthetic forms of somatostatin are used in the clinical practice in patients with enterocutaneous and pancreatico-biliary fistulae.

Peptide YY is a 36-amino-acid peptide secreted by the distal small bowel and it inhibits gastric acid and pancreatic secretion, as well as several intestinal hormones, and decreases intestinal motility.

Motilin is secreted by the duodenum and the proximal jejunum, where it acts to enhance contractility and accelerate gastric emptying.

Neurotensin is produced in the ileum and enteric nerves; it appears to affect a variety of enteric functions including gastric acid secretion, gastric emptying, intestinal motility, and secretion.

Other peptides (VIP, calcitonin-related peptide, galanin, bombesin, neuropeptide Y, gastrin-releasing peptides, and substance P) are released from enteric nerves, but their precise role has not been fully clarified.

SMALL BOWEL OBSTRUCTION

► General Considerations

Small bowel obstruction (SBO) is one of the most common disorders affecting the small bowel. It is characterized by impairment in the normal flow of intraluminal contents and can be divided into mechanical obstruction and paralytic ileus.

Mechanical obstruction implies an extrinsic or intrinsic obstacle that prevents the aboral progression of intestinal contents and it may be complete or partial. Simple obstruction occludes the lumen only; obstruction with strangulation impairs the blood supply also and leads to necrosis of the intestinal wall. Paralytic (or adynamic) ileus is due to a neurogenic failure of peristalsis to propel intestinal contents with no mechanical obstruction.

A. Etiology

The causes of mechanical obstruction can be divided into three groups according to the relationship to the intestinal wall: (1) intraluminal; (2) intramural; and (3) extrinsic. The three most common etiologies are intra-abdominal adhesions, hernias, and neoplasms (Table 29–1).

Table 29–1. Causes of obstruction of the small intestine in adults.

Causes	Relative Incidence (%)
Adhesions	60
External hernia	10
Neoplasms	20
Intrinsic	3
Extrinsic	17
Miscellaneous	10

1. **Adhesions** Sixty to 75% of cases of mechanical SBO are secondary to adhesions related to prior abdominal surgery. Lower abdominal and pelvic surgery appears to be associated with a higher incidence of adhesions compared to upper abdominal surgery. Congenital bands are rarely seen in children.
2. **Hernia** The most common cause of SBO in patients with no history of prior abdominal surgery is a hernia. A careful search for inguinal, femoral, and umbilical hernias must be made during evaluation of every patient presenting with symptoms consistent with obstruction. Internal hernias into the obturator foramen, the foramen of Winslow, or other anatomic defects must also be considered. In patients who have undergone previous surgery, incisional hernias represent another potential cause of SBO especially after laparotomy, in overweight or obese patients, in patients on steroid therapy or with wound infections.
3. **Neoplasms** Intrinsic small bowel neoplasms can progressively occlude the lumen or serve as a leading point in intussusception. Symptoms may be intermittent, onset of obstruction is slow, and signs of chronic anemia may be present. Peritoneal carcinomatosis from several tumors is an extrinsic cause of SBO due to adhesions of small bowel loops to neoplastic nodules.

Other causes of SBO include Crohn disease (CD), intussusception which is most often seen in children without an organic lesion and rarely in adults with a neoplastic intraluminal lesion; volvulus as a consequence of intestinal malrotation in children, or of adhesions in adults; and foreign bodies including bezoars, ingested foreign bodies, and gallstones through a cholecysto-duodenal fistula. Gallstone ileus is discussed in Chapter 25.

B. Pathophysiology

With the onset of obstruction, gas and fluid accumulate and distend the intestinal loops proximal to the site of obstruction. Fluid from the extracellular space also fills the lumen proximal to the obstruction, due to the impaired bidirectional flow of salt and water and fluid secretion enhanced by substances (endotoxins, prostaglandins) released from proliferating bacteria in the intestinal lumen. As a consequence, intraluminal and intramural pressures rise until microvascular perfusion to the intestine is impaired, leading to intestinal wall ischemia, and ultimately necrosis.

Activity of the smooth muscle of the small bowel is increased in an attempt to propel its contents past the obstruction consuming all energy sources. At this point the intestine becomes atonic and enlarges further. Emesis could be feculent due to bacterial overgrowth—particularly with distal obstruction—as the intestinal dilation progresses proximally (Figure 29–3). Bacterial translocation from the

lumen to the mesenteric nodes and the bloodstream occurs and abdominal distention elevates the diaphragm and impairs respiration resulting in potential pulmonary complications such as pneumonia, and atelectasis.

When full thickness necrosis of the intestinal wall occurs, luminal content with an elevated bacterial load enters the peritoneal cavity, is absorbed by the peritoneum causing septic shock.

The progression of pathophysiologic events when the bowel is strangulated occurs more rapidly than with simple obstruction and is characterized by an acute impairment of venous return initially followed by arterial flow with subsequent ischemia, necrosis, and perforation of the intestinal wall.

▶ Clinical Findings

Diagnostic evaluation should distinguish mechanical bowel obstruction from ileus, determine the cause of the obstruction, and recognize simple from strangulating obstruction.

Accurate diagnosis requires obtaining a detailed history paying particular attention to medications known to affect intestinal physiology, previous cancer, inflammatory bowel disease, and abdominal surgery and a meticulous physical examination.

A. Signs and Symptoms

Patients usually present with nausea, vomiting, colicky abdominal pain, and obstipation, although residual gas and stool distal to the obstruction may be expelled. With proximal SBO, emesis is usually profuse, containing undigested food in close temporal association with oral intake; abdominal pain is more often described as upper abdominal discomfort associated with epigastric distension. Distal SBO is characterized by diffuse and poorly localized crampy abdominal pain. Feculent vomiting present in cases of longstanding distal SBO is the consequence of bacterial overgrowth and is pathognomonic for a complete mechanical obstruction. In the presence of strangulation, fever often develops, and previously crampy abdominal pain becomes peritonitis.

Initially, vital signs may be normal, but tachycardia and hypotension usually develop as a result of progressive dehydration. Fever is often present with bowel ischemia or perforation. Inspection of the abdomen usually reveals distension that varies based on the site of obstruction and may be absent in cases of proximal obstruction. Peristalsis is usually tremendously increased in the early phases of mechanical SBO, as a result of intensive intestinal muscular contractions. This so-called “peristaltic rush” progressively decreases until it disappears in the late phase of obstruction. The presence of either surgical scars or hernias should be noted, indicating a possible cause of SBO. Rectal examination is essential to detect rectal lesions and to check for the presence of stool.

**High**

Frequent vomiting.
No distention. Intermittent pain but not classic crescendo type.

**Middle**

Moderate vomiting.
Moderate distention. Intermittent pain (crescendo, colicky) with free intervals.

**Low**

Vomiting late, feculent.
Marked distention. Variable pain; may not be classic crescendo type.

▲ **Figure 29–3.** Small bowel obstruction. Variable manifestations of obstruction depend on the level of blockage of the small bowel.

B. Laboratory Findings

Laboratory findings reflect intravascular volume depletion and dehydration. An elevated hematocrit is indicative of hemoconcentration. Leukocytosis is often the result of dehydration and an acute stress response rather than an underlying infection. Blood chemistries may reveal elevated serum creatinine levels, indicating hypovolemia with prerenal failure.

Features of strangulated obstruction or perforation include marked leukocytosis and metabolic acidosis.

C. Imaging Studies

Plain x-rays of the abdomen with the patient in supine and upright position can confirm the clinical diagnosis of SBO. They reveal dilated small bowel loops with air-fluid levels in a ladder-like appearance, and a paucity of air in the colon. These features may be minimal or absent in early or high grade obstructions.

Computed tomographic (CT) scan of the abdomen and pelvis with both intravenous and oral contrast is widely

used. CT scan can visualize the specific location of the obstruction, showing a discrepancy in the caliber between distended proximal bowel loops and collapsed distal intestine. Moreover, CT scan can also reveal the etiology of SBO and demonstrate signs of strangulation including thickening of the bowel wall, air in the bowel wall or portal venous system, and poor uptake of intravenous contrast by the affected bowel wall. Ascites between dilated bowel loops and in the pelvis is often reported in both simple and strangulated obstruction. Intraoperative free air indicates perforation.

► Differential Diagnosis

Pain in patients with paralytic ileus is usually not severe but is constant and diffuse, and the abdomen is often distended and mildly tender. If ileus has resulted from an acute intra-abdominal inflammatory process, there should be symptoms and signs of the primary disease as well as the ileus. Abdominal x-rays show the presence of gas in both the colon and in the small bowel.

A postoperative ileus may be caused by several factors, including drugs used for anesthesia and analgesia, and intraoperative manipulation of intestinal loops and the mesentery. Usually, it is temporary; but if it persists for more than 3-5 days, diagnostic evaluation to rule out mechanical causes of obstruction is mandatory.

Colonic obstruction is usually diagnosed by abdominal x-rays that show colonic dilation proximal to the obstructing lesion. In the presence of competent ileocecal valve, a closed loop obstruction occurs with an elevated risk of perforation of the colon. If the ileocecal valve is incompetent, the distal small bowel will be dilated, and patients will exhibit abdominal distension, nausea and vomiting.

Acute gastroenteritis, acute appendicitis, and acute pancreatitis can mimic simple intestinal obstruction, while acute mesenteric ischemia (AMI) must be considered in the differential of small bowel strangulation.

Intestinal pseudo-obstruction comprises a spectrum of specific disorders associated with irreversible intestinal dysmotility, in which there are symptoms and signs of intestinal obstruction without evidence for an obstructing lesion. Acute pseudo-obstruction of the colon carries the risk of cecal perforation and is discussed in Chapter 30. Chronic pseudo-obstruction affecting the small bowel with or without colonic involvement can be idiopathic, or secondary to several (sporadic and familial) visceral myopathies and neuropathies that affect intestinal smooth muscle, and the intra- and extraintestinal nervous system. Systemic disorders such as scleroderma, myxedema, lupus erythematosus, amyloidosis, drug abuse (phenothiazine ingestion), radiation injury, or progressive systemic sclerosis can be complicated by chronic intestinal pseudo-obstruction. In addition, cytomegalovirus and Epstein-Barr viral infections can cause chronic intestinal pseudo-obstruction.

The clinical manifestations of chronic intestinal pseudo-obstruction include recurrent episodes of vomiting, crampy abdominal pain, and abdominal distention. The diagnosis is suggested by clinical findings and medical history, and confirmed by radiologic and manometric studies. Diagnostic laparoscopic full-thickness biopsy of the small bowel may be required to establish the specific cause of the disease. Therapy focuses on palliation of symptoms and nutritional issues.

► Treatment

SBO is associated with a marked depletion of liquids caused by decreased oral intake, vomiting, and sequestration of fluid in the bowel lumen. Therefore, vigorous fluid resuscitation and correction of electrolyte disorders (hypochloremic, hypokalemic metabolic alkalosis) is mandatory. A urinary catheter should be placed to monitor urinary output. Gastrointestinal decompression with a nasogastric tube provides relief of symptoms, prevents further gas and fluid accumulation proximally, and decreases the risk of aspiration.

Obstruction that occurs in the early postoperative period is usually partial and only rarely associated with strangulation. Therefore, a period of prolonged total parenteral nutrition and hydration is warranted. Patients who have undergone numerous abdominal operations should initially be conservatively treated with decompression, bowel rest, and serial abdominal exams in hopes of avoiding reentering a hostile abdomen. Patients with CD rarely present with a complete bowel obstruction and these patients often benefit from steroids or other immunosuppressive therapy. However, if signs suggestive of ischemia are detected surgery should be promptly undertaken.

Finally, management of patients with diffuse carcinomatosis is often challenging and in most of cases limited to conservative and palliative treatment.

A. Surgery

The surgical procedure performed varies according to the etiology of the obstruction. However, regardless of the cause of obstruction all small bowel loops must be examined and nonviable segments resected. Criteria suggesting viability include normal pink color, presence of peristalsis, and arterial pulsation.

Laparoscopic adhesiolysis may be performed in carefully selected patients by surgeons skilled in this procedure. Generally, however, an open procedure is performed through an incision that is partly dictated by the location of scars from previous operations.

If the cause of the obstruction cannot be removed, as in case with infiltration of vital structures by cancer or in the case of diffuse carcinomatosis, an anastomosis between proximal small bowel and small or large bowel distal to the obstruction (bypass) may be the best procedure in these patients. In some cases, a stoma can be the only choice of treatment.

► Prognosis

Vast majority (more than 80%) of patients with adhesive SBO do not need an operation, since they improve with medical therapy. Among patients who require surgery, perioperative mortality rate for nonstrangulating obstruction is less than 5%; most of these deaths occur in elderly patients with significant comorbidities. Strangulating obstruction has a mortality rate of approximately 8% if surgery is performed within 36 hours of the onset of symptoms and 25% if operation is delayed beyond 36 hours.

REGIONAL ENTERITIS

► General Considerations

Crohn disease is a chronic inflammatory disease that commonly affects the small bowel, colon, rectum, and anus, but it can also involve the stomach, esophagus, and mouth. CD is a panintestinal condition which may affect any area from the mouth to the anus. The most commonly affected location is the terminal ileum and one-fifth of all patients have more than one intestinal segment affected simultaneously.

The United States, Canada, and Europe have the highest incidence of CD. The current estimated incidence of CD in the United States is approximately four new cases per year for every 100,000 persons, while the prevalence is much higher, between 80 and 150 cases per 100,000.

It is much less common in Asia, South America, and Japan, while accurate data regarding its incidence in Africa are lacking. The peak age for contracting CD is between 15 and 25 years. Familial clusters of disease are not uncommon, with a six- to tenfold increase in the risk of CD in first-degree relatives of those affected by CD or its sister ailment, ulcerative colitis. Although familial aggregations are common, the distribution within families does not indicate a pattern of simple Mendelian inheritance.

A. Etiology

The etiology of CD is not known. CD is an altered immune response that results in inflammation and destruction of intestinal tissues. If this altered immune response is the result of a primary dysfunction in the gut-related immune system or whether an unknown pathological trigger induces an otherwise normal immune system to overreact is still unclear. CD may occur in individuals with a genetic predisposition, while environmental triggers may start the pathological sequence that ultimately manifests as CD.

To date, even though an increase in intestinal permeability in both CD patients and their symptom-free first-degree relatives has been demonstrated no specific primary defect in the systemic or mucosal immune system has been identified. This may lead to an altered mucosal barrier function with abnormal interactions between the multitude of antigenic substrates normally found in the gut lumen and the immunocompetent tissue of the submucosa.

Concerning genetic predisposition, the *CARD15/NOD2* gene has been linked to susceptibility to CD. *CARD15* is a gene product related to innate immunity and it is preferentially expressed to Paneth cells of the ileum. Nevertheless, the known mutations of *CARD15* are neither necessary nor sufficient to contract the disease. Hence, it appears that the genetic relationship of *CARD15/NOD2* to CD is complex and still poorly understood.

The hypothesis that infectious agents may play a role, either directly as a primary cause of CD, or indirectly as a trigger to stimulate a defective immune system, has always found strength in the identification of noncaseating granulomas as the characteristic histopathologic lesion found in Crohn specimens, and in the isolation of *Mycobacterium paratuberculosis* from resected CD specimens. Nevertheless, even sensitive preliminary chain reaction studies have been unable to provide definitive evidence for the presence of *Mycobacterium paratuberculosis*-specific DNA in CD-affected segments of the bowel. Other infectious agents, including measles virus, non-*pylori Helicobacter* species, *Pseudomonas*, and *Listeria monocytogenes* have been studied, but none of them has been consistently associated with CD.

Although diet modification can ameliorate the symptoms of CD, no dietary factor has been identified as a cause of CD. Smoking, however, has been associated with the development of CD. In addition, smoking is known to exacerbate existing CD and can accelerate the recurrence of disease after resection.

B. Pathology

Histopathologic examination of CD typically demonstrates transmural inflammation characterized by multiple lymphoid aggregates in a thickened and edematous submucosa that can be found within the muscularis propria. Another typical microscopic feature of CD is the noncaseating granuloma. However, it is demonstrated in only 50% of resected specimens and is rarely detected on endoscopic biopsies. Additionally, the presence of granulomas does not correlate with disease activity.

Small mucosal ulcerations, called *aphthous ulcers*, are the earliest gross manifestations of CD. They appear as red spots or focal mucosal depressions, typically directly over submucosal lymphoid aggregates. As the inflammation progresses, the aphthous ulcers enlarge and become stellate. They then coalesce to form longitudinal mucosal ulcerations always

along the mesenteric aspect of the bowel lumen. Further progression leads to a serpiginous network of linear ulcerations that surround islands of edematous mucosa producing the classic “cobblestone” appearance. Mucosal ulcerations may penetrate through the submucosa to form intramural channels that can bore deeply into the bowel wall and create sinuses, abscesses, or fistulas.

The inflammation of CD also involves the mesentery and regional lymph nodes such that the mesentery may become massively thickened. With early acute intestinal inflammation, the bowel wall is hyperemic and boggy. As the inflammation becomes chronic, fibrotic scarring develops and the bowel wall becomes thickened and leathery in texture.

► Clinical Findings

A. Symptoms and Signs

The clinical presentation and symptoms of CD depend on the involved segment, the pattern and the severity of disease, and the associated complications. The onset of CD is often insidious and many patients will experience some symptoms for months or even years before the diagnosis is made. The most common complaints are intermittent abdominal pain, bloating, diarrhea, nausea, vomiting, weight loss, and fever. Abdominal pain occurs in 90% of cases: when related to partial obstruction it is mostly postprandial and crampy in nature, while when it is from septic complications it is typically steady and associated with fever. Weight loss is usually related to food avoidance, but in severe cases weight loss may be the result of malabsorption. Symptoms can also be related to complications including abdominal mass, pneumaturia, perianal pain and swelling, or skin rash. Rarely some patients can experience a more sudden onset of pain in the right-lower quadrant, mimicking an acute appendicitis.

In patients suspected of having CD, a complete physical exam should include a thorough abdominal evaluation. In cases of ileal CD, tenderness is typically present in the right-lower quadrant and occasionally a palpable mass is present. The oral cavity should be examined for aphthous ulcers, while the presence of fistulas, abscesses, or enlarged skin tags should be assessed in the perianal area. A digital rectal examination should assess for the presence of anal strictures, fissures, and rectal mucosal ulcerations. The skin in the extremities should be examined for the presence of erythema nodosum and pyoderma gangrenosum.

► Patterns of Disease

Even though CD can be categorized into three general manifestations, such as stricturing, perforating, and inflammatory disease, these three classes do not represent truly distinct forms of the disease. It is typical that the same

patient can present with more than one pattern even in the same segment of bowel. Nevertheless, one pattern tends to be predominant in most cases, determining the clinical presentation and affecting the therapeutic options.

A. Stricturing Pattern

Fibrotic scar tissue is the result of chronic inflammation of CD, and it constricts the intestinal lumen with cicatricial strictures often referred to as “fibrostenotic lesions.” Patients with a stricturing pattern of disease generally develop partial or complete intestinal obstruction, and hence their symptoms are primarily obstructive in nature. Being the result of scar tissue, these strictures are not reversible with medical therapy and surgical intervention is often required.

B. Perforating Pattern

Perforating CD is characterized by the development of sinus tracts, fistulae, and abscesses. The sinus tracts penetrate through the muscularis propria and give rise to abscesses or to fistulas if they penetrate into surrounding structures. Inflammatory response around the advancing sinus tract typically results in adhesion to surrounding structures, therefore, free perforation with spillage of intestinal contents into the abdominal cavity is uncommon. Typically, perforating disease is accompanied by a degree of stricture formation, but the fistula or abscess generated by the perforating component of the disease dominates the clinical picture.

C. Inflammatory Pattern

The inflammatory pattern of CD is characterized by mucosal ulceration and bowel wall thickening. The edema that results from inflammation can lead to an adynamic segment of intestine and luminal narrowing. This pattern often gives rise to obstructive symptoms. Of the three patterns of disease, the inflammatory pattern is much more likely to respond to medical therapy.

Other common symptoms and findings include anorexia and weight loss. Patients may develop a palpable mass, usually located in the right-lower quadrant, related to an abscess or phlegmon in perforating disease or a thickened loop of intestine in obstructive disease. Evidence of fistulization to the skin, urinary bladder, or vagina may also be elicited with an accurate history and physical exam.

► Laboratory Findings

There is no specific laboratory test that is diagnostic for CD. The diagnosis is made by a thorough history and physical examination along with intestinal radiography and endoscopy. Advanced imaging studies such as CT scan or magnetic resonance imaging (MRI) can assess or detect some of the complications and manifestations of CD, but

they are generally not useful in making the initial diagnosis of CD.

A. Imaging Studies

Small bowel follow-through or enteroclysis are the best means for assessing the small bowel for CD. The radiographic abnormalities are often distinctive. Mucosal granulations with ulceration and nodularity can be identified in the early stages of the disease. Thickening of the mucosal folds and edema of the bowel wall can be demonstrated as the disease progresses. With more advanced disease, cobblestoning becomes radiographically apparent. Small bowel contrast studies can also provide information regarding enlargement of the mesentery, as well as formation of an inflammatory mass or abscess demonstrated by a general mass effect separating and displacing contrast-filled loops of small intestine. Even though small bowel contrast studies can demonstrate some of the complications of CD, including high-grade strictures and fistulas, they may not identify all such lesions, including ileosigmoid and ileovesical fistulas. Additionally, small bowel studies may not demonstrate all the areas of disease with significant strictures. Small bowel radiographs can also help in assessing the extent of the disease by identifying the location and length of involved and uninvolved small bowel, and by recognizing whether the disease is continuous or discontinuous with skip lesions separated by areas of normal intestine. Experienced radiologists can also assess areas of luminal narrowing and determine if they are the result of acute inflammatory swelling or are the result of fibrostenotic scar tissue. Such a distinction provides valuable information regarding the value of medical therapy versus early surgical intervention, as inflammatory stenoses are likely to respond to medical therapy while fibrotic strictures are best treated with surgery.

Computed tomography findings of uncomplicated CD are nonspecific and routine CT is not necessary for the diagnosis of CD. CT, however, is very useful in identifying the complications associated with CD—thickened and dilated intestinal loops, inflammatory masses, abscesses, and hydronephrosis resulting from retroperitoneal fibrosis and ureteral narrowing (Figure 29–4). CT is also the most sensitive indicator of an enterovesical fistula as suggested by the presence of air within the urinary bladder. More recently cross-sectional imaging techniques have assumed an increasing role in the imaging of patients with CD. Computed tomography enterography (CTE) has been shown to have a higher sensitivity than barium small-bowel follow through. Based on these findings, CTE is often used combined with ileocolonoscopy as a first-line test for the diagnosis and staging of CD. CTE has several potential advantages over barium studies in the identification of fistulizing disease. CTE does not suffer from superimposition of bowel loops, and it displays the mesentery, retroperitoneum, and abdominal wall

▲ **Figure 29–4.** CT scan showing a markedly thickened loop of distal ileum (arrow) causing obstruction of the more proximal small bowel in regional enteritis.

musculature, typically involved by fistulas. CTE can also readily identify sinus tracts and abscesses. However, recent concerns about radiation-induced cancer arising from medically related CT in young CD patients have encouraged the use of magnetic resonance enterography (MRE). MRE has the same advantages of CTE but does not require ionizing radiation.

B. Endoscopy

While upper endoscopy is useful in the diagnosis of mucosal lesions of the esophagus, stomach, and duodenum a colonoscopy often allows the evaluation of the terminal ileum.

C. Capsule Endoscopy

Capsule endoscopy can detect subtle mucosal lesions that may not be apparent on small bowel x-rays. The value of capsule endoscopy in the diagnosis of CD has been recently evaluated: the rate of abnormalities detected on capsule endoscopy is higher than that of CTE only for the subgroup of patients with known CD. The need for a preliminary small bowel contrast study to detect asymptomatic partial small-bowel obstruction before the capsule endoscopy and the lack of a clear advantage over other imaging studies, limits the utility of capsule endoscopy as a first-line test in CD, and perhaps reserve this study for those cases in which there is a substantial diagnostic uncertainty.

► Differential Diagnosis

The differential diagnosis includes irritable bowel syndrome, acute appendicitis, intestinal ischemia, pelvic inflammatory disease, endometriosis, and gynecological malignancies. Other disorders are radiation enteritis, *Yersinia* infections, intestinal injury from nonsteroidal anti-inflammatory agents, intestinal tuberculosis, and small bowel tumors.

When malignancy is suspected, resection should be undertaken to make the diagnosis certain. The exclusion of intestinal tuberculosis can be difficult, as the inflammation and strictures of the terminal ileum can occur very similarly to CD. A previous exposure to tuberculosis should be evaluated and purified protein derivative skin test should be performed, along with chest radiography. Even when the diagnosis of CD is certain, patients who coincidentally are found to also have latent tuberculosis should be treated in accordance with the American Thoracic Society guidelines prior to the initiation of immunosuppressive therapy for management of CD.

Intestinal injury from nonsteroidal anti-inflammatory drugs (NSAIDs) can result in focal enteritis with ulcerations and strictures. These manifestations can be very difficult to distinguish from CD of the small bowel, and often require resection or biopsy to confirm the diagnosis.

► Treatment

A. Medical

Long-lasting symptomatic relief while avoiding excessive morbidity is the goal of medical treatment of CD. Even though CD cannot be cured by medical treatment long periods of disease control can be obtained avoiding a surgical intervention. Medical treatment for each individual is based on the course of the disease, the clinical presentation and associated complications.

Corticosteroids are the most effective agents for controlling acute exacerbations of CD, but their use is limited due to the risk of serious side effects, including diabetes, osteoporosis, cataracts, osteonecrosis, myopathy, psychosis, opportunistic infections, and adrenal suppression, that are related to both the dose and the duration of steroid therapy. The majority of patients with active small bowel CD will experience clinical remission with a short course of oral prednisone given in a dose between 0.25 and 0.5 mg/kg/d. For patients unable to take oral medications, methylprednisolone can be administered in the adult at doses of 40-60 mg given as a daily infusion.

The *aminosalicylates* include sulfasalazine and 5-aminosalicylic acid (5-ASA) derivatives. They inhibit leukotriene production by inhibiting 5-lipoxygenase activity and the production of inter-leukin-1 and tumor necrosis factor (TNF). Aminosalicylates are effective in the treatment of

mild to moderate CD. 5-ASA given in a controlled-release preparation is also effective as maintenance therapy to prevent recurrence after a flare of disease has been effectively managed either medically or surgically.

Aminosalicylates come in a variety of preparations, each designed to deliver the drug in a topical fashion to the affected bowel segments. For instance, Asacol is 5-aminosalicylic acid contained within a pH-dependent resin that releases the drug in the terminal ileum and colon where the pH is greater than 7.0. Pentasa is 5-aminosalicylic acid contained within ethylcellulose-coated microgranules that slowly releases the active compound throughout the entire small bowel and colon. *Azathioprine* and *6-mercaptopurine* (6-MP) are immunosuppressive agents that inhibit cytotoxic T-cell and natural killer cell function. These agents are effective in treating mild to moderate CD. Azathioprine given at 2.0-2.5 mg/kg/d or 6-MP in doses of 1.0-1.5 mg/kg/d will result in a 50%-60% response rate in patients with active CD. Both 6-MP and azathioprine are also effective in maintaining remission following surgery or successful medical management.

Infliximab is a chimeric mouse-human monoclonal antibody to TNF that is a proinflammatory cytokine that may be important in the pathophysiology of CD. Infliximab binds to both free and membrane-bound TNF, and prevents TNF from binding to its cell surface receptors. Clinical trials have demonstrated an 80% response rate with a single dose of infliximab. It is important to note that the doses and dosing intervals of infliximab must be individualized, but a typical regimen would include 5 mg/kg of infliximab given IV at weeks 0, 2, and 6, with a dose of 5 mg/kg every 8 weeks thereafter. Because infliximab is a potent immunosuppressive agent concerns have been raised about the risk for poor wound healing and postoperative septic complications. Nevertheless, current available data on the perioperative risks associated with infliximab does not seem to support this hypothesis.

Other agents that are used with varying success in the treatment of CD include methotrexate, metronidazole, cyclosporine, tacrolimus, and thalidomide.

B. Surgical Therapy

Similarly to medical treatment, the goal of surgical treatment of CD is to provide long-lasting symptomatic relief while avoiding excessive morbidity. Like medical treatment, surgery should be considered palliative. Therefore, treatment of complications and palliation of symptoms while avoiding excessive resection of small bowel should be the main aims of surgical treatment.

To avoid excessive loss of small bowel, nonresectional techniques such as strictureplasty may be required. In addition, optimal surgical therapy should be the resection of the only areas of severe and symptomatic CD, leaving behind

segments of small bowel affected by mild but asymptomatic CD based on the high risks of recurrence and repeated operations.

C. Indications for Surgery

1. Failure of medical treatment—The failure to respond to medical treatment, the inability to tolerate effective therapy are the most common indications for surgical treatment of CD, as the occurrence of complications related to the medical treatment or the progression of disease while on maximal medical treatment. Some patients may respond to the initial medical therapy only to rapidly relapse with tapering of the medical treatment. For example, some patients respond well to steroid therapy, but become steroid-dependent as tapering of the steroid dose results in recurrent symptoms. Due to the severe complications that are virtually inevitable with prolonged steroid treatment, surgery is warranted if the patient cannot be weaned from systemic steroids within 3-6 months.

2. Intestinal obstruction—Partial or complete intestinal obstruction is a common indication for operation. The clinical presentation of chronic partial SBO is much more typical than complete obstruction, and postprandial cramps, abdominal distension, borborygmi, and weight loss are common symptoms. To avoid them, many patients restrict the diet to soft foods or even liquids. In case of partial obstruction primarily due to acute inflammation and bowel wall thickening, initial medical therapy is warranted. If, however, the obstructive symptoms are secondary to high-grade fibrostenotic lesions, surgery is indicated because medical treatment will not reverse these lesions.

When complete intestinal obstruction occurs, initial conservative treatment consists of nasogastric decompression and intravenous hydration along with administration of intravenous steroids. This treatment leads to decompression of acutely distended and edematous bowel, and in most cases, to resolution of the complete obstruction. However, even patients with complete resolution of the acute obstruction after the initial conservative treatment are at high risk for recurrent episodes of obstruction and are best managed with elective surgery once adequate decompression and resuscitation is achieved. If the obstruction fails to respond to appropriate conservative treatment, then surgery is required. In these situations, a high index of suspicion for small bowel cancer as the cause of the obstruction is mandatory, as obstructions from cancers do not respond to bowel decompression and steroid treatment.

3. Fistulas—Intestinal fistulas occur in one-third of CD patients. However, the presence of an intestinal fistula is not in and of itself an indication for surgery. In general, it is the primary indication for surgery if the fistula is in connection with the genitourinary tract, or if their drainage causes personal embarrassment and discomfort (enterocutaneous

and enterovaginal fistulas), or if a bypass causing intestinal malabsorption is created.

Fistulas can be classified according to anatomic site, characteristics of the tract (simple vs. complex), and volume of output (high vs. low). A low volume output is less than 200 mL/24 h, while a high volume output is more than 500 mL/24 h.

4. Ileosigmoid fistulas—Ileosigmoid fistula is a common complication of perforating CD of the terminal ileum. Typically, the inflamed terminal ileum adheres to the sigmoid colon that is otherwise healthy. Most ileosigmoid fistulas are small and asymptomatic. These ileosigmoid fistulas do not in and of themselves require operative management. On the other hand, large ileosigmoid fistulas can result in bypass of the intestinal contents from the terminal ileum to the distal colon and thus give rise to debilitating diarrhea. Such symptomatic fistulas should be managed surgically, as they often fail to respond to medical therapy.

More than half of the ileosigmoid fistulas from CD are recognized intraoperatively. Ileosigmoid fistulas can be managed by simple division of the fistulous adhesion and resection of the ileal disease. The defect in the sigmoid colon is then debrided and simple closure is undertaken. In about 25% of cases, resection of the sigmoid colon is needed, particularly when primary closure of the fistula is at risk for poor healing. This is the case when either the sigmoid is also involved in CD, when the fistulous opening is particularly large, or when there is extensive fibrosis extending along the sigmoid colon. Also, fistulous tracts that enter the sigmoid colon in proximity to the mesentery can be difficult to close and often require resection and primary anastomosis.

5. Ileovesical fistula—Ileovesical fistulae occur in approximately 5% of CD patients. Although hematuria and fecaluria are virtually diagnostic of ileovesical fistula, these symptoms are absent in almost 30% of cases. Air within the bladder, as noted on CT scan, is often the best indirect evidence for the presence of an enterovesical fistula, while small bowel x-rays, cystogram, and cystoscopy often do not detect the fistula. An ileovesical fistula is an indicator of complex fistulizing disease, as most ileovesical fistulas occur along with other enteric fistulae.

The necessity for surgery for ileovesical fistula is controversial. While it is not mandatory to operate on all cases of enterovesical fistulas, surgery is warranted to avoid deterioration of renal function with recurrent infections or if symptoms persist in spite of appropriate medical therapy.

Surgical treatment of ileovesical fistulae requires resection of the ileal disease with closure of the bladder defect. Most ileovesical fistulas involve the dome of the bladder, and thus debridement and primary closure can be accomplished without risk of injury to the trigone. Decompression of the bladder with an indwelling Foley catheter should be continued postoperatively until the bladder is confidently healed

without leaks. A cystogram taken postoperatively is useful to confirm the seal of the bladder repair, before removing the Foley catheter.

6. Enterovaginal and enterocutaneous fistulas—These are rare fistulas caused by perforating small bowel disease draining through the vaginal stump in a female who has previously undergone a hysterectomy or through the abdominal wall, usually at the site of a previous scar. These fistulas often require surgical intervention because they cause physical discomfort and personal embarrassment. Surgical treatment requires resection of the small bowel disease. The vaginal cuff does not need to be closed; the chronic infection along the abdominal wall fistulous tract requires debridement and wide drainage to allow healing by secondary intention.

7. Abscess—Intra-abdominal CD abscesses tend to have an indolent course with modest fever, abdominal pain, and leukocytosis. In up to 30% of cases preoperative clinical signs of localized infection are absent and the abscesses are discovered only at the time of operation. When an abscess is suspected or an abdominal mass is palpated, a CT scan should be obtained, as 50% of tender intra-abdominal masses will harbor an abscess collection within. The CT scan can detect most chronic abscesses and can also delineate the size and location of the abscess as well as the relationship of the abscess to critical structures such as the ureters, duodenum, and the inferior vena cava.

In the majority of cases, abscesses are very small collections contained within the area of diseased small bowel and its mesentery. In the case of small intraloop or intramesenteric abscesses, resection of the involved bowel segment and its mesentery often extirpates the abscess such that drains are not necessary and primary anastomosis can be performed without risk.

Large abscesses are best managed with CT-guided percutaneous drainage. However, abscess drained percutaneously is very likely to recur or result in an enterocutaneous fistula, and surgical resection is often advised even after successful drainage. Such a fistula may spontaneously close or it may persist and the intestine may continue to be a source of sepsis. With successful drainage of the abscess, the sepsis often clears well enough that it can be tempting to try to manage the disease without subsequent surgery. In the absence of symptoms, initial non-operative management after successful percutaneous drainage can be undertaken in carefully selected patients. If drainage through the fistula continues, surgical resection of the affected segment of intestine becomes necessary.

8. Perforation—Free perforation is a rare complication of CD occurring in less than 1% of patients because the chronic progressive inflammation of CD usually leads to adhesions with adjacent structures, and it is an obvious indication for urgent operation with resection of the diseased segment and

exteriorization of the proximal bowel as an end ileostomy. The diagnosis of free perforation is made by detecting a sudden change in the patient's symptoms along with the development of the physical findings of peritonitis or the identification of free intraperitoneal air as demonstrated on plain x-rays or CT scan. The use of immunosuppressants and glucocorticosteroids can blunt many of the physical findings of acute perforation; therefore the index of suspicion for perforation must be higher in immunocompromised patients.

Creation of a primary anastomosis even with a proximal protecting loop ileostomy carries a high risk of anastomotic breakdown and should be avoided. Primary closure of the perforation should never be attempted, as sutures will not be able to approximate the edges of the perforated, edematous, and diseased bowel in a satisfactory and tension-free way and the presence of a distal intestinal stenosis or partial obstruction will cause an increase in the intraluminal pressure at the level of the local repair with subsequent dehiscence.

9. Hemorrhage—Hemorrhage is an uncommon complication from small bowel CD. Angiography in the presence of brisk bleeding leads to localization of the site of bleeding. Bleeding from small bowel tends to be indolent with episodic or chronic bleeding requiring intermittent transfusions, but rarely requires emergent surgery. However, because the risk of recurrent bleeding is high, elective resection of the areas of CD is recommended. Finally, risk for bleeding from peptic ulcer disease is increased in patients, particularly in those receiving corticosteroids.

10. Cancer or suspicion of cancer—The presence of CD increases the risk of adenocarcinoma of the small bowel. The diagnosis of adenocarcinoma of the small bowel is difficult because symptoms and radiographic findings can be similar to those of the underlying CD. Male patients, patients with long-standing disease and patients with defunctionalized segments of bowel appear to be at increased risk for small bowel adenocarcinoma. For this reason, bypass surgery should be avoided for CD of the small intestine and defunctionalized rectal stumps should either be restored to their function or excised.

Adenocarcinoma of the small intestine should be suspected in any patient with long-standing disease whose symptoms of obstruction progress after a lengthy quiescent period.

11. Growth retardation—Growth retardation occurs in a quarter of children affected by CD. Although steroid treatment may delay growth in children, the major cause of growth retardation in CD patients is due to the malnutrition associated with active intestinal disease.

D. Surgical Options

1. Intestinal resection—Intestinal resection with anastomosis is the most common surgical procedure performed for the treatment of small bowel CD. In most cases of CD

only limited resections are required with no risk for short bowel syndrome. Only grossly apparent disease should be resected, as wider resections do not improve the surgical outcomes. Grossly normal resection margins with microscopic evidence for CD activity are not associated with early recurrence or other complications. Therefore, intraoperative frozen section of the resection margins is not necessary.

The extent of mesenteric dissection does not affect the long-term results. Division of the thickened mesentery of small bowel CD can be the most challenging aspect of the procedure, as identification and dissection of individual mesenteric vessels is often not feasible. A common technique consists of the application of overlapping clamps on either side of the intended line of transection. The mesentery is then divided between the clamps and the tissue contained within the clamps is suture ligated. In severe cases, a vascular clamp may be used at the root of the small bowel mesentery to obtain proximal control: mattress sutures may then be need to be applied to the cut edge of the mesentery to control bleeding. Even when tissue welding devices such as the LigaSure device are used, mattress sutures in the mesentery are commonly needed for complete hemostasis.

2. Anastomosis—There is no consensus regarding the optimal technique for intestinal anastomosis in CD. Recurrent CD after resection of terminal ileum is most likely to occur at the ileocolonic anastomosis or at the pre-anastomotic ileum. It has been proposed that large caliber anastomoses require a longer period to stricture down to a critical diameter that becomes symptomatic. The argument is made that a longer side-to-side anastomosis may be beneficial over an end-to-end or end-to-side anastomosis. To date, however, clinical data do not indicate a benefit for one particular intestinal configuration over another. Intestinal anastomosis for CD cases can be fashioned with a stapling device or may be hand sutured. Under selective conditions, small bowel anastomotic dehiscence rates is under 1%. In the presence of sepsis, severe scarring, malnutrition, or recent treatment with methotrexate or infliximab, it may be wise to protect the anastomosis with a proximal loop stoma or to forego the anastomosis altogether and bring out an end stoma at the point of resection.

3. Bypass Procedures—Initially conceived to bypass an area of stricture or obstruction, the use of bypass procedures was eventually extended to CD complicated by septic complications. Increased experience with bypass procedures revealed that patients with persistent disease are at higher risk of persistent sepsis, and eventually neoplastic transformation. Therefore, bypass procedures were supplanted by limited intestinal resection as the main surgical option in the late 1960s in all intestinal districts except the duodenum, where a simple side-to-side retrocolic gastrojejunostomy adequately relieves the obstructive symptoms. With increased experience in the performance of strictureplasty, duodenal disease

is nowadays more and more commonly handled with strictureplasties.

4. Strictureplasty—Strictureplasties are best performed when resection would otherwise result in loss of a long segment of bowel with an increased risk for short bowel syndrome, including cases of stricturing disease involving long segments of bowel and patients with multiple prior resections. They are also indicated as a simpler alternative to resection in case of short recurrent disease at a previous ileocolic or enteroenteric anastomosis.

There is increased evidence that the acuity of the disease decreases at the site of the strictureplasty and the disease becomes quiescent, maybe in correlation with a simultaneous restoration of absorptive function.

The most commonly performed strictureplasty is the Heinecke–Mikulicz strictureplasty, that is appropriate for short segment strictures of 2–5 cm in length. A longitudinal incision is made along the antimesenteric border of the stricture extending for 1–2 cm into the normal elastic bowel on either side of the stricture. Once the enterotomy is made, the area of the stricture should be closely examined to rule out a malignancy. The longitudinal enterotomy of the Heinecke–Mikulicz strictureplasty is then closed in a transverse fashion with either single- or double-layered sutures.

The Finney strictureplasty can be used for strictures up to 15 cm in length. The strictured segment is folded onto itself in a U-shape, and a row of seromuscular sutures is placed between the two arms of the U. A longitudinal U-shaped enterotomy is then made paralleling the row of sutures. The mucosal surface is examined and biopsies are taken as necessary. In essence, the Finney is a short side-to-side functional anastomosis. A very long Finney strictureplasty may result in a functional bypass with a large lateral diverticulum that, in theory, could be at risk for bacterial overgrowth and the blind loop syndrome. However, this theoretical concern has not been observed in clinical practice.

Repeated Heinecke–Mikulicz or Finney strictureplasties to manage multiple strictures should be separated from each other by at least 5 cm, in order to avoid excessive tension on each suture line.

Patients with long segment stricturing disease and multiple strictures grouped close together are best managed with a side-to-side isoperistaltic strictureplasty, also called Michelassi strictureplasty. The segment of stricturing disease is divided at its midpoint. The proximal and distal ends are then drawn onto each other in a side-to-side fashion. Division of some of the mesenteric vascular arcades facilitates the positioning of the two limbs over each other. The proximal and distal loops are then sutured together with a layer of interrupted seromuscular sutures. A longitudinal enterotomy is then made along both of the loops. The intestinal ends are spatulated to provide a smoothly tailored fit to the ultimate closure of the strictureplasty. The outer

suture line is reinforced with an interior row of either interrupted or running full-thickness sutures. This inner suture line is continued anteriorly. The anterior closure is then reinforced with an outer layer of interrupted seromuscular sutures to complete the strictureplasty. In appropriately selected patients, perioperative morbidity from strictureplasty appears to be similar to that of resection and primary anastomosis. Specifically, intestinal suture line dehiscence appears to be uncommon with any of the described strictureplasty techniques. The most common postoperative complication directly related to strictureplasty is hemorrhage from the strictureplasty site, in up to 9% of cases. Usually, the gastrointestinal hemorrhage following strictureplasty is minor and can be managed conservatively with transfusions alone. Rarely, a reoperation to control hemorrhage after strictureplasty is necessary. It is by now also well established that strictureplasty techniques provide excellent long-term symptomatic relief which is comparable to resections with anastomosis.

5. Laparoscopy—Most CD patients are well suited for laparoscopy. They are usually young, otherwise healthy, and interested in undergoing an operation that involves minimal scarring, since they are facing the risk of multiple major abdominal operations in their lifetime.

The indications for laparoscopic surgery for CD should not differ from conventional open surgery as described before. Contraindications to a laparoscopic approach include patients who are critically ill and unable to tolerate the pneumoperitoneum due to hypotension or hypercarbia, patients with extensive intra-abdominal sepsis (abscess, free perforation, or complex fistula), and difficulty in identifying the anatomy (previous surgery, obesity, or adhesions). The same variety of surgical procedures described earlier can be performed laparoscopically.

MANAGEMENT CROHN DISEASE OF THE DUODENUM

Primary CD of the duodenum almost always manifests with stricturing disease that can be managed by strictureplasty or with bypass procedures, while resection of the duodenum for CD is almost never required. When CD fistulas involve the duodenum, it is always the result of disease within a distal segment of the small bowel that fistulizes into an otherwise normal duodenum. Heinecke–Mikulicz strictureplasties can be safely performed in the first, second, and proximal third portion of the duodenum, while strictures of the last portion of the duodenum are better handled with a Finney strictureplasty constructed by creating an enteroenterostomy between the fourth portion of the duodenum and the first loop of the jejunum.

If the duodenal stricture is lengthy or the tissues around the stricture are too rigid or unyielding, then a strictureplasty should not be performed and an intestinal bypass procedure

should be undertaken. The most common bypass procedure performed for duodenal CD is a side-to-side retrocolic gastrojejunostomy. This procedure effectively relieves the symptoms of duodenal obstruction related to CD strictures, but carries a high risk for stomal ulcerations. To lessen the likelihood of ulcerations forming at the anastomosis, it has been recommended that a selective vagotomy be performed along with the gastrojejunostomy in order to reduce the risk of vagotomy-related diarrhea. If only the third or fourth portions of the duodenum are involved by the structuring CD, a Roux-en-Y duodenojejunostomy to the proximal duodenum is preferred over a gastrojejunostomy, having the Roux-en-Y duodenojejunostomy the advantage of bypassing strictures and eliminating the risk of acid-induced marginal ulceration and the need for vagotomy.

Most of these duodenal fistulas are small in caliber and asymptomatic, but larger fistulas may shunt the duodenal contents to the distal small bowel resulting in malabsorption and diarrhea. In most cases, duodenoenteric fistulas are identified with preoperative small bowel radiography; however, many are discovered only intraoperatively. Most duodenal fistulas are located away from the pancreaticoduodenal margin, and thus these fistulas can be managed by resection of the primary CD with primary closure of the duodenal defect. In case of larger fistulas or fistulas that are involved with a large degree of inflammation closure with a Roux-en-Y duodenojejunostomy or with a jejunal serosal patch may be required.

► Prognosis

The risk for recurrence after surgery is high in CD patients. Most cases of histological or endoscopically detected recurrences, however, do not produce symptoms of CD. For this reason, histological or endoscopic evidence of recurrent disease are not typically used as a guide for clinical management.

The development of symptoms related to recurrent CD activity is the most commonly applied definition of disease recurrence, as it is the recurrence of symptoms that has the most relevance to the patient. The onset of symptoms of recurrent CD is often insidious and the severity of symptoms varies greatly. A CD Activity Index (CDAI) greater than 150 is generally accepted as defining clinical recurrence. Once symptoms suggestive of recurrent disease occur, it is necessary to carry out radiological and endoscopic tests to confirm that the symptoms are in fact related to CD.

The clearest end point as a definition of recurrence is the need for reoperation. While reoperation is the most precise definition of recurrence, even this standard does not allow for accurate and reproducible comparisons between series, as some centers may submit patients to surgery earlier than other centers.

Reported crude and cumulative recurrence rates vary greatly. Symptomatic recurrence occurs in about 60% of patients at 5 years and recurrences increase with time such

that at 20 years clinical recurrence can occur in between 75% and 95% of cases. Reports of surgical recurrence rates range from 10% to 30% at 5 years, from 20% to 45% at 10 years, and from 50% to 70% at 20 years. Recurrent CD is most likely to occur in proximity to the location of the previously resected intestinal segment, typically at the anastomosis and preanastomotic bowel, in particular in case of terminal ileal disease. Additionally, the length of small bowel involved with recurrent disease parallels the length of disease originally resected. Also, to a lesser degree of concordance, stenotic disease tends to recur as stenotic disease and perforating disease tends to recur as perforating disease.

While many factors that may influence the risk of recurrence have been studied, the cumulative literature has validated very few as true risk factors. Cigarette smoking has a significant effect on the clinical course of CD. Smoking not only exacerbates existing CD, but also has been identified as a risk factor for the development of CD, and for endoscopic, symptomatic, and surgical recurrence. While the mechanism by which smoking results in exacerbation of CD is not known, the risk from smoking appeared to be dose-related with heavy smokers being at higher risk, and reversible. There is concern that NSAIDs may exacerbate the activity of both ulcerative colitis and CD, but there are not conclusive data.

The risk for recurrent disease can be reduced with postoperative maintenance therapy. The most common agents are controlled-release 5-aminosalicylic acid and 6-mercaptopurine. Maintenance with 5-ASA is associated with few side effects, but up to sixteen pills have to be taken daily. 6-Mercaptopurine is less expensive and is taken on a once-daily basis. Additionally, 6-MP may be more effective in diminishing the risk of recurrence. 6-MP, however, is associated with potential bone marrow suppression, so that patients on 6-MP maintenance must be followed with periodic blood cell counts.

SMALL INTESTINE FISTULAS

► General Considerations

Fistulas are an abnormal connection between two epithelial lined organs and while enterocutaneous fistulas (ECF) may form spontaneously as a result of disease, about 80% are complications of surgical procedures (anastomotic dehiscence or injury to bowel during dissection). Fistulas are particularly prone to develop when the surgeon encounters extensive adhesions, inflamed intestine, radiation enteritis, a malnourished patient, or emergency procedures.

► Clinical Findings

A. Symptoms and Signs

Postoperative fistula formation is heralded by fever, abdominal pain, and distention. Frequently a wound infection is recognized and drained 7-10 days postoperatively with subsequent discharge of enteric contents through the abdominal incision. Spontaneous fistulas from neoplasms or inflammatory disease usually develop in a more indolent manner. ECF are often associated with abscesses, which often drain incompletely with fistulization, so that persistent sepsis is a common feature. Intestinal fluid escaping through the fistula may severely excoriate the skin and abdominal wall tissues. Persistent sepsis and difficulty in nourishing the patient contribute to rapid weight loss.

B. Laboratory Findings

Routine laboratory tests reflect the severity of deficits in red cell mass, plasma volume, and electrolytes. Hypokalemia is the most common electrolyte abnormality. Ongoing losses may be significant especially with high output fistulas necessitating serial measurement of serum electrolytes. Leukocytosis due to sepsis and hemo-concentration is common.

C. Imaging Studies

The goals of imaging are to detect concurrent abdominal pathology and to characterize the fistula. Contrast studies with contrast medium administered orally, per rectum, or

through the fistula (fistulogram) delineates the abnormal anatomy, including intrinsic bowel disease, and demonstrates the location and number of fistulas, the length and course of fistula tracts, associated abscess cavities, and the presence of distal obstruction. Radiologists can manipulate catheters into tracts and provide detailed diagnostic information; this procedure may also be therapeutic (see later). CT scans, endoscopy, and other special studies may be indicated in certain individuals.

► Complications

Fluid and electrolyte losses, malnutrition, and sepsis contribute to multiple-organ failure and death unless effective therapy is instituted promptly.

► Treatment

The initial management of an ECF involves recognition of the fistula, control of sepsis, resuscitation, local wound care, and nutritional optimization. A systematic approach combining diagnostic, supportive, and operative procedures is essential in the management of patients with fistulas (Table 29–2). The proper timing of intervention is as critical in few other conditions.

A. Fluid and Electrolyte Resuscitation

Many fistula patients are profoundly depleted of intravascular and interstitial volume especially if the fistula is large, if it is proximal, or if there is partial or complete intestinal obstruction distal to the fistula and correction of hypovolemia and electrolyte imbalances are the first priority. Central venous pressure, urine output, and skin turgor are guides to the progress of volume resuscitation. Fluid and electrolyte resuscitation can usually be accomplished within the first day or two. Subsequent maintenance of homeostasis depends on accurately measuring losses and replacing them.

Table 29–2. Treatment of fistulas.

First	Restore blood volume and begin correction of fluids and electrolyte imbalance. Drain accessible abscesses. Control fistula and measure losses. Begin nutritional support.
Second	Delineate anatomy of fistulas by radiographic studies.
Third	Maintain caloric intake of 2000–3000 kcal or more per day, depending on status of nutrition and energy expenditure. Drain abscesses as they appear.
Fourth	Operate if fistula fails to close.

B. Control of Fistula

Fistulous effluent must be collected to avoid excoriation of skin and abdominal wall tissues and to record volume losses. An ostomy appliance or pouch should be placed around the fistula and needs to be tailored based on the characteristics of the fistula. Alternatively, a catheter inserted by a radiologist under x-ray guidance may work best. In selected cases, a vacuum-assisted wound management device can be used to control fistula drainage and accelerate closure of the fistula. The assistance of a skilled and experienced wound care and/or enterostomal nurse is indispensable.

C. Control of Sepsis

Abscesses should be drained as soon as they are diagnosed. While therapy with broad-spectrum antibiotics may be necessary to control infection, is not a substitute for proper management of abscesses. Most contained abscesses can be drained percutaneously with CT or ultrasound guidance. Drainage catheters should be left in place until the abscess cavity has resolved which can be confirmed with a drain study once drainage has ceased. A drain study can also demonstrate the presence of persistent communication between the small bowel and the fistula. Free drainage of enteral contents into the abdominal cavity will likely cause peritonitis necessitating an emergent laparotomy.

D. Delineation of Fistula

Radiographic contrast studies (mentioned previously) should be obtained as soon as feasible.

E. Nutrition

Adequate nutrition and control of sepsis make the difference between survival and death for these patients. A useful general rule is to avoid oral intake during the initial stage of treatment. Nasogastric suction may be necessary temporarily. As soon as fluid, electrolytes, and vitamin abnormalities are corrected, parenteral nutrition should be instituted via a central intravenous catheter.

For many patients, total parenteral nutrition is the principal exogenous source of calories and nitrogen until the fistula heals or is closed surgically. For patients with low-output or distal fistulas, the enteral route for nutrition is preferred, and elemental or polymeric diets can be delivered into the distal gut in some patients with proximal fistulas.

F. Other Measures

H₂ receptor antagonists and proton pump inhibitors are useful adjuncts in patients with proximal fistulas. By reducing gastric acid secretion, fistula output is decreased and fluid and electrolyte management is simplified. Somatostatin analogs decrease fistula output and may accelerate fistula closure.

G. Operation

About 30% of fistulas close spontaneously with proper medical management. CD, irradiated bowel, cancer, foreign body, distal obstruction, extensive disruption of intestinal continuity, and a short (< 2 cm) fistula tract are associated with failure of fistulas to heal. Fibrin glue has been effective in some small bowel fistulas; in particular, it may be considered in complicated patients with a history of a hostile abdomen. Treatment may be successful if the fistula is long and the output is low. If they are going to heal spontaneously, fistulas usually close within 5-6 weeks after eradication of infection and institution of adequate nutritional support. Patients who fail 6 weeks of nonoperative management will often require surgical intervention. Serum levels of short-turnover proteins, particularly transferrin, might be useful in predicting which patients are unlikely to close their fistulas. The operation should be postponed, however, until one can predict that the phase of dense adhesions associated with ECFs has resolved and nutrition is optimized typically at least 3 months after the last operation. The fistulous segment should be resected, associated obstruction relieved, and continuity reestablished by a functional end-to-end anastomosis.

► Prognosis

The plan of management outlined earlier results in survival rates of 80%-95% in patients with external fistulas. Uncontrolled sepsis is the chief cause of death.

BLIND LOOP SYNDROME

The normal concentration of bacteria in the small intestine is about 10⁵/mL. Mechanisms that limit bacterial populations include the continual flow of luminal contents, gastric acidity, local effects of immunoglobulins, and the prevention of reflux of colonic contents by the ileocecal valve. Disturbance of any of these mechanisms can lead to bacterial overgrowth and blind loop syndrome. Strictures, diverticula, fistulas, and defunctionalized segments of bowel allow bacterial proliferation.

This entity is rare and clinical manifestations include steatorrhea, diarrhea, abdominal pain, vitamin deficiency, neurologic symptoms, anemia, and weight loss. Steatorrhea is

the consequence of bacterial deconjugation and dehydroxylation of bile salts in the proximal small bowel. Deconjugated bile salts have a higher critical micellar concentration, and micelle formation is inadequate to solubilize ingested fat in preparation for absorption. The presence of partially digested triglycerides in the distal ileum inhibits jejunal motility; nevertheless, the unabsorbed fatty acids enter the colon, where they increase net secretion of water and electrolytes, and diarrhea results. Hypocalcemia occurs because calcium is bound to unabsorbed fatty acids in the intestinal lumen. Macrocytic anemia is secondary to malabsorption of vitamin B₁₂, largely because it is consumed by anaerobic bacteria. Vitamin B₁₂ deficiency also causes neurologic symptoms due to demyelination of the posterior and lateral spinal columns. Malabsorption of carbohydrate and protein is due partly to bacterial catabolism and partly to impaired absorption of these nutrients because of direct damage to the small intestinal mucosa. All of these mechanisms contribute to malnutrition.

Quantitative culture of upper intestinal aspirates is valuable if properly performed; bacterial counts of more than 10⁵/mL are generally abnormal. Endoscopic biopsies of the duodenum can be helpful in patients with suspected small intestinal malabsorption. Laboratory studies reveal impaired absorption of orally administered vitamin B₁₂ (Schilling test), D-xylose, and ¹⁴C triolein.

Surgical treatment of the underlying disease is carried out whenever possible. If there is no a surgical cause of blind loop syndrome, treatment consists of broad-spectrum antibiotics and medications to control diarrhea. It may be necessary to use different antibiotics in sequence, guided by culture results and response to therapy. Damage to enterocytes appears to be reversible with treatment. Octreotide (somatostatin analog) may reduce bacterial overgrowth and improve abdominal symptoms in patients with scleroderma, according to a recent report.

ACUTE MESENTERIC ISCHEMIA

► General Considerations

Acute mesenteric ischemia (AMI) is a life-threatening clinical condition if not diagnosed promptly and treated adequately. Despite diagnostic and therapeutic advances, morbidity and mortality associated with AMI remains high. A high index of suspicion for this disease is essential since the clinical presentation is often nonspecific. AMI results from four main processes: (1) arterial embolism (50%) most commonly in patients with previous myocardial infarction or atrial fibrillation; (2) acute arterial thrombosis (25%) in patients with diffuse atherosclerosis or less frequently with

connective tissue disorders; (3) nonocclusive mesenteric ischemia (20%); and (4) venous thrombosis (5%) associated with portal hypertension, abdominal sepsis, hypercoagulable states, or trauma.

The clinical consequences of acute arterial or venous mesenteric ischemia depend on several factors, including the vessel involved, the level of occlusion, the development of collaterals, and reperfusion. Tissue injury caused by the ischemic event compromises the immune and barrier functions of the small bowel, allowing bacterial translocation, cellular degradation, reactive oxygen species formation in case of reperfusion and intravascular thrombosis. The release of these products into the portal system and the systemic circulation initiates a cascade of events leading to damage of target organs such as the lungs and kidneys.

A. Symptoms and Signs

The clinical presentation is nonspecific.

Patients with arterial embolism initially present with sudden-onset diffuse abdominal pain that is out of proportion to the clinical examination and often unresponsive to narcotics. The lack of well-developed collaterals causes ischemia which eventually becomes transmural. As ischemia worsens, patients develop nausea and vomiting, bloody diarrhea, and eventually peritonitis.

Patients with acute thrombotic mesenteric occlusion also present with severe abdominal pain, but it is usually chronic postprandial abdominal pain (intestinal angina) accompanied by weight loss.

With cardiogenic or hypovolemic shock, blood is shunted away from the mesenteric circulation and this process is exacerbated by the following local vasoconstriction. Pain in patients with nonocclusive mesenteric ischemia is usually not as sudden as that with embolic or thrombotic occlusion. Moreover, pain is more difficult to assess because many of these patients are hospitalized in intensive care units for life-threatening conditions.

Patients with venous thrombosis commonly complain of nausea, vomiting, diarrhea, and non-localized abdominal pain.

B. Laboratory Findings

There are no laboratory tests that are diagnostic for AMI. In most cases, the white blood cell count is elevated, as are lactic acid, amylase (50% of patients), and creatine kinase (BB isoenzyme) levels correlating with intestinal infarction. Significant metabolic acidosis is usually present.

C. Imaging Studies

Abdominal radiographs are not diagnostic, but can reveal late signs consistent with bowel ischemia, such as gas in the bowel wall or the portal venous system, and free air in the peritoneum.

Duplex ultrasonography plays a limited role in the diagnosis of AMI, given accompanying ileus with air and gas-filled loops of bowel. Moreover, it cannot assess distal mesenteric blood vessel flow and nonocclusive etiology of ischemia.

Angiography is considered the gold standard for diagnosis for acute embolic and acute thrombotic arterial mesenteric ischemia. Angiography should include both AP and lateral views of the celiac artery, the SMA and the inferior mesenteric artery. By selective injection of contrast into the SMA, emboli and thrombi can be identified, whereas patients with nonocclusive mesenteric ischemia typically exhibit evidence of SMA vasospasm. During the same procedure, catheters can be positioned selectively for treatment. Angiography is significantly less useful for the diagnosis of mesenteric venous thrombosis compared to CT scan.

Both CT and magnetic resonance angiography (MRA) have undergone significant advances over the past 10 years. Multislice helical CT scan with three-dimensional spatial resolution of the vascular anatomy allows rapid evaluation of atherosclerosis of the aorta and mesenteric vessels, the status of the small bowel wall, and identifies other causes of abdominal pain, such as pancreatitis, bowel perforation, bowel obstruction, and rupture of abdominal aortic aneurism. Nevertheless, it still has some limitations: while the origins of the main abdominal vessels are well-visualized, secondary, tertiary, and smaller branches are less well defined compared to angiography. On the contrary, CT is diagnostic for venous thrombosis and is the preferred diagnostic imaging modality in patients with a suspected mesenteric venous thrombosis.

One of the main advantages of MRA has is the use of gadolinium which is significantly less nephrotoxic than the contrast utilized for CT scan. However, this diagnostic imaging modality is not widely used due to the lack of access in many institutions.

► Differential Diagnosis

Acute pancreatitis, intestinal obstruction, aortic dissection, and cholecystitis are the most frequent pathologies that mimic the clinical presentation of AMI.

► Treatment

Once the diagnosis is made, fluid resuscitation, antibiotics, and anticoagulants or drugs that inhibit platelet aggregation should be started.

The treatment consists of nonsurgical and surgical options depending on the underlying cause.

The goals of surgery are to restore blood flow when feasible and resect the segments of bowel that are no longer viable. Because the appearance of ischemic bowel may improve dramatically after restoring blood flow, the small bowel should be observed for at least 30 minutes after reperfusion before any decision for resection is undertaken.

For acute SMA embolism, the standard treatment is a laparotomy and embolectomy, with a catheter passed under direct vision into the arterial segment in order to dislodge and retrieve the embolus. Nonsurgical treatments include catheter-directed thrombolytic therapy to treat early acute embolic occlusion in selected patients who present with a partially occluding embolus in the SMA and do not exhibit peritoneal signs on physical examination.

Surgical treatment of acute thrombotic mesenteric occlusion consists of an antegrade or retrograde bypass because a simple thrombectomy usually leads to reocclusion. Revascularization with saphenous vein or prosthetic graft (in the absence of peritonitis) is the most common procedure. Angioplasty can be performed during diagnostic angiography to dilate stenotic lesions; however, clinical findings suspicious for peritonitis frequently make a laparotomy necessary.

In case of nonocclusive mesenteric ischemia, the treatment requires reversal of the underlying causes of the hypoperfusion. Local infusion of vasodilators using selective catheterization of the SMA may also play a role.

Treatment of mesenteric venous thrombosis is nonsurgical and relies on anticoagulation to reverse the hypercoagulable state. Full anticoagulation with heparin is needed with careful monitoring for gastrointestinal bleeding. Long-term oral or subcutaneous anticoagulation therapy is then begun. Exploratory laparotomy is mandatory when clinical conditions worsen and bowel infarction is suspected.

Finally, second-look laparotomy within 24-48 hours is a key point in the management of patients with AMI who require extensive bowel resection during the first operation or have areas of marginally viable bowel after revascularization.

► Prognosis

The prognosis of AMI is poor because diagnosis and treatment are often delayed, infarction is extensive, and arterial reconstruction is difficult. Perioperative mortality rates range from 32% to 69%, and 5-year survival ranges from 18% to 50%. Mortality varies substantially according to the cause of AMI, being lower in cases of venous thrombosis than in cases of arterial origin. The only way to reduce the morbidity and mortality associated with this disease is early diagnosis and treatment, before bowel necrosis develops.

SHORT BOWEL SYNDROME

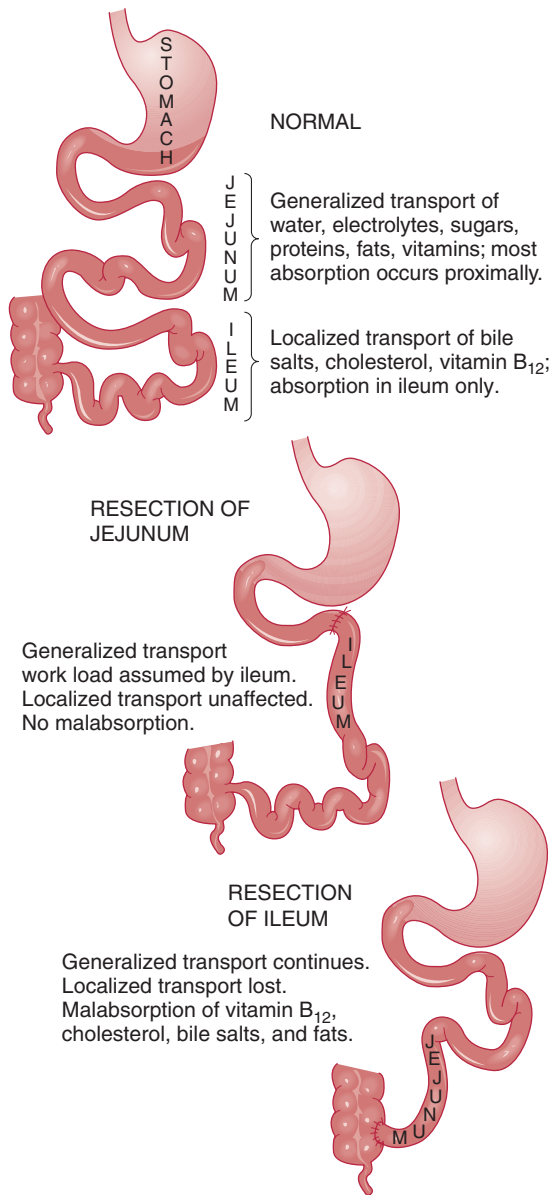

► General Considerations

Maintenance of adequate nutrition is dependent on the normal digestive and absorptive function of small bowel mucosa. A normal, healthy adult possesses an excess of gut mucosa such that limited resection is well tolerated. However, this depends on the amount of bowel removed and the specific level of resection, the presence or absence of the colon, the absorptive function of the intestinal remnant, adaptation of the remaining bowel, and the nature of the underlying disease process and its complications (Figure 29-5). Symptoms can ensue following surgery, in some cases leading to a condition known as “short bowel syndrome.” Because of the important functional capacities of the duodenum in iron and calcium absorption, and of the distal ileum in regard to vitamin B₁₂ and bile salts, resections of these specific regions tend to be poorly tolerated. In contrast, up to 40% of the mid-small bowel can be removed with only moderate clinical sequelae. As a general rule, resection of 50% of the small bowel produces significant malabsorption, and if 70% or more of the bowel is resected, survival is threatened. Clinical results in treating short bowel syndrome have improved in recent decades due to recognition of its pathophysiology, improved surgical techniques, and better enteral and parenteral nutritional support.

The most common etiology of short bowel syndrome is a massive resection occurring in the setting of AMI. In children, volvulus of the intestine caused by congenital malrotation can also result in the need for a large resection. Less commonly, patients with neoplasms, trauma, or recurrent Crohn disease develop short bowel syndrome.

The minimal amount of small bowel required to sustain life is variable, but in general survival is threatened in patients with less than 60 cm of intestine beyond the duodenum. Patients with short bowel syndrome have impairment in the absorption of water and electrolytes as well as that of all nutrients (fat, protein, carbohydrates, and vitamins). The colon is vitally important for preventing water loss. In addition, the colon plays an important role in nutrient assimilation by absorbing short-chain fatty acids. The ileocecal valve delays transit of enteric content from the small bowel into the colon, thereby prolonging the contact time between nutrients and the small bowel absorptive mucosa.

Important adaptive changes occur in the remaining intestine following massive resection. In addition to mucosal hyperplasia, there is generally seen to be an increase in the caliber of the remaining small bowel, perhaps adding to the absorptive area. From a functional point of view, the amount of fluid and electrolytes losses following massive resection decrease over time, whereas glucose absorption increases.

▲ **Figure 29-5.** The consequences of complete resection of jejunum or ileum are predictable in part from the loss of regionally localized transport processes.

Short bowel syndrome is associated with gastric hypersecretion that persists for 1-2 years postoperatively, likely related to loss of the “ileal brake,” a mechanism by which luminal fat within the distal small bowel inhibits gastric secretion. The increased acid load delivered to the

duodenum inhibits absorption by a variety of mechanisms, including the inhibition of digestive enzymes, most of which function optimally under alkaline conditions. Loss of the terminal ileum also results in impairment in the absorption of conjugated bile salts and fat. With limited ileal resections, an increase in the bile salt load to the colon can cause direct injury to the mucosa and resultant diarrhea. With an ileal resection greater than 100 cm, there is a gradual loss in the total bile salt pool, eventually leading to impairment in fat absorption and the onset of steatorrhea. Ileal resections are also associated with lithogenic bile, such that gallstone formation is seen in approximately 30% of patients who have undergone such surgery. Calcium oxalate urinary tract calculi form in 7%-10% of patients who have extensive ileal resection and an intact colon, due to excessive absorption of oxalate from the colon.

► Treatment

Initial therapy involves maintenance of fluid and electrolyte balance. Total parental nutrition is often indicated and, depending on the extent of resection, may be required throughout the lifetime of the patient. It is likely that even small amounts of enteral nutrition are beneficial; however, because the luminal nutrients appear to enhance the adaptive response of the remaining gut. Various anti-diarrheal and stool-bulking agents have also been used with some benefits. Gastric hypersecretion should be treated with either H₂-blockers or proton pump inhibitors. Cholestyramine may be beneficial in patients with limited ileal resections, but if the bile salt pool has been depleted, then cholestyramine is contraindicated. The efficacy of intensive medical management, including maintenance of oral hydration, along with a combination of a high-fiber diet, growth hormone and glutamine is controversial.

The surgical treatment of patients with short bowel syndrome has been disappointing. Various procedures including intestinal lengthening, reversal of short segments, and placcation of excessively dilated bowel have been attempted. Although some improvement has been seen in isolated cases, such operations are not widely performed. The results of small bowel transplantation have also been disappointing because of the high rate of rejection. However, more recent experience with small bowel transplantation suggests that this may become a viable surgical alternative in patients with short bowel syndrome.

INTESTINAL DIVERTICULA

► General Considerations

Small bowel diverticular disease is an uncommon clinical entity. However, with progressive aging of the general population, small bowel diverticulosis is encountered more often. Overall, the frequency reported in the literature of small bowel diverticula varies with the anatomic location of the disease and the type of investigation used for diagnosis. Clearly, autopsy series report a higher incidence, since small bowel diverticulosis is usually asymptomatic and is found often upon post mortem examination only.

A. Etiology

Diverticular disease of the small bowel is generally classified into two groups: the more common, acquired form and the congenital form which is somewhat rare, other than Meckel's diverticulum in the distal ileum. Primary acquired small bowel diverticula result from the herniation of the mucosa and submucosa through the muscular layer of the bowel wall. These lesions are considered to be false diverticula, with no muscular wall covering. Patients with small bowel diverticula frequently have associated diverticular disease of the colon, diverticula of the esophagus (2%), stomach (2%), or urinary bladder (12%).

In the pathogenesis of small bowel diverticulosis, abnormalities of the myenteric plexus with consequent motor dysfunctions of the small intestine are thought to play a major role. These motility disorders vary in severity and magnitude from localized dysmotility to universal jejunoileal dyskinesia that result in increased intraluminal pressure and ultimately herniation of the mucosa and submucosa through the muscular wall of the small bowel. Usually, diverticula occur where the paired blood vessels penetrate the small bowel wall at the mesenteric site.

In contrast, congenital diverticula are usually considered true diverticula involving the full thickness of the small intestine. Congenital diverticula are often limited to the duodenum (wind-sock diverticulum) and ileum (Meckel diverticulum). Both acquired and congenital diverticula are usually asymptomatic, however, symptoms can originate from small bowel diverticula owing to diverticulitis, perforation, obstruction, or hemorrhage.

B. Duodenal Diverticula

Acquired diverticula are extra-luminal and are a fairly common incidental finding usually visualized either upon esophagogastroduodenoscopy (EGD), endoscopic retrograde cholangiopancreatography (ERCP), or by barium swallow and small bowel follow through. Incidences vary significantly in the literature depending on the diagnostic modality used. In the ERCP literature, incidences up to 23% have been reported, usually increasing with advancing age.

In terms of location, these diverticula are generally located within 2 cm of the ampulla. This is an area of weakening of the duodenal wall mucosa, especially around the papilla of Vater, due to the configuration and orientation of the smooth muscle fiber and the sphincter mechanism of Oddi. If the papilla is involved or included in these diverticula, sphincter dysfunction may lead to biliary dyskinesia, formation of biliary stones, cholangitis, and even pancreatitis. Acquired diverticula are also present in the third and fourth portion of the duodenum with decreasing frequency.

Usually, these diverticula are asymptomatic. Symptoms, when present, often are caused by either dysfunction of the sphincter of Oddi or, when the diverticula are significantly large, by obstruction of the biliary and pancreatic ducts due to external compression. Recurrent episodes of pancreatitis potentially evolving into chronic pancreatitis and formation of biliary stones have been reported in patients with large duodenal diverticula. Furthermore, large diverticula can cause bacterial overgrowth resulting in malabsorption and anemia. Diverticulitis with potential perforation and bleeding from duodenal diverticula has been reported.

Diagnosis is often obtained by EGD or ERCP. An upper GI with a small bowel follow through is also very helpful in localizing the diverticula and in defining the size of it. When a perforation is suspected, CT scan of the abdomen with oral and IV contrast can accurately define the location of the diverticula and the extent of the inflammatory reaction to the diverticular perforation.

Surgical treatment of duodenal diverticula is complicated by significant morbidity and mortality, therefore a prophylactic resection of an asymptomatic duodenal diverticulum is not routinely recommended. In the presence of perforation or bleeding, a generous Kocher maneuver should be performed in order to identify the posterior aspect of the duodenum. It is very important at this stage of the procedure to have a clear idea of the relationship of the biliary and pancreatic ducts with the ampulla in order to avoid an injury that will be extremely difficult to repair in this setting and location. If the pancreatic and biliary structures are not involved with the diverticulum, in the absence of significant retroperitoneal contamination, a primary excision of the diverticulum is indicated. The resulting defect should be closed in two layers using absorbable suture for the inner layer and non-absorbable suture for the outer layer. With a large duodenal defect, a serosal patch technique using a defunctionalized loop of jejunum is a useful alternative. However, in the presence of significant edema and contamination, primary closure around a T-tube with drainage of the surrounding area may be the only solution. In extreme cases, duodenal diverticulization by gastrojejunostomy with a stapled closure of the pylorus may be necessary. A large diverticulum in the third or fourth portion of the duodenum requires mobilization of the distal duodenum with excision and primary closure. In this area, the relationship with the

biliary and pancreatic duct is not obviously as crucial and therefore, a more aggressive approach can be undertaken.

C. Jejunoleal Diverticula

The acquired forms of jejunoileal diverticula are usually more common in the proximal jejunum decreasing in frequency throughout the small bowel. Extreme forms of diffuse diverticulosis of the small bowel have been reported. It is a disease of advanced age and is prevalent during the seventh decade of life. These diverticula are located on the anti-mesenteric border of the small bowel. Due to primary motility disturbances of the small intestine, these patients usually present with chronic abdominal pain, early satiety, and different gastrointestinal conditions, such as diarrhea, malabsorption, steatorrhea, Vitamin B₁₂ deficiency, and anemia. These patients can present with an acute abdomen in the presence of a free perforation secondary to diverticulitis. Bleeding is also one of the possible complications and localization of the bleeding diverticulum, in the presence of diffuse diverticulosis may present a significant diagnostic challenge to the clinician.

Jejunoleal diverticula are usually identified by small bowel follow-through or enteroclysis. CT scan can help in the diagnosis of large diverticula or in the presence of acute diverticulitis or perforation. More recently, the use of capsule or wireless endoscopy has helped the clinician in diagnosing patients with unclear gastrointestinal symptoms and especially patients with recurrent significant GI bleed secondary to diverticular disease. After the initial experimental papers, several human studies, looking at patients with occult gastrointestinal bleeding, have shown capsule endoscopy to be significantly superior to push enteroscopy and preferred by patients undergoing both procedures. Although small bowel diverticular disease is a rare condition, it may be the cause of a lower GI bleed resulting in a diagnostic dilemma. In the presence of acute significant bleeding, angiography should be attempted for localization of the bleeding diverticulum and possible treatment either by vasopressin injection or, in selected cases by super selective embolization. Injection of methylene-blue to help identifying the bleeding diverticulum at the time of exploration is very helpful technique when the bleeding persists despite medical management.

Asymptomatic jejunoileal diverticula are usually treated conservatively. In the presence of localized segments of multiple diverticula, it has been suggested that a resection, even in the absence of symptomatology, might be indicated because the morbidity from a small bowel resection nowadays is much less than the potential complication from acute diverticulitis. This approach has not been validated by any clinical data thus far. In the presence of diverticulitis and perforation, obviously resection and primary anastomosis is indicated. In the presence of bleeding, if the source is localized by either angiography or capsule endoscopy, the

bleeding site should be resected with primary anastomosis. Laparoscopy has been extensively used in the management of this unusual problem.

Woods K et al. Acquired jejunoileal diverticulosis and its complications: a review of the literature. *Am Surg* 2008;74:849.

TUMORS OF THE SMALL BOWEL

► General Considerations

Although the small bowel accounts for 75% of the gastrointestinal length and 90% of its absorptive surface, neoplasms of this organ, both benign and malignant, are relatively rare. They represent less than 10% of all gastrointestinal tumors, 1%-3% of gastrointestinal malignancies and 0.4% of all malignancies.

In recent years, the incidence of two small bowel tumors, lymphomas, and gastrointestinal stromal tumors (GIST), have increased substantially. In the case of primary small bowel lymphoma, the incidence in the United States has nearly doubled in the last two decades, due to the increased numbers of immunocompromised patients and immigrants from developing countries. In the case of GIST, the recognition of the KIT protein (CD117) has changed the way spindle cell tumors of the gastrointestinal tract are classified and has led to an increased awareness and recognition.

Several predisposing conditions associated with small bowel malignancies have been identified: CD, familial adenomatous polyposis, hereditary nonpolyposis colorectal cancer, blind loop syndrome, Peutz-Jeghers syndrome, celiac sprue, neurofibromatosis, and IgA deficiency.

The disproportion between the low incidence of malignant tumors of the small bowel and the size of its surface area suggests a significant sparing from or resistance to the development of malignancy. Several hypotheses, based on experimental animal models, have postulated that carcinogens in the enteric content may be in contact with small bowel mucosa over a limited time due to the relatively rapid transit time or may be in a diluted and less carcinogenic form. The preponderance of small bowel adenocarcinomas in the duodenum suggests a role for bile or pancreatic secretions either as primary small bowel carcinogens or even as simple vectors for unknown carcinogens.

Other specific characteristics of the small bowel microscopic and chemical environment might be responsible for the observed cancer resistance. The limited and metabolically inactive bacterial flora of the small bowel is likely unable to transform procarcinogens into their active metabolites especially in an alkaline milieu. In addition, the proximal small bowel secretes a number of enzymes that detoxify carcinogens.

Finally the presence of a high concentration of B cells and lymphocytes and high amounts of secretory IgA in the distal

small bowel might constitute an effective local immunosurveillance system that prevents carcinogenesis. This theory seems to be supported by the observation that immunocompromised patients have an increased incidence of lymphoma and Kaposi's sarcoma of the distal small bowel.

Dietary risk factors, such as high caloric dietary intake in general and more specifically consumption of red meat, fat, and salt-cured smoked foods have been shown to increase the incidence of small bowel carcinoma in large population based studies. This similarity in risk factors explains the relatively high risk of synchronous or metachronous colorectal cancer in patients with a known small bowel malignancy.

► Pathology

Approximately one-third of primary small bowel neoplasms are benign and two-thirds are malignant. The most common benign tumors are leiomyomas and adenomas; less common lesions include inflammatory polyps, hemangiomas, lipomas, hamartomas (Peutz-Jeghers syndrome), and fibromas. These tumors can occur throughout the small bowel but tend to increase in frequency from proximal to distal, with the exception of adenomas, which occur with the highest frequency in the duodenum.

Adenomas are the most common benign tumors of the small intestine. The duodenum is the most common site of involvement, and the lesion most commonly noted is a villous adenoma. These lesions tend to involve the region of the ampulla of Vater. They may present with obstructive jaundice and are easily diagnosed by upper endoscopy and biopsy. Up to 30 percent of these tumors may have malignant degeneration. The risk of malignant degeneration in a significant proportion of patients poses challenges to treatment planning.

Leiomyomas arise from smooth muscle and can grow both intra- and extraluminally. They can often become very large before causing symptoms. On gross inspection, it is sometimes difficult to distinguish these lesions from their malignant counterparts. This distinction is made histologically with standard criteria including nuclear pleomorphism, increased mitosis and the presence of necrosis although, at times, even histological examination may fail to unequivocally distinguish between benign and malignant histology.

Malignant tumors tend to increase in frequency from proximal to distal, with the exception of adenocarcinomas which are most frequent in the duodenum. Adenocarcinoma is the most common histologic type (45%), followed by carcinoids (30%), lymphomas (15%), sarcomas, and GISTs (10%). Pathologic staging is performed according to the American Joint Committee on Cancer (AJCC) tumor-node-metastasis (TNM) system.

Most small bowel *adenocarcinomas* are solitary, sessile lesions, often appearing in association with adenomas. They are usually moderately to well differentiated and almost

always positive for acid mucin. Most arise in the duodenum: within the duodenum, 15% of these tumors are located in the first portion, 40% in the second portion, and 45% in the distal duodenum. Most of these tumors are sporadic with the exception of the ones originating in the context of familial adenomatous polyposis. Presenting symptoms include epigastric and abdominal pain or discomfort, and possibly jaundice and gastric outlet obstruction, depending on the location of the tumor. These symptoms and the accessibility of the duodenum and proximal small bowel to endoscopic modalities allow a relatively high rate of diagnosis and resectability.

Carcinoid tumors are the most common endocrine tumors of the gastrointestinal system.

In the small bowel itself, carcinoids are the most common distal small-bowel neoplasm. These neoplasms arise from enterochromaffin cells and are characterized by the ability to secrete many biologically active substances, including serotonin, bradykinin, dopamine, histamine, and 5-hydroxyindoleacetic acid (5-HIAA). They tend to be small (< 2 cm) and submucosal in location, with a propensity for multicentricity. The most common classification for these tumors is based on embryologic derivation: foregut (stomach and pancreas), midgut (small bowel 90% or more), and hindgut (colon and rectum). Their presentation depends largely on the hormones elaborated and on the site of origin. Up to 40% of small bowel carcinoids are associated with a second gastrointestinal malignancy and 30% present as multiple synchronous lesions.

The gastrointestinal tract is the most frequent site of extra nodal *lymphoma*: the stomach is the most common site followed by the small bowel and the colon, respectively; within the small bowel, lymphomas parallel the distribution of lymphoid follicles, resulting in the ileum being the most common site of involvement. These tumors may be primary or secondary as a manifestation of generalized involvement of systemic lymphoma. For the diagnosis of primary small bowel lymphomas there must be no peripheral or mediastinal lymphadenopathy, with a normal white cell count and differential, and the tumor must be predominantly in the gastrointestinal tract. When primary, they may be multifocal in as many as 15% of cases. Predisposing conditions include immunodeficiency conditions, CD, and celiac disease.

There are five distinct clinical pathologic subtypes of primary small intestinal lymphoma: the adult Western type, the pediatric type, the immunoproliferative or Mediterranean type, enteropathy associated (celiac sprue) T-cell lymphoma, and Hodgkin's lymphoma. The most common is the adult Western type, occurring in the sixth and seventh decade of life with a male predominance.

Sarcomas make up only 10% of small-bowel malignancies. Overall these tumors are located in the jejunum and ileum, are relatively slow growing, and are locally invasive. Their growth pattern is most commonly extramural and

therefore, they rarely result in obstruction, but sometimes present with free intra-abdominal bleeding. Due to their insidious nature and growth pattern, greater than three-fourths of these tumors exceed 5 cm in diameter at the time diagnosis. The most common histologic subtypes are GISTs, leiomyosarcomas, fibrosarcomas, liposarcomas, and malignant schwannomas and angiosarcomas. Similarly to sarcomas from other anatomic regions, small-bowel sarcomas rarely metastasize to regional lymph nodes. Hematogenous dissemination tends to be the preferred route of distant spread, primarily to the liver, lungs, and bone. Peritoneal sarcomatosis is noted in later stages of the disease.

Malignant *GIST* is now considered the most common sarcoma of the gastrointestinal tract and accounts for about 5% of all small bowel malignancies. Clinical, histopathological, ultrastructural, and molecular-biological findings have made clear that GIST is a completely separate entity from leiomyoma and leiomyosarcoma. It is currently thought that GISTs originate from stem cells that differentiate towards the interstitial cells of Cajal (ICCs). ICCs arise from precursor mesenchymal cells and are the pacemaker cells of the gastrointestinal tract. Both ICCs and GISTs express KIT protein, have similar ultrastructural features, and express the embryonic form of the heavy chain of smooth muscle myosin.

KIT immunostaining has become the gold standard for the diagnosis of GIST and the term “GIST” should apply only to tumors with KIT immunopositivity. In rare situations a GIST maybe immunohistochemically inert, or, after therapy with imatinib mesylate, KIT immunostaining may become negative. Furthermore a minority of GISTs lacks demonstrable KIT mutations, but KIT is nonetheless strongly activated. Such GISTs might contain KIT mutations, which are not readily detected by conventional screening methods, or alternately, KIT might be activated by non-mutational mechanisms. To better characterize these tumors, other markers have been studied: about 60%-70% of GISTs show immunopositivity for CD34, 30%-40 % for smooth-muscle actin (SMA) and around 5% for S-100 protein. None of the latter antigens are therefore specific for GIST, but can help in the differential diagnosis in KIT negative tumors.

► Clinical Findings

A. Symptoms and Signs

The vast majority of patients with benign neoplasms are asymptomatic whereas most of those with malignancies are symptomatic prior to diagnosis. The most common presentation of benign tumors is intermittent episodes of acute crampy abdominal pain associated with intussusception, followed by chronic bleeding with iron deficiency anemia in up to 50% of patients.

Malignant lesions are generally associated with weight loss. Symptoms, when they occur, tend to be vague and

nonspecific. In general, most symptoms can be attributed to the location of the tumor, its rate of growth, and its size. For example, tumors in the duodenum tend to be symptomatic at an earlier stage, presenting with pain, gastric outlet obstruction, or obstructive jaundice, whereas those in the jejunum or ileum may present at a later stage with obstructive symptoms. Obstruction in this setting tends to be progressive, compared to benign lesions, whose obstructive symptoms tend to be intermittent as they relate to episodes of intussusception. Bleeding and perforation (in up to 10%) may also occur, predominantly in lymphomatous lesions, but this can also be a feature of any malignant tumor because of ulceration or necrosis.

Carcinoid tumors produce symptoms secondary to hormone production, including hot flashes, bronchospasms, and arrhythmias. This constellation of symptoms, called carcinoid syndrome, occurs when the liver is not able to metabolize the active substances produced by the carcinoid tumor. This is usually the case when tumors are either bulky or metastatic or their venous drainage bypasses the liver.

B. Laboratory Findings

A high index of suspicion is required due to the lack of specificity of these tumor's signs and symptoms. A correct preoperative diagnosis is made in up to only 50% of patients. Biochemical and hematologic studies are often not helpful. Iron deficiency anemia may be detected with chronic blood loss; elevated liver enzymes may be noted with periampullary lesions or hepatic metastases; elevated 24-hour urinary 5-hydroxyindoleacetic acid can be detected in more than 50% of patients with carcinoid tumors.

C. Imaging Studies

Radiographic-contrast imaging modalities tend to be the most useful in the establishment of the diagnosis. Plain films of the abdomen are generally not helpful and at best may demonstrate nonspecific signs of obstruction or a mass effect. Except for the duodenum and the very proximal jejunum, which can often be evaluated by endoscopy, the diagnosis of small intestinal neoplasms depends on contrast studies such as a small-bowel follow-through or preferably enteroclysis. Small bowel follow-through is still the most commonly used method in the evaluation of small bowel pathology although enteroclysis may be a superior imaging modality.

Computed tomography, ultrasonography, and MRI are complementary to barium studies in the detection of small bowel neoplasms. Abdominal CT has a sensitivity of 50%-80% in detecting the primary small bowel tumors and occasionally plays an important role in differentiating benign from malignant tumors. Additionally CT is valuable in staging malignant tumors (presence or absence of

hepatic metastases) and in providing important information related to local extent (presence or absence of local invasion, mesenteric implants, and metastatic lymph nodes). More recently, the association of multi-detector CT and MRI with small bowel lumen distension (CTE and MRE) has led to a considerable improvement in the diagnosis of small bowel neoplasms. On CTE, small bowel adenocarcinomas may manifest as a discrete tumor mass, a circumferential narrowing with abrupt concentric or irregular edges, or as an ulcerative lesion with adjacent enlarged lymph nodes. Mucosal ulceration is a suggestive feature, which is well depicted by CTE. Jejunal lesions have a tendency for being annular. Usually, only a short segment of the small bowel is involved. The mass itself usually shows moderate and heterogeneous enhancement after intravenous administration of iodinated contrast material. Rarely, adenocarcinoma may present as an aneurysmal dilatation of a small bowel segment, similar to that observed in case of lymphoma. On MR imaging, small bowel adenocarcinomas have morphological features similar to those observed on CT.

On CTE, small GISTs typically present as regular, round, or lobulated masses with homogeneous and relatively marked enhancement after intravenous administration of contrast material, whereas larger tumors are heterogeneous with central necrosis and more prone to extraluminal growth. Due to excellent spatial resolution with multi-detector CT, the submucosal origin of the tumor may be suspected in case of small tumors. The malignant potential of these lesions cannot be stated with certainty on cross-sectional imaging unless metastases are present. In some instances, GISTs may display an aneurysmal pattern similar to that observed in case of lymphoma, so that differentiation between these two entities is difficult. On MR imaging, mesenteric small bowel tumors are usually hyperintense on T2-weighted MR images, with variable degrees of enhancement after intravenous administration of a gadolinium chelate. Because of the lower spatial resolution obtained with MR by comparison with CT, the submucosal origin of the tumor may be difficult to ascertain.

Angiography is rarely helpful in establishing or refining a diagnosis of small-bowel malignancy. In rare cases angiographic demonstration of tumor neovascularity without contrast agent extravasation may be of diagnostic importance in patients with chronic occult bleeding when other diagnostic studies, such as endoscopy and barium contrast have been negative. By contrast, this study is rarely beneficial in localizing bleeding tumors since the vast majority bleeds at a rate considerably below the limit of detection for this technique. Nuclear medicine scan with technetium-labeled red blood cells may identify bleeding sites with blood loss rates as low as 0.1 mL/min.

Fluorodeoxyglucose (labeled with fluorine-18) positron emission tomography (FDG-PET) has been shown to be highly sensitive to assess disease status in patients with

GISTs. FDG-PET is used for preoperative staging, but more importantly to assess response to therapy.

D. Endoscopy

Enteroscopy is now available in a fiber optic form, using conventional endoscopes or in a wireless form. Push enteroscopy is currently the most frequently used endoscopic method for small bowel examination. The endoscope is introduced orally. After traversing the curve of the second part of the duodenum, the enteroscope is straightened to reduce any loops formed in the stomach. The enteroscope is then pushed to the maximum length of insertion. Dedicated push enteroscopes are 2-2.5 m in length and offer the opportunity of taking biopsies when the neoplastic lesion has been identified.

The double balloon (push and pull) enteroscopy system consists of a high-resolution video endoscope with a working length of 200 cm, and a flexible overtube 145 cm long. The inflated balloon on the overtube is used to maintain a stable position while the enteroscope is advanced. The overtube balloon is deflated whilst the enteroscope balloon is inflated, and the overtube is advanced along the distal end of the enteroscope (push procedure). This is followed by the "pull procedure." Both the enteroscope and the overtube are pulled back under endoscopic guidance, with both balloons inflated. This procedure is repeated multiple times to visualize the entire small bowel. Few complications have been reported: post-procedure abdominal pain in up to 20% of patients, pancreatitis, bleeding and small bowel perforation which is more common after polypectomy of large polyps (> 3 cm).

The capsule endoscope is a capsule containing a battery-powered imager, a transmitter, antenna and four light emitting diodes. The imager takes two images per second through the transparent plastic dome of the capsule. The capsule is swallowed and is propelled through the intestine by peristalsis. Images taken by the capsule are transmitted to a battery-powered data recorder worn on a belt. The equipment is removed after 8 hours by which time the capsule has reached the caecum in most of cases. The data from the recorder is then downloaded onto a computer workstation which allows approximately 50,000 images to be viewed as a video. The average reading time of the video images takes between 40 and 60 minutes depending on the experience of the endoscopist. This technique may be affected by two problems: firstly, the presence of dark intestinal contents in the small bowel which may impair visualization of the mucosa, and secondly the rate of gastric emptying and small bowel transit which could lead to the exhaustion of the capsule batteries before the capsule reaches the ileocecal valve. Incomplete examination occurs in 10%-25% of cases.

The main risk is capsule retention. Therefore, this procedure is contraindicated in patients with known strictures or swallowing disorders.

E. Laparoscopy

Limited information is available regarding the efficacy of diagnostic laparoscopy in the diagnosis and work-up of small-bowel neoplasms. At present, its usefulness may reside in obtaining staging information and determining resectability prior to formal laparotomy in the case of tumors of the duodenum, and in obtaining images and potentially tissue diagnoses when other imaging studies have failed to suggest an etiology. It is clear, however, that despite the currently available technology, the diagnosis of these tumors is difficult to establish preoperatively in a significant group of individuals. Laparotomy is often required for definitive diagnosis.

► Staging Classification

Radiological staging is mainly based on the use of CT and MRI. Intraoperative assessment plays a role in clinical staging. Metastatic involvement of the liver may be further evaluated by intraoperative ultrasonography. As far as pathologic staging, the TNM staging system has been recently revised by the AJCC, but no major changes have been implemented for small bowel neoplasms. The primary tumor is staged according to its depth of penetration and the involvement of adjacent structures or distant sites. There is no subdivision within the N category based on the number of nodes involved with tumor. Hematogenous metastases or peritoneal metastases are coded as M1. Cancers of the small intestine can metastasize to most organs, especially the liver, or to the peritoneal surfaces. Involvement of the celiac nodes is considered M1 disease.

For small bowel lymphoma the most commonly used staging system is the Ann Arbor system based on lymphatic and extralymphatic involvement on either side of the diaphragm.

► Treatment

Treatment of *adenocarcinoma* of the small intestine with localized disease is based on oncologic and anatomic principles. For duodenal lesions the availability of endoscopic ultrasound has allowed better preoperative staging and the availability of endoscopic resection techniques has offered additional therapeutic options. Ultrasound proven benign duodenal or ampullary adenomas can be resected endoscopically with excellent results. Invasive lesions of the first and second portion of the duodenum without major vessel involvement and distant spread are best treated by a pancreaticoduodenectomy (Whipple procedure). For tumors in the third or fourth portion of the duodenum segmental resection with regional lymphadenectomy is indicated. Debate persists about the optimal surgical management of early duodenal cancer. Although early reports suggest that an endoscopic approach could be justified in early favorable lesions,

long-term follow-up is still lacking and surgical resection is to be preferred in the good-risk patients. Palliative options for unresectable or metastatic duodenal carcinoma include gastrojejunostomy and/or biliary enteric bypass or endoscopic/interventional placement of stents to relieve the intestinal and/or biliary obstruction.

Adenocarcinoma of the jejunum and ileum is treated by wide excision, including areas of contiguous spread and the associated mesentery, with negative surgical margins.

Although only small series have been published, these tumors do not seem to respond to the conventional 5-FU based chemotherapy regimens and there is a radiation dose limitation due to small bowel toxicity. However, for palliation of chronic blood loss in patients with locally advanced unresectable duodenal carcinomas radiotherapy may provide short-term benefit.

The mainstay of therapy for *carcinoid* tumors is radical surgical excision. In preparation for surgery a complete assessment of the entire gastrointestinal tract is warranted since up to 40% of midgut carcinoids are associated with a second gastrointestinal malignancy and 30% present with multiple synchronous lesions. In addition, preemptive treatment with octreotide is indicated to prevent carcinoid crisis at the time of surgery. At surgery, wide en block resection including the draining mesentery is the standard approach. This is particularly true for small bowel carcinoid, because these lesions have the propensity to metastasize even when very small. Large lesions near the ampulla may require a pancreaticoduodenectomy for cure, while smaller lesions may be treated with either local excision or endoscopic resection with close endoscopic follow-up. Likewise lesions of the terminal ileum or carcinoid tumors of the appendix larger than 2 cm require a formal right hemicolectomy for oncologic clearance of disease.

Treatment for advanced locoregional and distant disease includes both medical and surgical modalities. Surgery should be indicated in patients with resectable metastatic disease for potential cure or at least meaningful palliation. Orthotopic liver transplantation has been used in the treatment of metastatic neuroendocrine tumors to the liver, with discouraging results.

The role of multimodality therapy, including alpha2b interferon and octreotide, for metastatic carcinoid remains limited. The addition of liver chemoembolization has not been shown to have a significant effect on survival in patients with metastatic disease to the liver but may have a role in controlling or decreasing the symptoms associated with carcinoid crisis. Octreotide has been effective in the treatment of patients with carcinoid syndrome by improving diarrhea in up to 83% of the patients and abolishing flushing and wheezing, but has no effect on survival. In consideration of the slow growth rate of many carcinoid tumors, patients with distant metastatic disease can also undergo resection for debulking and palliation of symptoms. For those

patients with extensive unresectable disease, the indications for surgical intervention are limited to the occurrence of obstruction, perforation and bleeding. Radiation therapy has not been proven to be effective in either the adjuvant or palliative setting.

Treatment of small bowel *lymphoma* requires conservative resections with para-aortic and mesenteric lymph node sampling, liver biopsy and bone marrow biopsy performed for staging. Low-grade localized lesions are treated with resection alone, while for intermediate and high-grade lesions resection and chemotherapy is recommended. Radiation is used only for palliation in poor performance patients. This modality is associated with significant side effects, such as bowel necrosis, bleeding and perforation, and is offered for palliation only to patients unfit for surgery or chemotherapy.

Surgical treatment for small bowel *sarcomas* consists of an *en block* resection with tumor free margins. There is no role for extended lymphadenectomy in these tumors. Hematogenous dissemination is the preferred route of metastatic spread to the liver lungs and bones. Carcinomatosis is noted in later stages of the disease. In the presence of metastatic disease, local excision or palliative bypass procedure might be indicated to prevent or ameliorate bleeding and obstruction. Furthermore there is no clear benefit from chemoradiation therapy in the adjuvant setting, since radiation doses are limited due to small bowel toxicity. In the presence of recurrent or metastatic disease partial response rates after palliative chemoradiation therapy have been reported in the 10%-20% range, with minimal improvement in survival at best.

Treatment of localized GISTs is based on surgical resection: the tumor should be removed *en block* with its pseudocapsule and margins of normal soft tissue or bowel. In the presence of large lesions involving other organs, where an *en block* resection may be associated with significant morbidity, preoperative neoadjuvant use of imatinib mesylate may be entertained.

A significant breakthrough in the management of small bowel tumors and specifically GISTs has come from the understanding of the molecular and genetic makeshift of these lesions. After the discovery that GISTs characteristically express the KIT protein, a transmembrane tyrosine kinase receptor for a stem cell factor, a specific tyrosine kinase inhibitor, imatinib mesylate (Gleevec, Novartis), has been introduced in clinical practice with reduced risks of recurrence.

The role of surgery for recurrent or metastatic disease has been questioned since the introduction of imatinib mesylate. Surgery should still be considered in patients with bleeding or obstructive disease and after partial response to imatinib mesylate if the residual disease is deemed to be resectable.

► Prognosis

Prognosis for small bowel *adenocarcinoma* is based on similar variables as for colorectal cancer, including stage, perineural and vascular invasion, grade, resectability, and surgical margins. The majority of tumors have regional spread at time of diagnosis, and up to one-fourth of patients have distant organ disease. Overall, the 5-year survival rate is 20%-30%. For resectable disease of the duodenum, the 5-year survival rate approaches 50%.

The prognosis for *carcinoid* tumors with localized disease is excellent with 5-years survival rates approaching 100% after resection. More than 90% of the symptomatic patients have metastatic disease at the time of surgical exploration. The likelihood of distant disease correlates closely with both the size of the primary lesion and the depth of invasion. For tumors less than 1 cm in size, the risk of lymph node metastases is on the order of 2%; for 1-2 cm lesions, there is an approximate 50% incidence of lymph node involvement; and 80% of tumors greater than 2 cm have positive nodes. Survival rates of up to 68% at 5 years have been reported when all gross metastatic disease, including hepatic metastases, is resected. For extensive unresectable disease, debulking has proven to be of some benefit in terms of symptomatic palliation. The 5-years survival for unresectable disease is approximately 35%-40%, reflecting the relatively indolent growth of these tumors.

Prognostic factors for primary small bowel *lymphomas* include higher grade, greater depth of tumor penetration, lymph node involvement, peritoneal disease and distant metastases. Overall 5-year survival rates range from 20% to 40% for all stages. Five-year survivals of up to 60% have been reported for patients with resected localized low-grade tumors.

Sarcomas tend to have an insidious growth pattern and greater than three-fourths of these tumors are larger than 5 cm at the time of diagnosis and up to 50% of them are not resectable for cure when the diagnosis is established. Prognosis correlates most closely with grade, followed by stage. Five-year survival after curative resection ranges from 60% to 80% for low-grade tumors and is no more than 20% for high-grade lesions.

Assessment of the malignant potential of a primary *GIST* lesion is difficult in many cases unless tumor spread can be documented beyond the organ of origin at the time of diagnosis. Historically, size has been used to assess tumor behavior. While almost all small (< 1 cm) GISTs are clinically benign and tumors larger than 5 cm in diameter are generally malignant, intermediate size GISTs have uncertain malignant potential and no cut-off diameter predicts subsequent malignant behavior with certainty.

Other factors, which have shown prognostic value, include mitotic rate, presence of tumor necrosis, high cellularity, and pronounced pleomorphism; a high S-phase fraction and

DNA aneuploidy in flow or image cytometry; a high Ki-67 score; proliferating-cell nuclear-antigen expression; presence of telomerase activity, incomplete surgical resection, tumor rupture at surgery and invasion of adjacent structures.

Recently *KIT* mutations have been shown to be an independent prognostic factor for patients with GISTs.

The median disease-specific survival is about 5 years for primary disease, and 10-20 months in recurrent or metastatic disease. Most recurrences take place within 5 years of the primary diagnosis, but in the slowly proliferating subset of GISTs and especially after therapy with imatinib mesylate, metastases can appear more than 10 years after the primary diagnosis.

The outcome of patients with *metastatic malignancies* to the small intestine (more commonly ovarian, colon, lung cancers, renal cell carcinoma, and melanoma) is dismal despite palliative therapeutic intervention.

► Follow-up

Routine follow-up for small bowel cancers is accomplished with endoscopy and radiologic imaging. The only exception is GIST. As previously discussed, PET scan is used to follow tumor response to imatinib mesylate; to detect recurrence after either complete response to imatinib mesylate or after curative surgery; to identify secondary resistance to imatinib mesylate before tumor progression on treatment.

MULTIPLE CHOICE QUESTIONS

- The most common cause of small bowel obstruction is
 - Intra-abdominal adhesions
 - Neoplasms
 - Intussusception
 - Crohn's disease
- The treatment of small bowel obstruction includes
 - Nasogastric suction
 - Fluid and electrolyte resuscitation
 - Laparoscopic adhesiolysis in highly selected case
 - All of the above
- One of the following sentences about acute mesenteric ischemia is wrong:
 - The most common cause is the arterial embolism.
 - Thrombosis of mesenteric veins is often associated with portal hypertension.
 - Deep venous thrombosis can be a cause.
 - Abdominal pain is the main clinical finding.
- Which sentence about small bowel tumors is correct?
 - Adenomas are more common in the distal ileum.
 - The most common neoplasm is GIST.
 - Peutz-Jeghers syndrome has a very high malignant potential.
 - Carcinoid syndrome develops in the presence of liver metastases.
- Which is the most common intestinal fistula in patients with Crohn's disease:
 - Ileosigmoid
 - Ileovesical
 - Ileocutaneous
 - Ileovaginal

Madhulika G. Varma, MD

ANATOMY

The colon begins at the ileocecal valve and ends at the rectum, spanning 140 cm (5 feet) in length. The colon has both intraperitoneal and retroperitoneal components. The cecum, ascending, and descending colon are retroperitoneal, whereas the transverse colon and sigmoid are intraperitoneal (Figure 30-1). The diameter of the lumen is greatest at the cecum (~ 7 cm), and decreases distally. As a result, mass lesions of the cecum are least likely to cause obstruction and the thin wall of the cecum is most vulnerable to ischemic necrosis and perforation from large bowel obstructions. There are four layers of the wall—mucosa, submucosa, muscularis propria, and serosa (Figure 30-2). The mucosa is composed of three layers—a simple columnar epithelium organized to form crypts, lamina propria, and muscularis mucosa. The submucosa is the strength layer of the colon because it has the highest concentration of collagen. Therefore, this layer is especially important to incorporate during anastomoses. The muscularis propria is composed of an inner circular layer and an outer longitudinal layer that thickens into three bands around the circumference to form the taenia coli. The appendix can be found at the point on the cecum where the taenia converge. At the rectosigmoid, these bands fan out to form a uniform layer, marking the end of the colon and the beginning of the rectum. The forces of these muscular components of the wall result in shortening of the colon to form sacculations called haustra (Figure 30-3). These are not fixed structures, but can be observed to move longitudinally. The appendices epiploicae are fatty appendages on the serosal surface.

The rectum begins at the sacral promontory and ends at the anorectal ring. It lies between the colon and the anus and is 12-16 cm in length. There are no taeniae as the longitudinal muscle fans out and encompasses the circumference of the rectal wall. The rectum can be further differentiated

from the colon by its lack of appendices epiploicae and haustra. The rectum is both an intra- and extraperitoneal organ. Posteriorly, the rectum is only intraperitoneal at the level of the rectosigmoid. However, the anterior and lateral walls of the upper rectum are intraperitoneal. The anterior peritoneal reflection extends low into the pelvis, approximately 5-8 cm above the anal verge and lies between the rectum and the bladder in men and uterus in women (the Pouch of Douglas). Tumors or abscesses in this location can be palpated on digital rectal or vaginal examination. Denonvilliers fascia envelops the anterior wall of the rectum. Beyond the anterior peritoneal reflection lie the seminal vesicles and prostate gland in men. In women, the cervix and rectovaginal septum lie anteriorly and the adnexa anterolaterally. The rectum has three major mucosal folds called the valves of Houston. They are variable in location, but classically occur every 3-4 cm. The superior and inferior folds are on the left and the middle fold is on the right. The middle fold marks the distal extent of the intraperitoneal rectum.

The pelvic floor is made of three muscles—the pubococcygeus, iliococcygeus, and puborectalis collectively known as the *levator ani*. The puborectalis forms a sling at the anorectal junction and is an important component of continence and the defecation mechanism.

► Blood Supply & Lymphatic Drainage

The arterial supply of the colon is dictated by its embryological origin. The foregut, which extends to the distal transverse colon, is supplied by the superior mesenteric artery (SMA) through the ileocolic, right colic, and middle colic arteries. The hindgut, which includes the distal transverse colon to the rectum, is supplied by the inferior mesenteric artery (IMA). This gives off the left colic, 2-6 sigmoid branches, and terminates as the superior rectal (hemorrhoidal) artery. The middle and inferior rectal (hemorrhoidal) arteries

▲ **Figure 30-1.** The large intestine: anatomic divisions and blood supply. The veins are shown in black. The insert shows the usual configuration of the colon.

▲ **Figure 30-2.** Cross-section of colon. The longitudinal muscle encircles the colon but is thickened in the region of the taeniae coli.

originate from the internal iliac artery. There is redundancy in the arterial circulation via the meandering mesenteric artery (Arc of Riolan) as well as the marginal artery of Drummond, which is a network of arterial branches that runs the length of the colon approximately 2.5 cm from the bowel wall. The vasa recta are the terminal arteries arising from the marginal artery. These penetrate the colon wall in multiple areas on the mesenteric side, creating focal areas of weakness that have the potential to form false diverticula. The left colic, sigmoid, and superior rectal branches also originate from the IMA in a variable pattern. The venous drainage generally follows the arterial supply with the exception of the inferior mesenteric vein, which runs lateral to the ligament of Treitz to join the splenic vein. The vascular supply too is highly variable, and “normal” anatomy is found in only 15% of individuals.

The lymphatics drain via continuous plexuses in the submucosal and subserosal layers of the bowel wall. These continue on to the mesenteric lymphatic channels and nodes that accompany the blood vessels, which explain why standard planning for oncologic resections of the colon and rectum is based on the vascular supply.

▲ **Figure 30-3.** Barium enema of normal colon. Note the appearance of haustra and the location of the splenic and hepatic flexures.

► Nerve Supply

The nerve supply to the colon and rectum is autonomic and, like the blood supply, is divided according to embryologic development. Sympathetic nerves to the midgut, including the right and proximal transverse colon, originate in T6-12. These synapse in the superior mesenteric plexus and then follow the SMA and its branches to the right colon. The vagus nerve provides parasympathetic fibers to the midgut. Sympathetic innervation to the hindgut (distal transverse colon to the rectum) arises from L1-3. These sympathetic fibers synapse in the preaortic plexus and then follow the IMA to the bowel wall. Nervous impulses to the bowel wall synapse in the myenteric (Auerbach's) plexus and submucosal (Meissner's) plexus. The myenteric plexus is located in between the circular and longitudinal layers of smooth muscle and is responsible for coordinating motility. The submucosal plexus (Meissner's plexus) is located in the submucosa and regulates secretions, blood flow, and absorption.

The distal rectum and anus is innervated by the hypogastric nerves and the nervi erigentes. The hypogastric nerves are sympathetic fibers that originate from L1-3. These fibers course over the sacral promontory to the hypogastric plexus and form the paired hypogastric nerves near the root of the

IMA. The parasympathetic fibers run in the nervi erigentes, which arise from S2-4 and join the hypogastric nerves near the lateral rectal stalks. The fibers continue anterior and laterally to innervate the rectum, pelvic floor muscles, and bladder, as well as the prostate and seminal vesicles in men. The location of these nerves makes them prone to injury during proctectomy. The superior hypogastric plexus is at risk during high ligation of the IMA, the hypogastric nerves are at risk during retrorectal dissection, the inferior hypogastric plexus and nervi erigentes are at risk during mobilization of the lateral stalks, and the periprostatic plexus is at risk during dissection of Denonvillier fascia. Injury to these nerves during proctectomy can cause bladder and sexual dysfunction that is a significant source of postoperative morbidity.

Bleier JI, Maykel JA. Outcomes following proctectomy. *Surg Clin North Am* 2013 Feb;93(1):89-106.

Sakorafas GH, Zouros E, Peros G. Applied vascular anatomy of the colon and rectum: clinical implications for the surgical oncologist. *Surg Oncol* 2006 Dec;15(4):243-255.

PHYSIOLOGY

The primary functions of the colon are absorption, secretion, motility, and intraluminal digestion. These interrelated processes are responsible for converting ileal effluent into semi-solid feces. The rectum functions as a capacitance organ, storing feces produced by the colon and allowing defecation at a convenient time. When surgery or disease results in loss of colonic function, there is a significant increase in intestinal losses of water and electrolytes. If the rectum is overloaded by large volume watery stool or its capacity to distend is lost or impaired by surgery or disease, fecal urgency and frequency are noted.

► Intestinal Gas

Normal volume and composition of intestinal gas has great variation amongst individuals depending on air swallowing, diet, and the composition of the microbial flora. Small amounts of intestinal gas are absorbed through the bowel wall and excreted through the lungs, but the majority (~ 400-1200 mL/d) is discharged as flatus.

Intestinal gas is comprised of nitrogen, oxygen, carbon dioxide, hydrogen, methane, and trace substances such as methyl sulfide, hydrogen sulfide, indole, and skatole. By far, the largest component is nitrogen, which makes up 30%-90% of intestinal gas. Most nitrogen comes from swallowed air, but some also diffuses from the plasma. Fermentation of nonabsorbed carbohydrates such as fiber is responsible for most of the hydrogen and carbon dioxide in gas. In lactase deficient individuals, lactose fermentation contributes as well. Methane is produced by specific hydrogen reducing bacteria (*Methanobrevibacter smithii*) and is only present

in 30% of people. Both methane and hydrogen gases are explosive and require caution when using cautery in the bowel lumen.

Patients reporting crampy abdominal pain, bloating, and increased flatus may be suffering from increased gas production. Overproduction may be a result of a malabsorptive state and eliminating lactose, legumes, and/or wheat in the diet may be of help.

► Absorption & Secretion

The colon is primarily an absorptive organ. The absorptive capacity is greatest in the cecum and ascending colon and decreases distally. Most nutrients are absorbed in the small bowel; however, when enteric contents reach the colon, they are still rich in water, electrolytes, and some nutrients. Approximately 1-2 L of ileal effluent containing 250 mEq of sodium reaches the cecum every 24 hours. The passive absorption of water and active transportation of sodium allows recovery of more than 90% of the water and sodium content. Every 24 hours, approximately 100-200 mL of water and 2-5 mEq of sodium are excreted in the feces. Table 30-1 gives average values for the composition of ileal effluent and feces. Normal feces are composed of 70% water and 30% solids. Bacteria constitute over half of the solid component. The remaining solids are food waste and desquamated epithelium. Although the absorptive capacity of the colon serves an important role in maintaining homeostasis, it is not essential to life.

This effluent also contains small amounts of nutrients which are absorbed by the colon including fatty acids, amino acids, and vitamin K. Approximately 10% of undigested starch reaches the colon where colonic bacteria fermentation produces short chain fatty acids, which are important both systemically and as a nutrient source for colonocytes.

In addition, the colon is part of the enterohepatic circulation. Bile acids not absorbed in the terminal ileum are passively absorbed in the colon. When this capacity is exceeded,

the remaining bile acids are metabolized by colonic bacteria into urobilin and stercobilin. Urobilin, stercobilin, and their metabolites are responsible for giving stool its brown color.

The colon also serves an important secretory function. It secretes hydrogen, bicarbonate, chloride, and potassium ions. The colon is in communication with the circulation and is able to adjust over a wide range as needed. Pathologic states such as inflammatory bowel disease (IBD), shigellosis, cystic fibrosis, and collagenous colitis cause electrolyte and acid-base disturbances by altering colonic secretion.

► Motility

Colonic motility serves to maximize absorption and move feces distally in preparation for excretion. There are numerous types of motility and these occur with great variation along the length of the colon. Normal movements are slow, variable, and complex and result in nonorganized flow of the fecal stream. In patients with normal bowel function, enteric contents reach the cecum 4 hours after a meal and the rectosigmoid by 24 hours. However, portions of the fecal stream are mixed so that new effluent may bypass old effluent, and residue from a single meal may pass in bowel movements over 3-4 days.

The enteric nervous system coordinates motility. It is increased by physical activity, stress, and diets high in fiber. In addition, the act of eating stimulates colonic transit. The gastrocolic reflex refers to the activation of colonic motor activity in response to a meal. The magnitude is determined by the fat and caloric composition. This increased activity increases ileal and colonic emptying, causing an urge to defecate.

The colon has three distinct patterns of activity that are under control of the enteric nervous system and a postulated pacemaker in the transverse colon. Retrograde peristalsis consists of annular contractions occurring most commonly in the right colon. These contractions work to keep the stool in the right colon and therefore facilitate absorption. As ileal

Table 30-1. Mean values for electrolyte and water balance in the normal colon. A plus (+) sign indicates absorption from the colonic lumen; a minus (–) sign indicates secretion into the lumen.

	Ileal Effluent		Feces		Net Colonic Absorption (per 24 hours)	
	Concentration (mEq/L)	Quantity (per 24 hours)	Concentration (mEq/L)	Quantity (per 24 hours)	Normal	Maximal Capacity
Na ⁺	120	180 mEq	30	2 mEq	+178 mEq	+400 mEq
K ⁺	6	10 mEq	67	5 mEq	–5 mEq	±45 mEq
Cl [–]	67	100 mEq	20	1.5 mEq	+98 mEq	+500 mEq

effluent continues to empty into the cecum, some of the liquid stool flows to the transverse and descending colon, where segmentation predominates. This action consists of random, uncoordinated annular contractions over short segments that propel feces both proximally and distally. Finally, mass movement occurs as a strong coordinated contraction that starts proximally and propels colonic contents distally and occurs in concert with the gastrocolic reflex.

► Bowel Habits

There is a broad range of normal bowel habits that varies across cultures. A cross-sectional study of 20,000 men and women across all age groups in Britain showed an average of 1-1.5 bowel movements per day, which increased with fiber and fluid intake and physical activity.

► Defecation

The urge to defecate is stimulated by rectal stretch in response to feces. This elicits the rectoanal inhibitory reflex which causes relaxation of the internal anal sphincter and allows the rectal contents to be “sampled” by specialized mucosa in the anorectal transition zone. This mucosa contains sensory fibers that can discriminate between flatus and solid and liquid stool. Immediately following this sensory process, the external sphincter contracts and the contents are moved proximally back into the rectum. Flatus and stool can be discharged, if appropriate. If not, the rectum relaxes and the urge to defecate passes. Normal defecation requires regular colonic function, specifically with regards to stool consistency, in addition to coordinated colonic motility, rectal sensation, sphincter function, and pelvic floor relaxation. When the rectum senses presence of feces and the decision is made to defecate, intra-abdominal pressure is increased and the pelvic floor and anal sphincters relax, allowing the rectum to straighten. After elimination of the stool bolus, the sphincters and pelvic floor resume their tone.

► Diarrhea

Diarrhea is defined by the loss of more than 300 mL of fluid per day and chronically affects 5% of the United States population. It can result in severe electrolyte disturbances and dehydration. There are four main etiologies of diarrhea—invasive, secretory, osmotic, and malabsorptive. *Invasive diarrhea* results when enterocytes are destroyed by pathogens such as *Shigella*, *Campylobacter*, and *Entamoeba histolytica*, resulting in low volume loose bowel movements with blood and leukocytes. *Secretory diarrhea* is the result of excessive secretion by colonocytes or enterocytes. This results in high volume, isotonic diarrhea with a low osmotic gap. The primary causes are enterotoxins produced by *E coli* and *Vibrio cholera*, and excessive serotonin secretion in the carcinoid syndrome. *Osmotic diarrhea* occurs when

an osmotically active substance in the bowel lumen draws hypotonic fluid from the circulation. Osmotic diarrhea is characterized by high volume output with a high osmotic gap and no leukocytes. Most commonly, this occurs in patients with disaccharidase deficiencies such as lactose intolerance. *Malabsorptive diarrhea* results from the lack of normal digestive or absorptive processes. Pancreatic insufficiency results in loss of proteolytic and lipase activity causing steatorrhea. Whipple’s disease (caused by infection with *Tropheryma whippelii*) and celiac sprue (autoantibodies to gluten) are characterized by inflammatory changes with loss of absorptive capacity of the small bowel. Surgery can also cause malabsorption. Extensive small bowel or colonic resections compromise the absorptive capacity and may result in diarrhea. A portion of patients undergoing cholecystectomy will also experience transient diarrhea with fatty meals due to the loss of the bile reservoir capacity of the gallbladder and subsequent steatorrhea.

CONSTIPATION

► Epidemiology

Based on an epidemiologic review of the literature, constipation affects 7%-79% of the United States population with a mean of 16%. The wide variation in reports is likely due to broad definitions of constipation including infrequent or hard stools, excessive straining, or incomplete evacuation. Incidence is associated with lower socioeconomic and educational status, non-Caucasian ethnicity, female gender, and increasing age. Low fiber intake is especially important, as it normally bulks stool, triggering colonic motility.

► Etiology

Although idiopathic constipation occurs, changes in bowel habits should prompt a search for a cause. Numerous medications cause constipation, such as opiates, antiemetics (ondansetron), antipsychotics (chlorpromazine, haloperidol, risperidone, clozapine), antihypertensives (calcium channel blockers, atenolol, furosemide, clonidine), as well as over the counter medications such as ibuprofen, calcium, and iron supplements. The patient should be asked about previous laxative use, as rebound constipation may occur in patients with a history of laxative abuse. Constipation can be a symptom of a systemic disease such as hypothyroidism, hyperparathyroidism, diabetes, electrolyte disturbance, or connective tissue disorders. It may result from a primary colonic disorder such as Hirschsprung, endometriosis, and benign or malignant strictures. Neurologic disease or injury, psychiatric illness, and physical or sexual abuse may be contributory.

If none of these factors is present, patients may be suffering from a functional constipation syndrome, such as colonic inertia, irritable bowel syndrome, or pelvic floor

dysfunction. Patients with colonic inertia report lifelong constipation with laxative dependence. Irritable bowel syndrome (constipation subtype) causes irregular bowel habits, bloating, and abdominal pain classically relieved with bowel movements. Patients with pelvic floor dysfunction or obstructed defecation syndrome report incomplete evacuation and excessive straining that is often improved with digital manipulation. They may have coexistent urinary dysfunction, pelvic organ prolapse, and sexual dysfunction.

► Diagnosis

Evaluation for constipation includes a history and physical examination, including review of medications, and digital rectal and anoscopic evaluation. Metabolic etiologies may be ruled out with laboratory tests including TSH, calcium, electrolytes, and blood sugar in the appropriate patient. Anatomic lesions can be identified by colonoscopy. This should be considered in any patient with alarm symptoms (hematochezia, anemia, or weight loss), refractory constipation, and patients who are due for age-appropriate colon cancer screening. Medical therapy with fiber supplementation and laxatives should be tried first. Patients should be encouraged to keep a written record of their bowel habits. In refractory cases, and those in which a functional disorder is suspected, additional testing is indicated.

Anorectal manometry and balloon expulsion test should be considered in severe, refractory cases of constipation where the etiology is not clear and in patients with symptoms of pelvic floor dysfunction. Manometry allows evaluation of the rectoanal inhibitory reflex, sphincter tone, rectal sensation, and coordination. Patients with constipation tend to exhibit a hypertonic internal sphincter with poor squeeze pressures. Electromyography may reveal nonrelaxation or paradoxical contraction of the puborectalis. Balloon expulsion can be performed as an adjunctive study. It involves placing a balloon in the rectum and filling it until the urge to defecate is perceived. The patient is then asked to evacuate the balloon. Normal function is indicated by the ability to evacuate a 50-100 mL balloon in less than 1 minute. This simple test was shown to have 88% sensitivity and 89% specificity for diagnosing defecatory disorders compared with defecography. Defecography (barium, scintigraphic, or magnetic resonance) is useful when the results of manometric testing are not diagnostic.

Colonic transit can be evaluated using radiopaque marker studies. Patients ingest 24 markers and avoid laxatives. An abdominal radiograph is taken on the fifth day with note made of the distribution and number of retained markers. Normal patients will have fewer than five retained markers. In fact, eighty percent of normal patients will have passed all markers by the fifth day. Colonic inertia, a primary disorder of colonic motility, is diagnosed when more than five markers are retained and are scattered throughout the colon.

Obstructed defecation is suggested if markers have accumulated in the rectum. A more detailed examination involves ingestion of radiopaque markers daily for three consecutive days and taking abdominal films on the fourth and seventh days. The number and distribution of retained markers are compared with established normal controls.

► Treatment

Initial treatment of constipation should focus on lifestyle and dietary modification. Physical activity, fluid intake, and consumption of fruits, vegetables, and whole grains are increased. A fiber supplement is started in an effort to soften and bulk the stool. A low dose is recommended at first and slowly increased to the desired effect to minimize bloating and flatulence.

Laxatives, stimulants, and enemas should be used only for short periods of time for treatment of acute discomfort. Osmotic laxatives include lactulose, magnesium hydroxide, sodium phosphate, and polyethylene glycol (MiraLAX). These work by increasing the intraluminal osmolarity, creating a gradient that reduces fluid reabsorption. Magnesium hydroxide should be avoided in patients with renal insufficiency. Polyethylene glycol is one of the most commonly recommended laxatives as it is safe and effective, even for use in the long term. Colonic irritants work by increasing motility. Examples include senna, cascara, and bisacodyl. These medications can be limited by crampy abdominal pain. Long-term use of senna and cascara causes melanosis coli (brown discoloration of the mucosa). Stool softeners such as mineral oil and docusate work by increasing stool fluid retention. Enemas stimulate bowel movements by causing direct rectal stretch and irrigation (saline, soap suds), or softening of the stool (mineral oil). Colonic irritants and enemas can cause reduced colon and rectal motility and should not be used for prolonged periods of time. Lubiprostone, linaclotide, and prucalopride are newer agents indicated for the treatment of refractory idiopathic constipation and constipation-predominant irritable bowel syndrome. They cause increased secretion via activation of chloride channels (lubiprostone and linaclotide) and 5-HT₄ receptors (prucalopride).

Defecatory disorders, as diagnosed by anorectal manometry, are best managed using biofeedback and pelvic floor retraining. Patients can learn to relax and strengthen the pelvic floor muscles and can develop increased rectal sensation awareness. These techniques have been studied in a randomized fashion and have been shown to be superior to medical management.

Selected patients with constipation benefit from surgery if all functional aspects of defecation have already been addressed. If there is pelvic floor dysfunction, this should be first addressed using biofeedback. Surgery is considered if patients have obstructed defecation from mechanical reasons such as rectal prolapse, rectocele, enterocele, or

sigmoidocele may benefit from procedures to address the specific condition. Patients with colonic inertia without pelvic floor dysfunction, irritable bowel syndrome, or diffuse upper gastrointestinal involvement are treated with abdominal colectomy with ileorectal anastomosis. Multiple other approaches, including segmental colectomy and preservation of the cecum have shown conflicting, but overall worse, outcomes. Complications have been reduced with the use of laparoscopic techniques, which have been shown to be safe and effective. The antegrade colonic enema procedure is used more often in pediatric patients. It involves bringing up a piece of bowel (appendix, ileum, cecum, and left colon have been described) to the abdominal wall to allow intermittent catheterization with irrigation of the colon. This technique has been reported in adults with obstructive defecation and neurologic deficits with success. Newer therapies such as sacral nerve stimulation are currently under investigation.

MICROBIOLOGY

The colon of the fetus is sterile but the process of colonization begins immediately after birth. There is marked variation in the composition of the microbial flora between individuals, likely related to genetic, environmental, and dietary factors. Humans have 10 times more bacterial cells in their bodies than human cells, and in fact, bacteria make up 50% of the dry weight of feces. Microbes are present throughout the gastrointestinal tract, and their concentration increases from proximal to distal, with the highest concentrations in the colon and rectum. The majority of colonic organisms are anaerobic, but there is a substantial population of facultative anaerobes. *Bacteroides spp* account for the 60%-70% of the bacterial flora. Other predominant organisms include *Escherichia coli*, *Lactobacillus bifidus*, *Kelbsiella*, *Proteus*, *Clostridium*, *Enterobacter*, and *Enterococcus*. *Methanobrevibacter smithii* is responsible for methane production.

These bacterial populations are instrumental for the health of the colon. They serve a barrier function and maintain epithelial integrity. Fermentation of undigested polysaccharides creates short chain fatty acids that are an important energy source for colonocytes. In addition, bacteria play an active role in the immune function of the gut. Healthy bacterial populations make it difficult for pathogens to establish infection. In addition, normal microbial flora also serves a role in numerous physiologic processes. They deconjugate unabsorbed bile acids, creating the pigments that give stool its characteristic color, synthesize vitamin K for systemic absorption and use, and recycle colonic nitrogen in the form of urea.

DISEASES OF THE COLON AND RECTUM

LARGE BOWEL OBSTRUCTION

General Considerations

Fifteen percent of intestinal obstructions in adults occur in the large bowel and the incidence increases with age. Obstruction can result from actual pathology of the bowel wall including malignancy and strictures, mechanical problems such as volvulus, incarcerated hernia, and intussusception, or intraluminal factors such as fecal or foreign body impaction (Table 30–2). Benign strictures are commonly associated with diverticulitis or IBD, but may occur as a result of ischemia, radiation, or as a result of a surgical anastomosis. Acute functional obstruction of the colon (Ogilvie syndrome) can cause the same spectrum of clinical symptoms. It is important to differentiate pseudo-obstruction from mechanical obstruction because the management is different. In contrast to small bowel obstruction, adhesive disease of the large intestine is a very rare cause.

A major factor in the clinical course of large bowel obstruction depends on the competence of the ileocecal valve. Ten to twenty percent of patients have an incompetent ileocecal valve which allows decompression of the large bowel contents into the ileum. However, in the majority of patients, the ileocecal valve does not allow reflux to occur, resulting in a closed loop obstruction with rapidly increasing intraluminal pressure (Figure 30–4). This results in impaired capillary circulation, mucosal ischemia, and subsequent bacterial translocation with systemic toxicity. This process ultimately progresses to gangrene and perforation. This same

▲ **Figure 30-4.** The role of the ileocecal valve in obstruction of the colon. The obstruction is in the upper sigmoid. **A:** The ileocecal valve is competent, creating a closed loop between the obstruction and the valve. Tension in the closed loop is increased further by emptying of gas and fluid from the ileum into the colon. **B:** The ileocecal valve is incompetent. Reflux into the ileum is permitted. The colon is relieved of some of its distention, and the small bowel has become distended.

process occurs in volvulus, which by definition is a closed loop obstruction. The cecum has the largest diameter and therefore, by the law of LaPlace, is at greatest risk for perforation. The normal diameter is approximately 7 cm. The risk of perforation is high if the diameter increases acutely or to a size greater than 10-12 cm.

► Clinical Findings

A. Symptoms and Signs

The history and physical examination can help distinguish a large bowel obstruction from other causes of an acute abdomen and identify those patients requiring urgent therapy.

Obstipation is a universal feature of complete obstruction, though the patient may pass stool and gas located distal to the obstruction after the initial symptoms begin. Classically, the digital rectal examination reveals an empty vault except in cases of distal fecal impaction. Vomiting is a late finding and may not occur at all if the ileocecal valve prevents reflux. If reflux decompresses the cecal contents into the small intestine, the patient may also present with symptoms of small bowel obstruction.

The onset of symptoms may be acute or gradual, depending on the location and etiology of the obstruction. A patient may report a history of constipation for months preceding any acute obstructive symptoms. Deep, visceral, cramping pain from obstruction of the colon is usually referred to the hypogastrium. Right-sided lesions tend to grow to a large size prior to causing obstruction owing to the larger diameter of the lumen and the liquid stool. Therefore, these lesions may be palpable on abdominal examination. If the patient reports repeated episodes of fever and abdominal pain, a diverticular stricture is suspected; a history of hematochezia and weight loss suggests colorectal cancer (CRC). Alternatively, when symptoms occur acutely, volvulus, incarcerated hernia, or intussusception are more likely. A patient with fever, leukocytosis, and peritonitis has likely progressed to develop intestinal ischemia and/or perforation.

B. Imaging Studies

Abdominal films will frequently reveal dilated colon outlining the abdominal cavity. The colon can be distinguished from the small intestine by its haustral markings, which do not cross the entire lumen of the distended colon. Sigmoid volvulus can be identified by a characteristic “coffee bean” appearance which represents a dilated loop of colon starting in the left-lower quadrant extending medially. This finding is seen in 60% of patients. Cecal volvulus tends to appear as a dilated loop originating in the right-lower quadrant extending medially. In patients with other forms of obstruction, the extent of distention is dependent on the competency of the ileocecal valve and its relation to the location of the obstruction. A transition point with no distal colonic gas indicates complete obstruction. If gas is present in the distal rectum, it can represent residual material present prior to the obstruction or the presence of a partial obstruction. In acute pseudo-obstruction, the colon is diffusely dilated with stool and gas throughout (Figure 30-5). A CT scan with rectal contrast is the most useful single test for large bowel obstruction because it can yield information regarding the location and etiology of the bowel obstruction. This has largely replaced contrast enema. A water-soluble contrast medium, such as gastrografin, should be used if strangulation or perforation is suspected. Barium should not be given orally in the presence of suspected colonic obstruction.

▲ **Figure 30-5.** Plain radiograph demonstrating the dilated colon with pseudo-obstruction (Ogilvie syndrome). (Courtesy of Dr. Santhat Nivatvongs)

► Treatment

A. Obstruction

An operation is almost always required for mechanical large bowel obstructions. The extent of surgery depends on the patient's acuity and the etiology of the obstruction. The primary goals of treatment are resection of all necrotic bowels and decompression of the obstructed segment. Removal of the obstructing lesion is a secondary goal, but a single operation to accomplish both objectives is preferred whenever possible. Options include resection with primary anastomosis, resection with diversion, diversion alone, and endoscopic stent placement.

Endoscopic stents are being used as a bridge to surgery and as palliative therapy. When used in acutely ill patients with a malignancy, there is no clear advantage of endoscopic stent placement as a bridge to surgery in terms of mortality or complications. However, they do allow decompression of the obstruction and time for physiologic optimization. This can increase the chances of resection with primary anastomosis and reduce the chance for diversion. This comes, however, at the risk of stent-related perforation. Stents may be considered also for palliation in high risk patients whose obstructing cancers are not resectable; however, if the patient will tolerate it, a permanent diverting colostomy is a more durable option.

▲ **Figure 30-6.** Primary resection for diverticulitis of the colon, also used in acute large bowel obstructions. The affected segment (shaded) has been divided at its distal end. If primary anastomosis is to be done, the proximal margin (dotted line) is transected, and the bowel is anastomosed end to end. If a two-stage procedure will be used, a colostomy is formed at the proximal margin, and the distal stump is oversewn (Hartmann procedure, as shown) or exteriorized as a mucous fistula. The second stage consists of colostomy takedown and anastomosis.

Generally speaking, obstructing lesions of the right colon can be resected in one stage if the patient's condition is stable. If the patient's condition is precarious or if the colon has perforated, the bowel should be resected and an ileostomy created. Intestinal continuity can be restored at a second operation. Intestinal bypass is sometimes used for unresectable lesions although the relief of the obstruction is not always as effective.

Obstructing lesions of the left colon more commonly require diversion. Ideally the lesion is resected at the initial operation. After resection, anastomosis may be postponed with creation of a temporary end colostomy and Hartmann's pouch (Figure 30-6). If the patient's clinical condition will allow it, a primary anastomosis may be performed with a diverting loop ileostomy if needed to protect the anastomosis. If resection is not possible, the bowel can be decompressed proximally and distally with a loop or double barrel colostomy. These stomas are difficult to manage and are associated with a high rate of prolapse and are thus, avoided if at all possible.

The prognosis depends upon the age and general condition of the patient, the extent of vascular impairment of the bowel, the presence or absence of perforation, the cause of obstruction, and the promptness of surgical management. The overall mortality rate is about 20%. Cecal perforation carries a 40% mortality rate. Obstructing cancer of the colon has a worse prognosis than nonobstructing cancer because

it is more likely to be locally invasive or metastatic to nodes or distant sites.

B. Pseudo-Obstruction

Acute pseudo-obstruction of the colon (Ogilvie syndrome) presents with massive colonic distention in the absence of a mechanically obstructing lesion (Figure 30–5). It is a severe form of ileus that occurs most commonly in systemically ill patients and results from an imbalance in the autonomic tone with subsequent absence of peristalsis. Electrolyte disturbances and medications are contributing factors. These patients are usually recovering from major surgery or are hospitalized for other causes, most commonly cardiac disease, trauma, and infection. The mortality rate is 15% overall but increases to 30% in patients who develop ischemia or perforation.

The initial presentation may be missed in critically ill patients. Abdominal distention is the earliest manifestation, but later symptoms include abdominal pain, vomiting, and obstipation and may mimic those of true obstruction; however, 40% of patients will have diarrhea. The differential diagnosis includes toxic megacolon (in patients with ulcerative colitis [UC] and *C difficile* colitis) and mechanical large bowel obstruction. Plain x-rays of the abdomen show marked distention of the colon, often most severe in the right and transverse colon. Contrast enema proves the absence of obstruction, but instillation of radiopaque material should cease as soon as the dilated colon is reached. As opposed to a mechanical bowel obstruction, surgical management in Ogilvie syndrome is reserved for complications including perforation and ischemia.

If the patient has no signs of obstruction or perforation, the initial measures include nasogastric suction, rectal tube placement, fluid resuscitation, and correction of electrolyte imbalances. Systemic illnesses contribute and should be treated appropriately (respiratory failure, cardiac disease, and sepsis). All anticholinergic and narcotic medications should be discontinued. These measures will be effective in 75%–85% of patients. The patient should be followed with serial imaging. The risk of perforation is related to cecal diameter. The highest risk patients have a diameter > 10 cm and should be closely monitored. If there is any sign of clinical deterioration or no improvement in 48 hours, more aggressive treatment is warranted.

The acetylcholinesterase inhibitor neostigmine is an effective treatment for acute colonic pseudo-obstruction in patients without response to conservative measures. It works by acutely increasing acetylcholine levels in the body thereby prompting immediate bowel contraction and decompression. Patients require telemetry monitoring during and after administration as symptomatic bradycardia requiring atropine occurs in 10% of patients. The most common side effects include abdominal cramping and excessive salivation.

It is successful in 90% of patients with a recurrence rate of 7%. If this is unsuccessful, or neostigmine is contraindicated (renal insufficiency, pregnancy, bronchospasm, bradycardia), colonoscopic decompression is the next step in management. Endoscopic decompression carries a risk of perforation but when performed by an experienced team, the risk of perforation is reduced to 2%. This procedure also offers the benefit of visualization of the colonic mucosa for evidence of ischemia. This is initially successful in 80% of patients, but recurrence is common. Ideally a tube is placed into the right colon using fluoroscopic guidance to maintain decompression.

In patients with refractory disease, surgical intervention is required. A percutaneous cecostomy tube is possible in patients who are high risk for surgery. If there is evidence of ischemia or perforation, patients are offered segmental or subtotal colectomy depending on the distribution of disease. This operation carries a high morbidity and mortality, likely related to patient's underlying illness. Primary anastomosis is considered based on the patient's clinical status, but often diversion is performed and intestinal continuity created at during a second procedure months after resolution of disease.

COLON CANCER AND POLYPS

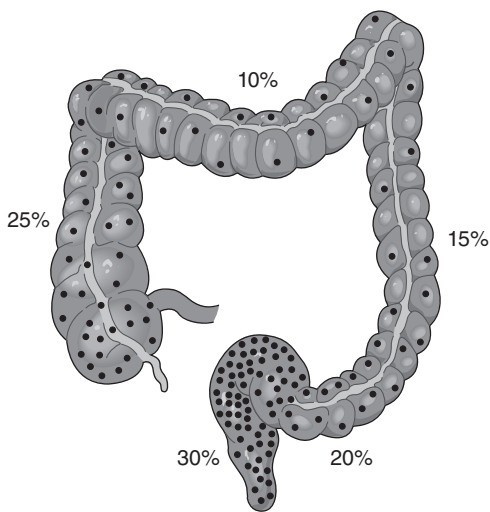

► Background

In the United States, colorectal cancer (CRC) ranks third after prostate and lung cancer in men, and after breast and lung cancer in women in both incidence and mortality. The American Cancer Society predicts that in 2012, more than 143,000 patients will be diagnosed and 51,000 will die as a result of their disease. Men have a higher incidence and mortality than women, and Black Americans have a higher incidence and mortality than other ethnic groups. The overall incidence and mortality from CRC has been decreasing since the early 1980s, likely owing to improved screening.

The frequency of CRCs by location in the colon is shown in Figure 30–7. The average age at diagnosis is 68 years for men and 72 years for women.

The average lifetime incidence of CRC in the United States is more than 5%. Multiple risk factors for CRC have been identified. The most significant are considered non-modifiable. For instance, having a single first degree family member with a diagnosis of CRC increases one's lifetime risk by 2.2. If the relative is diagnosed at an early age, the risk is increased by 3.9 and if there is more than one relative, this risk increases to 4.0. The most significant personal risk factors include IBD, especially with pancolitis, a history of adenomatous polyps, diabetes, and obesity. Modifiable risk factors include increased red and processed meat consumption, smoking, and alcohol. Case control and cohort studies have suggested that protective factors include a high fiber diet, calcium as well as vitamin D supplementation and physical activity. Randomized controlled intervention trials have been unable to demonstrate that these interventions significantly reduce risk for CRCs; however, they are limited by the older age of the study population at the time of intervention, poor adherence, and a relatively short follow up. A large Danish cohort study concluded that 25% of cancers are preventable through a healthy lifestyle.

In addition to lifestyle, chemoprevention in colon cancer has also been suggested as a way to reduce the burden of disease. Celecoxib and low dose aspirin have been shown to reduce the rate of metachronous adenomas in average risk patients found to have adenomas on screening colonoscopy. However, the adverse effects of these medications including cardiovascular events with celecoxib and peptic ulcer disease with aspirin likely outweigh these risks and therefore their use is limited in average risk patients. However, the benefits

▲ **Figure 30–7.** Distribution of cancer of the colon and rectum.

of celecoxib are more likely to outweigh the risk in patients with familial adenomatous polyposis (FAP), an inherited CRC syndrome, and it has been FDA approved for this indication.

► Genetics

CRC develops through a stepwise accumulation of mutations that allow the progression of normal mucosa to adenoma to carcinoma in a pathway known as Loss of Heterozygosity. The inciting event in 85% of sporadic CRCs is the development of chromosomal instability. This allows a cell to accumulate inactivating mutations in tumor suppressors such as adenomatous polyposis coli (APC), P53, deleted in colorectal carcinoma (DCC) and SMAD 4, as well as activating mutations in oncogenes such as K-ras, c-myc, c-src, and BRAF in a stepwise fashion. A less common pathway involves the development of mutations in the genes responsible for DNA mismatch repair and subsequent microsatellite instability. A third mechanism involves the epigenetic silencing of tumor suppressor genes through abnormal methylation. The familial cancer syndromes are caused by germline mutations in these genes, such as APC in familial adenomatous polyposis and mismatch repair genes in Lynch Syndrome, also known as hereditary nonpolyposis colorectal cancer (HNPCC). Approximately 5% of CRCs occur in patients with a hereditary syndrome.

HEREDITARY NONPOLYPOSIS COLORECTAL CANCER

The most common genetic colon cancer syndrome is Lynch syndrome, formerly known as HNPCC. The name of the condition has reverted to Lynch syndrome as these patients may have polyps in addition to cancer. It is an autosomal dominant condition with 80% penetrance whose basis is a mutation in the DNA mismatch repair system clustered on chromosome 2p. Ninety percent of all patients have a mutation in MLH1 or MSH2 which results in microsatellite instability (MSI). Other known mutations include MSH6, PMS2, and PMS1. The lifetime risk of CRC is 66% in men and 43% in women with a median age at diagnosis of 42 and 47 years, but this varies between affected families depending on the mutation. These cancers tend to occur in the ascending colon. A hallmark of the disease is the association with other cancers, including the endometrial, ovarian, gastric, upper urinary tract, biliary, small bowel, and brain.

The diagnosis is usually suspected on clinical grounds using the patient's medical and family history. Four sets of criteria were developed to help make the diagnosis. The Amsterdam criteria were initially developed in 1990 and are based on an accurate, extended family history of colon cancer. They were found to have a sensitivity of 61% and a specificity of 67% for the diagnosis. In 1999 the Amsterdam II criteria were published, which increased the sensitivity by

Table 30–3a. Amsterdam I and II criteria.

Amsterdam I Criteria	
At least three relatives must have histologically verified colorectal cancer.	<ol style="list-style-type: none"> (1) One must be a first-degree relative of the other two. (2) At least two successive generations must be affected. (3) At least one of the relatives with colorectal cancer must have received the diagnosis before age 50.
Amsterdam II Criteria	
At least three relatives must have a cancer associated with hereditary nonpolyposis colorectal cancer (HNPCC) (colorectal, endometrial, stomach, ovary, ureter or renal-pelvis, brain, small bowel, hepatobiliary tract, skin [sebaceous tumors])	<ol style="list-style-type: none"> (1) One must be a first-degree relative of the other two. (2) At least two successive generations must be affected. (3) At least one of the relatives with HNPCC-associated cancer must have received the diagnosis before age 50.

including extracolonic cancers (Table 30–3a). Patients who meet either of these criteria should be offered genetic testing, which can be used to provide diagnostic and prognostic information for the patient and his or her family. A separate set of criteria, known as the Bethesda Guidelines, was published in 1997 (Table 30–3b). These were designed to have very high sensitivity (94%) at the expense of specificity (49%) and are used to select tumor specimens appropriate for MSI testing. If this test is positive, it is followed by a confirmatory genetic test for the HNPCC mutations, because 15% of sporadic CRC exhibit MSI.

Once a diagnosis has been made, an aggressive screening regimen is initiated including colonoscopy every 1-2 years starting at age 20-25. Women are advised to undergo endometrial cancer screening or hysterectomy if childbearing is complete. In families with a history of upper urinary tract or gastric cancers, screening for renal and ureteral cancer is

Table 30–3b. Revised Bethesda criteria.

1. Colorectal cancer (CRC) diagnosed in individual under age 50 years.
2. Presence of synchronous, metachronous colorectal or other HNPCC-associated tumors, regardless of age.
3. CRC with the microsatellite instability-high (MSI-H) histology (presence of tumor-infiltrating lymphocytes, Crohn-like lymphocytic reaction, mucinous/signet-ring differentiation, or medullary growth pattern) in patient 60 years of age.
4. CRC in one or more first-degree relatives with an HNPCC-related tumor, with one of the cancers being diagnosed under age 50 years.
5. CRC diagnosed in two or more first- or second-degree relatives with HNPCC-related tumors, regardless of age.

initiated at age 30-35 years. A decision analysis model suggested that prophylactic total abdominal colectomy at age 25 would offer a very small survival benefit (1.8 years) and a decreased quality of life compared with colonoscopic surveillance. Therefore, surgical intervention is generally reserved for patients who develop a cancer or polyp that is unable to be removed endoscopically. However, because metachronous tumors occur in 40% of patients at 10 years an aggressive surgical approach is warranted. If a patient presents with a colon cancer, one option would be total abdominal colectomy with ileorectal anastomosis; however, even with this aggressive approach, the risk of developing a future rectal cancer is 6%-20%. Because any rectal remnant left in situ is a risk for developing a future cancer, an aggressive approach is appropriate; however, the decision regarding the specific intervention is multifactorial and depends on the patient's preoperative continence, ability to cope with the change in bowel habits that occur after low anastomoses, and desire to participate in postoperative surveillance. If the patient prefers proctectomy or presents with a rectal cancer a restorative proctocolectomy with ileal pouch anal anastomosis (IPAA) (J-pouch) can be offered if safe from an oncologic perspective. However, if the tumor precludes sphincter preservation or the patient is otherwise not a candidate for a J-pouch, a total proctocolectomy with end ileostomy is performed.

FAMILIAL ADENOMATOUS POLYPOSIS AND MYH-ASSOCIATED POLYPOSIS

The second most common CRC syndrome is FAP. This syndrome accounts for less than 1% of all CRCs. Like HNPCC, it is autosomal dominant with nearly 100% penetrance; however, in contrast, these patients are more likely to develop left-sided CRC at an earlier age (> 90% by age 40). Twenty percent of cases of FAP are sporadic. Most are a result of a mutation of the DNA mismatch repair gene APC located on chromosome 5q21. Depending on the location and type of mutation, the phenotypic presentation can range from mild to severe. Individuals with classic FAP typically have more than 100 colonic adenomas but can have more than 1000. These develop at an early age and are present in 50% of patients by age 15. In contrast, patients with attenuated FAP (aFAP) have an average of 30 polyps that develop after age 25. Although most patients with the attenuated form develop colon cancer, the average age is 59 years.

MYH-Associated polyposis (MAP) is clinically similar to FAP and aFAP. Most patients develop a mean of 50 polyps, although cases have been documented with 5-750. However, it is distinguished by family history as it is an autosomal recessive condition caused by mutations in the base excision repair gene MYH.

There are a variety of extracolonic manifestations described in patients affected by the polyposis syndromes. Duodenal neoplasms and desmoid tumors occur in 85% and 15% of patients, respectively. These two manifestations are

important because they contribute to increased morbidity and mortality in FAP patients. Esophagogastroduodenoscopy (EGD) is recommended for duodenal screening in these patients beginning at the age of 20. Desmoid tumors are commonly intra-abdominal in FAP patients. They are often found incidentally at surgery but can be aggressive and result in significant GI symptoms. Other manifestations include retinal pigment epithelium hypertrophy, osteomas, and sebaceous cysts. Gardner syndrome is applied to families with the constellation of polyposis, osteoma, dental abnormalities, and soft tissue tumors; Turcot syndrome refers to patients affected by polyposis and medulloblastoma.

Management involves genetic counseling, aggressive screening, and prophylactic colectomy. Patients at risk for FAP should undergo initial colonoscopy at the age of 12, or 20 if suspected to have aFAP. Considering the predominantly left-sided disease in FAP, it has been suggested that these patients can be followed with annual or biannual flexible sigmoidoscopy; however patients with aFAP should be followed with colonoscopy. Prophylactic colectomy is warranted in all patients, especially those with severe polyposis, dysplasia, symptoms, or large adenomas. This can be delayed if there is a mild presentation, but otherwise should be performed as soon as practical. Options are the same as those for HNPCC, and include total proctocolectomy with end ileostomy, restorative proctocolectomy with IPAA, and total abdominal colectomy with ileorectal anastomosis, again depending on preoperative bowel function and patient preference. Abdominal colectomy is reserved for patients with rectal sparing and attenuated disease, which most often occurs in the presence of a specific mutation upstream of c1250. However, the retained rectum is still at risk and these patients still require surveillance proctoscopy with resection or destruction of polyps every 6 months. More commonly, patients elect to undergo restorative proctocolectomy with IPAA. Patients who have a stapled anastomosis will retain about 1 cm of the anal transition zone (ATZ) and due to the predilection for ileal polyps, patients undergoing IPAA require lifelong surveillance. Some surgeons favor mucosectomy to reduce the risk of polyps in the ATZ but the ileal polyps are not affected and the functional outcome of a mucosectomy with handsewn anastomosis is less favorable than for those with a stapled anastomosis. Celecoxib is approved by the FDA for chemoprevention and may be a useful adjunct in these patients. Even with perfect surveillance and appropriate surgical management, FAP patients have an excess mortality related to extracolonic disease including upper GI malignancy and desmoids.

JUVENILE POLYPOSIS

Juvenile polyposis is a rare syndrome characterized by the development of excessive non-adenomatous polyps. It is an autosomal dominant condition, most commonly associated

with germline mutations in the SMAD4 or BMPRIA genes. The polyps are a distinct histologic subtype referred to as “juvenile” polyps, which are similar to hamartomas with edematous lamina propria and inflammatory changes. Although the pathway to carcinoma in these patients has not yet been fully elucidated, these patients have an elevated lifetime risk of developing CRC of 39%-68%. It is thought that carcinoma development is a result of neoplastic epithelial changes in the setting of exposure to the inflammatory stromal environment. The syndrome is diagnosed by the presence of five or more juvenile polyps in the gastrointestinal tract or the presence of any number of juvenile polyps with a family history of juvenile polyposis. There are three associated syndromes: Cronkhite–Canada syndrome (juvenile polyposis and ectodermal lesions), Bannayan–Riley–Ruvalcaba syndrome (juvenile polyposis, macrocephaly and genital hyperpigmentation), and Cowden disease (juvenile polyposis, facial trichilemmomas, thyroid cancer, goiter, and breast cancer).

These patients should undergo surveillance of the entire gastrointestinal tract for polyps beginning at the time of diagnosis or the onset of symptoms. This should continue annually in the presence of polyps. However, if the patient is polyp-free, the interval can be extended to 2-3 years. Surgery is reserved for patients with severe diarrhea, bleeding, or intussusception, those who fail endoscopic management of their polyps, exhibit dysplastic changes, and for those patients with a strong family history of CRC.

PEUTZ–JEGHERS SYNDROME

Peutz–Jeghers syndrome is a rare autosomal dominant condition (1/200,000 population) caused by a mutation in the STK11 gene on chromosome 19. The syndrome is defined by multiple hamartomas in the gastrointestinal tract (stomach to the rectum), mucocutaneous pigmentation, and elevated risk of gastrointestinal, breast, pancreatic, cervical, ovarian, and testicular cancers. The lifetime risk of CRC is reported to be 39%. Diagnosis is made in patients with two or more Peutz–Jeghers polyps or a combination of polyps, mucocutaneous pigmentation, or family history. There is insufficient evidence to suggest that the polyps themselves represent a premalignant lesion; however, they do become symptomatic in 50% of patients by the age of 20. Symptoms include anemia secondary to bleeding and abdominal pain secondary to intussusception, obstruction. Because of the rarity of the condition, management has not been well defined. Regular endoscopic surveillance (including small bowel capsule endoscopy) is advocated for the early detection of malignancy and resection of symptomatic lesions. This is recommended to begin at age 8, with the frequency determined by the burden of hamartomas. When endoscopic removal is not possible, exploratory surgery with resection and intraoperative small bowel endoscopy

is advised. These patients also must undergo appropriate screening for the extra-intestinal malignancies. Optimal regimens are under active study.

COLORECTAL CANCER SCREENING

CRC screening is important for two reasons. The first is the early detection of colorectal carcinomas and the second is preventing CRC through the identification and removal of colorectal adenomas, which are cancer precursors. Trials have shown that the detection of early CRCs by surveillance reduces mortality. Similarly, patients who undergo endoscopic removal of adenomas have a 53% reduction in CRC-specific mortality at 16 years. The benefit is increased in patients with above average risk for CRC.

The most updated guidelines on CRC screening were published in 2008. This includes three separate guidelines from the American College of Gastroenterology (ACG), the United States Preventative Services Task Force (USPSTF), and a joint guideline from the American Cancer Society, the US Multi-Society Task Force on Colorectal Cancer (which includes the American Society of Colon and Rectal Surgeons), and the American College of Radiology (Table 30–4). While they vary in certain recommendations, all agree that screening for average risk patients should begin at age 50 and should occur at regular intervals depending on the method, of which several are available. These include fecal occult blood test (FOBT), fecal immunochemical test (FIT), stool DNA, barium enema, CT colonography, flexible sigmoidoscopy, and colonoscopy. All abnormalities detected

Table 30–4. American Society of Colon and Rectal Surgeons guidelines for colorectal cancer screening.¹

Risk	Procedure	Onset (Age, y)	Frequency
I. Low Risk			
A. Asymptomatic—no risk factors	Fecal occult blood testing and flex-sig	50	FOBT yearly. Flex-sig every 5 years
B. Colorectal cancer in none of first-degree relatives	Total colon examination (colonoscopy or double-contrast barium enema and proctosigmoidoscopy)	50	Every 5-10 years
II. Moderate Risk (20%-30% of people)			
A. Colorectal cancer in first-degree relative, age 55 or younger, or two or more first-degree relatives of any ages	Colonoscopy	40, or 10 years before the youngest case in the family, whichever is earlier	Every 5 years
B. Colorectal cancer in a first-degree relative over age 55	Colonoscopy	50, or 10 years before the age of the case, whichever is earlier	Every 5-10 years
C. Personal history of large (> 1 cm) or multiple colorectal polyps of any size	Colonoscopy	1 year after polypectomy	If recurrent polyps—1 year
D. Personal history of colorectal malignancy—surveillance after resection for curative intent	Colonoscopy	1 year after resection	If normal—5 years If normal—3 years
			If still normal—5 years If abnormal—as above
III. High Risk (6%-8% of people)			
A. Family history of hereditary adenomatous polyposis	Flex-sig; consider genetic counseling and genetic testing	12-14 (puberty)	Every 1-2 years
B. Family history of hereditary nonpolyposis colon cancer	Colonoscopy; consider genetic counseling and genetic testing	21-40	Every 2 years
		40	Every year
C. Inflammatory bowel disease			
1. Left-side colitis	Colonoscopy	15th	Every 1-2 years
2. Pancolitis	Colonoscopy	8th	Every 1-2 years

¹Flex-sig, flexible sigmoidoscopy; FOBT, fecal occult blood testing.

by screening tests require a colonoscopy for diagnosis and treatment. The decision of which method to use must be individualized, taking into account several factors, including sensitivity and specificity, risks, costs, patient adherence, and availability. The ACG guidelines suggest that African American men should begin screening at age 45. The USPSTF guidelines recommend screening selectively in patients between ages 75 and 85 years and not screening patients over 85 years. The USPSTF does not recommend the newer stool DNA and CT colonography tests until more performance data are available. All guidelines agree that prevention of colon cancer is the primary goal of screening and that the decision should be made on an individual basis to maximize effectiveness.

All methods have their strengths and weaknesses. Stool tests, like FIT, FOBT, and the stool DNA test are noninvasive with essentially no risks. They are more acceptable to patients as a screening modality; however, there is poor adherence in clinical trials on the part of both the physician and patient with the examination not being performed at the proper intervals or patients not undergoing colonoscopy for positive tests. The sensitivity of FOBT is poor (33%-40%), but this increased to 50%-75% with the development of the SENSEA FOBT that is now the standard. Sensitivity and the false positive rate were addressed with the development of the stool DNA test and FIT, although these are substantially more expensive and, as mentioned, the stool DNA test is still undergoing clinical trials. It is important to note that these tests are not designed for prevention, but rather for early detection, as most advanced adenomas are not detected by these tests.

Radiographic options, including barium enema and CT colonography, are more sensitive for the detection of malignant and premalignant lesions. Both require full bowel preparation and have the drawback of radiation exposure; however, procedural risk is low. Barium enema has fallen out of favor as a screening test as it cannot detect small lesions, is unable to provide pathologic information and is very uncomfortable for patients. As CT colonography is still early in its development, its performance and appropriate screening intervals has yet to be defined; however it has been shown to have good sensitivity and specificity. It has a 90% sensitivity and a specificity of 86% for polyps more than 1 cm in size. For polyps more than 6 mm, sensitivity was 78% and specificity 88%. It is likely a poor test for detecting sessile adenomas. Using a cutoff of 6 mm for referral for colonoscopy, 15%-25% of patients would be referred, requiring an additional bowel preparation and the cost of another procedure. In addition, 5%-16% of patients will have an incidental extracolonic finding requiring further evaluation.

Flexible sigmoidoscopy is not often used in the United States for screening purposes. Its utility in preventing CRC is limited because it does not evaluate the proximal colon.

It is therefore combined with a fecal screening test and colonoscopy is recommended if the fecal test is positive. Colonoscopic studies have shown that 30% of patients with advanced adenomas have no distal lesions and would therefore have a normal examination to the splenic flexure. This is more common in women and patients over age 60. This, in combination with the need for bowel preparation, patient discomfort, and poor reimbursement, has made this test infrequently utilized for screening purposes.

Colonoscopy at 10-year intervals is the preferred screening test in the ACG guidelines and is the final common step in every screening program for CRC. Its major drawback is poor adherence, likely related to the need for bowel preparation and sedation, which usually requires a chaperone and a day off work. It is the most expensive screening test and does have a small but real risk of complications (3-5/1000). A concern for missed lesions has prompted the development of tools for measuring quality. However, it is overall a safe and effective screening regimen.

Screening for high risk patients is individualized. Children with possible FAP should begin screening at puberty. Patients in families with HNPCC should begin at age 21. Patients with UC for more than 10 years should begin annual colonoscopy with random biopsies. Patients with a history of early (< age 60) CRC in one first degree relative are offered colonoscopy starting at age 40, or 10 years earlier than the family member's diagnosis. The most recent ACG recommendations state that patients with a family history of CRC occurring in one family member older than age 60 may undergo screening as an average risk patient.

SPORADIC COLORECTAL POLYPS

The term "polyp" is a morphologic term given to tissue that project into the lumen of the gastrointestinal tract and therefore is a broad term encompassing many entities, both benign and malignant. Non-neoplastic polyps account for 90% of all colonic polyps. Subtypes include juvenile, hyperplastic, and inflammatory polyps, as well as hamartomas (Table 30-5). There have been rare reports of carcinoma developing in association with hamartomas, but in general these polyps do not portend an increased risk for cancer. Neoplastic polyps, or adenomas, are the precursor lesions to the vast majority of colorectal adenocarcinomas in a well-studied "polyp to carcinoma" sequence, where colonic mucosa transforms into small tubular adenomas, increases in size, and develops high risk features prior to frank carcinoma. The genetic mechanisms behind this process have been well characterized and are discussed above. An exception to this is the more recently recognized serrated adenoma, which can be difficult to distinguish from hyperplastic polyps. These are found more commonly in the right colon and are thought to progress to carcinoma via MSI.

Table 30–5. Polyps of the large intestine.

Type	Histologic Diagnosis
Neoplastic	Adenoma
	Tubular adenoma (adenomatous polyp)
	Tubulovillous adenoma (villoglandular adenoma)
	Villous adenoma (villous papilloma)
	Carcinoma
Hamartomas	Juvenile polyp
	Peutz–Jeghers polyp
Inflammatory	Inflammatory polyp (pseudopolyp)
	Benign lymphoid polyp
Unclassified	Hyperplastic polyp
Miscellaneous	Lipoma, leiomyoma, carcinoid

Adenomas, while accounting for only 10% of polyps, are common. Screening colonoscopy in asymptomatic patients detects adenomas in 25% of men and 15% of women. In autopsy series, they are detected in up to 60%. They are more common in older age with a prevalence of 30% at age 50 years and 55% at age 80. About 50% of patients with adenomas have more than one lesion, and 15% have more than two. They are predominantly found distal to the transverse colon and approximately half occur in the rectosigmoid area of the colon.

The presence of an adenoma indicates an increased risk for CRC. Further, adenomas themselves may harbor malignancy. The characteristics of the adenoma, including histology, location, shape, and size, significantly influence this risk. Adenomas are subdivided into tubular, tubulovillous, and villous subtypes and these exist on a spectrum. If followed over time, only 5% of tubular adenomas will develop into a malignancy, however, 22% of tubulovillous and 40% of villous adenomas will progress. Further, risk increases with size. Adenomas less than 1 cm harbor carcinoma only 1% of the time, however this risk increases to 10% in adenomas 1–2 cm and 45% of adenomas greater than 2 cm. Other factors include sessile (as opposed to pedunculated) polyps, location in the ascending colon, male sex, age greater than 60, and family history. Overall, the greatest risk factors for both the presence of carcinoma within a polyp and the future development of CRC are size greater than 1 cm and tubulovillous or villous histology. These have been termed “advanced adenomas.” Of note, these polyps require surgical resection more often as these features make them less amenable to endoscopic methods.

Adenomas, even in the absence of malignancy, are associated with risk of CRC. Patients found to have adenomas have a risk of developing metachronous cancers twofold to fivefold over patients without them. The risk is estimated to be

5%–10% per year. For these reasons, the consensus guidelines recommend complete excision of the adenoma plus more frequent colonoscopic surveillance. Colonoscopy is repeated at 5–10 years for 1–2 low risk adenomas, at 3 years if 3–10 low-risk or any high-risk adenomas, and less than 3 years if greater than 10 adenomas. Colonoscopy is repeated sooner if there is a question regarding the adequacy of the polypectomy.

Although techniques for endoscopic polypectomy are improving, surgery still remains an important option in the management of colorectal polyps. Surgery is indicated if complete endoscopic resection is not possible. Large polyps, sessile polyps, and those found in the distal rectum are the most challenging to manage endoscopically and result in a higher likelihood of positive margins or incomplete removal. Because up to 20% of these will harbor carcinoma, they require surgical resection. Surgery is also indicated in some completely resected polyps found to contain invasive adenocarcinoma.

Carcinoma is found in 5% of benign appearing endoscopically resected polyps. In 1985, Haggitt reported that depth of invasion was the most important indicator of metastasis and developed a classification system based on depth of invasion (Table 30–6). Level 1, through 4 (limited to proximal two-thirds of submucosa) with favorable histology have a < 1% risk of nodal metastasis and are adequately treated by endoscopic resection with a margin > 2 mm. However, carcinomas exhibiting evidence of vascular or lymphatic invasion, indeterminant margins, a margin < 2 mm, or level 4 with invasion into distal third of submucosa have a 12%–25% chance of lymph node involvement and therefore require formal oncologic resection.

► Clinical Findings

A. Signs and Symptoms

The majority of patients with CRC are asymptomatic. Based on a median doubling time of 130 days, it takes at

Table 30–6. Haggitt classification.¹

Level	Depth
0	Carcinoma <i>in situ</i> or intramucosal carcinoma
1	Carcinoma invading through muscularis mucosa into the submucosa but limited to the head of the polyp
2	Carcinoma invading the neck of the polyp
3	Carcinoma invading any part of the stalk
4	Carcinoma invading into the submucosa of the bowel wall below the stalk of the polyp but above the muscularis propria (T1)
Sessile	By definition, equivalent to level 4

¹From Haggitt RC et al: Prognostic factors in colorectal carcinomas arising in adenomas: implications for lesions removed by endoscopic polypectomy. *Gastroenterology* 1985;89:328.

least 5 years, and often 10-15 years, before a cancer causes symptoms. When symptoms do appear, they are variable, non-specific, and often indicate an advanced lesion or complications. CRCs may cause subclinical bleeding, resulting in an asymptomatic iron deficiency anemia. For this reason, any iron deficiency anemia in a male or nonmenstruating female should prompt a work up to rule out bleeding from the GI tract. However, one-third of patients with CRC have normal hemoglobin at the time of diagnosis. A minority of patients will present emergently with acute obstruction, perforation, or significant bleeding with symptomatic anemia.

Compared with the left colon, tumors of the right colon may reach a more advanced stage before they cause symptoms. Obstruction is rare because the right colon is larger in diameter and has liquid stool. If these tumors bleed, melena, or more commonly occult blood, will be present in the stool. There may be associated vague abdominal pain. Ten percent of patients present with a palpable abdominal mass.

In contrast, the left colon and rectum has a smaller diameter and semisolid feces. Tumors here can cause luminal narrowing and obstruction resulting in narrowing of the stool, constipation, and increased frequency of bowel movements. Rectal cancer can produce tenesmus. When bleeding occurs, it tends to be dark to bright red and may streak or be mixed with the stool. Any patient with ongoing hematochezia, even in the presence of another clinical explanation, such as hemorrhoids, must undergo evaluation for CRC.

Physical examination may help localize and determine the extent of disease. The abdomen should be palpated for masses and the liver examined to rule out enlargement. Auscultation of the lungs is poorly sensitive for metastatic disease. A digital rectal examination may detect a distal rectal cancer. Its location, size, and mobility should be noted. Retrorectal nodes or drop metastases in the Pouch of Douglas (Blumer shelf) may be palpated. Rigid proctoscopic examination gives an accurate location of the tumor, which is important for treatment planning. Lymph node examination may reveal metastasis in the supraclavicular nodes.

The preoperative work up for CRC will determine a clinical stage, allow initial prognostics, and inform the treatment plan. It consists of laboratory tests, radiographic imaging, and endoscopy with biopsies.

B. Laboratory Findings

Useful laboratory tests include a complete blood count, serum chemistries, urine analysis, and liver function tests as clinically indicated. These will detect anemia and other abnormalities that may need to be addressed prior to initiating treatment. The serum marker for CRC is carcinoembryonic antigen (CEA). It is a glycoprotein found throughout the gastrointestinal tract as well as other tissues. It is not sensitive or specific for patients with CRC, specifically for patients without metastatic disease. It is therefore not recommended as a screening test; however, it has been shown

to be a useful adjunct to postoperative monitoring for recurrence, specifically in patients with an elevated preoperative CEA that returns to normal after surgery.

C. Colonoscopy

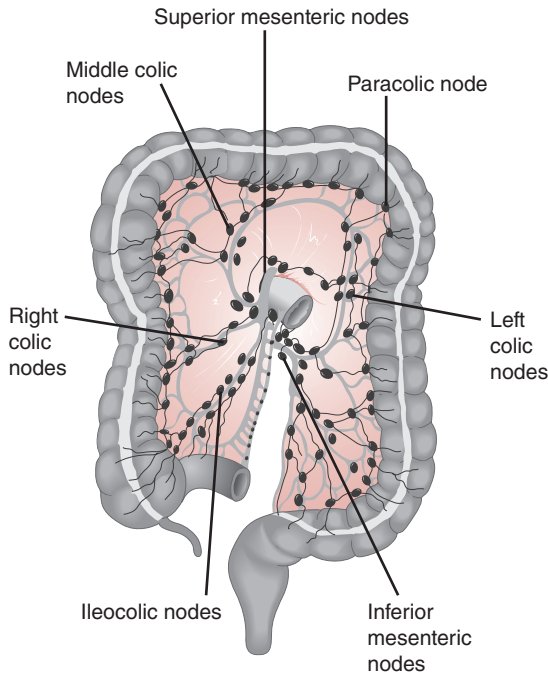

Colonoscopy is the gold standard for the diagnosis of CRC. Complete colonoscopy is indicated in all patients who have suspected or known CRC. It allows tissue diagnosis, localization of the lesion using tattoo, and evaluation for synchronous neoplasms. Three percent of patients with a known colon or rectal cancer have a synchronous lesion. In patients with obstructing lesions, the remaining colon should be evaluated using contrast enema or CT scan. These patients should undergo postoperative surveillance as soon as feasible after their surgery.

D. Mechanisms of Spread

CRC generally grows circumferentially. It takes approximately 1 year for a tumor to encircle three-fourth of the circumference of the bowel wall. This is especially true in the left colon which is smaller in diameter. Submucosal extension through the lymphatic network rarely extends beyond 2 cm from the tumor. As the tumor extends radially, it may penetrate the wall and extend into neighboring structures including the liver, greater curvature of the stomach, duodenum, small bowel, pancreas, spleen, bladder, kidney, ureter, and abdominal wall. Rectal tumors in particular may invade the vaginal wall, bladder, prostate, sacrum, or levators due to the confined space of the pelvis. The inflammatory response incited by extension of the tumor is indistinguishable from frank invasion during gross examination at the time of surgery.

Metastatic disease most often occurs through the lymphatics, although it is also known to occur via seeding, intraluminal spread, or hematogenously. Rectal cancer metastasizes proximally to the mesorectal, iliac, and inferior mesenteric lymph nodes, as well as radially along the pelvic side walls where obturator nodes can become involved. Very distal rectal cancers can also spread to inguinal lymph nodes. Colon cancer spreads along the superior and inferior mesenteric lymph node basins (Figure 30-8). Approximately half of patients undergoing surgery for CRC will have lymph node involvement. Hepatic and pulmonary metastases occur via hematogenous invasion. In colon cancer this may occur through the portal system to the liver, and less commonly the lumbar and vertebral veins to the lungs and other organs. Metastases to ovaries are mostly hematogenous; they are found in 1%-10.3% of women with CRC. Rectal cancer spreads through the systemic circulation via the hypogastric veins.

The “no touch” technique, while never definitively shown to reduce metastatic disease or improve survival, is one of the basic tenets of surgical management of colon cancer. The

▲ **Figure 30-8.** Lymphatic drainage of the colon. The lymph nodes (black) are distributed along the blood vessels to the bowel.

concept is to minimize manipulation of the tumor prior to ligation of the blood supply in order to avoid tumor embolus and subsequent metastasis. Transperitoneal metastasis or peritoneal “seeding” may occur when a tumor has extended through the serosa leading to peritoneal implants or generalized carcinomatosis. When found in the Pouch of Douglas, these deposits are palpated on digital rectal examination and referred to as Blumer’s shelf.

E. Staging

Accurately staging patients with CRC is important as it allows the development of an adequate treatment plan and determination of prognosis. The clinical stage is determined using preoperative imaging. Pathologic staging is based on imaging and information obtained after resection.

The initial determination required for developing a treatment plan for a patient with colon cancer is whether the tumor is resectable. This can be determined by searching for metastatic disease and determining local invasion. CT of the abdomen and pelvis is used routinely for this purpose. It may reveal lymphadenopathy, hepatic metastases, as well as evidence of obstruction, perforation, or direct extension (Figure 30-9). It has a sensitivity of about 78% for metastatic disease. Metastatic disease to the lungs is most often assessed using a routine preoperative chest x-ray. CT can be used to

A

B

▲ **Figure 30-9.** CT scan images. **A:** Primary, circumferential carcinoma of the sigmoid colon (arrow). **B:** Hepatic metastasis (arrow).

further evaluate abnormalities; however, it is not used as an initial test because these patients generally do not develop pulmonary metastases without first developing liver disease. This is because the lymphatic drainage of the colon follows the portal circulation. Positron emission scanning (PET) is not routinely recommended, however it is indicated in patients with suspicious abnormalities on CT that require evaluation for proper treatment planning.

Surgical planning for rectal cancer requires detailed evaluation of the depth of invasion of the rectal wall as well as lymph node involvement and invasion of nearby pelvic structures including the levators, sphincter complex, and genitourinary tract. This information is used to make

decisions about neoadjuvant therapy, sphincter sparing procedures, and local excision (LE). Endorectal ultrasound (ERUS) and pelvic magnetic resonance imaging (MRI) are commonly used. ERUS is particularly useful for determining the depth of invasion of the rectal wall and lymph node involvement. MRI is used to detect involvement of the mesorectal fascia and nearby pelvic structures to determine the likelihood of a circumferential resection margin, which is an important predictor of local recurrence. CT and PET CT are often used to assess pulmonary and liver metastasis, although the utility of this imaging modality requires further study.

The standard staging system in the United States is the tumor, node, metastasis (TNM) staging system from the American Joint Committee on Cancer (AJCC). This has replaced the Dukes classification. These are shown in Table 30–7. The clinicopathologic stage is the most important determinant of survival. Stage for stage, patients with colon cancer have a better prognosis than patients with rectal cancer. Similarly, patients with proximal rectal cancers have a better prognosis than those with distal cancers. Poor prognostic factors include complications such as obstruction or perforation, as well as histologic features such as poor differentiation and lymphovascular or perineural invasion.

Table 30–7. TNM classification of cancer of the colon and rectum.¹

Primary Tumor (T)					
TX	Primary tumor cannot be assessed				
T0	No evidence of primary tumor				
Tis	Carcinoma <i>in situ</i>				
T1	Tumor invades submucosa				
T2	Tumor invades muscularis propria				
T3	Tumor invades through the muscularis propria into the subserosa or into nonperitonealized pericolic or perirectal tissues				
T4	Tumor perforates the visceral peritoneum, or directly invades other organs or structures				
Regional Lymph Nodes (N)					
NX	Regional lymph nodes cannot be assessed				
N0	No regional lymph node metastasis				
N1	Metastasis in 1-3 pericolic or perirectal lymph nodes				
N2	Metastasis in four or more pericolic or perirectal lymph nodes				
N3	Metastasis in any lymph node along the course of a named vascular trunk				
Distant Metastasis (M)					
MX	Presence of distant metastasis cannot be assessed				
M0	No distant metastasis

TREATMENT OF COLON CANCER

► Surgery

Surgical resection of colon tumors is generally performed for patients with curative intent. Patients who are stage I-III or stage IV with resectable metastatic disease in the liver and/or lung are candidates for surgery. However, operative intervention may be necessary in patients with metastatic disease not amenable to complete surgical excision to treat complications of the primary tumor such as obstruction, perforation, or bleeding. Options include resection, diversion, and endoscopic stent placement. Emergency surgery has been associated with significant morbidity (30%) and mortality (10%). For patients specifically with obstruction, a meta-analysis showed no clear advantage of endoscopic stent placement as a bridge to surgery in terms of mortality or complications. In patients with unresectable disease, there is no evidence that prophylactic resection of the primary tumor improves prognosis or outcomes compared with primary chemotherapy treatment. These patients may become resectable after treatment with chemotherapy.

When possible, a laparoscopic approach to colon resection is preferred in most patients as it is associated with decreased hospital stay, postoperative pain, duration of ileus, and better pulmonary function and postoperative quality of life. The long-term oncologic outcomes for the open and laparoscopic approaches have been examined with multiple randomized controlled trials and are equivalent. This approach is not always appropriate for patients with obstructive or perforated lesions and should be abandoned in patients with prohibitive adhesions.

Upon entering the abdomen, the first step is to explore the abdominal cavity to search for metastatic disease not identified on preoperative imaging. If there are no findings that would preclude colectomy, attention is turned to resection. A “no touch” technique minimizes manipulation of the tumor prior to ligation of its blood supply to reduce tumor embolization which has a theoretical risk of causing metastatic disease. Although the extent of resection depends on the necessary lymphadenectomy, a margin of 5 cm on each side of the lesion in the bowel wall is generally considered adequate for clearance of any intramural spread. If there is any invasion into adjacent structures, these must be excised en bloc to achieve negative margins.

An important aspect of the surgical management of colon cancer is the removal of the draining lymph node basin because this allows accurate staging and treatment. Lymph node status is the most sensitive predictor of survival and adjuvant chemotherapy prolongs survival. Sentinel lymph node mapping has been trialed but with poor sensitivity and specificity with both technetium colloid and lymphazurin blue. Therefore, resection of all draining mesenteric lymph nodes remains the standard of care, often necessitating a larger segmental resection than would otherwise be needed

for the purpose of margins. An adequate lymphadenectomy contains 12 or more lymph nodes. The extent of resection of the colon and mesocolon for tumors in various locations is shown in Figure 30–10.

A right hemicolectomy is performed for tumors of the cecum and ascending colon. This requires high ligation of the ileocolic, right colic, and right branches of the middle colic artery. If the tumor is at the hepatic flexure or proximal transverse colon, an extended right hemicolectomy is performed with additional ligation of the middle colic artery. During mobilization of the ascending colon and hepatic flexure the surgeon must identify and protect the right ureter, superior mesenteric vessels, and duodenum.

A transverse colectomy with ligation of the middle colic artery is indicated for tumors in the transverse colon. If the tumor is in the splenic flexure or descending colon, a left hemicolectomy is performed with ligation of the IMA at its origin and resection of the distal transverse, descending, and proximal sigmoid colon. Sigmoid tumors are treated with sigmoid colectomy which includes part of the descending colon and proximal rectum. Tumors of the rectosigmoid and upper third of the rectum are removed with an anterior resection, requiring ligation of the sigmoid arteries as well as the middle hemorrhoidal arteries. The extraperitoneal rectum is mobilized and if needed, the splenic flexure may also be mobilized to ensure a tension free anastomosis. With all these resections, attention must be paid to the identification and preservation of the ureters, right kidney, and spleen. Stapled ileocolic anastomoses are associated with a decreased leak rate compared with hand-sewn. However, there does not appear to be a superior type of anastomosis in colocolonic or colorectal anastomoses. Thus, after resection for non-right sided colon cancers, the type of anastomosis is best left to the discretion of the surgeon.

► Chemotherapy

Adjuvant chemotherapy is standard of care for patients with stage III (node positive) disease and has been shown to improve survival by 33% and reduce recurrence by 40%. Chemotherapy regimens are based on 5-fluorouracil (5-FU) with levisimole and oxaliplatin (FOLFOX) or capecitabine. Determination of KRAS mutations may also dictate therapy as research shows that two drugs used for CRC, cetuximab (Erbix) and panitumumab (Vectibix), are not effective in tumors that carry the KRAS mutation. There continues to be debate about the utility of chemotherapy for stage II disease. Without chemotherapy, stage IIb patients have worse 5-year survival than stage III patients likely as a result of routine adjuvant therapy in the stage III patients. However, multiple trials and large database outcomes studies were unable to demonstrate improved survival in stage II patients treated with adjuvant chemotherapy with the exception of QUASAR, a 2007 European randomized trial, which did

▲ **Figure 30-10.** Extent of surgical resection for cancer of the colon at various sites. The cancer is represented by a black disk. Anastomosis of the bowel remaining after resection is shown in the small insets. The extent of resection is determined by the distribution of the regional lymph nodes along the blood supply. The lymph nodes may contain metastatic cancer.

showed a modest improvement in survival. A Cochrane review including all these patients showed an improved disease free survival but no difference in overall survival. The current thinking is that there is a subset of patients who will benefit from treatment. The NCCN guidelines recommend adjuvant chemotherapy for patients with high risk stage II disease (including T4 tumors, poor differentiation, high grade, perineural or lymphovascular invasion, obstruction, perforation, close or positive margins, or inadequate lymphadenectomy) and consideration of limited treatment of low risk patients. In addition, there is evidence that patients with MSI have a better overall prognosis and are resistant to

5-FU-based chemotherapies. Several trials are in progress to address these areas of uncertainty.

Chemotherapy is the mainstay of treatment for patients with stage IV disease or otherwise unresectable colon cancers. Although a minority of patients with metastatic disease will be candidates for surgical resection, chemotherapy is used in the perioperative period to treat microscopic foci of disease or in an effort to convert unresectable disease to resectable disease. There is also data to suggest that response to chemotherapy can be used to identify patients who will benefit from surgical metastasectomy. These patients are treated with a chemotherapy regimen similar to patients

with stage III disease, with the possible addition of irinotecan and/or a VEG-F inhibitor such as bevacizumab.

TREATMENT OF RECTAL CANCER

► Surgery

The choice of operation for rectal cancer depends on many factors. These include the location of the lesion, the depth of penetration and local invasion, histological features such as degree of differentiation and the presence of lymphovascular invasion, and the patient's individual anatomy, general condition, and preoperative bowel function.

A. Local Excision

The surgical management of rectal cancer differs from colon cancer for many reasons, mostly related to its unique anatomy. One aspect of rectal cancer that differentiates it from colon cancer is its accessibility. Very early stage rectal cancers can be treated with LE. This involves resection of a full thickness segment of the rectal wall transanally for distal lesions that are within reach. Transanal endoscopic microsurgery is used for more proximal rectal lesions. This utilizes a specialized proctoscope that allows passage of dissecting instruments and insufflation with carbon dioxide. The resection must involve at least 1 cm margins around the circumference of the tumor and the deep margin must be free. This technique does not sample or treat nodal disease and thus should be limited to a select group of patients at low risk for nodal metastasis. Appropriate patients include those with mobile tumors less than 3 cm in size and that extend less than one-third of the circumference of the rectum. They should be histologically low grade, extend only to the mucosa or submucosa (Tis, T1) and have no radiographic or clinical evidence of nodal metastasis.

The T stage is an important predictor of outcome following local excision (LE). LE was initially offered for all patients with stage I disease, however, the local recurrence rates were found to be unacceptably high (up to 47%) with patients with T2 lesions. Therefore, this therapy is generally reserved for patients with T1 disease, where the local recurrence rate is 5%-18%. There is a newer body of literature suggesting that patients with T1 lesions invading to the outer third of the submucosa have a higher risk for recurrence. If pathological analysis reveals a T2 lesion, positive margins, or high risk features, consideration should be given to radical resection (low anterior resection [LAR] or abdominoperineal resection [APR]) or adjuvant chemoradiation due to the higher risk for lymph node metastases. There is preliminary data that patients who are downstaged using neoadjuvant therapy may be appropriate for this procedure as well but this is not yet standard care.

The initial choice of operation is important, because patients who recur tend to present with advanced disease.

Only 50% of patients with recurrent disease after LE will be candidates for radical resection and their overall survival is poorer than that of patients who initially undergo radical resection. The advantages of LE include decreased morbidity and mortality, short recovery, and in some cases, the opportunity to avoid a colostomy.

B. Radical Excision

When radical excision of a rectal tumor is considered, planning must include assessment of resection for adequate margins, preoperative bowel function, and patient preference while minimizing morbidity. These procedures have a perioperative mortality of 2%. The options include low anterior resection (LAR) or abdominoperineal resection (APR), which includes a permanent colostomy. For cancers in the distal third of the rectum, an ability to achieve a distal margin of 1-2 cm and negative radial margins with complete mesorectal excision is considered the minimum needed to proceed with LAR. Therefore, tumors at the dentate line, with extramural spread to involve the sphincter complex, or direct extension into pelvic structures, require APR. Restoring intestinal continuity is generally considered best when possible from an oncologic standpoint. However, the more distal the anastomosis, the more postoperative bowel function is affected after resection of the rectum. Therefore, a careful evaluation of the patient's preoperative bowel function as well as a discussion with the patient about lifestyle changes is an important aspect of surgical planning.

Historically, recurrence rates were high and survival was low for rectal cancers, however, this has been greatly improved with the technique of total mesorectal excision (TME) and the use of neoadjuvant chemoradiation. TME has dramatically reduced local recurrence rates from 15%-40% to 4%-11% and increased survival in patients without metastatic disease. It generally requires full mobilization of the rectum with en block removal of the mesorectum and bowel wall 5 cm distal to the tumor (tumor-specific TME) if the tumor is in the upper rectum, or completely (TME) if the tumor is in the mid- to distal rectum. It requires dissection posteriorly in the avascular plane between Waldeyer's fascia and the presacral fascia, laterally to encompass the peritoneal reflection but medial to the hypogastric plexus, and anteriorly to include Denonvilliers fascia (Figure 30-11). TME is completed by extending the dissection inferiorly to the levators. This allows removal of the mesorectum *en block* with the rectum and ensures adequate lymph node removal. Further, it removes any tumor that has perineural spread or direct extension outside of the rectum. It is one of the major principles of both LAR and APR.

The laparoscopic approach to rectal tumors is attractive from the standpoint of increasing exposure in the pelvis and minimizing morbidity and length of stay. This approach is associated with earlier return of bowel function and

▲ **Figure 30–11.** Total mesorectal excision as depicted in Heald's original publication.

decreased analgesic requirement, although operative time is generally longer. Multiple trials have shown no difference in overall survival or local recurrence rates with follow up extending beyond 5 years.

Because LAR and APR are major operations with extensive pelvic dissection in an often radiated field, the morbidity is higher than colon cancer operations. In addition, LAR includes a technically challenging low anastomosis. Concerns are anastomotic leak, anterior resection syndrome (bowel dysfunction), urinary and sexual dysfunction, wound infection, anastomotic stricture, and injury to the ureters. In cases where identification of the ureters is expected to be difficult, that is, obese patients, those with previous pelvic surgery, and those who have undergone neoadjuvant chemoradiation, preoperative stent placement can assist with intraoperative identification and preservation of the ureters.

1. Low Anterior Resection—LAR is used when the decision is made to restore intestinal continuity for patients with tumors in the mid- to distal rectum who have good preoperative sphincter function and in whom adequate margins can be achieved. It involves resection of the sigmoid colon and the rectum with the distal transection point being determined by the complete mesorectal excision and attainment of an adequate 1-2 cm distal margin. The operation begins with abdominal exploration to assess metastatic disease. The superior hemorrhoidal artery is ligated at its origin. A higher ligation may be required if there is evidence of lymph node involvement. The rectum is mobilized using the previously described procedure for TME. The rectum elongates after mobilization, potentially adding length to the distal margin. The sigmoid colon is generally resected because its mesentery is removed as part of the vessel ligation. It is also a very muscular segment of the colon and thus, makes for a poor reservoir for bowel function. Furthermore, in patients who have received neoadjuvant chemoradiation,

this segment of the colon has been irradiated and use of the bowel for anastomosis will increase the risk of anastomotic complications such as leak and stricture. The anastomosis is generally performed via a transanal end-to-end stapling device, although a handsewn coloanal anastomosis may be required to achieve an adequate distal margin. There are multiple variations used for low colorectal anastomoses. The most common options are the colonic J pouch, the side-to-end anastomosis and transverse coloplasty. The choice is related to a desire to increase the colonic reservoir without obstructing the outflow. A meta-analysis of 16 trials showed an improvement in bowel function in the colonic J pouch compared to the straight coloanal anastomosis, however, care must be taken to limiting the size of the reservoir to avoid difficulty with complete evacuation.

Temporary diversion of the fecal stream is used to protect the colorectal anastomosis in LAR. This is particularly important in patients who are considered higher risk, including those undergoing neoadjuvant chemoradiation or with a very low anastomosis. Diversion significantly reduces the risk of anastomotic leak and need for reoperation. Both loop ileostomy and colostomy are used. Loop ileostomy is favored as it results in fewer stoma complications including prolapse and sepsis, although this method is associated with a higher risk for dehydration and anastomotic stenosis after closure.

Anastomotic leak occurs in 11% of patients undergoing LAR. Patients at greatest risk for anastomotic leak include elderly patients with low anastomoses and neoadjuvant chemoradiation who were not diverted. Some reports cite patient factors such as male sex, older age, smoking, obesity, and medical comorbidities such as renal failure. The type of anastomosis has not been shown to affect the leak rate. Prophylactic drainage has not been shown to alter the postoperative mortality, clinical or radiological leak rates, wound infection, or need for reoperation.

The Anterior Resection Syndrome occurs in 10%-30% of patients after sphincter preserving operations for rectal cancer and is more pronounced the more distal the anastomosis. Symptoms include clustering (frequent bowel movements in a short period of time), urgency, and incontinence to gas, stool, or both. These symptoms can have a significant impact on quality of life and are likely related to colonic dysmotility, neorectal reservoir dysfunction, sphincter complex damage, and aberrant anal canal sensation. It is worse in patients with a history of pelvic irradiation, rectal prolapse, or anorectal surgery. Most patients have improvement of their symptoms with time, and by 6-9 months after surgery, have a decreased, more manageable number of bowel movements per day. Loperamide, fiber supplementation, and biofeedback are useful adjunctive therapies. Loperamide has the benefit of increasing sphincter tone and slowing stool transit. In patients with intractable incontinence, a permanent stoma may be required.

2. Abdominoperineal Resection—APR is the operation of choice for patients with tumors in the distal third of the rectum in whom achieving negative margins would result in sphincter compromise, as well as those patients who would not tolerate a low anastomosis from a functional standpoint. Resection includes the distal colon, rectum, and anus with creation of an end colostomy. The initial abdominal dissection for APR is similar to that described for LAR. Rectal mobilization is carried down to the levators. The perineal dissection is performed most often with the patient in lithotomy position and can be done by a second team or after the abdominal dissection is complete. For tumors that are anterior in location or to facilitate visualization, a prone positioning after completion of the abdominal portion of the operation is also advocated by some surgeons. An elliptical incision is made around the anus and it is circumferentially dissected in the ischiorectal fat to achieve negative margins with care taken anteriorly in the plane between the anus and the vagina or prostate. This is extended through the levators to reach the inferior aspect of the abdominal dissection. The specimen is removed transanally. The perineal wound is washed out, closed in multiple layers. A drain is placed to prevent wound complications. An effort is made to keep intra-abdominal structures out of the pelvis by closure of the pelvic peritoneum and omental interposition.

Because LAR and APR involve wide dissection in the pelvis, the postoperative complications include those associated with disruption of the pelvic nerves. Urinary dysfunction, specifically urinary retention is reported in 3%-15% of patients, but this is generally transient. Sexual dysfunction tends to become progressively worse with time. In a recent large survey-based analysis, more than half of men experienced erectile dysfunction and two-thirds experienced problems with ejaculation. One-third of women reported dyspareunia. These factors are also likely related to pelvic irradiation.

► Palliative Procedures

If a rectal cancer is unresectable after neoadjuvant therapy, palliative surgery may be indicated to improve symptoms including obstruction, bleeding, or tenesmus. Obstructing cancers can be treated with diversion or endoluminal stents, however, there is a high risk of stent occlusion and perforation. Bleeding and tenesmus may be responsive to fulguration or photocoagulation, although outcomes have been disappointing.

► Chemotherapy and Radiation

Stage I rectal cancers are adequately treated with surgical excision. However, stage II and stage III rectal cancers have high local recurrence rates. Combined-modality therapy including preoperative chemoradiation, surgery, and adjuvant chemotherapy has been shown to increase survival in

these patients. Standard neoadjuvant treatment uses 5-FU as a radiosensitizer. Compared with postoperative chemoradiation, neoadjuvant treatment has been shown to decrease local recurrence and toxicity and increase sphincter preservation. However, it has not been shown to improve overall survival. Twenty percent of patients will have a complete pathologic response which is associated with improved survival. Surgery is planned 4-10 weeks after the completion of treatment. Following resection, adjuvant therapy with FOLFOX or capecitabine is standard, although trials are in progress to determine the optimal duration of treatment.

METASTATIC DISEASE

Metastatic disease is reported in 20% of patients with CRC at presentation and up to 30%-70% of patients will eventually be found to have metastasis. The two most common locations are the liver and the lung. Untreated, these patients have a 5-year survival of 5%. However, selected patients are candidates for surgical resection with curative intent. Surgery results in an improved 5-year survival of 22%-49% for patients with metastatic disease in the liver and 14%-78% for patients with lung disease. If both liver and lung disease are treated surgically, 5-year survival is 30%. After surgery for metastatic disease, 50%-70% of patients have a subsequent recurrence.

Liver and lung metastases are considered resectable if they, and all other sites of disease, including the primary tumor, are amenable to a R0 resection. This is based on the anatomic location as well as leaving an adequate quantity of normal tissue to maintain normal function. Options for patients with extensive disease include preoperative portal vein embolization or staged resection. There are reports of patients being treated with ablative therapies (microwave, radiofrequency) or external beam radiation; however, there are no long-term data available for these procedures. If metastatic disease in the liver initially appears unresectable, induction chemotherapy will result in a clinical response allowing resection in 16% of patients. If metastatic disease recurs after treatment, re-resection is considered in selected patients.

Peritoneal metastasis generally results in poor outcomes with median overall survival of 5-24 months. Current guidelines recommend chemotherapy as the primary treatment. Investigational treatments such as cytoreductive surgery and intraperitoneal chemotherapy show promise in improving survival, however these treatments are associated with significant morbidity and mortality and are not considered standard of care.

POSTOPERATIVE SURVEILLANCE

The goal of postoperative surveillance is to measure the efficacy of treatment and to diagnose recurrences, metastases, and metachronous lesions. After appropriate treatment for

CRC, one-third to one-half of patients will recur. The majority of these (60%-80%) will be in the first 2 years and 90% in the first 5 years after surgery. Three percent will develop a new metachronous tumor by 6 years.

Seventy-five patients with recurrent CRC will have an elevated CEA. Using a cutoff of 6 IU/L yields a sensitivity of 80% and specificity of 42%. It is most sensitive for detection of metastatic disease in the liver, and is elevated months before symptoms appear. Although less sensitive, CT of the abdomen has a similar benefit. Earlier detection improves resectability and survival. If the CEA is elevated, PET scanning is a useful adjunct to the evaluation as it has been shown to have better sensitivity and specificity for recurrent disease than CT.

After many well-designed randomized trials, there is still no consensus on what constitutes appropriate follow up for treated CRC patients. The 2012 NCCN guidelines suggest a history, physical examination, and CEA every 3-6 months. In addition, patients with high risk features such as lymphovascular invasion or poorly differentiated tumors should undergo CT of the chest, abdomen, and pelvis every year for 3-5 years. Colonoscopy should be performed at 1 year, and if normal, subsequent examinations should be scheduled in 3 years, and then every 5 years. For patients with rectal cancer who underwent LAR, proctoscopy should be considered every 6 months for 5 years. Although cost-effectiveness and survival benefit has been suggested for these surveillance strategies, they have not been proven definitively. However, they do increase the possibility of treating recurrences with intent for cure.

► Treatment for Recurrent Disease

CRC recurs in up to 50% of patients. In patients with rectal cancer, 35% will have a local recurrence compared with 15% of patients with colon cancer. Otherwise, the most common sites are the liver, lung, and regional lymph nodes. If R0 resection is possible, this can be undertaken in patients who are good surgical candidates in combination with adjuvant chemotherapy. In patients who present with unresectable disease, a combination of palliative chemotherapy and radiation therapy (if appropriate based on location) is administered, although this is unlikely to improve survival. However, the overall prognosis for recurrent CRC is poor. Survival is 35% at 5 years in patients who are candidates for curative surgical resection.

OTHER TUMORS OF THE COLON & RECTUM

► Neuroendocrine Tumors

Neuroendocrine tumors (NETs), or carcinoids, of the colon and rectum account for approximately 6% of all NETs of the gastrointestinal tract. They are rare, although the incidence

is increasing. More than half are found in the rectum. Incidence is increased in patients with IBD. They are rarely symptomatic and are most often diagnosed during screening colonoscopy or incidentally during laparotomy or imaging for other conditions.

Although the prognosis for these tumors is largely undefined because of their rarity, important factors include histologic subtype, tumor size, depth of invasion, and location. They are classified as benign (previously typical carcinoid), low grade malignant (atypical carcinoid), or high grade malignant (small and large cell carcinoma) and are staged according to the tumor, node, metastasis (TNM) system. Survival for rectal carcinoids is better than colon carcinoids, which tend to be associated with colon adenocarcinoma. Benign and low-grade malignant tumors are best managed surgically. There is controversy over the extent of surgery required, but it has been suggested that tumors greater than 1-2 cm or with high-risk histological features are best treated with standard oncologic resection whereas smaller lesions can be managed with local excision. High-grade malignant carcinoids of the large intestine are extremely aggressive and have a poor prognosis even if diagnosed at an early stage. These are best treated with chemotherapy.

► Lymphomas

The most common site of extranodal non-Hodgkin lymphoma is the gastrointestinal system; however, the colon and rectum are rarely affected. This disease is more common in middle-aged men and immunosuppressed patients. Symptoms are generally nonspecific, and more than half of patients present with a palpable abdominal mass. On imaging it appears as an infiltrating submucosal lesion with associated mesenteric lymphadenopathy, making it difficult to discern from adenocarcinoma. Another form, lymphomatous polyposis, can mimic familial polyposis coli. Colonoscopy with biopsy is important because depending on the subtype of lymphoma, chemotherapy and/or radiation is the primary treatment. Because the diagnosis is often delayed, patients may need urgent or emergent surgery for acutely symptomatic lesions.

► Lipomas

The colon is the most frequent site of gastrointestinal lipomas. They are benign fatty submucosal tumors with an incidence of 1%-4%. They are more common in women and in the right colon. Lipomas are generally asymptomatic, however, they may cause vague abdominal symptoms or intussusception, especially if large in size. Although they can sometimes be difficult to differentiate from colon malignancy, the diagnosis can be made by characteristic findings on endoscopic ultrasound (hyperechoic submucosal lesion). Resection is indicated for symptomatic lipomas or if the diagnosis is not clear by radiographic or endoscopic findings.

GASTROINTESTINAL STROMAL TUMORS

Gastrointestinal stromal tumors (GISTs) are derived from the pluripotential interstitial cells of Cajal and are associated with activating mutations in a specific tyrosine kinase found in the large intestine called KIT or CD 117. Like many of the aforementioned neoplasms, these are submucosal tumors that can grow to a large size before causing symptoms. They are commonly diagnosed radiographically, although occasionally percutaneous or endoscopic biopsy is necessary to confirm or rule out metastatic disease for treatment planning purposes. Surgery is the standard treatment for patients with localized tumors > 2 cm, tumors with high risk features, or symptomatic tumors. Because GISTs spread hematogenously, local resection with negative margins is adequate. Care must be taken to prevent intraoperative rupture of the tumor pseudocapsule as this is associated with high rates of recurrence. Medical therapy with imatinib mesylate, which selectively inhibits KIT is used for patients with unresectable tumors, metastatic disease, or poor prognostic factors. Sunitinib malate has been introduced as salvage therapy for patients with imatinib-resistant disease. Prognostic factors include location in the GI tract (stomach most favorable), mitotic index, and size. They are associated with generally good overall survival but recurrence is common.

ENDOMETRIOMAS

Endometriosis refers to the presence of endometrial tissue that forms implants in the pelvis and abdomen. Deeply infiltrating endometriosis refers to a subtype with locally invasive implants on the bowel wall. Symptoms include abdominal pain, hematochezia, and pain with defecation. Most patients present with palpable, tender nodules on rectal or vaginal examination. The diagnosis is made endoscopically in most patients. Medical management with NSAIDs, oral contraceptives, and GnRH agonists is generally limited by side effects and does not appear to prevent progression of the disease. Surgery is indicated for persistent symptoms or if malignancy cannot be excluded. The implants are treated with superficial excision, full thickness excision with primary defect closure, and resection with anastomosis. Although early reports cited concern over the development of anastomotic leak and rectovaginal fistulas, these complications have proven to be rare. While the majority of patients experience symptomatic improvement, recurrence is over 10% and long-term follow-up is lacking.

OTHER TUMORS

Other rare tumors of the large intestine have been reported, including neurofibromas, teratomas, rectal duplication cysts, lymphangiomas, and cavernous hemangiomas. Rare malignancies include adenosquamous carcinoma, primary squamous cell carcinoma, and melanoma.

DIVERTICULAR DISEASE OF THE COLON

DIVERTICULOSIS

► General Considerations

Diverticula (singular: diverticulum) are more common in the colon than in any other portion of the gastrointestinal tract. Their presence is referred to as diverticulosis. Most colonic diverticula are false, referring to the fact that they consist of mucosa and submucosa that have herniated through the muscular layer of the colon wall. True diverticula, which contain all layers of the bowel wall, are rare in the colon. In the United States, the most common location for diverticula is the sigmoid colon. The descending, transverse, and ascending portions of the colon are involved in decreasing order of frequency. Diverticula form as a result of increased intraluminal pressure acting at areas of relative weakness on the bowel wall caused by the blood supply. The vasa recta extend onto the colon wall, then penetrate the muscular layer between the taenia to supply the mucosa. Therefore, diverticula are most commonly located in the area between the mesenteric taenia and the antimesenteric taenia with a skip area on the antimesenteric border (Figure 30–12).

► Epidemiology

In Western countries, 30%-60% of individuals develop diverticula. There is no gender predilection. The prevalence increases with age, although recently there has been an increase in the younger population. Ten percent of patients are affected by age 40 and 65% by age 80. Diverticular disease is more common in Western nations. In Asian countries, there is a predominance of right-sided diverticula. The geologic differences in the incidence of diverticular disease suggest that cultural factors may play an etiologic role. The contribution of a low fiber diet rich in red meat is a

▲ **Figure 30–12.** Cross-section of the colon depicting the sites where diverticula form. Note that the antimesenteric portion is spared. The longitudinal layer of muscle completely encircles the bowel and is not limited to the taenia as depicted here.

commonly cited risk factor but this has not been shown conclusively. Other reported factors include physical inactivity, constipation, increasing age, smoking, obesity, alcohol, and NSAID use. Patients with Ehlers–Danlos and Marfan syndrome, both of which involve abnormal connective tissue, are at increased risk.

► Symptoms and Signs

Diverticulosis remains asymptomatic in up to 80% of people and is usually detected incidentally on barium enema x-ray, CT scan, or colonoscopy. A history of constipation is often elicited. An abdominal examination may reveal mild tenderness in the left-lower quadrant, and the left colon is sometimes palpable as a firm tubular structure.

► Treatment

Asymptomatic patients with diverticulosis may be given a high-fiber diet, although its role is unclear except as a treatment for constipation. There is no evidence to suggest that avoiding nuts, seeds, or popcorn has a protective effect. In fact, no dietary change has been conclusively shown to treat diverticulosis or prevent its complications, although weight loss, smoking cessation, and a diet low in red meat have been suggested as possibilities. Surgery is not indicated for uncomplicated diverticulosis.

► Prognosis

The natural history of diverticulosis has not been defined. Complications of diverticulosis including diverticulitis,

hemorrhage, stricture, and fistula formation occur in approximately 20% of patients with diverticulosis. Because these estimates rely on patients with known diverticulosis, the incidence of complications in the general population (who have undiagnosed, asymptomatic diverticulosis) may be much lower. About 75% of patients who present with complications of diverticular disease report no prior colonic symptoms.

DIVERTICULITIS

► General Considerations

Acute diverticulitis is the result of micro- or macroscopic perforation of a diverticulum resulting in an inflammatory response. The sigmoid colon is the most common location for diverticula and therefore is the most common location of diverticulitis. The severity of disease can range from mild inflammation localized to a segment of the bowel wall (microperforation) to feculent peritonitis (macroperforation). The majority of patients (75%) present with simple, uncomplicated, diverticulitis. This occurs when microperforation is immediately walled off, resulting in localized inflammation. Complicated diverticulitis occurs in 25% of patients and refers to macro- or gross perforation with abscess or peritonitis, as well as those who develop complications including stricture or fistula.

► Clinical Findings

A. Symptoms and Signs

Patients with acute diverticulitis classically present with abdominal pain and fullness localized to the left-lower quadrant. The average age of presentation is 62 years. The severity of abdominal pain ranges from mild to severe, often described as steady aching or cramping. It often resembles acute appendicitis except that it is situated in the left-lower quadrant. Occasionally, pain is suprapubic, in the right-lower quadrant, or throughout the lower abdomen depending on the location of the sigmoid and the distribution of disease. Changes in bowel habits, including constipation, diarrhea, or both are common. Dysuria is indicative of inflammation adjacent to the bladder. Nausea and vomiting may be present depending on the location and severity of the inflammation. Physical findings characteristically include low-grade fever, mild abdominal distention, and left-lower quadrant tenderness. There may be a palpable mass. Leukocytosis is common.

Acute diverticulitis can also present with other nontypical symptoms. Small bowel obstruction may occur if a loop of small bowel becomes entrapped in inflammatory tissue. Free perforation of a diverticulum can result in generalized peritonitis rather than localized inflammation. Episodes of recurrent diverticulitis may produce mild symptoms until a complication such as stricture or fistula develops that

prompts the patient to seek medical attention. The course of diverticulitis may be insidious, particularly in the elderly. Patients may present with vague abdominal pain associated with an abscess or recurrent urinary tract infections from a colovesical fistula. In some cases, pain and inflammatory signs are not marked, but a palpable mass and signs of large bowel obstruction are present, so that carcinoma of the left colon seems the more likely. Diagnosing malignancy can be difficult in the setting of inflammation.

B. Imaging Studies

Plain abdominal films are generally not useful unless they show free abdominal air from a diverticulum that has perforated. Other nonspecific findings include ileus, partial colonic obstruction, or left-lower quadrant mass.

CT scan of the abdomen and pelvis with intravenous contrast is the preferred initial imaging study. In most studies, CT has sensitivity, specificity, and accuracy greater than 90%, although 5% of patients will ultimately be found to have cancer as the underlying cause. It is also helpful to rule out other intra-abdominal pathology that may present in a similar fashion. Findings include wall thickening, fat stranding, and diverticula. Complications such as abscess or fistula may be evident (Figure 30-13). Findings on CT scan may also be predictive of the need for surgical intervention or successful nonoperative expectant management. The Hinchey classification was developed in 1978 to help guide clinical decision making for patients with complicated disease and standardize radiographic reporting. These have been updated to reflect improved resolution of CT and currently include the following stages: (0) mild clinical diverticulitis; (1a) pericolic inflammation or

▲ **Figure 30-13.** CT scan showing sigmoid colon involved with diverticulitis. Note the pericolic stranding, bowel wall thickening, and intramural abscess.

phlegmon; (1b) pericolic or mesocolic abscess; (2) pelvic, intra-abdominal, or retroperitoneal abscess resulting from an extension of a pericolic abscess; (3) purulent peritonitis; and (4) feculent peritonitis.

Colonoscopy is not needed for the evaluation of a patient presenting with classic signs, symptoms, and imaging. However, differentiating acute diverticulitis from other pathology such as IBD, carcinoma, and ischemic colitis can be difficult. If endoscopy is determined to be necessary for appropriate management, a delayed examination after inflammation has subsided is preferred. If timing is critical, then a sigmoidoscopy with low insufflation is recommended over colonoscopy to reduce the risk of perforation.

► Differential Diagnosis

Acute diverticulitis presents with such variation that the differential diagnosis is broad. It may simulate appendicitis, perforated colonic carcinoma, obstruction with strangulation, colonic ischemia, Crohn disease, cystitis, infectious colitis, and gynecologic disease such as pelvic inflammatory disease, tubal pregnancy, and tubo-ovarian abscess. Differentiation from appendicitis is especially difficult when a redundant sigmoid colon lies in the right-lower quadrant. Free perforation with generalized peritonitis is difficult to differentiate from the other causes of perforation. A thorough history and physical examination as well as imaging studies may be helpful in differentiating these conditions. Colonoscopy is usually deferred upon initial presentation of suspected acute diverticulitis, but may be useful in cases with a high suspicion of carcinoma, vascular insufficiency, or inflammatory disease of the colon. It can be difficult in some cases to rule out carcinoma of the colon, particularly in the more silent forms of diverticulitis that present with a mass or fistula. Occasionally the diagnosis may not be known until the surgical specimen is examined by the pathologist.

► Complications

The clinical spectrum of diverticulitis includes complications such as free perforation, abscess, fistula, and obstruction. Fecal peritonitis requires immediate surgery. Abscesses can often be drained percutaneously. Fistulas most commonly involve the bladder or colon, but may also extend to involve the ureter, urethra, vagina, uterus, small bowel, ovaries, fallopian tubes, perineum, and abdominal wall. Colonic obstruction is usually slow in onset and incomplete. Small bowel obstruction may result from inflammatory involvement of the small bowel.

► Treatment

A. Medical Management

Approximately 80% of patients with mild acute diverticulitis (Hinchey 0 and Ia) can be managed on an outpatient basis.

However, hospitalization should be considered in patients with mild attacks if they are elderly, immunosuppressed, or have significant comorbidities including diabetes or renal failure. Any patient will need inpatient treatment if there is significant pain, inability to tolerate oral intake, or there is evidence of severe systemic illness. Patients not requiring hospitalization are generally treated with a clear liquid diet, broad spectrum antibiotics (ciprofloxacin and metronidazole or amoxicillin-clavulanate), and close follow up, although this management strategy is largely historical and is being challenged. There is evidence that patients with uncomplicated diverticulitis do not require antibiotics. A recent trial showed no difference in hospital stay, development of complications, or recurrence within 1 year. Patients who were pregnant, immunosuppressed, or septic were excluded.

For those patients requiring hospitalization, treatment depends on the severity of presentation. Generally, patients are managed with bowel rest, intravenous fluids, and systemic broad-spectrum antibiotics. Common regimens cover colonic flora and are chosen based on the patient's allergies and previous antibiotic exposure. Common regimens include a beta-lactam/beta-lactamase inhibitor, a carbapenem, or the combination of a fluoroquinolone plus metronidazole. As clinical manifestations resolve, oral feeding is resumed gradually, initially with a low residue diet. After recovery, a high fiber diet is prescribed if there is no stricture, although this intervention has not been shown conclusively to reduce recurrence. Conservative management is successful in up to 85% of patients. Repeat CT or intervention is indicated when patients fail to improve or if there is clinical deterioration over the initial 48 hours of medical therapy. This often indicates progression to complicated disease that may require surgery.

Over the last decade, more and more patients are being managed conservatively, which has prompted study into strategies to prevent subsequent episodes. Small randomized trials have been conducted on patients who developed diverticulitis twice in 1 year. Mesalamine and rifaximin taken at 1 week intervals every month decreased symptoms and recurrence compared with rifaximin alone. Two small trials of probiotics have shown no significant improvement. However, it has been shown that avoidance of nuts, popcorn and seeds does not reduce the risk of diverticulitis and thus, patients do not need to be counseled to do so.

► Interventional Management

Patients with diverticulitis complicated by phlegmon or small abscess without peritonitis (Hinchey Ib) are candidates for conservative treatment. However, large abscesses (> 3 cm) are less likely to resolve with conservative management and should be drained percutaneously if possible. This provides source control and generally results in clinical improvement within days. Percutaneous treatment of an

intra-abdominal abscess allows surgical intervention to be performed on an elective basis when there is reduced risk of complications and higher probability of a one-stage operation without a stoma.

► Surgical Management

A. Elective Surgery

Recent studies examining the natural history of diverticulitis have demonstrated that over a period of 10 years, recurrent diverticulitis following nonoperative management is expected in 10%-30% of patients. In patients who have a recurrence, a similar proportion will have a third episode. Recurrences tend to occur with similar severity of the previous episode and patients who require urgent surgery usually do so during the first presentation. In other words, it is rare for a patient with a recurrence to require urgent surgery. This indicates a generally benign course for uncomplicated diverticulitis and calls into question the potential benefits of elective prophylactic surgery for patients with a history of acute diverticulitis.

In addition, elective sigmoid colectomy is not without risks. A retrospective review found that 20% of patients experience fecal incontinence, urgency, or incomplete evacuation after sigmoid resection for diverticulitis. The exact indications for surgery have yet to be defined, but overall there has been a general decrease in elective colon resections for diverticulitis in the past 10 years. The American Society of Colon and Rectal Surgeons (ASCRS) guidelines recommend that surgery is offered on an individual basis. Consideration should be given to the patient's previous episodes, frailty, reliability, and access to medical resources. Surgery is generally reserved for complicated disease such as abscess, perforation, stricture, fistula, or high risk patients such as those who are immunologically suppressed. Surgery should also be considered in patients in whom an underlying cancer cannot be excluded.

When interval colectomy is recommended, it is generally delayed by 6-8 weeks to allow resolution of acute inflammation that may add difficulty to the operation. There is evidence that delaying surgery increases the rate of a successful laparoscopic resection with primary anastomosis, which is possible in more than 90% of patients. However, delaying surgery comes with the small but significant risk (2%) of interval development of recurrent severe diverticulitis requiring emergency surgery with high morbidity. Further study is required to determine the optimal timing of surgery.

Definitive resection for sigmoid diverticulitis should include the sigmoid colon distally to the uninvolved rectum. The proximal extent of resection should be the point at which the bowel is soft and appears healthy—this generally includes the entire sigmoid colon. It is unnecessary to resect additional bowel proximally; even if it is involved with diverticula, as they are unlikely to become symptomatic

(Figure 30-6). Laparoscopy has been shown in randomized trials to decrease hospital stay and postoperative pain without increased complications; however, it is a technically challenging operation that should be undertaken only by surgeons comfortable with the technique. In some cases, even in experienced centers, laparoscopy may not be possible due to persistent inflammation and an open approach is required.

A subset of patients will present with colonic stricture as a result of chronic inflammation and scarring. This generally results in symptoms of partial obstruction. If an inflammatory stricture is diagnosed after radiographic and endoscopic evaluation, elective resection is recommended. The distal extent of resection should always include the rectosigmoid junction so that the proximal colon is anastomosed to healthy proximal rectum.

B. Urgent Surgery

Less than 10% of patients will present with complications requiring urgent surgery. Indications include uncontrolled sepsis and failure to improve with medical therapy or percutaneous drainage. There is a lower threshold for surgery for immunocompromised patients given their greater risk of morbidity and mortality with medical management. These are generally features found in patients with Hinchey III or IV disease.

At laparotomy for severe acute diverticulitis, exploration may reveal an inflammatory mass involving large bowel, mesocolon, mesentery, omentum, and sometimes small bowel. Except in cases of free perforation with generalized fecal peritonitis, the diseased diverticulum is not often visible. The type of operation performed is dependent on the extent of colonic inflammation, the amount of peritonitis, the patient's general condition, comorbidities, and nutritional status, the extent of blood loss, and the surgeon's experience and preference.

Ideally, a resection with primary anastomosis is performed as a one-stage procedure. It may not be possible to perform a primary anastomosis if there is gross contamination or infection in the surgical field because of the increased risk of anastomotic leakage. In patients who can tolerate an anastomosis but are still considered high risk, a diverting loop ileostomy is an option.

However, if the risk of an anastomosis is perceived to be too high, two options are available. The standard is the Hartmann procedure, which is a two-stage operation. At the initial operation, the diseased bowel is removed, the proximal end of the colon is brought out as a temporary colostomy, and the distal colonic stump is closed (Figure 30-6). Intestinal continuity is restored in a second operation after the inflammation subsides. There have been reports in the literature of Hinchey III patients having laparoscopic washout and drainage without resection as an alternative to resection. This approach has not been widely adopted

and a randomized controlled trial is currently underway to compare this approach with the Hartmann procedure. Increasingly, percutaneous drainage of abscesses avoids the need for staged procedures and allows for primary resection with anastomosis once the inflammation has resolved. However, if percutaneous drainage is unsuccessful, operative drainage is indicated.

A three stage procedure, consisting of diversion and washout followed by resection of the diseased bowel at a second operation, and finally colostomy takedown, is not advised due to the ongoing inflammation of the diseased bowel and associated morbidity despite fecal diversion. However, if the patient will not tolerate a resection, this is an option.

► Follow-Up

Colonoscopy is recommended 6-8 weeks after the resolution of symptoms and prior to elective surgical resection to rule out other underlying pathology such as IBD and cancer. Although the presence of malignancy is less than 5% in patients with a radiographic diagnosis of acute diverticulitis, it is especially important to exclude malignancy in the presence of rectal bleeding stricture, or mass. The entire colon should be evaluated prior to elective resection for presumed diverticular disease.

► Prognosis

The mortality for diverticulitis can be divided by Hinchey stage. Patients with stage I or II disease have a mortality of less than 5%, stage III 13%, and stage IV 43%. Approximately 25% of patients hospitalized with acute diverticulitis require surgical treatment. The operative mortality rate is about 5% in recent reports, compared with 25% historically. Some of this improvement is attributable to the greater use of percutaneous drainage.

Diverticulitis recurs in one-third of patients managed conservatively and in 2%-10% of patients after surgical resection. Most of these recurrences develop within the first 5 years and are most commonly in the rectosigmoid junction due to inadequate resection. More study is required prior to the routine use of mesalamine and probiotics to reduce this risk.

LARGE BOWEL FISTULAE

► Colovesical Fistula

Diverticulitis is the etiology of more than half of all colovesical fistulas. This complication occurs in 2%-4% of cases of patients. Other causes include colon cancer, bladder cancer, Crohn colitis, radiation exposure, trauma, and iatrogenic causes. They occur three times more often in men. This predilection is likely anatomical: in women the uterus and adnexa are situated between the colon and the bladder.

The most common presentation is recurrent urinary tract infection. Pneumaturia is reported by up to 70% of patients and fecaluria in up to 50% depending on the size of the fistula. There are no specific physical examination findings, although some patients may have a palpable pelvic mass. There is usually no leukocytosis. Urine analysis is often indicative of urinary tract infection and cultures are polymicrobial. CT of the pelvis with rectal contrast is the most sensitive imaging study and will often show a segment of inflamed colon and bladder wall with air in the bladder. The fistulous connection is rarely seen. Endoscopy and cystoscopy may reveal inflammation at the site of the fistula, but the fistula is rarely visualized. These tests are useful for ruling out malignancy prior to surgical intervention. If the diagnosis is still in question, ingestion of charcoal or poppy seeds with elimination in urine is diagnostic.

The treatment for symptomatic colovesical fistula is elective surgery. The operation should be delayed until any active inflammation (ie, from diverticulitis) has resolved. Up to 50% of colovesical fistulas will undergo spontaneous closure. In these patients, the decision to proceed with surgery depends on the underlying cause of the fistula. In most patients, surgery involves resection of the involved colon with a primary anastomosis. Large bladder fistulas are closed primarily, but most often they do not require closure but are left to close spontaneously with Foley catheter drainage.

However, in malignant fistulas, the tract should be excised en block with the colon and the involved bladder wall, which can be repaired primarily. Omentum is interposed between the anastomosis and the bladder. A urinary catheter is used to decompress the bladder for 5-10 days after surgery. The optimal timing of catheter removal or need for urine cultures or cystogram has not been prospectively validated.

In minimally symptomatic patients at high risk for surgery, conservative management with intermittent antibiotics may be successful. A trial of medical management is also indicated in patients with Crohn colitis, in whom spontaneous closure may be possible.

The prognosis for colovesical fistula is related to the etiology and the general health of the patient. Recurrence is reported to be 4%-5% overall, but is highest in patients with fistulas secondary to radiation therapy and Crohn colitis.

RECTOVAGINAL & COLOVAGINAL FISTULA

Colovaginal fistulae are commonly a complication of diverticulitis, especially in women with a history of hysterectomy. The most common cause of rectovaginal fistula is obstetric injury, followed by Crohn colitis, iatrogenic causes, malignancy, radiation, and trauma. Fistula between the lower third of the rectum and lower half of the vagina are classified as low rectovaginal fistulas, while high fistula are defined as those between the middle to upper third of the rectum and the posterior vaginal fornix. The most common presentation is feculent vaginal discharge, which may be mistaken for fecal incontinence. Patients may also report vaginal flatus, recurrent genitourinary infections, and dyspareunia. There is a significant negative impact on quality of life. A fistula may be observed on anoscopy, rigid sigmoidoscopy, and/or vaginal speculum examination in 85% of patients. Endorectal ultrasound (ERUS), CT with rectal contrast, or barium enema may confirm the diagnosis.

The treatment for recto- and colovaginal fistula is surgical. Colovaginal fistulas are often successfully managed with resection of the involved colon. The vaginal defect may be closed, but will generally close spontaneously if this is technically challenging. The optimal surgical treatment for rectovaginal fistula, on the other hand, is less clear. The treatment is largely based on etiology, individual patient factors and surgeon experience. Numerous procedures have been reported, including direct repair, fibrin glue, endorectal

advancement flaps, vaginal advancement flaps, biologic mesh, tissue interposition, and rectal resection. Choice of repair depends on the etiology, size, and location of the fistula. However, the recurrence rate is disappointingly high, especially for patients with Crohn disease who have an ongoing source of inflammation. The optimal approach consists of aggressive medical treatment of the colitis and control of pelvic sepsis followed by surgery. However, reported recurrence rates are 25%-50%. Good results have been reported in patients with multiple recurrences using fecal diversion and repair with a gracilis or omental interposition flap or even proctectomy with permanent stoma.

ACUTE LOWER GASTROINTESTINAL BLEEDING

► Background

Lower gastrointestinal bleeding refers to bleeding originating distal to the ligament of Treitz and involves the small bowel, colon, or rectum. Unlike upper GI bleeds, it occurs in predominantly elderly patients. It accounts for 20% of all GI bleeds and results in over 300,000 hospitalizations in the United States each year. The incidence appears to be increasing with time. Hematochezia refers to the passage of bright red blood, maroon blood, or clots per rectum. Classically, hematochezia indicates a lower GI source of bleeding, however, the color is a function of time spent in the intestinal tract. The black color of melena is the result of the oxidation of iron in hemoglobin. Bright red blood may stem from brisk esophageal variceal bleeding and melena may be the result of slow blood loss from a right-sided colon cancer.

► Etiology

Lower GI bleeding can originate from numerous sources. In elderly patients common causes include diverticula, angiodysplasia, malignancy, and ischemia. Younger patients are more commonly affected by IBD, solitary rectal ulcer, and infection. In the appropriate patient, bleeding may be related to coagulopathy, radiation injury, chemotherapy, or a recent procedure such as polypectomy. Chronic, low volume bleeding is seen in patients with malignancy, polyps, hemorrhoids, and fissures. The small intestine can be the source of bleeding in 5% of patients. Other more unusual

causes include Meckel's diverticulum (especially with ulceration from ectopic gastric mucosa), and aorto-enteric fistula.

Diverticulosis is the most common source of acute lower GI bleeding. Although bleeding occurs in only 5% of patients with diverticulosis, this presentation is common because of the high prevalence of diverticula in the general population. Diverticula form in areas of weakness where vasa recta penetrate the bowel wall. Structural changes in the bowel wall causes damage to the artery, which can lead to rupture. Diverticular bleeding often presents with painless and massive, but self-limited, hemorrhage. There is a dose-related increase in risk in patients who use NSAIDs. The long-term recurrence rate after the first episode is 25%, however, this increases to 50% after the second episode. Therefore surgery is commonly recommended in the elective setting after a patient presents with recurrent bleeding.

Angiodysplasia, or vascular ectasia, is found in 2% of asymptomatic patients on screening colonoscopy. They are generally located in the right colon in elderly patients and the jejunum in younger patients. These lesions are composed of dilated submucosal vessels with a central feeding vein that have a propensity to bleed spontaneously. Bleeding is typically intermittent and low volume. These patients often present in the outpatient setting with iron deficiency anemia and heme-positive stool. The diagnosis is made in some cases by colonoscopy, and colonoscopic therapy is often successful. There is no need to treat incidentally identified ectasias, as it is estimated that only 15% will cause clinically significant bleeding. Surgery is rarely indicated.

Colitis resulting from IBD, ischemia, radiation, or infection is a third cause of hematochezia. These tend to cause mild blood loss rarely requiring transfusion. These should be suspected in patients with abdominal pain and diarrhea. Acute ischemia may be caused by an acute decrease in blood supply from embolism, hypotension, or spasm. The watershed areas, including the splenic flexure and rectosigmoid junction, are most commonly affected. Infectious colitis can be diagnosed by stool culture. The most common organisms causing bloody diarrhea are *E coli* 0157-H7, *Campylobacter*, and *Shigella*. UC and Crohn colitis can also cause hematochezia during periods of acute inflammation. UC is more commonly associated with bleeding, although it can sometimes be difficult to distinguish between these two entities during an initial colonoscopy. However, the management in this setting is the same. Treatment with steroids and immunomodulators depends on the severity of the disease. This is discussed further in the section on colitis.

► Management

Chronic rectal bleeding, as seen in patients with colorectal polyps or cancer, and anorectal conditions can be evaluated electively. It is important to include colonoscopy in the evaluation, even if the bleeding can be explained by a benign

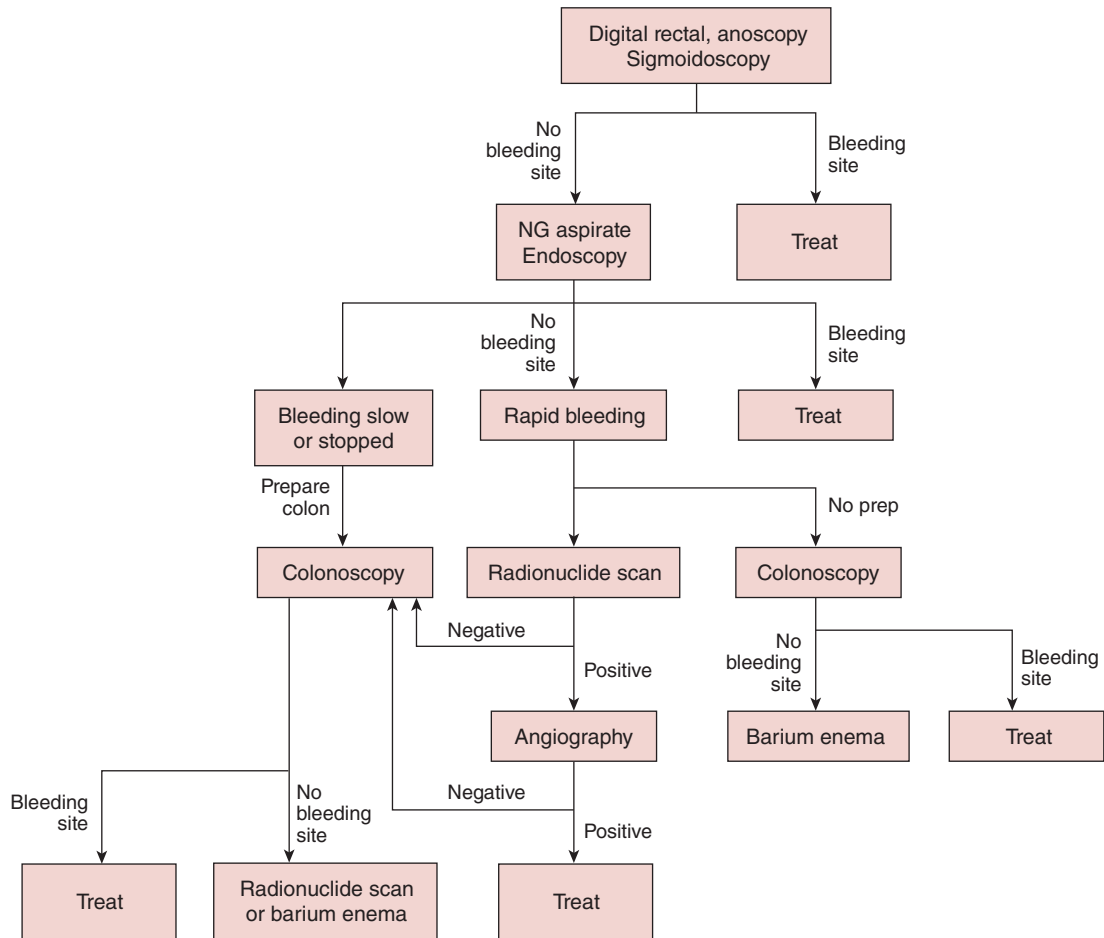

condition such as hemorrhoids. This is especially true for patients who are more than 50 years of age or have a family history of CRC as it ensures that there is not a more proximal lesion that needs to be addressed.

Acute severe hemorrhage, however, is a potentially life-threatening problem, and prompt evaluation and treatment are critical. The first step in the management of these patients is to evaluate and manage the airway, breathing, and circulation (ABCs). A significant portion of these patients present with hemorrhagic shock. Resuscitation with intravenous fluids and blood products takes priority over initiation of diagnostic procedures. Large bore intravenous catheters should be placed and efforts made to keep the patient warm. Strong consideration should be given to transferring the patient to the intensive care unit or other closely monitored setting. Labs are checked for a coagulation profile, platelet count, and hematocrit. Any coagulation abnormalities should be corrected. Patients should be asked about the recent use of antiplatelet agents and blood thinners. Associated medical conditions should be identified and treated as soon as possible. Digital rectal and anoscopic examinations are performed first to look for an obvious source of bleeding and consideration should be given to the possibility of an upper source. A nasogastric aspirate should be examined to rule out an upper source in most patients. While this is not a perfect test, it can provide quick and useful information in a patient with a life threatening upper GI bleed. If blood is aspirated, there is confirmation of an upper source and EGD should be performed. If bile is aspirated, the source is more likely from the lower GI tract and the diagnostic work up should continue. The next step is determined by patient stability and availability.

A plan of management of acute lower gastrointestinal hemorrhage is outlined in Figure 30-14. Many decisions depend on the rate of bleeding, which is difficult to include in an algorithm. Bleeding stops spontaneously in 90% of patients before transfusion requirements exceed two units, but there are no reliable methods to predict who these patients are or who will have recurrent bleeding. Therefore all brisk GI bleeding must be taken seriously.

There are a wide range of procedures that can be used for both diagnostic and treatment purposes in the acute setting. These include endoscopy, angiography, and radiographic techniques including radionuclide scintigraphy and CT angiography. There is no current gold standard and prospective trials are lacking.

Colonoscopy can be a very useful first test to localize the bleeding in stable patients in whom the colon is the suspected source. It has the advantages of being able to visualize the entire colon and any potential bleeding lesions, even after active hemorrhage has ceased. The sensitivity is 74%-100% and is limited by the fact that there is often no active hemorrhage at the time of the examination and stigmata of recent bleeding are seen in only 8%-43% of cases.

▲ **Figure 30-14.** Plan for diagnosis and treatment of acute lower gastrointestinal hemorrhage. (NG = nasogastric)

This limits the utility of preventative treatment in cases with multiple possible sources, such as diverticular bleeding. Depending on the lesion, clips, electrocautery, and/or sclerotherapy may be used. If there is a neoplastic lesion, it can be biopsied or removed. From an efficiency standpoint, colonoscopy makes sense as a first step because it is required at some point in all patients with hematochezia. The disadvantages, including availability of the procedure, need for sedation, and bowel preparation, often preclude its use. It is a generally safe procedure with complication rates of 0%-2%. In order to maximize the utility of colonoscopy, it should be done urgently versus electively. Prospective studies show that lesion identification is more common if colonoscopy is performed urgently versus electively (42% versus 22%), which facilitates the use of directed methods to control and prevent recurrent hemorrhage. In addition, early colonoscopy reduces length of stay and overall cost. Although this

has not been shown to improve other outcomes, the power of these trials is limited by small sample size. If the patient is stable and EGD and colonoscopy are both normal, a capsule endoscopy or double balloon enteroscopy may be performed to evaluate for a small bowel source.

If there is ongoing active hemorrhage, a radionuclide scan may be considered. It is used as a screening examination to identify patients in whom angiography may be useful. It utilizes ^{99m}Tc -labeled red blood cells. The accuracy increases with increased bleeding rates, but has been reported to detect hemorrhage as low as 0.1 mL/min. Radionuclide imaging is particularly useful in patients with intermittent bleeding owing to the long half-life of the tracer. This allows patients to be scanned on multiple occasions during symptomatic periods. In patients with active bleeding, scans are sensitive and specific for identifying the presence of hemorrhage into the GI tract, however they are unable to precisely localize

the source in most circumstances. Once bleeding has been confirmed, angiography is performed for localization and possible treatment. This method has been criticized for causing a delay in therapeutic intervention, although it can prevent angiography in patients who are unlikely to benefit.

CT angiography is a newer technique that is growing in popularity as the technology improves. It does require active bleeding, but can identify the location of bleeding in patients with a rate as low as 0.3 mL/min. Unlike radionuclide scanning, CT angiography can localize bleeding, making for a more accurate and timely intervention by formal angiography. The disadvantages include the additional radiation and contrast exposure for a diagnostic test that cannot be used to treat any identified lesion.

If the radionuclide scan or CT angiogram is positive, it can be followed by selective mesenteric angiography, especially if the source appears to be in the small bowel. Angiography requires ongoing hemorrhage of at least 0.5 mL/min and will likely be of no use if the imaging tests are negative. During angiography, if the site of bleeding is demonstrated, which occurs in 40%-86% of patients, vasopressin or embolization can be used to treat the feeding vessel. Embolism is used if possible because re-bleeding is observed in up to 50% of patients treated with vasopressin alone. Embolization is successful 80%-90% of patients when followed for 30 days. Vascular ectasias can be diagnosed by angiography based on a characteristic pattern of an early filling vein, a vascular tuft, and a delayed emptying vein. These lesions should not be treated if bleeding is not demonstrated as they are quite prevalent and usually asymptomatic. The risks of angiography have decreased with the development of super-selective embolization, however, minor complications occur in 26% and major complications (including death and need for surgery) occur in 17%. One must be especially careful in patients with pre-existing renal insufficiency or diabetes, where the combination of hypovolemia and a large dye load creates a high risk for renal failure. In addition, angiography can rarely provide details about the cause of the bleeding and further work up is required after successful treatment.

In patients who have ongoing hemorrhage and a negative the radionuclide scan, colonoscopy should be considered. This can sometimes be performed successfully in the actively bleeding patient without a bowel preparation because blood acts as a cathartic. Even so, colonoscopy in this situation is difficult. However, a complete examination to the cecum is possible in 55%-70% of patients and there is suggestion that the risk of perforation is increased. Endoscopic therapeutic measures can be applied in up to 40% of patients, with success in half of them. Some gastroenterologists favor performing a bowel preparation under urgent conditions. There are multiple regimens, but usually these consist of a large volume preparation (6-8 L) over a short period of time (4 hours) which increases the chances of electrolyte

abnormalities, aspiration, and results in a poor to fair prep in more than half of patients.

The majority of lower GI bleeds will stop spontaneously or be controlled by colonoscopy or angiography. However, 10%-25% of patients will have continued or recurrent bleeding and ongoing shock. Surgery should be considered once the transfusion requirement exceeds six units of blood. However, localization of bleeding is critical to the success of the procedure and the reduction of morbidity and mortality. Rarely, the bleeding site has been localized conclusively and the procedure is limited to segmental colonic resection. The mortality rate is less than 10%. When the source is unclear, intraoperative endoscopy can be performed to try to localize the source. If the patient continues to be unstable and the bleeding is suspected to be in the colon, a total abdominal colectomy may be required. This carries a mortality of 10%-30%. This is a fortunately rare occurrence today with improvements in imaging, endoscopy, and interventional techniques.

► Prognosis

Up to 90% of lower GI bleeds will stop spontaneously; however, 25% of patients will experience recurrent bleeding. Mortality has been reported in up to 3.6% of patients.

VOLVULUS

► General Considerations

Volvulus involves rotation of a segment of the intestine on an axis formed by its mesentery (Figure 30-15). This results in a closed-loop obstruction and is therefore a surgical emergency. Luminal obstruction occurs when the bowel rotates 180 degrees. If the bowel rotates 360 degrees, the veins are occluded and arterial flow is interrupted. This leads to ischemia, followed by necrosis and perforation if prompt treatment is not instituted. Sigmoid volvulus can be complicated by the additional development of cecal perforation in patients with a competent ileocecal valve. Physiologically this forms a second closed loop obstruction because the proximal colon is unable to decompress into the small bowel. In this situation, the cecum is at greatest risk of perforation by the law of LaPlace because it has the largest diameter.

Most cases of volvulus in the United States involve the cecum or sigmoid colon. A minority of patients present with volvulus of the transverse colon or splenic flexure. Volvulus

▲ **Figure 30-15.** Volvulus of the sigmoid colon. The twist is counterclockwise in most cases of sigmoid volvulus.

accounts for 5% of all cases of large bowel obstruction in the United States. In pregnant women, volvulus accounts for 25% of intestinal obstructions; most commonly in the third trimester. This may be secondary to the displacement of the colon by the enlarging uterus.

Cecal volvulus often occurs in patients with a hypermobile cecum as a result of incomplete embryologic fixation. The average age of presentation is 53 years. This is in contrast to sigmoid volvulus, which tends to occur in elderly or institutionalized patients who experience high rates of constipation and associated motility disorders. It is thought that a long sigmoid colon with an associated narrow-based mesentery is a risk factor. In parts of Africa and the Middle East, sigmoid volvulus accounts for about 50% of bowel obstructions and tends to affect younger, healthy, male patients. In South America, it is seen in association with megacolon in patients with Chagas disease.

Cecal bascule accounts for 10% of cecal volvulus. It involves anterior-superior movement of the cecum, causing obstruction at the site of the transverse fold in the ascending colon. Patients may describe intermittent bloating, pain, and obstructive symptoms improved by lying down and massaging the abdomen. Mesenteric blood flow is not compromised because there is no twist in the mesentery. However, without

treatment these patients are still at risk of gangrene and perforation as a result of the closed loop obstruction.

► Clinical Findings

A. Cecal Volvulus

The cecum and terminal ileum are involved in the rotation, so the symptoms generally include those of distal small bowel obstruction. Severe intermittent colicky pain begins in the right abdomen. Pain eventually becomes continuous, and the patient will experience the classic symptoms of obstruction: vomiting, distention, and obstipation. Patients may report a history of similar but milder attacks.

Imaging studies are the key to diagnosis. In the early stages, a plain film of the abdomen may show single fluid level that may be mistaken for gastric dilation. In later stages there may be a hugely dilated ovoid cecum that favors the epigastrium or left-upper quadrant. It is classically described as the “coffee bean” sign. In cecal volvulus, the dilated loop points toward the right-lower abdominal quadrant. If a film is taken later in the course, the x-ray may show classic findings of small bowel obstruction superimposed on the cecal volvulus. The distal colon will be decompressed. The success rate of diagnosis based on plain abdominal films is extremely variable, ranging from 5% to 90%. CT shows a distended cecum, often with a mesenteric swirl sign, indicating the rotation of the mesentery. Ischemia and necrosis can be identified by a lack of bowel wall enhancement.

B. Sigmoid Volvulus

Sigmoid volvulus presents in a similar fashion to cecal volvulus. Symptoms include intestinal colic, nausea, and obstipation. Distention tends to be more pronounced in sigmoid volvulus. There may be a history of chronic constipation and dysmotility or transient attacks in which spontaneous reduction of the volvulus has occurred. Abdominal x-rays show a markedly distended loop of bowel like a “bent inner tube” that has lost its haustral markings rising up out of the pelvis extending towards the diaphragm. Barium enema reveals a pathognomonic “bird’s beak” deformity with spiral narrowing of the upper end of the lower segment (Figure 30–16). CT should be performed in cases where the diagnosis is unclear as it can demonstrate a dilated sigmoid loop with a mesenteric swirl sign, indicating the mesenteric twist. As with cecal volvulus, the pattern of bowel wall enhancement may help identify patients with ischemia and necrosis of the bowel wall.

► Differential Diagnosis

Cecal volvulus must be differentiated from colonic pseudo-obstruction and from other causes of small bowel and colonic obstruction. Sigmoid volvulus mimics other types of large bowel obstruction. Although x-ray examinations can be helpful, they are often not diagnostic for volvulus, and

▲ **Figure 30-16.** Volvulus of the sigmoid colon. Barium enema taken with the patient in the supine position. Note the massively dilated sigmoid colon. The distinct vertical crease, which represents juxtaposition of adjacent walls of the dilated loop, points toward the site of torsion. The barium column resembles a “bird’s beak” or “ace of spades” because of the way in which the lumen tapers toward the volvulus.

often a CT is performed which eliminates other causes of the abdominal pain and can provide additional information about the presence of complications.

► Treatment

Early diagnosis and treatment are imperative because the involved segment of colon is at risk of gangrene and perforation. The first step in the management of these patients is fluid resuscitation and correction of electrolyte imbalances. Vital signs and urine output should be monitored and a nasogastric tube placed. If there is evidence of ischemia, necrosis, or perforation, antibiotics should be administered as the patient is prepared for emergency surgery.

Many techniques have been described for managing patients with cecal volvulus and cecal bascule, but the recommended treatment is ileocecectomy. This can be done via the laparoscopic or open technique depending on the clinical scenario and surgeon preference. If there is necrotic bowel, the blood supply is ideally controlled prior to releasing the volvulus in an attempt to reduce the systemic release

of the potentially infected, acidotic, and hyperkalemic fluid that can cause cardiac arrest. In unstable patients, the bowel can be left in discontinuity and anastomosis performed at a second look laparotomy. However, a primary ileocolic anastomosis is almost always possible. This approach is associated with less than 5% mortality. Cecopexy (suture fixation of the bowel to the parietal peritoneum) and tube cecostomy (placement of a decompressive transabdominal drain) has been used to avoid a resection and anastomosis in the acute setting, however, these techniques have generally been abandoned due to high rates of both recurrence (30%) and complications (50%). Colonoscopic decompression may be attempted if an expert is available, especially in patients who have serious comorbidities that would make operation hazardous. However, this is successful in less than half of patients. This treatment is contraindicated in patients with suspected strangulation, which occurs in about 20% of cases.

In contrast, sigmoid volvulus without strangulation is more commonly treated initially by urgent endoscopy. A flexible sigmoidoscope or colonoscope is advanced to the obstruction. Under direct visualization, the colon is insufflated and the tip of the scope is used to apply gentle pressure. In 70%-90% of patients, decompression is achieved with the immediate release of gas and stool. The mucosa can then be inspected for signs of ischemia. If there is no evidence of ischemia, the patients is ideally scheduled for resection of the affected bowel with primary anastomosis during the same admission. Half of patients managed with decompression alone will have a recurrence within the first year. However, in patients with severe comorbidities, surgery may need to be delayed or may not be an option. Urgent surgery is indicated if strangulation or perforation is suspected or if endoscopic decompression is unsuccessful. In this case, primary anastomosis is not usually possible and a Hartmann’s procedure with washout is performed.

► Prognosis

The outcome for patients with volvulus depends on comorbidities, the urgency of the surgery, and the presence of strangulation or perforation. The mortality rate for patients with cecal and sigmoid volvulus is less than 10%, but this increases to 30%-50% if strangulation or perforation has occurred. Patients who undergo semi-elective resection after endoscopic decompression have a mortality rate less than 10%.

INFLAMMATORY BOWEL DISEASE

Inflammatory bowel disease (IBD) refers to UC, Crohn disease (CD), and indeterminate colitis. The cause of IBD is not known. The disease is likely the result of a combination of genetic, environmental, and host immune response factors.

There is a positive family history of IBD in 15%-40% of patients. Crohn disease seems to have a stronger genetic link than UC. Genome-wide association studies initially identified normal variants of multiple loci associated with the development of IBD; however, these associations are still poorly understood. These genetic associations are heterogeneous and have precluded the development of a useful screening test.

It is postulated that the interplay between the immune system, normal microflora, and colonic epithelium is a factor in the development of IBD, but this is still being investigated. Patients with UC are known to have an increased concentration of normal bacterial flora compared to healthy controls; however, it is not known if this contributes to the disease process. The mucosal immune system has been implicated by the finding that patients with CD have a predominantly Th1 mucosal population, whereas patients with UC have a Th2 predominance. An autoimmune component is suggested by circulating perinuclear antineutrophil cytoplasmic antibody (pANCA) and abnormally high levels of auto-IgG1 antibodies. These antibodies cross react with the epithelium of the colon, biliary tract, skin, eye, and cartilage and have been hypothesized to contribute to extraintestinal manifestations.

Environmental factors are also important. The use of NSAIDs has been associated with flares in patients with CD. Smoking has been shown to be a protective factor for UC. Smokers are less likely to develop the disease, and smoking cessation leads to worsening of disease in smokers with UC. For unclear reasons, this disease is also less common in patients who have undergone appendectomy.

ULCERATIVE COLITIS

► General Considerations

UC has a bimodal age distribution, with the first peak between ages 15 and 30 years and a second, smaller peak in the sixth to eighth decades. The annual incidence varies from 1 to 20 per 100,000, and the prevalence is 8-246 per 100,000. UC is more common than CD in adults but less common in children. The disease is found worldwide but is more common in Western countries and the incidence is increasing in Asia. This finding has also contributed to the theory of bacterial flora contributing to the development of the disease.

UC is a diffuse but contiguous mucosal inflammatory disease. Abscesses form in the crypts of Lieberkühn and penetrate the superficial submucosa. In the acute setting,

neutrophils predominate whereas in the chronic setting, the infiltrate is largely composed of lymphocytes and plasma cells. There are no granulomas. The overlying mucosa sloughs as the inflammation spreads. Vascular congestion and hemorrhage are prominent, and there is often diffuse thickening of the muscularis mucosa. The normal tissues surrounding the ulcerated areas appear endoscopically protruberant and thus are called pseudopolyps. Except in the most severe forms, the muscular layers are spared. In fulminant disease, the full thickness of the colon wall can be involved, which leads to dilation and ultimately perforation. In patients with long standing or severe disease, the colon becomes shortened and loses its normal haustral markings.

UC classically starts at the rectum and extends proximally without skip lesions. The disease is confined to the rectum (proctitis) or up to the rectosigmoid region (proctosigmoiditis) in at least half of patients. The disease is classified as left-sided colitis if it involves the descending colon, extensive colitis if it extends proximal to the splenic flexure, and pancolitis if the cecum is involved. In patients with pancolitis, a few centimeters of terminal ileum may be involved by proximity in patients with an incompetent ileocecal valve. This is termed backwash ileitis and can make the differentiation of UC from CD challenging. There are no strict diagnostic criteria, but generally a clinical and histologic appearance of UC without evidence of CD is enough to establish a diagnosis and initiate treatment.

► Clinical Findings

A. Symptoms and Signs

Patients commonly report frequent, small volume watery stools mixed with blood, pus, and mucus accompanied by tenesmus, rectal urgency, and even fecal incontinence. Many patients will report crampy abdominal pain and variable degrees of fever, vomiting, weight loss, malaise, and dehydration. The symptoms can be episodic with periods of spontaneous improvement or severe and unrelenting. Mild disease may be manifested only by loose or frequent stools, or occasionally constipation. In isolated instances, the only symptoms may be from extraintestinal manifestations such as arthropathy or pyoderma.

If the disease is mild, physical examination may be normal, but in severe disease the abdomen is tender and distended. Severe rectal inflammation may result in considerable tenderness and spasticity of the anus during digital rectal examination. The examining finger may be covered with blood, mucus, or pus. Perianal disease can occur in UC patients as they do in the general population, but signs of anal disease should prompt a workup for CD.

A simple classification of the severity of an attack was devised by Truelove and Witt in 1955. The assessment of disease severity is based on six simple clinical signs including

Table 30–8. Ulcerative colitis disease severity (based on the Truelove and Witt classification).

Symptoms	Mild	Severe	Fulminant
Stools (per day)	< 4	> 6	> 10
Hematochezia	Intermittent	Frequent	Continuous
Temperature	Normal	> 37.5°C	
Pulse (beats/min)	Normal	> 90	
Hemoglobin	Normal	< 75% of normal	Requires transfusion
ESR	< 30 mm/h	> 30 mm/h	

stool frequency, hematochezia, pulse, temperature, hemoglobin, and erythrocyte sedimentation rate (Table 30–8).

B. Laboratory Findings

There is no single diagnostic test for UC, although in unclear cases, serum antibody tests can help differentiate UC from CD. Serum pANCA are found in 60%–70% of patients with UC but also are found in up to 40% of patients with CD. In patients with IBD for whom the differentiation between UC and CD is unclear, the combination of a positive pANCA and negative anti-saccharomyces cerevisiae antibodies (ASCA) has a specificity of 97%, sensitivity of 48%, and a positive predictive value of 75% for UC. A negative pANCA and positive ASCA has a positive predictive value of 86% for CD. Thus serologic testing in patients with IBD may be helpful when considered in the context of other clinical factors.

During an acute flare, basic laboratory tests are used to assist in determining the severity of disease. Anemia, leukocytosis, and an elevated sedimentation rate or C reactive protein is usually present. Severe disease leads to hypoalbuminemia, dehydration, and electrolyte abnormalities. There is often evidence of steatorrhea. To look for signs of superinfection, the stool should be sent for ova and parasite examination, culture (*E. coli* 0157:H7 and *Campylobacter*), and *C difficile* toxin assay.

C. Imaging Studies

In the acute setting, colonoscopy and barium enema should be avoided due to the risk of perforation. If needed for diagnosis, biopsies obtained by proctoscopy should be sufficient. Abdominal x-rays may show dilation of the colon, and can be used to detect free air when perforation is suspected. CT scan has become the most common imaging modality during an acute episode. CT will often show thickened rectum and colon with associated inflammatory changes, however, it does not often lend much to the clinical management of these patients.

Barium enema, which is now infrequently used, shows mucosal irregularity that varies from fine serrations to extensive ulceration with pseudopolyps. As the disease progresses,

haustrations are gradually effaced, and the colon narrows and shortens because of muscular rigidity (Figure 30–17). Widening of the space between the sacrum and rectum is due either to proctitis or to shortening of the bowel. The presence of a stricture should always arouse suspicion of cancer or CD.

In cases where the diagnosis is unclear, a small bowel series or CT enterography may be performed to look for involvement suggestive of CD.

D. Colonoscopic Findings

Colonoscopy is an essential part of diagnosis and surveillance. The characteristic mucosal changes include loss of

▲ **Figure 30–17.** Ulcerative colitis. Barium enema x-ray of colon. Note shortening of colon, loss of haustral markings (“lead pipe” appearance), and fine serrations at the edges of the bowel wall that represent multiple small ulcers.

vascular pattern, granularity, friability, hyperemia, and ulceration. Pseudopolyps represent islands of normal mucosa against a background of inflamed, denuded bowel wall. These findings begin in the distal rectum and proceed proximally in a continuous fashion. In more advanced disease, the mucosa is purplish-red, velvety, and extremely friable. Blood mixed with mucus is evident in the lumen. If the mucosa is not grossly diseased, biopsy may be helpful to confirm the diagnosis. In the recovery phase, mucosal hyperemia and edema subside. The healing mucosa is typically dull and granular and has a neovascular pattern of telangiectatic vessels that differs from the normal pink mucosa. Patients with disease distal to the splenic flexure may have a “cecal patch,” an inflammatory lesion at the appendiceal orifice, that can be misidentified as a skip lesion associated with CD. In the acute setting, colonoscopy is important in determining the severity of disease and response to treatment. These patients are at increased risk for CRC. Screening colonoscopy begins 8-10 years after the initial diagnosis of pancolitis and 12 years after left-sided colitis. Surveillance for dysplasia should be done every 1-2 years. At least 30 random biopsies should be taken throughout the colon to detect dysplasia.

► Differential Diagnosis

The differential diagnosis of patients presenting with new onset UC is extremely broad and includes all forms of colitis. Cancer and diverticulitis should also be considered. Infectious colitis can mimic UC but can also be superimposed on patients with underlying UC. Salmonellosis and other bacillary dysenteries are diagnosed by repeated stool cultures. Shigellosis may be suspected on the basis of a positive methylene blue stain for fecal leukocytes. *Campylobacter jejuni* is a common cause of bloody diarrhea; the organisms can be cultured from the stool, and serum antibody titers rise during the illness. Hemorrhagic colitis—a syndrome of bloody diarrhea and abdominal cramps but no fever—is associated with infection by *E coli* O157:H7. Legionella infections can mimic UC. Gonococcal proctitis is detected by culture of rectal swabs. Herpes simplex virus is the most common cause of nongonococcal proctitis in homosexual men. In patients with suspected amoebiasis, corticosteroids should be held until amoebiasis is excluded by microscopic examination of stool, rectal swabs, rectal biopsies, or serologic tests.

Cases of histoplasmosis, tuberculosis, cytomegalovirus disease, schistosomiasis, amyloidosis, or Behçet disease may be very difficult to diagnose. Drug-induced colitis may be suspected based on the patient's history. NSAIDs can cause mucosal inflammation and even strictures in the large intestine. Collagenous colitis may or may not be related to NSAID use. Watery diarrhea is the main symptom of this syndrome, endoscopy is grossly normal, and biopsies

show a thickened band of collagen just beneath the mucosa. Ischemic colitis has a segmental pattern of involvement quite unlike the contiguous distribution of UC. Functional diarrhea can mimic colitis, but organic disease must be excluded before it can be concluded that the diarrhea is functional. Diversion colitis refers to inflammation of a previously normal segment of colon or rectum following construction of a temporary colostomy. Deficiency of mucosal nutrients may be responsible, and inflammation may be treated with topical application of short-chain fatty acids or restoration of intestinal continuity.

The most difficult differential diagnosis is between mucosal UC and Crohn colitis (Table 30-9). None of the features are specific for one disease, and often the differentiation can be made only after all the data have been assembled. Luckily, in the acute phase, the medical treatment is similar, however, the differentiation is important because it can dictate appropriate surgical therapy. About 10% of cases cannot be classified (indeterminate colitis).

► Complications

A. Extraintestinal Manifestations

Extraintestinal manifestations (EM) occur in approximately 21% of patients with UC. They are more common in women and patients with pancolitis. The pathogenesis is unknown, but it is thought that they may be a result of a systemic autoimmune process. A genetic component is suggested by the fact that they tend to cluster in families. Nearly 80% of patients who develop EM do so after the development of colonic symptoms, but a minority will present with EM prior to symptomatic colonic disease that may lead to a diagnosis of UC. The most common EMs are musculoskeletal (arthralgias, arthritis, ankylosing spondylitis), anterior ocular chamber inflammation (uveitis, iritis, scleritis, and conjunctivitis), skin (erythema nodosum, pyoderma gangrenosum), and primary sclerosing cholangitis (PSC) in order of decreasing frequency. PSC can lead to cirrhosis requiring liver transplant and puts the patient at increased risk for cholangiocarcinoma. For unclear reasons, patients with PSC also develop colorectal cancer at an increased rate. PSC is not improved with treatment of the colonic disease and may develop or progress after curative proctocolectomy. However, arthritis, ocular disease, and skin manifestations are known for paralleling disease activity. Most patients will develop only one EM, but a subset will develop multiple.

Patients with UC also develop symptoms as a result of the disease process in the colon, including iron deficiency anemia and malnutrition. They are at high risk for thrombosis, especially during flares. Patients are also at risk of developing complications from medical treatment using long-term corticosteroids such as diabetes, osteoporosis, cataracts, and adrenal insufficiency.

Table 30–9. Comparison of various features of ulcerative colitis with those of Crohn colitis.

	Ulcerative (Mucosal) Colitis	Crohn Colitis
Signs and symptoms		
Diarrhea	Marked	Present; less severe
Gross bleeding	Characteristic	Infrequent
Perianal lesions	Infrequent, mild	Frequent, complex; may precede diagnosis of intestinal disease
Toxic dilatation	Yes (3%-10%)	Yes (2%-5%)
Perforation	Free	Localized
Systemic manifestations (arthritis, uveitis, pyoderma, hepatitis)	Common	Common
X-ray studies	Confluent, diffuse Tiny serrations, coarse mucosa, mucosal tags Concentric involvement Internal fistulas very rare Colon only except in backwash ileitis; may be limited to left side	Skip areas. Longitudinal ulcers, transverse ridges, "cobblestone" appearance Eccentric involvement Internal fistula common Any portion of intestinal tract may be involved; may be limited to ileum and right colon
Morphology		
Gross	Confluent involvement Rectum usually involved Mesocolon not involved; nodes enlarged Widespread, ragged, superficial ulceration Inflammatory polyps (pseudopolyps) common No thickening of bowel wall	Segmental involvement with or without skip areas Rectum often not involved Thickened mesocolon; pronounced lymph node enlargement Large longitudinal ulcers or transverse fissures Inflammatory polyps not prominent Thickened bowel wall
Microscopic	Inflammatory reaction usually limited to mucosa and submucosa; only in severe disease are muscle coats involved; no fibrosis Granulomas rare	Chronic inflammation of all layers of bowel wall; damage to muscle layers usual; submucosal fibrosis Granulomas frequent
Natural history	Exacerbations, remissions; may be explosive, lethal	Indolent, recurrent
Treatment		
Response to medical treatment	Good response in 85% of cases	Difficult to evaluate; less well controlled over long term
Type of surgical treatment and response	Colectomy with ileoanal anastomosis; proctocolectomy with ileostomy No recurrence	Segmental colectomy; total colectomy with ileorectal anastomosis; proctocolectomy if rectum severely diseased Recurrence common

B. Hemorrhage

Gross hematochezia is common during acute flares of UC. In the chronic setting, patients frequently develop a chronic iron deficiency anemia. Ten percent of patients will require blood transfusion for bleeding during a flare. Massive hemorrhage is a potentially life threatening complication that occurs in up to 5% of patients. This is an indication for urgent colectomy and accounts for approximately 10% of all urgent colectomies in patients with UC.

C. Fulminant Colitis

Fulminant colitis occurs in less than 10% of all patients with UC, but in up to 50% of these patients, it develops during their initial presentation. This represents the most severe, acute form of the disease. Patients are systemically ill and develop inflammation extending into the muscular layer of the bowel. Electrolyte disturbances, especially hypokalemia, may contribute to toxicity and should be treated aggressively. Opioids and anticholinergics should be avoided.

These patients should be fluid resuscitated and treated with broad spectrum antibiotics. Electrolyte disturbances should be corrected. A nasogastric tube is placed for patients with significant signs of distension. A CT scan can detect perforation or ischemia, as well as other causes of abdominal sepsis. Serial abdominal x-rays can trend colonic distention. However, if there is clinical deterioration or no improvement with maximal medical therapy over the course of 48-72 hours, surgery should be considered. Although barium enema is no longer used to diagnose toxic colon, one can see the classic findings in Figure 30-18. These include a thickened bowel wall and dilation of the lumen greater than 6 cm. Luminal air can be seen outlining irregular nodular pseudopolyps. However, patients do not need to have colonic dilatation to have toxic colitis.

D. Perforation

Colonic perforation is the most dreaded complication of severe acute UC and occurs in 3% of hospitalized patients. It is responsible for more deaths than any other complication. The risk of perforation is highest during the initial attack of the disease and correlates well with its extent and severity. It may also occur as a complication of endoscopy or barium enema in acutely ill patients. Patients with toxic colitis are especially vulnerable. Perforation is most common in the sigmoid or splenic flexure and may result in a localized

▲ **Figure 30-18.** Barium enema showing acute colonic dilation in ulcerative colitis. Note dilation of the transverse colon, the multiple irregular densities in the lumen that represent pseudopolyps, and the loss of haustral markings.

abscess or generalized fecal peritonitis. Systemic therapy (corticosteroids and antibiotics) may mask the development of this complication. Therefore, serial abdominal examinations, laboratory tests, and abdominal imaging are important in detecting this complication.

E. Malignancy

Colorectal cancer risk increases above that of the general population 10 years after the onset of UC, although the rates vary widely between studies. The risk increases with the duration and severity of disease, and is higher in patients with a family history of CRC, extensive colitis, and PSC. Decreased risk in recent reports may be associated with improved medical treatment of colitis. Cancers in UC tend to be multicentric and broadly infiltrating. They are difficult to recognize endoscopically because they arise from small, flat areas of dysplasia located in a background of ulceration and inflammation. They do not follow the typical adenoma-carcinoma sequence seen in sporadic CRC in the general population. Newer techniques, including narrow-band imaging and chromoendoscopy may improve detection.

Colonoscopic surveillance is recommended beginning 8-12 years after the onset of colitis and continues at 1-2 year intervals. Ideally, approximately 48 random biopsies are taken throughout the colon and rectum to screen for dysplasia. Synchronous CRC is found in 20% of patients undergoing proctocolectomy for low-grade dysplasia, 40%-60% of patients with high-grade dysplasia, and 40%-85% of patients with dysplasia-associated lesion or mass (DALM) regardless of the degree of dysplasia. Low-grade dysplasia places the patient at a ninefold increased risk of developing CRC compared to UC patients without dysplasia. In addition, low-grade dysplasia has been reported to progress to carcinoma without progressing to high-grade dysplasia. IBD-associated cancers account for 1%-2% of all CRCs but occur in younger patients and confer a poorer prognosis. High-grade dysplasia and DALM are clear indications for proctocolectomy, and consideration should be given to patients with low-grade dysplasia. Intensive study is ongoing to identify more sensitive screening methods.

▶ Treatment

A. Medical Therapy

The goals of medical therapy are to stop an acute flare as rapidly as possible and to maintain remission of mucosal inflammation. Traditionally, medical management has been approached in a “step up” fashion, with treatment depending on the severity of disease (classified as mild, moderate, severe, or fulminant), the extent of colonic involvement, and history of previous response to treatment. However, a new paradigm of “top down” treatment has evolved for patients with severe disease as research has shown improved outcomes with more aggressive treatment. The endpoints of

therapy have shifted away from symptomatic improvement to objective mucosal healing and steroid free remission. Mild to moderate disease usually can be treated on an outpatient basis. If the disease flare is refractory or progressive, hospitalization may be required. Patients with severe or fulminant disease may require inpatient treatment for supportive therapy (IV hydration, antibiotics, blood transfusion, and monitoring).

Mild to moderate disease is treated with sulfasalazine or 5-aminosalicylates, such as mesalamine, olsalazine, or balsalazide. Sulfasalazine is cheaper, but associated with more side effects and should not be given to sulfa-allergic patients. These drugs can be administered orally or topically in the form of suppositories or enemas in patients with disease limited to the rectum or sigmoid. Seventy percent of patients will respond to this regimen within 1 month. The remaining 30% are started on prednisone 40–60 mg/d. In patients who do not exhibit objective evidence of response or who remain steroid dependent, azathioprine, 6 mercaptopurine, infliximab, and adalimumab are additional options to induce and maintain remission.

In patients with severe disease, these initial steps are bypassed and treatment with intravenous glucocorticoids is initiated. In addition, biologic agents or immunomodulators are added. Infliximab, an anti-TNF antibody, tacrolimus and cyclosporine have been shown in randomized controlled trials to be effective for treatment of severe flares.

If these regimens are not successful, additional medications or surgery are considered. Multiple new drugs show promise in the treatment of patients with refractory disease. Newer biologic agents, such as certolizumab and naticlizumab, as well as Tofacitinib, an oral Janus kinase inhibitor have been shown to be effective in inducing remission in patients with steroid refractory moderate to severe UC. Other treatments, such as stem cells and fecal transplants, are currently under investigation.

Once remission has been obtained, a maintenance regimen is required to prevent relapse in most patients. These regimens should be individualized based on the response to the induction regimen and revised as clinically indicated. For mild disease, mesalamine is commonly used. Patients unable to wean from steroids require intensified treatment. Azathioprine, 6 mercaptopurine, methotrexate, infliximab, adalimumab, or newer immunomodulators may be needed to successfully wean patients off steroids.

B. Surgical Therapy

1. Indications—Indications for surgery fall under three broad categories: patients who require urgent or emergency surgery due to severe illness or complications during a flare, patients who have chronic intractable disease or medication intolerance, and those who require treatment for dysplasia or carcinoma. Twenty percent of patients who present with

fulminant colitis will go on to require surgery. There have been no trials comparing medical therapy to surgery for any of these indications. Crohn disease should be ruled out in any patient in whom surgery is being considered, as a proctocolectomy, especially with J-pouch reconstruction, is inappropriate for these patients.

In the acute setting, emergency surgery is indicated for colonic perforation. Other complications, such as toxic megacolon, fulminant colitis, or uncontrolled hemorrhage are initially managed medically. However, if there is no improvement with aggressive medical therapy, surgery is warranted. There are no firm guidelines for how long patients should be treated medically prior to considering surgery. These patients are monitored closely for 48–72 hours. If there is clinical deterioration or no improvement, surgery is indicated.

Another group of patients in whom surgery is considered are those with intractable disease despite maximal medical therapy or those who cannot wean off steroids due to worsening symptoms. In children this may present with growth retardation. Adults may become physically debilitated, psychosocially limited, and experience poor quality of life. There may be medication intolerance, especially in those patients who are steroid dependent. Surgery is also considered for patients with severe extraintestinal manifestations that have developed in parallel with the UC flares such as peripheral arthritis, pyoderma gangrenosum, and ocular manifestations. These may respond to colectomy.

Patients who have biopsy-proven carcinoma are offered proctocolectomy as opposed to standard oncologic resection because this treats both the UC and the cancer. Further, colitis-related CRC tends to be widely infiltrative, multicentric, and difficult to visualize making standard oncologic resection dangerous. Patients with dysplasia or dysplasia-associated lesion or mass are also candidates for surgery as the risk for a synchronous or metachronous malignancy is high as discussed previously.

C. Surgical Procedures

In the elective setting there are two surgical options. Proctocolectomy with ileal pouch-anal anastomosis (IPAA) is the operation of choice in most patients because it provides intestinal continuity (Figure 30–19). However, total proctocolectomy with a permanent end ileostomy is indicated in a subset of patients. Factors include preoperative sphincter function, presence of carcinoma low rectal cancer, and the patient's age, general health, and preferences. IPAA is contraindicated in patients with poor baseline sphincter tone or in whom a diagnosis of CD cannot be excluded. Both procedures are now increasingly performed laparoscopically with equivalent functional results and improved short-term outcomes.

A permanent end ileostomy may be desired by patients who have concerns about the postoperative complications or

▲ **Figure 30-19.** View of the pelvis after colectomy and ileoanal anastomosis in a male. The J-pouch, shown here, is one of several types of reservoirs and is most commonly utilized. The pouch is anastomosed to the anal canal just above the dentate line.

anticipate difficulty managing the changes in bowel function associated with the ileoanal pouch. Patients frequently experience greater than 10 bowel movements per day during the first 3 months. This eventually decreases to an average of 5-7 bowel movements per day. Twenty percent of patients experience nocturnal seepage or incontinence 1 year after surgery. The most common complications after surgery include small bowel obstruction, infertility, sexual dysfunction, and pelvic sepsis as a result of anastomotic or pouch leaks. Pelvic sepsis occurs in 25% of patients and is the most common cause of pouch failure. Pouchitis affects 40% of patients in the first 10 years after surgery. This is an idiopathic inflammation of the ileoanal pouch that causes abdominal pain, increased bowel movements, and bleeding. It is treated with antibiotics.

Proctocolectomy with IPAA can be performed as a one-, two-, or three-stage procedure. In the elective setting, a two-

stage procedure is most common, involving proctocolectomy with IPAA and diverting loop ileostomy at the first surgery followed by ileostomy reversal as a second surgery. A single stage operation (without diverting loop ileostomy) is performed only in the most ideal candidates. This approach eliminates the ileostomy-associated complications and avoids a second surgery at the increased risk of the potentially significant consequences of pelvic sepsis from an undiverted anastomotic leak. The three stage procedure is reserved for ill patients who would not tolerate the IPAA during the first surgery secondary to malnutrition or severe active disease. It is also useful in patients with indeterminate colitis in whom confirmation of UC may be made after pathologic evaluation of the surgical specimen allowing the safe formation of the IPAA. The first procedure is a subtotal colectomy with end ileostomy, followed by completion proctectomy, and IPAA. At the time of this procedure, an ileostomy may be avoided in selected patients, otherwise the ileostomy is reversed at a third operation. In the interval between subtotal colectomy and proctectomy, the residual disease in the rectal remnant improves with fecal diversion and if symptoms persist, it can be treated locally with suppositories or enemas.

Proctocolectomy involves mobilizing and resecting the entire colon and rectum. If IPAA is planned, the anal sphincter complex is left in place. The ileum is made into a reservoir most commonly with a “J” configuration (although multiple configurations have been described) and an anastomosis is created just above the dentate line (Figure 30-19). A diverting loop ileostomy is used to protect the anastomosis if there is any intraoperative concern about the anastomosis or if the patient has risk factors for impaired healing such as steroid exposure, anemia, diabetes, or malnutrition. Most of these patients will have been treated with immunosuppressants or immunomodulators in the preoperative period. Although these medications theoretically impact healing, there is no clear evidence to suggest that they increase surgical complications in the setting of diversion.

The continent ileostomy, which was first reported by Kock in 1969 is plagued by complications requiring reoperation in 50% of patients. It has largely been replaced with the IPAA and is mainly mentioned for historical purposes.

D. Prognosis

The mortality rate of UC has dropped sharply in the past two decades. First attacks are seldom fatal when treated by specialists. In one large series, emergency colectomy was required in 25% of patients with severe first attacks; 60% responded rapidly to medical therapy; and 15% improved slowly on medications alone. Overall, the colitis-related mortality rate during the year after onset is about 1%. Emergency colectomy has a mortality rate of 6%; most of these deaths occur in patients with preoperative perforation, a complication that has a fatal outcome in 40% of cases.

Compared to pancolitis, the long-term prognosis of ulcerative proctitis is excellent; only 10% of patients will develop colonic disease by 10 years, and the mortality rate is very low. In patients with pancolitis, the likelihood of operation during the first year is about 25% and the mortality rate is 5% over 10 years. Colorectal cancer in UC is more often diagnosed at an advanced stage than is sporadic cancer, but the stage-for-stage prognosis is the same. Screening with colonoscopy and biopsies seems to have reduced the cancer mortality rate, but there are still many patients who escape detection until the malignancy has progressed to an advanced stage. The operative mortality rate is less than 1% for elective colectomy.

CROHN COLITIS

► General Considerations

Approximately 45% of patients with CD have diffuse involvement of the GI tract; 30% have disease limited to the small bowel, 20% have disease limited to the colon, and another 5% have isolated anorectal involvement. Symptoms, including diarrhea, abdominal pain, constitutional effects, and extraintestinal manifestations are approximately the same in colonic and enteric disease. Fistulas, abscesses, and intestinal obstruction are more often complications of small bowel disease. Anorectal complications such as anal fistula, fissure, abscess, rectal stricture, as well as hemorrhage occur more commonly in patients with disease affecting the large bowel.

► Clinical Findings

Patients present with abdominal pain, diarrhea, and systemic signs such as low-grade fevers, weight loss, and malaise. Symptoms are generally dictated by the distribution of disease, but patients with Crohn colitis may report urgency or mucous, blood, or pus per rectum. Patients with perianal disease may present with perianal pain or discharge. If the inflammatory process has caused structuring, partial obstructive symptoms may be present.

Radiographic features include sparing of the rectum, right colonic and ileal involvement, skip areas, transverse fissures, longitudinal ulcers, strictures, and fistulas. Typical anal lesions of CD include fissures, abscesses or fistulas. Large external skin tags are also common. The differential diagnosis is broad and includes all forms of colitis including UC, infectious and ischemic. Features differentiating CD from UC are summarized in Table 30-9.

► Colonoscopy

Colonoscopy is indicated for diagnosis, evaluation for severity of disease, determining response to treatment, and screening for colorectal cancer. Colonoscopy with biopsy is a mainstay in diagnosis. Patients with Crohn colitis have rectal sparing about 50% of the time. Skip lesions are common, with irregular ulcerations separated by edematous or even normal-appearing mucosa. Patients with pancolitis appear to have similar risk profile for cancer as their UC counterparts. The risk of colorectal cancer in Crohn colitis patients is 4 to 20 times that of the general population. The 25-year risk of dysplasia in patients with Crohn colitis is 12%-25%. Data to support surveillance and management strategies for patients with Crohn colitis are limited and often extrapolated from UC patients. Routine annual colonoscopy with random biopsies is recommended beginning 8 years after the diagnosis. Surveillance should include high risk areas, such as segments of intestine excluded from the fecal stream, strictures, and fistulas with focused biopsies performed as needed.

► Treatment

A. Medical Therapy

Steroids are effective for acute attacks in up to 70% of patients, but they are not used for maintenance therapy because of the associated side effects and complications. Up to 45% of patients who initially improve with steroids will relapse upon tapering or withdrawal. Oral 5-aminosalicylates (sulfasalazine, 4 g/d; or mesalamine, 2-5 g/d) are effective treatment for Crohn colitis. Topical 5-aminosalicylates are beneficial for disease of the rectum and sigmoid and are often used to wean patients off steroids. Anal abscesses and fistulas require surgical drainage and seton placement to treat local sepsis, but healing is improved with biologic agents.

Immunosuppressants (azathioprine, mercaptopurine, methotrexate) are steroid-sparing drugs that seem to control Crohn colitis well enough that surgery is delayed or avoided. Biologic agents including infliximab and other anti-TNF therapies are effective for inflammatory CD and also specifically indicated for fistulizing or refractory disease. Patients who respond to infliximab induction should receive maintenance therapy. Adalimumab is an effective therapy for patients who are refractory or intolerant to infliximab. Newer human monoclonal antibodies, such as the anti-TNF natalizumab and anti-interleukin ustekinumab have shown promising results in preliminary clinical trials and are now being used more frequently for patients who initially responded to other agents.

B. Surgical Therapy

Failure of medical therapy, neoplasia, and complications of CD are indications for surgery. Patients whose symptoms do not respond to medical treatment, are unable to achieve remission, have intractable weight loss, or have unmanageable side effects should be considered. The choice of operation depends on the severity and distribution of disease, but the general principle is bowel preservation, with resection of only diseased, actively symptomatic areas. In contrast to UC, CD is not cured surgically, and procedures are performed with palliation in mind. However, patients who have distal colon and rectal disease or multiple segments of disease often do better with a proctocolectomy. Disease tends to recur, especially at areas of intestinal anastomosis and short bowel syndrome is a major concern. Cigarette smoking is an independent risk factor for recurrence of CD after resection.

Strictures are more common in patients with longstanding disease. The use of CT or MR enterography is useful to localize the lesion. If the lesion is symptomatic and unresponsive to medical therapy, resection is indicated. If the lesion is asymptomatic, malignancy should be ruled out with biopsies or brushings. Lesions not amenable to surveillance should be considered for resection, as 7% are malignant.

Intra-abdominal abscesses may be managed with percutaneous drainage and antibiotics. Those who do not respond to conservative management may need an operation. Patients with CD are at risk of developing enterocutaneous and enteroenteric fistulas spontaneously or after surgical intervention, and if diagnosed, nutritional optimization and control of sepsis are of utmost importance.

Five percent of patients will develop severe or fulminant colitis. These patients should be treated in a similar fashion as patients with UC including bowel rest, intravenous fluids, broad spectrum antibiotics, and aggressive CD therapy. They should be closely monitored with serial abdominal examinations, laboratory tests, and imaging as indicated. Patients with CD more commonly respond to medical management than patients with UC. When patients require surgery, total abdominal colectomy with end ileostomy is the most common operation performed in the acute setting, although if by operative inspection the disease is limited to a specific part of the large bowel, this can be resected with creation of a colostomy and Hartmann's pouch or mucous fistula. Isolated perforation without toxic megacolon is preferentially treated with segmental resection, as simple closure is associated with a higher mortality rate. Diversion is commonly performed in colonic perforations and occasionally for perforation of small bowel depending on the clinical status of the patient and the intraoperative findings.

Perianal complications include perianal abscess, fistula, ulcer, and fissure. These processes are treated using the same methods as are used in non-IBD patients, although these problems tend to be more complicated and chronic, requiring dedicated surgical follow-up. The key elements to treatment are elimination of sepsis and protection of the anal sphincter.

Dysplasia or cancer of the colon requires surgical treatment. Depending on the location and extent of disease, proctocolectomy or segmental resection is performed for high-grade dysplasia, dysplasia-associated lesions or mass lesions. Twenty percent of patients with high grade dysplasia are found to have carcinoma in the surgical specimen, and half of patients known to have cancer preoperatively are found to have remote dysplasia upon pathologic review. For this reason, total proctocolectomy with end ileostomy should be considered in patients found to have cancer or high grade dysplasia on surveillance colonoscopy.

► Prognosis

Surgical procedures—like medical therapy—should be regarded as palliative, not curative, in patients with CD. Although recurrence rates are high and chronic disease is common, a productive life is usually possible with the aid of combined medical and surgical management. The mortality rate is about 15% over 30 years.

PSEUDOMEMBRANOUS COLITIS

Pseudomembranous colitis is caused by *C. difficile*. *C. difficile* colitis was first reported in 1978 but the incidence and severity of infection is increasing with time. Of particular concern is the increasing virulence, with reports of antibiotic resistance and mutant strains with uncontrolled toxin production. Infection causes a range of illness from mild diarrhea to fulminant, life threatening colitis and is particularly dangerous in frail or immunocompromised patients.

► Microbiology

Clostridium difficile is a spore-forming organism that is ubiquitous in the environment. It is a commensal gut organism that exists in 5%-15% of the general population and up to 57% of patients in long-term care facilities. The spores are dormant and extremely resistant to disinfectants and extreme environments. Spread by health care practitioners is reduced significantly by the use of standard contact precautions including disposable gowns and gloves and hand washing with water and soap. Alcohol-based hand sanitizers are not effective. Once ingested, the spore is reactivated after contact with bile salts in the small intestine.

The bacterium exists in both toxin-producing and non-producing forms. Only the toxin-producing bacterium is capable of causing colitis. Toxins A, B, and binary toxin induce apoptosis and provoke inflammation. The epidemic-associated 027 strain is thought to have a mutation causing increased production of toxins A and B, as well as enhanced sporulation making it particularly virulent and transmissible. These toxins as well as a variety of nontoxin virulence factors cause pseudomembranous colitis.

Although *C. difficile* is commensal and the spores are easily transmitted, the presence of normal colonic flora is usually enough to prevent infection. Symptoms generally only occur when the normal flora is disrupted. Therefore, pseudomembranous colitis most often occurs in patients taking antibiotics. Clindamycin is historically the most common cause, but all antibiotics that alter the gut flora have the potential to cause infection. Pseudomembranous colitis may develop as early as 2 days after exposure to antibiotics but has been reported many weeks after they are discontinued. Other risk factors include surgery of the gastrointestinal

tract, immunosuppression, and use of proton pump inhibitors and H2 blockers.

► Symptoms and Signs

The most common symptom is diarrhea, which is usually watery, occasionally bloody, and has a characteristic foul odor. Other symptoms include colicky abdominal pain, vomiting, and fever. *C. difficile* infection may also cause a paralytic ileus and therefore, can present without diarrhea. Depending on the severity, patients may present with abdominal distention, tenderness, dehydration, and sepsis. The stool is usually positive for leukocytes. Radiographic studies may reveal colonic wall thickening due to submucosal edema. On abdominal films, this may appear as a "target sign." CT scanning is reserved for patients with complicated disease. It may show colonic wall thickening, ascites, colonic dilation, or perforation.

Changes in the colonic mucosa depend on the severity of the infection. Endoscopy performed for mild to moderate cases will show erythema and edema of the mucosa, with occasional hemorrhage. In severe cases, findings include elevated whitish-green or yellow plaques like "pseudomembranes" overlying inflamed mucosa. The pseudomembrane is made up of leukocytes, necrotic epithelial cells, and fibrin. The rectum is spared in about one-fourth of cases.

► Diagnosis

The gold standard for diagnosis of *C. difficile* colitis was a cytotoxin neutralization assay. This has largely been abandoned owing to its technical difficulty and length of time required to obtain a result (24-48 hours). Instead, the 2013 American College of Gastroenterology (ACG) guidelines recommends using PCR amplification of the genes for toxins A and B from a stool sample. This test has high sensitivity (87%) and specificity (97%) and is cost effective. It can be used as a sole diagnostic test or as part of a two-step approach using a glutamine dehydrogenase (GDH) screening assay, and if positive, following with the PCR confirmatory test. The guidelines recommend against the popular enzyme-linked immunoassay for toxins A and B owing to a cited lack of sensitivity and specificity (75%-95% and 83%-98% respectively); however, the test is still widely used for its ease of performance, low cost, and some studies show similar effectiveness. Stool culture is limited to use in epidemiologic studies. Finally, retesting stool for cure is not recommended because there is a high rate of positive tests after clinical cure, which may lead to prolonged and unnecessary treatment.

► Treatment

A. Medical

After discontinuing the inciting antibiotic agent, which is the first step in treatment for any patient, management

is determined by severity of disease. In the United States, vancomycin and metronidazole are the drugs of choice. ACG guidelines recommend treatment of mild to moderate infections with Metronidazole 500 mg three times daily for 10 days. If there is no clinical improvement by day 5, vancomycin is started at a dose of 125 mg orally four times daily for 10 days. Both antibiotics have similar efficacy in patients with mild to moderate disease, but metronidazole is cheaper (\$2/d vs. \$71-\$143/d). A third agent, fidaxomicin, was FDA approved for treatment in 2011 after phase III trials showed non-inferiority for clinical cure and decreased rates of relapse compared to vancomycin in mild-moderate disease. However, this drug is more expensive than vancomycin (\$280/d) and post-marketing clinical trials are still underway. There is some evidence that teicoplanin, a bacteriocidal antibiotic, is more effective than vancomycin. However, its use is limited as it is extremely expensive and not available in the United States.

Severe infections (serum albumin < 3 with either a WBC > 15,000 or abdominal tenderness) are treated initially with vancomycin, 125 mg orally four times daily for 10 days, which has been shown to be more effective in patients with severe disease. Patients with complicated disease (admission to ICU, hypotension, fever > 38.5, abdominal distention, altered mental status, WBC > 35,000 or < 2000, lactate > 2.2, or organ failure) are treated with combination therapy consisting of vancomycin 500 mg orally four times daily, vancomycin enemas, and metronidazole 500 mg IV every 8 hours.

Recurrent disease is less well studied, however, ACG guidelines recommend standard treatment if symptoms are mild to moderate. If the patient has more severe illness, treatment should be stepped up as indicated. Oral vancomycin should be administered as a first line treatment and there is some evidence to suggest that pulsed vancomycin can be helpful in patients with multiple recurrences. There is mounting evidence, including a small randomized clinical trial, showing superior clinical efficacy in patients treated with vancomycin plus fecal transplant as opposed to vancomycin alone.

B. Surgical

Although most patients will respond to initial medical management, a subset will develop complicated or “fulminant” colitis. Risk factors include patients with IBD, recent gastrointestinal surgery, and WBC greater than 16,000. These patients are critically ill and have a mortality rate of 35%-80%. An abdominal CT scan is indicated to look for complications of *C. difficile* colitis, such as toxic megacolon and perforation, and exclude other intra-abdominal pathology. Surgical evaluation is recommended for patients with shock (altered mental status, organ dysfunction, lactic acidosis) peritonitis, significant leukocytosis, or failure to improve on medical therapy for 5 days. Although there have been

no randomized controls, timely surgery for these patients provides a substantial decrease in mortality. Given the diffuse involvement of the colon and the severity of the illness, a subtotal colectomy with end ileostomy is recommended. Residual rectal disease may be treated with vancomycin enemas if needed. Intestinal continuity is restored at a later operation.

ISCHEMIC COLITIS

Ischemic colitis refers to colonic inflammation caused by inadequate perfusion. It is more common in elderly patients and has a mortality of 13%. It occurs as a result of an occlusive or non-occlusive insult. Examples of occlusive ischemic colitis include embolism, thrombosis (arterial or venous), atherosclerosis, trauma, and postsurgical causes such as patients with loss of inferior mesenteric blood supply after aortic aneurysm repair and those with inadequate perfusion to colonic anastomoses. Nonocclusive injury may occur as a result of shock, vasopressors, vasospasm, mechanical obstruction of the lumen, or systemic vasculitides.

An important clinical distinction that must be made when evaluating patients is assessing the colon for gangrenous and non-gangrenous ischemic colitis. Patients with gangrenous forms have transmural, nonreversible injury that is rapidly fatal without surgery. The non-gangrenous type is divided into transient reversible and chronic forms. The chronic form involves the muscularis propria and is prone to stricture development. Transient reversible ischemia involves the submucosa and heals without sequelae. Most cases of ischemic colitis are idiopathic and attributed to a nonocclusive state.

Patients with ischemic colitis present with diarrhea (90%), hematochezia (65%), and abdominal pain (58%). A history of atrial fibrillation, thrombophilia, atherosclerotic

arterial disease, recent trauma or surgery, or systemic vasculitis should be sought. Recent severe systemic illness with shock is a common suspected cause. There may be localized or diffuse peritonitis. Blood tests may reveal leukocytosis, hyperamylasemia, and acidosis, as well as electrolyte derangements. The most common location is the sigmoid colon (40%) followed by the transverse colon (17%), splenic flexure (11%), ascending colon (12%), and the rectum (6%).

The most useful diagnostic tests are endoscopy and abdominal CT. Colonoscopy is the diagnostic modality of choice (although contraindicated in critically ill patients with peritonitis) as it allows diagnostic confirmation, determination of severity, and can rule out other types of colitis. The mucosa of the involved segment is edematous, hemorrhagic, friable, and sometimes ulcerated. A grayish membrane may be present, resembling pseudomembranous colitis, but the presence of hyalinized, hemorrhagic lamina on biopsy will differentiate colonic ischemia from *C difficile* colitis. Serial endoscopy can be used to identify patients with progression of mucosal lesions who require surgery. Abdominal CT with contrast shows a thickened colonic wall, decreased wall enhancement, pneumatosis, and occasionally a disruption in the arterial circulation. It is also useful to exclude other conditions.

Initial treatment for patients without gangrene suspected to have reversible ischemic colitis consists of intravenous fluids, bowel rest, broad spectrum antibiotics, and observation with serial abdominal examinations. Approximately 20% of patients will have irreversible disease, whether gangrenous from the beginning, becoming more severe over several days, or just failing to resolve after treatment. These patients need surgery. The extent of the resection is based on the amount of necrotic or severely diseased colon. Most commonly a segmental resection is required, although a subtotal or total colectomy is performed in 20% of patients. Depending on the etiology of the ischemia and the appearance of the remaining bowel, a second-look laparotomy may be planned 12-24 hours later. Primary anastomosis is rarely performed and intestinal continuity is restored during a subsequent operation.

O'Neill S, Yalamarthy S: Systematic review of the management of ischaemic colitis. *Colorectal Dis* 2012 Nov;14(11):e751-e763.

NEUTROPENIC COLITIS

Neutropenic colitis, also referred to as neutropenic enterocolitis, necrotizing enteropathy, ileocecal syndrome, and typhlitis, is a syndrome of colonic necrosis occurring in neutropenic patients. The cause is poorly understood, but likely involves mucosal injury and unimpeded bacterial translocation as a result of profound immunosuppression. Neutropenic colitis should be on the differential diagnosis for any immunosuppressed patient with abdominal pain; however, it is most common in neutropenic patients

undergoing chemotherapy with cytotoxic agents such as the vinca alkaloids and doxorubicin. There are reports in patients with acquired immunodeficiency syndrome (AIDS), aplastic anemia, cyclic neutropenia, and those being treated with a variety of immunosuppressants for other conditions.

The clinical presentation ranges from mild to life-threatening and overall mortality is 30%-50%. Symptoms include fever, nausea, abdominal pain, distention, and watery or bloody diarrhea. These patients often present late and with deceptively benign findings on physical examination owing to the inability to mount a normal inflammatory response. The cecum and right colon are most often affected; however, any part of the small or large bowel, including the appendix, can be involved. Patients are commonly bacteremic and/or fungemic. Causative organisms include gram-negative rods, gram positive cocci, anaerobes, and candida.

Diagnosis is confirmed using abdominal CT scan, which demonstrates bowel wall thickening, distention, and may show pneumatosis or perforation. Initial management consists of bowel rest, intravenous fluids, and broad spectrum antibiotics. Antifungals are started if there is evidence of fungemia or persistent fevers on antibiotics. Resolution of neutropenia is an important prognostic factor, therefore, discontinuation of immunosuppressants, chemotherapeutics, and administration of granulocyte colony stimulating factor (G-CSF) should be considered. Surgery is recommended for patients with perforation, persistent bleeding, or who do not improve with medical management. Most patients undergo segmental resection with proximal diversion.

INTESTINAL STOMAS: ILEOSTOMY AND COLOSTOMY

Creating an intestinal stoma involves exteriorizing a part of the bowel wall onto the surface of the abdomen. This section will focus on the two most common stomas created in colon and rectal surgery—those made from the ileum (ileostomy) and colon (colostomy).

► Indications

Stomas are generally created to protect a distal anastomosis temporarily or as a permanent route for enteric contents when the colon and/or rectum has been resected. There are two configurations for a stoma. The end ileostomy or colostomy is created by fixing the end of the ileum or colon to the

abdominal wall. The loop ileostomy or colostomy involves bringing a segment of ileum or colon to the abdominal wall and opening the side of the bowel leaving both a proximal and distal opening. In general, very little, if any, stool passes through the distal limb if the stoma is well constructed. This allows retrograde decompression of the distal bowel and has the benefit of being easier to reverse as both limbs are at the abdominal wall.

In the elective setting, loop ileostomies are commonly used to protect ileoanal anastomoses and low pelvic colorectal or colo-anal anastomoses. These ileostomies are temporary, and divert most of the fecal stream away from the anastomosis. End ileostomies (Figure 30–20) are used in the elective setting for patients who require proctocolectomy and do not desire or are not candidates for IPAA reconstruction. They are also commonly used in patients who require emergency subtotal colectomies and will not tolerate an anastomosis due to severe illness.

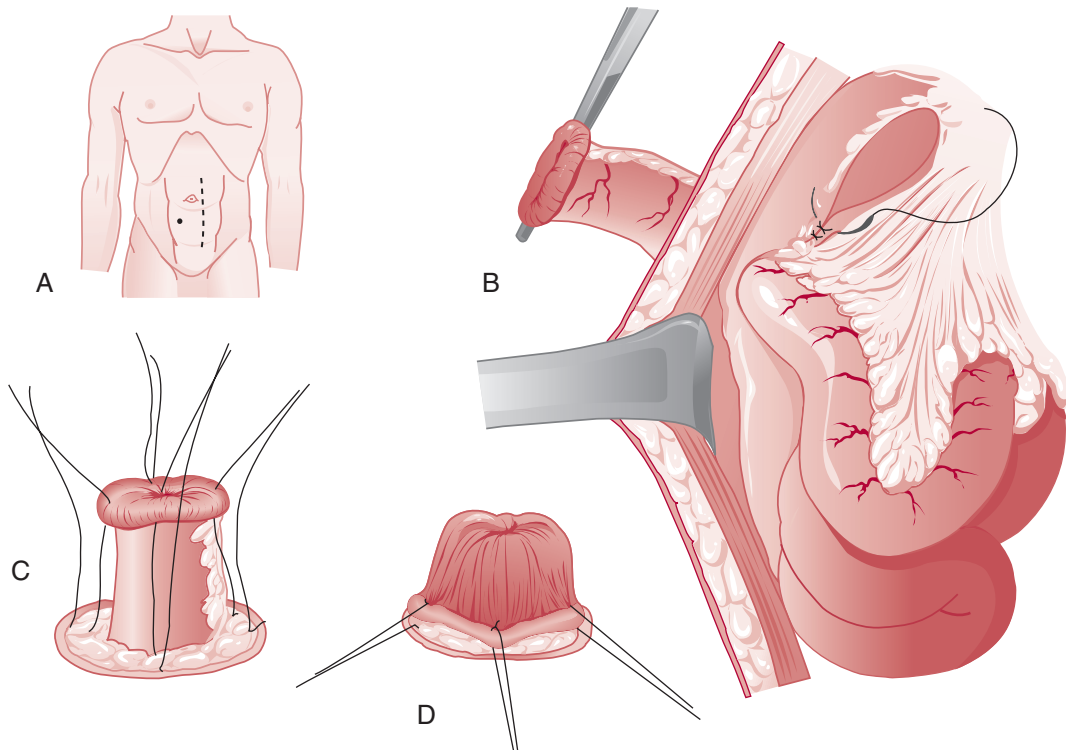

The Kock pouch, or continent ileostomy, involved an ileal reservoir and construction of a valve at skin level to allow the patient to catheterize the stoma multiple times per day. This allowed patients not to wear a stoma appliance

and to control the timing of stool output. However, this procedure is associated with a high rate of complications and failure. It has largely been replaced with the IPAA.

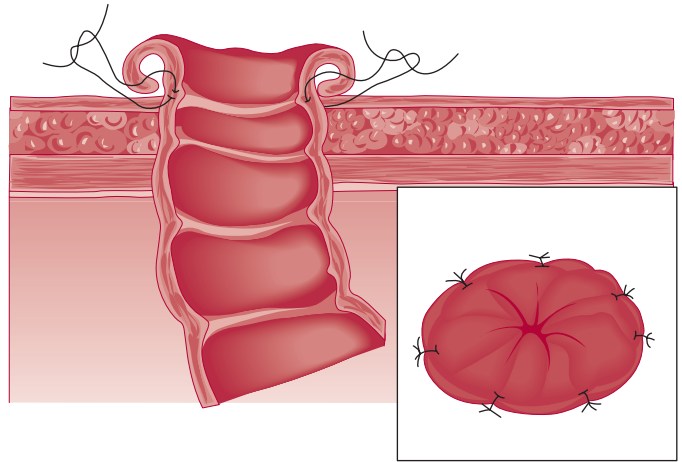

Colostomies (Figure 30–21) are used in patients with low rectal cancers requiring APR or LAR who are not candidates for a low anastomosis. In addition, they are useful in patients who require diversion for chronic fistula disease or in the emergency setting for patients with a large bowel obstruction, perforation, or trauma where an anastomosis is unlikely to heal or the patient is too ill to tolerate it. Loop colostomies are infrequently used as they are associated with a higher complication rate, particularly prolapse, although they are easier to reverse.

► Technical Aspects

When possible, patients should meet with their enterostomal therapist or surgeon prior to their operation for education, counseling, and stoma marking. Preoperative stoma marking has been shown to reduce complications and improve postoperative quality of life. Ileostomies are typically placed in the right-lower quadrant and colostomies in the left-lower

▲ **Figure 30–20.** Ileostomy after colectomy. **A:** A midline incision for colectomy is indicated by the dotted line and the site of the ileostomy by the black dot. **B:** The ileum has been brought through the abdominal wall. **C and D:** The ileostomy stoma has been everted and its margins sutured to the edges of the wound.

▲ **Figure 30-21.** End colostomy. The margins of the stoma are fixed to the skin with sutures.

quadrant. The placement should avoid wrinkles, folds, scars, and hernias on the abdominal wall. It should be at least 2 inches from the surgical incision and have a clear area extending 2-3 inches around it. It must be visible to the patient. Ideally, it is situated below the patient's belt line in the lateral rectus. The patient should be evaluated in the sitting, standing, and lying positions with and without clothing. The mark is made with active patient participation and it is ideal to provide a stoma appliance for the patient to wear over the mark for several days prior to the operation to ensure it is the optimal position.

There are several key steps during the operation that when followed, can reduce the chance of complications. The first step is to ensure adequate mobilization of the bowel so that the stoma will lie without any tension and will not retract into the abdominal wall. The second step is to pay close attention to the blood supply and preserve the mesentery and associated vessels during mobilization to avoid ischemic injury and subsequent stenosis. The third step is to create a defect in the rectus that is as small as possible that will still allow the stoma to pass without ischemia in order to prevent herniation. Lastly, when maturing the stoma, the aim should be to create 2-3 cm of bowel protrusion to ensure good appliance adhesion and improve skin protection.

► Management

Having a stoma changes a patient's life in many ways and is associated with an overall complication rate of 20%-70%. For this reason, these patients, especially those with newly created stomas and those experiencing complications require dedicated management.

An ileostomy has a near-continuous stream of liquid and semi-solid material whereas a colostomy tends to produce more formed stool. Both generally require an appliance to be worn at all times. Some patients choose to irrigate their

colostomies to avoid stool output during the day. The sound and timing of flatus cannot be controlled by patients.

After ileostomy creation, there are significant changes in water and electrolyte absorption owing to the loss of the colon (Table 30-1). The small bowel adapts over the first 2 months after surgery. Output increases over the first week up to 1-2 L per day, stabilizes, and over the next 2 months steadily decreases to a steady state of 500-800 mL per day. Output can be higher in patients with diseased small bowel or more proximal stomas. Sodium excretion averages 60 mEq per day, which is two to three times that of patients with intact colons. These patients are at risk for developing salt depletion and dehydration, especially during times of illness or exposure to hot weather. They must take care to stay hydrated and to consume enough salt and potassium in their diets to make up for this. Generally, switching to a bland, constipating diet high in breads, cereals, dairy, peanut butter, bananas, and rice will help decrease high output and reduce fluid and electrolyte losses. Fiber supplements and antimotility agents such as loperamide or diphenoxylate can be added as needed.

Patients with colostomies are less prone to metabolic disturbances, especially with the more common distal (sigmoid) colostomy configuration. Generally, they will continue to have formed bowel movements similar to their previous bowel habits. Fecal impaction will require irrigation in some patients. Transverse colostomies produce semi-liquid effluent and tend to be difficult to manage. They should be avoided for this reason.

► Complications

Stomas are associated with a complication rate of 20%-70%. Ileostomies and colostomies are associated with similar complication rates. There is an association of loop colostomy and transverse colostomy with higher complication

rates; however, this has never been studied in a randomized fashion and the data are conflicting. The complications seen in ileostomies are different than those seen with colostomies. Ileostomies are more likely to cause high output and dermatitis, whereas colostomies are more likely to develop hernia and odor.

A parastomal hernia refers to herniation of intra-abdominal contents through the defect in the fascia created for the stoma. In the chronic setting, parastomal hernias cause pain, difficulty with stoma appliance fitting, obstruction, and changes in stooling patterns. In the acute setting, there is a risk of incarceration and strangulation. Herniation is more common in patients with end-stomas as opposed to loop-stomas and more common in colostomies than ileostomies. The risk is minimized by creating a fascial defect that is just large enough to accommodate the bowel without ischemia. Some studies have shown a decreased risk of hernias in stomas placed through the rectus muscle, with fascial fixation, and when the preoperative marking is performed by an enterostomal therapist. Other risk factors for hernia development include obesity, COPD, poor nutritional status, and immunosuppression. There is also an increased risk of hernia with time. Conservative management is successful in 70% of patients and includes abdominal binders and restriction on heavy lifting. Flexible ostomy appliances may decrease leaking. Up to 30% of patients will require surgical revision either for failure of conservative management or for presentation with incarceration or strangulation. Surgical treatments vary depending on individual patient factors. Options include stoma relocation and mesh repair. Mesh repairs can be local or intraperitoneal, open or laparoscopic. Intraperitoneal synthetic mesh repairs have the lowest recurrent rates, although this approach involves more surgical risk as well as the risk of mesh erosion or infection. Some small studies have shown prophylactic mesh placement to reduce the incidence of parastomal hernia without increasing surgical morbidity, although it is unclear if this approach is cost effective or if the effect is long term.

Stoma prolapse occurs in up to 42% of patients and is associated with similar risk factors as parastomal hernia. In fact, these two complications frequently coexist. It is more common in colostomies and specifically the distal limb of loop colostomies owing to defunctionalization and atrophy from non-use. Symptoms include pain, poor fitting of the stoma appliance, and may progress to obstruction, incarceration, or strangulation. Indications for repair include intractable symptoms or an acute presentation with impending bowel compromise. Incarcerated prolapsed stomas can often be reduced using topical sugar, which draws edema fluid out of the bowel wall allowing reduction. Surgical treatment depends on individual patient factors and options include resection, revision, and relocation.

High volume stoma output is defined as effluent greater than 2 L or any volume leading to dehydration. It is the

most common cause of hospital readmission in patients with ileostomies. Patients with intrinsic small bowel disease (such as CD) or proximal stomas are at particularly high risk. Symptoms include dark urine, fatigue, irritability, muscle cramps, and headache. Patients develop dehydration and hyponatremia, which can result in secondary hyperaldosteronism and urinary potassium and magnesium wasting. Treatment is through rehydration, correction of electrolyte abnormalities, and antimotility medications. In the acute setting, intravenous fluids and electrolyte repletion are used, with some patients requiring total parenteral nutrition for a period of time. For marginally dehydrated patients, an isotonic glucose and sodium oral rehydration solution is effective. Long term, patients can use elemental, high carbohydrate, low fat diets to slow output. Helpful foods include breads, cereals, peanut butter, bananas, and rice. Medications such as loperamide, diphenoxylate, and tincture of opium can be used as adjunctive therapy. In refractory cases, the addition of H₂ antagonists or proton pump inhibitors as well as octreotide have been shown to be effective.

Skin complications are common in patients with ileostomies. It is associated with parastomal herniation, retraction, and prolapse, which contribute to poor appliance adherence, and high volume output, which increases leaking. Obese and diabetic patients are more commonly affected. It is most commonly a chemical dermatitis but can result from underlying *Candida* infection or even pyoderma gangrenosum in patients with IBD. Skin irritation can be avoided with dedicated skin care, reducing the number of appliance changes as much as possible (with a goal of one to two times per week), and surgical correction of contributing factors such as hernia or prolapse. *Candida* infections are treated with topical antifungals. Pyoderma gangrenosum is a notoriously difficult condition to treat, but may be responsive to local wound care, tacrolimus ointment, and intralesional steroid injections. Occasionally systemic tacrolimus or steroids are required.

Stoma retraction affects 1%-6% of patients with colostomies and 3%-17% of patients with ileostomies. This generally occurs in the immediate postoperative period as a result of tension on the bowel or poor wound healing and occurs more often in obese patients. It causes poor fitting of the stoma appliance and may lead to severe skin irritation. Some patients will be adequately treated with convex appliances, however, many will require surgery. Local revision is a reasonable first step. However, because this does not address tension on the bowel, some patients will progress to require laparoscopic or open revision.

Stenosis is uncommon, affecting 1%-10% of patients. Patients present with obstructive symptoms, or intermittent periods of no stoma output and crampy abdominal pain followed by a sudden large volume discharge. Most commonly, they are a result of ischemic injury, although in rarer

cases they may be due to a technical error (fascia or skin is too tight) or underlying disease of the small bowel such as CD or malignancy. Diagnosis should be made by inspection and digital exploration. Hegar dilation in multiple sessions may be effective, but patients often require stoma revision either locally or by a laparoscopic or open intra-abdominal approach.

PERIOPERATIVE MANAGEMENT

BOWEL PREPARATION

Because of the high bacterial load of the large intestine, elective colorectal surgery without prophylaxis carries a 40% risk of wound infection. This has also been reported as a cause for anastomotic dehiscence. It was previously believed that mechanical lavage (bowel prep) of the gastrointestinal tract would prevent these complications by removing fecal waste and the associated bacterial flora. This involves administration of a large volume of unabsorbed fluid, such as polyethylene glycol or alternatively small volume sodium phosphate, which induces an osmotic diarrhea. Retrograde enemas have been used in distal colon and rectal surgery. Healthy patients usually tolerate these preparations well. However, osmotic agents can lead to dehydration and electrolyte disturbances in more fragile patients.

Although mechanical bowel preparation used to be routine for colorectal surgery, there is debate about its safety and utility. Multiple randomized controlled trials have been completed, with few suggestions of adverse outcomes in both bowel prepped and non-prepped patients. Meta-analyses have shown no differences in outcomes. Specifically, mortality, anastomotic leaks (colo-colonic and colo-rectal), and wound infection rates are similar between the two groups. When a leak occurs, the clinical severity is also not influenced by bowel preparation. There is also no difference between patients treated with preoperative enema versus bowel preparation. This suggests that mechanical

bowel preparation can be safely omitted before surgery, especially in patients at risk for prep-related complications.

PERIOPERATIVE ANTIBIOTICS

The use of preoperative parenteral antibiotics significantly reduces surgical wound infection by 75% and should be used routinely. There is no evidence to suggest that infection rates are further reduced by continuing antibiotics postoperatively. Ertapenem has been shown to be superior to cefotetan in preventing surgical site infections in a large randomized controlled trial of 1002 patients undergoing elective colorectal surgery. Parenteral antibiotics are superior to oral antibiotics alone in preventing wound infections, although there is evidence that in patients undergoing bowel preparation those who receive oral antibiotics in combination with parenteral antibiotics have decreased infectious complications compared to those patients who are treated with parenteral antibiotics alone. However, oral antibiotic regimens are poorly tolerated and this is less likely to be important as the use of routine bowel preparation decreases.

DEEP VEIN THROMBOSIS PROPHYLAXIS

Colorectal surgery patients are at higher risk than general surgery patients for the development of perioperative thromboembolism. In historical series, deep venous thrombosis was diagnosed in 20% of general surgery patients and 30% of colorectal patients without prophylaxis. The rate of symptomatic pulmonary embolism is fourfold higher (0.8% vs. 3.1%). This is related to a variety of factors, including the prevalence of IBD and malignancy in this patient population. Extended operative times, pelvic dissection, and modified lithotomy may also be contributing factors. Subcutaneous heparin and low-molecular-weight heparin are equivalent in reducing both deep venous thrombosis and pulmonary embolism. Low-molecular-weight heparin has a simplified dosing regimen and a decreased incidence of heparin induced thrombocytopenia, however, it is more expensive and there seems to be a dose-related increased risk of bleeding complications. Fondaparinux is a newer Xa inhibitor that has also shown efficacy as a prophylactic agent. There is insufficient evidence to recommend one medication over the other at this time. Sequential compression devices are a useful adjunct.

PAIN MANAGEMENT

There is debate about the most useful postoperative analgesia for colorectal surgery patients. The three most commonly used methods are epidural, spinal, and patient controlled analgesia. Multiple studies have shown decreased subjective pain in patients managed with epidurals, however, this does not translate into better outcomes, and in fact, may lead to increased length of stay. This may be related to the increased

use of laparoscopy in colorectal surgery. However, fast track programs to reduce length of stay for colorectal surgery have used short-term epidurals for 24-48 hours with some success. Further study is required to define the impact of these regimens on return of bowel function, pulmonary complications, and mortality.

POSTOPERATIVE NUTRITION

Early initiation of nutrition postoperatively has become the standard of care for patients undergoing colorectal operations. The most studied regimen includes initiating a liquid diet within 24 hours after surgery and advancing as tolerated to a regular diet as opposed to older protocols, which mandated fasting until there was evidence of bowel function in the form of flatus or defecation. Initiating feeding early leads to decreased hospital stay but doesn't seem to impact other clinical indicators. However, early feeding must be initiated with other interventions such as minimizing fluids and early ambulation.

MULTIPLE CHOICE QUESTIONS

- Proctectomy requires pelvic dissection and has the potential to cause injury to the nerves that supply the rectum, pelvic floor muscles, and bladder, as well as the prostate and seminal vesicles in men. Which of the following associations is incorrect regarding the nerves at risk at different points in the operation?
 - Superior hypogastric plexus near root of IMA
 - Hypogastric nerves in the retrorectal space
 - Nervi erigentes near lateral stalks
 - Inferior hypogastric plexus near Denonvillier fascia
- A 60-year-old man presents with abdominal pain, fevers, and nausea. He is febrile, focally tender in the LLQ, and has a WBC of 18,000. CT shows sigmoid diverticulitis with a 4 cm pericolonic abscess. What is the optimal management strategy for this patient?
 - Bowel rest, intravenous fluids, broad spectrum antibiotics
 - Bowel rest, intravenous fluids, and broad spectrum antibiotics
 - Bowel rest, intravenous fluids, broad spectrum antibiotics, and percutaneous drainage
 - Urgent exploratory laparotomy
- An otherwise healthy 60-year-old man presents with abdominal pain. His CT shows an obstructing mass in the sigmoid colon with dilation of the cecum to 13 cm. After fluid resuscitation, what is the next step in management?
 - Nasogastric decompression and observation
 - NPO, antibiotics, and observation
 - Flexible sigmoidoscopy with biopsies to further evaluate the mass
 - Exploratory laparotomy
- A 65-year-old, asymptomatic, woman is found to have a 3 cm sessile polyp in the ascending colon on screening colonoscopy. It was biopsied but could not be resected. Pathology shows tubulovillous adenoma. What is next step in management?
 - Colonoscopy in 1 year
 - Colonoscopy in 3 years
 - Local excision
 - Right hemicolectomy
- What is the most common symptom patients experience after removal of the colon?
 - Vitamin K deficiency
 - Renal stones
 - Dehydration
 - Hyponatremia
 - Short chain fatty acid deficiency

Stephen M. Sentovich, MD

ANORECTAL ANATOMY

The anatomy of the anus and rectum dictates the clinical evaluation and treatment of patients with anorectal disorders (Figure 31–1).

From external to internal, the surface anatomy of the anorectum is comprised of gluteal skin, anoderm, the anal transitional zone, and proximally the rectal mucosa. The gluteal skin includes hair, sebaceous glands, and sweat glands. This area, particularly 3–5 cm of anal margin skin circumferentially around the anus, can commonly become infected with the human papilloma virus resulting in anal condyloma. Anal condyloma can also affect more proximal tissue in the anoderm and lower rectal mucosa. Perianal hidradenitis is also relatively common and develops in the apocrine sweat glands of the perianal skin. Unlike anal condyloma, perianal hidradenitis can only occur in the gluteal skin as there are no sweat glands in the anoderm.

The anoderm begins at the anal verge and ends at the dentate line. Unlike the gluteal skin, the anoderm is devoid of hair and sweat glands. Anal fissures occur in the anoderm and can be associated with a sentinel tag externally and a hypertrophied anal papilla internally (Figure 31–2). Surgical excision of too much anoderm during hemorrhoidectomy or other anorectal surgery can result in anal stenosis.

The anal transitional zone lies between the squamous anoderm and the rectal mucosa. In this zone, squamous, cuboidal, transitional, and columnar epithelium exist with longitudinal ridges called the columns of Morgagni. Between the columns of Morgagni are anal crypts with associated anal glands that open into their bases. Clinically, the anal transitional zone is important for two main reasons. First, the anal transitional zone is the crossover from somatic to visceral innervation and for lymphatic drainage from the inguinal to the pelvic nodes. Lymphatics from the anal canal above the dentate line drain via the superior rectal lymphatics to the inferior mesenteric lymph nodes and laterally to the

internal iliac nodes. Below the dentate line, drainage occurs to the inguinal lymph nodes but can occur to the inferior or superior rectal lymph nodes. Second, the anal glands in the crypts are the site of anorectal abscesses and anal fistulas. Anatomically the anal glands in the crypts extend to a variable depth resulting in perianal, intersphincteric, or ischio-rectal abscesses when these glands become blocked.

Proximal to the anal transitional zone is the rectal mucosa. Above the dentate line and underlying the rectal mucosa are the vessels that, when abnormally engorged, manifest as internal hemorrhoids. Hemorrhoids are not veins but arteriovenous connections that have pulsatile flow. Patients with bleeding from hemorrhoids can have significant blood loss. Further, internal hemorrhoids are covered by mucosa and because they are above the dentate line, they are viscerally innervated. This is the reason rubber-band ligation of internal hemorrhoids is possible without anesthesia. In contrast, external hemorrhoids are below the dentate line, covered by anoderm and skin. Any surgical intervention on external hemorrhoids requires some type of anesthesia.

Hemorrhoidal vessels are anchored by Treitz' muscle. When the Treitz' muscle attachments weaken, internal and external hemorrhoids can prolapse, bleed and cause perianal irritation and discomfort. Internal hemorrhoids can prolapse and can be confused with rectal prolapse. Generally, internal hemorrhoids prolapse in columns occurring in the right anterior, right posterior and left lateral quadrants around the anus. When the anus is examined, these prolapsing columns of internal hemorrhoids appear as radial folds. This is distinguished from the circumferential folds of rectal prolapse.

The rectum extends 12–15 cm proximal to the dentate line. The rectum has three curves that create folds called the valves of Houston. It is supported by the puborectalis and levator muscles that are also called the pelvic floor. In addition, the rectum is fixed posteriorly by presacral (Waldeyer)

▲ **Figure 31-1.** Anatomy of the anorectal canal.

fascia, laterally by the lateral ligaments, and anteriorly by Denonvilliers fascia. The arterial supply of the anorectum is via the superior, middle and inferior rectal arteries. The superior rectal artery is the terminal branch of the inferior mesenteric artery and descends in the mesorectum. It supplies the upper and middle rectum. The middle rectal arteries arise from the internal iliac arteries and enter the rectum anterolaterally at the level of the pelvic floor musculature. They supply the lower two-thirds of the rectum. Collaterals exist between the middle and superior rectal arteries. The inferior rectal arteries—branches of the internal pudendal arteries—enter posterolaterally, do not anastomose with the blood supply to the middle rectum, and supply the anal sphincters and epithelium.

The venous drainage of the anorectum is via the superior, middle, and inferior rectal veins draining into the portal and systemic systems. The superior rectal veins drain the upper and middle thirds of the rectum and empty into the portal system via the inferior mesenteric vein. The middle rectal veins drain the lower rectum and the upper anal canal into the systemic system via the internal iliac veins. The inferior rectal veins drain the lower anal canal, communicating with the pudendal veins, and draining into the internal iliac veins. Communication between the venous systems allows low rectal cancers to spread via the portal and systemic systems.

Lymphatic drainage of the upper and middle rectum is into the inferior mesenteric nodes. Lymph from the lower rectum may drain into the inferior mesenteric system or into lymphatics around the lower rectum that drain into the inguinal nodes and then into periaortic nodes. Below the dentate line, lymphatic drainage occurs primarily to the inguinal nodes but may drain into the inferior mesenteric lymph nodes.

▲ **Figure 31-2.** Diagram of the anorectum showing the fissure or ulcer triad.

The innervation of the rectum is from both the sympathetic and parasympathetic nervous systems. The sympathetic nerves originate from the lumbar segments L1-3, form the inferior mesenteric plexus, travel through the superior hypogastric plexus, and descend as the hypogastric nerves to the pelvic plexus. The parasympathetic nerves arise from the second, third, and fourth sacral roots and join the hypogastric nerves anterior and lateral to the rectum to form the pelvic plexus. Sympathetic and parasympathetic fibers pass from the pelvic plexus to the rectum and internal anal sphincter (IAS) as well as other pelvic viscera. Injury to these nerves can lead to sexual and bladder dysfunction, and loss of normal defecatory mechanisms.

Beneath the surface anatomy of the anus and rectum are the anal sphincter muscles. The IAS muscle is involuntary and is responsible for anal canal resting tone. The IAS is innervated with sympathetic and parasympathetic fibers. Both are inhibitory and keep the sphincter in a basal state of contraction. The external anal sphincter (EAS) muscle is voluntary and responsible for anal canal squeezing tone. The external sphincters are skeletal muscles innervated by the pudendal nerve with fibers that originate from S2-4. The EAS muscle fuses with the pelvic floor muscles to create a bowl-like muscular support of the lower rectum.

While systemic diseases such as diabetes, scleroderma and multiple sclerosis can affect the anal sphincter muscles, far more common is direct injury to the sphincter muscles from vaginal delivery or surgery. Using transanal ultrasound to evaluate the anal sphincter muscles before and after vaginal delivery it has been demonstrated that approximately one-third of women injure their anal sphincter at the time of delivery. Fortunately, only one-third of these women develop fecal incontinence.

Operative intervention for hemorrhoids, anal fissure, and anal fistula can result in anal sphincter injury. Sphincter injury should not occur during hemorrhoid surgery as hemorrhoidal vessels are superficial to the anal sphincter muscles. Division of the anal sphincter is necessary and curative for anal fissure and for anal fistula treated by fistulotomy. While lateral internal sphincterotomy for anal fissure carries a fecal incontinence rate of less than 0.5%, fistulotomy for complex anal fistulas has a rate of over 50%. For this reason, sphincter-sparing approaches to anal fistulas are now the standard of care for patients with anal fistulas involving a significant amount of anal sphincter muscle.

COMMON SYMPTOMS AND THEIR DIFFERENTIAL DIAGNOSIS

► Anorectal Pain

Pain is one of the most common presenting symptoms of anorectal disorders. The common causes of anorectal pain are shown in Table 31–1. The vast majority of patients have

Table 31–1. Causes of anorectal pain.

Thrombosed external hemorrhoids
Anorectal abscess
Anal fissure
Anal mass: anal cancer, anal condyloma
Trauma: direct injury, foreign body
Infections: HSV, HIV, CMV, and others
Functional: levator spasm, proctalgia fugax

either thrombosed external hemorrhoid, anal fissure, or anorectal abscess. The other causes of anorectal pain are relatively unusual. The etiology of anorectal pain can often be determined with a careful history that is then confirmed with the physical examination.

For patients with anorectal pain, the most important aspects of the patient history are the nature and onset of the pain and any associated symptoms. If the pain is acute in onset (< 1-3 d) and associated with a lump at the anus, a diagnosis of a thrombosed external hemorrhoid is highly likely. If the pain is acute in onset and associated with fever and swelling at the anus, then an anorectal abscess should be suspected. Finally, if the pain is described as a “cut,” “tear,” or “sharp as a knife” and associated with bowel movements, then an anal fissure is the probable cause. Inspection alone will usually confirm the suspected diagnosis as an external hemorrhoid, abscess or cellulitis or anal fissure will be present. It is important to efface the anus by pulling the gluteal cheeks apart in order to identify an anterior or posterior anal fissure that occurs just inside the anal canal. Most patients with anorectal pain cannot tolerate a digital examination and anoscopy but fortunately these evaluations are often unnecessary. If after obtaining a history and carefully inspecting the anus and the diagnosis is still in doubt, an examination under anesthesia may be indicated as small number of patients may have an intersphincteric or supralelevator abscess that usually cannot be diagnosed by inspection alone.

► Anorectal Bleeding

Bleeding is the most common presenting symptom in patients with anorectal disorders. Common causes of anorectal bleeding are shown in Table 31–2. While a careful history may suggest the etiology of bleeding, patients can tolerate and require a thorough physical examination as well as anoscopy and lower endoscopy. Even if anorectal pathology is identified on physical examination or anoscopy, endoscopic evaluation is always necessary in order to rule out proximal pathology such as polyps or cancer.

In patients with anorectal bleeding, the history can help identify the source of the bleeding by fully characterizing the amount, timing and location of the bleeding. Blood seen just on the toilet paper suggests anal canal pathology whereas

Ulceration/infection
Rectal prolapsed/solitary rectal ulcer

blood seen mixed with the stool suggests a more proximal bleeding source. Inspection of the anus may reveal prolapsing hemorrhoids, an anal fissure, an anal fistula, or anal ulcer. Anoscopy is necessary to evaluate for possible internal hemorrhoids and distal proctitis. Flexible sigmoidoscopy is typically recommended for younger patients (< 40 years old) who do not have a family history of colon cancer. Colonoscopy is recommended for patients over age 40 with anorectal bleeding or patients under age 40 who have a family history of colon cancer. While these general guidelines are appropriate for most patients, the choice between flexible sigmoidoscopy and colonoscopy is individualized to each patient's clinical scenario.

► Anorectal Mass

Most anorectal mass lesions are either anal skin tags, a thrombosed external hemorrhoid or a sentinel pile associated with an anal fissure (Table 31–3). In addition to the history, physical examination and anoscopy, most patients with mass lesions need either flexible sigmoidoscopy or colonoscopy depending on their age, diagnosis, and whether or not there is a family history of colon cancer. The unusual tumors such as lipoma and GIST that occur deep to the skin, anoderm, and rectal mucosa are difficult to diagnose preoperatively. These tumors often require additional preoperative anatomic evaluation with transanal ultrasonography and/or pelvic MRI to determine their extent and relationship to the anal sphincter muscles.

Mucosal/rectal prolapsed
Fecal incontinence/leakage (multiple etiologies)
Post-surgical: keyhole deformity

► Anorectal Discharge

Discharge from the anus is a relatively common complaint and has a wide range of possible etiologies (Table 31–4). The most common causes of anorectal discharge are mucosal prolapse, anal fistula, and fecal leakage. Patients with anal fistula often have a history of perirectal abscess. On examination, the patient should be asked to strain in order to identify mucosal and rectal prolapse. Anal sphincter tone should be assessed during the digital examination. In patients with previous anorectal surgery, careful inspection of the anus is important to identify any anal contour abnormalities (keyhole deformities). In addition to anoscopy, most patients will require lower endoscopy. Patients with fecal leakage or incontinence often require further functional and anatomic studies.

HEMORRHOIDS

Hemorrhoids are blood vessels in the lower rectum and anal canal. They are not veins but rather arteriovenous connections with pulsatile flow. External hemorrhoids are located below the dentate line and anatomically identified by the presence of anoderm or skin overlying the hemorrhoidal vessel. Due to either diarrhea, constipation, or straining, a hemorrhoidal vessel can become thrombosed with a clot resulting in a painful lump and possibly some bleeding if the clot ruptures through the anoderm. External hemorrhoids typically cause symptoms when they thrombose, prolapse, or cause irritation/hygiene difficulties. Internal hemorrhoids originate from above the dentate line and are covered by mucosa. These blood vessels can become enlarged/engorged (eg, pregnancy) and/or their anchoring muscle, the Treitz muscle, can become weakened (eg, straining, constipation). When either one or both of these circumstances occur, the hemorrhoidal vessels can prolapse into the lumen of the anal canal as well as can prolapse externally. This mechanical prolapse of hemorrhoidal vessels can cause bleeding, irritation, and pressure-like pain.

Internal hemorrhoids can be classified as grade I–IV by their symptoms and degree of prolapse. Grade I hemorrhoids

are prominent but do not prolapse. Grade II hemorrhoids prolapse but spontaneously reduce. Grade III hemorrhoids prolapse but require manual reduction. Grade IV hemorrhoids prolapse and cannot be manually reduced. The four-level grading system helps guide the choice of treatment of hemorrhoids.

► Signs & Symptoms

Patients with thrombosed external hemorrhoids complain of acute pain and swelling or lump at the anus. Patients with external hemorrhoid skin tags will have more chronic symptoms of prolapsed, “extra skin,” irritation, and difficulty with hygiene after bowel movements. Patients with internal hemorrhoids complain of bleeding, pressure-like pain and prolapse. Patients with bleeding internal hemorrhoids can have significant blood loss and become anemic acutely or chronically. Other than thrombosed external hemorrhoids, patients with hemorrhoids do not complain of sharp pain but rather bleeding, prolapse, irritation, and sometimes a pressure-like pain due to the prolapse. Both external and internal hemorrhoids can become incarcerated and gangrenous resulting in necrosis of skin and mucosa as well as bleeding.

Examination of the patient with a thrombosed external hemorrhoid reveals a purple swelling at the anus consistent with a clot in an external hemorrhoid vessel. Patients with external prolapse and tags reveal chronic protrusion and lumps without acute pain and discoloration. Patients with internal hemorrhoids may reveal nothing externally unless the internal hemorrhoids prolapse externally. Digital evaluation of the rectum can rule out any mass lesions or malignancy but internal hemorrhoids cannot be assessed adequately using digital rectal examination. Anoscopy is necessary to properly evaluate internal hemorrhoids. The examiner asks the patient to push or strain while visualizing each of the three common hemorrhoidal piles in the right anterior, right posterior and left lateral positions within the anal canal. Internal hemorrhoids are present if prolapse or bleeding occurs in any of the three locations visualized during anoscopy. Physical examination alone establishes a diagnosis of hemorrhoids. Further evaluation with laboratory or imaging studies is unnecessary unless there has been significant hemorrhage. All patients should also undergo evaluation of the more proximal colon with flexible sigmoidoscopy or colonoscopy as indicated.

► Differential Diagnosis

Since patients and many primary care providers identify any anorectal symptom as being due to hemorrhoids, nearly all patients complain of “hemorrhoids” or will have been told that they have “hemorrhoids.”

Patients with rectal bleeding need to be carefully evaluated not only with anoscopy but also with flexible

endoscopy to rule out proximal pathology such as colitis, polyps or cancer. Patients with rectal bleeding, under age 40 and without a family history of colon cancer, can undergo anoscopy and flexible sigmoidoscopy. Patients with rectal bleeding between 40 and 50 years of age need evaluation with anoscopy and flexible sigmoidoscopy or colonoscopy with colonoscopy preferred for most patients. Patients over age 50 with bleeding need to be evaluated with anoscopy and colonoscopy. Finally, all patients with a significant family history of colon cancer should undergo anoscopy and colonoscopy regardless of age. Thus, it is very important in patients with rectal bleeding to evaluate the whole colon in most circumstances in order to rule out malignancy.

In patients with symptoms of prolapse, the surgeon must differentiate hemorrhoidal prolapse from true rectal prolapse. Patients with hemorrhoidal prolapse have prolapsing hemorrhoids in one or more of the standard hemorrhoid locations—right anterior, right posterior, and/or left lateral position. Because the hemorrhoids prolapse in these specific locations, the examiner sees prolapsing mucosa and underlying hemorrhoidal vessels with radial folds between the various prolapsing hemorrhoids. Patients with true rectal prolapse have circumferential prolapse of mucosa and full-thickness rectal wall that results in concentric folds. Patients with full-thickness rectal prolapse have decreased sphincter tone whereas patients with prolapsing hemorrhoids typically have normal to increased sphincter tone.

► Treatment of External Hemorrhoids

Patients with chronic tags and external hemorrhoids are treated with reassurance particularly if the tags are small and minimally symptomatic. If they have symptoms of irritation, topical hydrocortisone cream can be helpful. If the external hemorrhoids are causing recurring symptoms of irritation, discomfort, and difficulty with anal hygiene then simple surgical excision may resolve them. If a patient with a thrombosed external hemorrhoid is seen within 3 days of the onset of symptoms then excision of the clot may be beneficial. Excision of the clot in these patients who present early to the surgeon allows for faster resolution of their symptoms. Simple incision of the clot is associated with a higher recurrence rate so if surgical intervention is undertaken it should be complete excision of the hemorrhoidal vessel and clot. Most patients with thrombosed external hemorrhoids seek medical attention after 3 days of symptoms. Surgical excision will not hasten resolution of symptoms in these patients, and management is topical and oral pain medications, stool softeners and laxatives. The clot typically resolves in 2 weeks-2 months. After resolution of their clot, occasionally patients are left with a residual skin tag. Hemorrhoidal disease is common during pregnancy and can be treated postpartum if symptoms persist.

► Treatment of Internal Hemorrhoids

Patients with mild to moderate internal hemorrhoids (grades I-II) and constipation are treated with fiber, fluids, and possibly laxatives to improve their bowel habits. For most of these patients this medical treatment to improve their bowel function will resolve their hemorrhoidal symptoms. For patients with “hemorrhoids” and hyperactive bowel function, treatment should be directed at the cause of the diarrhea/multiple bowel movements. These patients should not undergo hemorrhoid surgery. Patients with normal bowel habits and persistent hemorrhoidal symptoms are candidates for a surgical approach.

► Surgical Treatment of Hemorrhoids in the Office Setting

Internal hemorrhoids can be treated with in-office procedures such as rubber band ligation, sclerotherapy, and infrared coagulation. Most patients with grades I-III hemorrhoids can be successfully treated with office-based procedures. Of the office-based procedures, rubber band ligation is typically the most effective option.

A. Rubber Band Ligation of Hemorrhoids

Small to moderate-sized symptomatic internal hemorrhoids (grades I-III) can be treated with rubber band ligation. This in-office treatment involves placement of an anoscope then grasping the largest hemorrhoidal pile above the dentate line with a clamp and then using a rubber band ligator to place a rubber band around the “neck” of the hemorrhoid. Because the rubber band is placed above the dentate line, patients can tolerate this procedure without anesthesia and usually do not have significant postprocedure pain. After banding patients have either no symptoms or a mild to moderate pressure sensation that resolves in hours to a day or two. The rubber band is a noose around the hemorrhoid’s “neck,” and the hemorrhoid and rubber band will fall off within 5-10 days resulting in a scar that reduces the hemorrhoid size and degree of prolapse. When this sloughing of the hemorrhoid and rubber band occurs, the patient may experience bleeding that occasionally is severe enough to require an emergent visit. Patients are banded without antibiotics as sepsis after banding is exceedingly uncommon. Since post-banding sepsis presents with urinary retention, fever and increasing pain, any rubber band ligation patient with this constellation of symptoms needs to be evaluated urgently. Treatment of post-banding sepsis requires intravenous antibiotics, band removal, debridement of necrotic tissue and supportive care in an intensive care unit. Banding is usually performed one “pile” at a time but placement of multiple bands at one setting is possible. Postbanding instructions include keeping the stools soft, using pain

medication as needed and returning for urgent reevaluation if signs and symptoms of sepsis develop. Rubber band ligation is well-tolerated and quite successful for patients with grades I-III internal hemorrhoids.

B. Sclerotherapy

Sclerotherapy involves using anoscopy to inject a sclerosing agent into the apex of grades I- II internal hemorrhoids. A variety of sclerosing agents have been used with a commonly used option being phenol in oil. Typically, 3-5 mL of sclerosing solution is injected. While the initial success rate approaches that of rubber band ligation, recurrences are common. Complications are unusual but necrosis, rectal perforation, and sepsis have all been reported.

C. Infrared Coagulation

Infrared coagulation involves application of infrared energy directly to the internal hemorrhoids with an infrared coagulation probe. Using anoscopy, the probe is placed on the hemorrhoid for 1-2 seconds which results in coagulation of the hemorrhoid with a decrease in size and blood flow through the hemorrhoid. Recent studies have shown that infrared coagulation is as good as rubber band ligation for patients with grades I-II internal hemorrhoids. Complications are unusual but include bleeding, necrosis, and sepsis.

► Surgical Treatment of Internal Hemorrhoids in the Operating Room

Patients with persistent symptoms despite in-office treatment of their hemorrhoids are candidates for surgery in the operating room. Surgery is usually performed only for patients with grades III-IV internal hemorrhoids. In the operating room, surgical treatment of internal hemorrhoids can be by surgical excision, stapled hemorrhoidopexy or doppler-guided ligation.

A. Excisional Hemorrhoidectomy

Classic excisional hemorrhoidectomy is performed either in the lithotomy or prone position. After the induction of anesthesia the hemorrhoidal piles are excised with scissors, cautery or harmonic scalpel. The resulting wounds are closed, partially-closed or left open depending on surgeon preference. Care is taken to excise just the mucosa, submucosa, and hemorrhoids and to avoid injury to the underlying anal sphincter muscle. In addition, care is taken not to excise too much mucosa and anoderm as this could result in anal stenosis. The procedure takes less than an hour and is scheduled as outpatient surgery. Given that the incisions start externally and end in the anal canal/lower rectum, patients can have significant discomfort postoperatively. Adequate pain control, keeping the bowel movements soft and avoiding constipation are all important postoperatively.

Early complications after excisional hemorrhoidectomy include bleeding, infection, and urinary retention. The rate of urinary retention can be reduced by limiting the amount of intravenous fluids during surgery. Late complications include anal stenosis and mucosal ectropion and whitehead deformity (circumferential mucosal ectropion). Given its high success rate and low recurrence rate, all other surgical interventions are compared to excisional hemorrhoidectomy to determine their efficacy.

B. Stapled Hemorrhoidopexy

A stapled hemorrhoidopexy is useful for patients with circumferential grade II-III hemorrhoids who fail in-office treatment. The technique involves placement of a purse-string suture 3-4 cm above the dentate line in the submucosal plane. The circular stapler's anvil is then placed proximal to the purse string suture and the suture is tied drawing the internal hemorrhoids into the circular stapler. The stapler is then closed and fired removing a circumferential strip of internal hemorrhoids. The staple line, 1-2 cm above the dentate line, is inspected and any bleeding oversewn. Thus, the procedure removes a strip of internal hemorrhoids and creates a hemorrhoidopexy at the staple line that reduces hemorrhoidal prolapse. The procedure does not address external hemorrhoids and thus would not be useful for patients with significant external hemorrhoidal disease. Because the procedure's incision (at the staple line) is above the dentate line, stapled hemorrhoidopexy is associated with less pain and discomfort than traditional excisional hemorrhoidectomy. The results of stapled hemorrhoidopexy have been good and are comparable to excisional hemorrhoidectomy. Complications from stapled hemorrhoidopexy are also comparable to excisional hemorrhoidectomy with the exception of including some unique complications such as rectovaginal fistula and rectal obstruction. Appropriate patient selection and meticulous surgical technique are required to achieve the best results with stapled hemorrhoidopexy. Thus, stapled hemorrhoidopexy is a good option for grade II-III internal hemorrhoids that are not associated with significant external hemorrhoids.

C. Doppler-Guided Hemorrhoidectomy

Doppler-guided hemorrhoidectomy involves the use of a specially designed anoscope with a doppler probe that allows for precise identification and ligation of the hemorrhoidal vessels. Six to eight hemorrhoidal vessels are identified and suture ligated using the doppler probe to identify the vessels and then confirm the interruption of blood flow after suture ligation. Early results have demonstrated that this technique is comparable to excisional hemorrhoidectomy for grade II-III internal hemorrhoids. The complication profile is also favorable. More experience with the doppler-guided hemor-

rhoidectomy is necessary in order to adequately evaluate the long-term effectiveness of the procedure.

► Prognosis

The successful treatment of external and internal hemorrhoids is related to changing the patient's bowel habits. Increasing dietary fiber, decreasing constipating foods, introducing exercise, and decreasing time spent on the toilet all decrease the amount of time spent straining in the squatting position. These behavioral modifications are the most important steps in preventing recurrence.

ANAL FISSURE

An anal fissure is a tear in the anoderm usually located in the posterior or anterior midline of the anal canal. An anal fissure may be associated with a sentinel tag located at the distal aspect of the anal fissure (anal verge) and/or a hypertrophied anal papilla at the proximal aspect of the fissure. The inciting event causing an anal fissure is thought to be trauma to the anal canal from a hard bowel movement or other cause. This trauma results in a tear that leads to pain and spasm of the internal anal sphincter muscle particularly during and after bowel movements. The spasm results in elevated anal resting pressures that can unfortunately lead to a vicious cycle of further spasm and pain. With elevated resting pressures, the blood flow to the posterior and anterior midline decreases inhibiting healing of the fissure. Fissures are usually classified as either acute with symptoms occurring just over the past month or chronic with symptoms present for greater than 2-3 months. Over 90% of fissures are located in the posterior midline with the rest located in the anterior midline. Given their etiology of spasm and elevated resting pressures

resulting in decreased blood flow, chronic anal fissures can be considered “ischemic ulcers” of the anal canal.

► Clinical Findings

Patients with an anal fissure complain of sharp pain with or immediately after bowel movements. They may also complain of rectal bleeding and a “hemorrhoid” or sentinel tag. Patients often describe moderate to severe pain like a “knife” or “razor blade” during defecation. Due to the pain, patients fear going to the bathroom that can result in delaying defecation, hardened stool, and additional pain. On inspection of the external anus, there may be a sentinel tag in either the posterior or anterior midline. To visualize the fissure, the examiner needs to evert the anus by pulling the right and left anal margin skin laterally. As the anus is everted, the examiner can carefully inspect the anoderm in the posterior and anterior midline for a tear in the anoderm. Patients with significant pain and spasm may not even tolerate this maneuver. In these patients it is helpful to gently expose the anus and ask the patient to strain to defecate to see if during straining self-eversion of the anus occurs. Due to pain, digital rectal examination, and anoscopy are not performed immediately, but reserved for when the symptoms resolve or the patient is in the operating room. Laboratory and imaging studies are not necessary but flexible endoscopy of some type should be scheduled if it has not been performed recently.

► Differential Diagnosis

Classic anal fissures occur in either the posterior (90%+) or anterior (1%-10%) midline. Not all posterior and anterior anal canal tears are anal fissures. Anal canal ulcers can occur from Crohn disease, leukemia, HIV, cancer and infections such as herpes, syphilis, cytomegalovirus, and tuberculosis. These anal canal ulcers mimic anal fissures. A careful history can help identify possible etiologies of an anal ulcer. On the other hand, typical anal fissures are associated with increased sphincter tone so any patient with decreased sphincter tone should be suspected of having an anal canal ulcer rather than a fissure. Further, whenever a “fissure” is located laterally rather than in the posterior or anterior midline, an anal canal ulcer should be suspected. There should be a low threshold to suspect an anal ulcer rather than fissure. In these patients, an examination under anesthesia with biopsy of the ulcer is necessary to rule out an infectious or malignant etiology.

► Complications

In addition to causing pain and bleeding, anal fissures can become infected and develop a fissure-fistula complex. This relatively unusual complication is easily treated with a posterior intersphincteric fistulotomy.

► Medical Treatment

The pathogenesis of an anal fissure is pain and spasm resulting in increased internal anal sphincter (IAS) muscle pressures, decreased blood flow, and a nonhealing fissure in the anoderm of the anal canal. Treatment is directed at breaking this pain and spasm cycle to relax the internal sphincter muscle, increase blood flow, and allow the fissure to heal. To do this, patients should keep their stools soft with stool softeners and laxatives to avoid further anal canal trauma. In addition, warm baths are recommended to relax the sphincter muscle and allow the fissure to heal. Stool softeners, bulking agents, and sitz baths will heal 90% of anal fissures. Topical ointments can also be prescribed to decrease the anal sphincter pressure. Nitroglycerin ointment (0.2% or 0.4%) or calcium channel blocker ointment (0.2% diltiazem gel) can be used to chemically relax the IAS muscle. Side effects include headache which occurs more frequently after nitroglycerin ointment. Patients who fail this regimen and have a persistent fissure are candidates for surgery or treatment with botulinum toxin. Botulinum toxin injection into the anal sphincter can be successful but is costly and has a higher recurrence rate than surgery. Thus, medical treatment of anal fissures includes stool softeners, bulking agents, warm baths, topical nitroglycerin ointment or diltiazem gel, and possibly botulinum toxin injection. Most patients with acute anal fissures and over 50% of patients with chronic anal fissures are successfully treated without surgery. Patients who fail medical management of their anal fissure should undergo surgical intervention.

► Surgical Treatment

Surgical treatment of an anal fissure involves performing a lateral internal sphincterotomy. While the fissure may be biopsied and a sentinel tag or hypertrophied anal papilla excised, the most important part of an operation for anal fissure is directed via a lateral incision at the IAS muscle. In the operating room, a lateral incision is made in the intersphincteric groove between the internal and EAS muscles and a submucosal and intersphincteric dissection is performed in order to clearly identify the IAS muscle. The IAS muscle is then cut the length of the fissure in order to permanently relax the anal canal. After sphincterotomy, relaxation of the anal canal is readily appreciated by the surgeon. This short, outpatient operation has over a 90% success rate and a recurrence rate of less than 10%. Patients often have less pain after surgery. Complications include bleeding, infection, and rarely fecal incontinence (< 0.5%).

Patients who have preexisting fecal leakage or lack increased anal sphincter muscle pressures are poor candidates for lateral internal sphincterotomy which could result in worsening bowel control. These relatively rare patients are better treated with an anal advancement flap that does not

involve dividing any sphincter muscle. For a description of the anal advancement flap, see the section on anal stenosis.

ANORECTAL ABSCESS & FISTULA

An anorectal abscess is one of the three common causes of anorectal pain and is the only cause that usually requires urgent surgical treatment. Most anorectal abscesses have a cryptoglandular etiology. When the anal glands in the crypts of the dentate line become blocked, an anorectal abscess can develop. Because these glands extend a variable depth, the developing abscess can track in various anatomic planes. Abscesses are classified by their anatomic location:—perianal, ischiorectal, intersphincteric, and supralelevator (Figure 31–3). Fortunately, most abscesses are perianal or ischiorectal and can be relatively easily identified on physical examination. Intersphincteric and supralelevator abscesses are unusual and often are only identified by MRI/CT or examination under anesthesia. Most abscesses are cryptoglandular in etiology but some patients develop abscesses related to another disease process such as Crohn, tuberculosis, and cancer. While many abscesses will heal with simple incision and drainage, some 30%-60% of abscesses will not heal and patients will complain of persistent drainage and recurrent inflammation related to an anal fistula. In these patients, the cryptoglandular source and external surgical drainage site remain connected allowing for passage of mucus and stool through this tract. The location of the abscess, thus, determines the location and tract of the resulting anal fistula. Anal fistulas are classified by their relationship with the anal sphincter muscle—intersphincteric, transsphincteric, suprasphincteric, and extrasphincteric. Due to the frequency of the abscesses that created them, intersphincteric and transsphincteric fistulas are the most common anal fistulas.

▲ **Figure 31–3.** Composite diagram of acute anorectal abscesses and spaces. (a) Pelvirectal (supralelevator) space. (b) Ischiorectal space. (c) Perianal (subcutaneous) space. (d) Marginal (mucocutaneous) space. (e) Submucous space. (f) Intermuscular space.

Suprasphincteric and extrasphincteric fistulas are exceedingly rare. Due to their relationship with the anal sphincter muscle, treatment of anal fistulas should be evaluated and treated by highly specialized surgeons familiar with sphincter-saving techniques in order to avoid complications such as fecal incontinence. Since fistulas occur in 30%-60% of patients after anorectal abscess drainage, patients undergoing abscess drainage should be warned about the possibility of a fistula and should be given appropriate follow-up to insure healing and absence of a persistent fistula tract.

► Clinical Findings

Patients with an anorectal abscess complain of acute pain, swelling, and possibly a fever. An occasional patient may complain of leakage of mucus and pus related to the spontaneous drainage of the abscess. For patients with perianal and ischiorectal abscesses, physical examination often reveals erythema, fluctuance, and asymmetry between the right and left perirectal tissues. An occasional patient will present with a symmetric horseshoe abscess cavity circling half or more of the circumference and may have no left-right asymmetry. If a patient has an intersphincteric or supralelevator anorectal abscess, there is often none of the above findings on physical examination. Thus, patients with a suspicion of an abscess but no obvious physical examination findings should either be imaged with MRI or taken to the operating room for an examination under anesthesia. Laboratory testing is usually not helpful in patients with an anorectal abscess although

frequently these patients will have an elevated white blood cell count. Radiologic studies are also not necessary as the vast majority of anorectal abscesses are obvious on the basis of history and physical examination alone. Some patients with symptoms of an abscess and no physical examination findings may benefit from imaging studies as well as patients with recurrent or complex abscesses such as some patients with Crohn disease. Potential imaging studies include CT, MRI, and anorectal ultrasound. Anorectal ultrasound is not well tolerated in patients with an acute abscess and CT will miss some abscesses. Thus, if an imaging study is necessary, an MRI is the imaging test of choice being able to readily identify complex abscesses and their anatomic extensions.

Patients with an anorectal fistula complain of chronic drainage of mucus and blood, irritation, and usually have an antecedent history of an anorectal abscess. If a patient has persistent drainage 6-8 weeks after abscess drainage, then a fistula should be suspected, and evaluation and treatment for an anal fistula should be initiated. Some patients with anal fistulas will have a relatively remote or no history of an abscess. Physical examination reveals the external opening and often there is a palpable subcutaneous tract between the external opening and the anus. It is important to remember that any nonhealing wound or opening around the anus should be presumed to be a fistula until proven otherwise. Laboratory testing is not necessary in patients with anal fistulas but imaging studies may be useful for recurrent and complex anal fistulas. MRI is the imaging procedure of choice to identify anal fistula tracts, side tracts, and the relationship of the tracts to the anal sphincter muscle. Transanal ultrasonography can also be useful and can be performed intraoperatively using hydrogen peroxide enhancement to highlight the fistula tract.

► Differential Diagnosis

The differential diagnosis for patients with anorectal abscess or fistula includes perianal hidradenitis, pilonidal disease, and rarely Bartholin gland cyst. On physical examination, it may be difficult to differentiate an anorectal abscess/fistula from complex hidradenitis or pilonidal disease. Further, hidradenitis or pilonidal disease can occur concurrently with an anorectal abscess or fistula. Careful evaluation in the operating room is necessary to determine if an abscess is communicating only with the skin (hidradenitis), only with the midline gluteal cleft (pilonidal disease) or with the anus (fistula). Rare causes of anorectal abscesses and fistulas include tuberculosis, actinomycosis, cancer, and diverticulitis.

► Complications

Abscesses can enlarge and spread along various anatomic planes around the anus. Abscesses can form a posteriorly based horseshoe around the anus usually just sparing the anterior perirectal space. Abscesses can also track around

just one side of the anus (1/2 horseshoe). While it may be unusual for a single abscess to destroy a significant amount of anorectal tissue and diminish anorectal function, multiple recurrent abscesses can result in destruction of anorectal anatomy and muscle function resulting in a deterioration of anorectal function.

In rare circumstances, an anorectal abscess can result in systemic sepsis. Treatment should include adequate drainage of the abscess, intravenous antibiotics, and supportive intensive care unit care.

Anorectal abscesses can recur after treatment. The reasons for recurrence include inadequate initial drainage (often because deep postanal space was not drained), the presence of a fistula, and Crohn disease. Nearly all patients with recurrent or complex abscesses should be evaluated for Crohn disease.

Anal fistulas should be treated when identified because although they may be minimally symptomatic they can develop into an acute anorectal abscess. Fistulas, too, may recur after treatment due to undiagnosed side tracts or Crohn disease. Crohn disease should be ruled out in all patients with complicated or recurrent anal fistulas.

► Treatment of Anorectal Abscesses

Anorectal abscesses are treated by incision and drainage. For the common perianal and ischioanal abscesses, a cruciate incision is made over the area of fluctuance as close to the anal verge as possible to decrease the length of a fistula tract if one should develop. Frequently it is useful to excise the skin tips of the cruciate incision in order to allow for adequate drainage and insure that the abscess heals from the inside out as premature skin healing could result in a recurrent abscess. When draining an acute abscess, it is very unlikely to be able to identify an internal opening and the course of the fistula tract if one is present. Thus, when draining an abscess either in the office or the operating room, it is important to concentrate effort at insuring that the abscess is adequately drained and worry about a fistula later if it should develop. For the relative rare intersphincteric abscess, transanal drainage is performed. In the operating room, the intersphincteric abscess is palpated within the anal canal and via an anoscope a longitudinal incision is made to drain the abscess internally into the rectum. Supralelevator abscesses can also be treated in this way. Alternatively, supralelevator abscesses can be drained in the interventional radiology suite using CT-guidance but this may result in an extrasphincteric fistula if the etiology of the abscess is cryptoglandular.

After surgical drainage, only immunocompromised patients or patients with associated sepsis are treated with antibiotics. For large abscesses, placement of a penrose or mushroom-catheter drain may be necessary to insure adequate drainage. After draining a horseshoe abscess posteriorly,

it is useful to make counter incisions at the anterior extent of the abscess on both sides of the anus and put looped penrose or vessel-loop drains from the posterior opening to the anterior opening. These drains are left for at least 2-3 weeks and will allow for better drainage of the entire abscess cavity. Finally, follow-up of patients after abscess drainage is important to insure that the abscess completely heals and does not evolve into a persistently draining fistula tract.

► Treatment of Anorectal Fistula

Traditionally, anorectal fistulas have been treated by fistulotomy. Fistulotomy is performed one of three ways. The simplest fistulotomy is a single-stage procedure laying open the fistula tract. A two-stage approach is used for fistulas that involve a significant amount of sphincter muscle. The two-stage approach uses a seton which is a suture or vessel loop drain that is tied to itself after placement in the fistula tract. With the two-stage approach, the first step is a partial fistulotomy and seton placement. After healing from this first step, the second step is a completion fistulotomy. A final method of fistulotomy involves placement of a cutting seton and then gradual division of the fistula tract and involved sphincter muscle by tightening of the cutting seton over time. While fistulotomy may still be utilized for subcutaneous, intersphincteric, and low transphincter fistulas (all have little or no muscle involvement), fistulotomy has fallen into disfavor because division of the sphincter muscle during fistulotomy as well as contour deformities associated with fistulotomy can result in fecal incontinence and leakage. Thus, while fistulotomy is a highly successful way to treat subcutaneous and intersphincteric fistulas that involve minimal to no anal sphincter muscle, transsphincteric fistulas are better treated with a sphincter-sparing approach to avoid the complication of fecal incontinence.

Sphincter-sparing treatment approaches for transphincteric anal fistulas include fibrin glue, anal fistula plug, the ligation of the intersphincteric fistula tract (LIFT) procedure, and the rectal advancement flap. Prior to any of these sphincter-sparing procedures, a vessel loop draining seton is placed into the fistula tract, and the tract is allowed to heal around the seton for 3 months. While this seton placement procedure step can be omitted, studies have shown that the success rate of the subsequent definitive sphincter-sparing procedure is higher after seton placement. For the fibrin glue procedure, the seton is removed, the internal opening suture closed and then fibrin glue is instilled via the external opening to seal the tract. The anal fistula plug procedure is done in a similar fashion just using the plug rather than the glue. No incisions are made with either of these procedures which tend to be very well-tolerated by patients. Unfortunately, the success rate is only 60%-70% for fibrin glue and probably even lower for the anal fistula plug. Thus, a number

of patients (30%-40%) will fail glue or plug at which time further treatment by repeating the glue or plug or by opting for the more invasive LIFT procedure or rectal advancement flap. The main complications for glue/plug are recurrence and abscess (rare).

The relatively new procedure is called LIFT because it involves ligation of the intersphincteric fistula tract. During this outpatient operation after removal of the seton (if placed previously), an intersphincteric groove incision is made and the fistula tract in the intersphincteric space is identified and circumferentially dissected free. This dissection allows for proximal and distal suture ligation and division of the fistula tract within the intersphincteric space. This procedure is well-tolerated, spares the sphincter muscle, and is successful 80% of the time. Complications include recurrence of a simpler intersphincteric fistula and rarely abscess formation.

If the previously mentioned sphincter-sparing techniques are unsuccessful in healing an anal fistula, an anorectal advancement flap can be performed. For patients, this is a significantly more involved operation than the above options as it involves much larger incisions, longer operative time, and longer healing time. In the operating room, patients are placed prone for an anterior internal opening or placed in lithotomy position for a posterior internal opening. A U-shaped flap of mucosa, submucosa, and some underlying sphincter muscle is dissected proximally with the base of the "U" just distal to the internal opening. Once the flap is completely mobilized, the internal opening in the underlying sphincter muscle is closed with one or two figure of eight sutures. The tip of the flap is then excised and the flap is advanced distally to cover the suture closure of the internal opening in the sphincter muscle. The flap is then sutured into place providing a double layer closure of the internal opening. The external opening is enlarged and left open for drainage. Patients undergoing anorectal advancement flap are typically observed overnight to control pain and monitor for anorectal bleeding. If the flap remains in place and heals, the internal opening will be closed, and the rest of the fistula tract will heal. The success rate for the rectal advancement flap procedure is 85%-95% with the higher success rates associated with preoperative seton drainage.

► Prognosis

With the exception of Crohn patients who can develop recurring anal abscesses and fistulas, the prognosis with anorectal abscesses and fistulas is excellent. The new sphincter-sparing techniques for anal fistulas do require multiple operations, but that is a small price to pay in order to minimize the occurrence of fecal incontinence which can be over 50% in patients after traditional fistulotomy.

CONDYLOMATA ACUMINATA

Condylomata acuminata are caused by the human papillomavirus (HPV) and are transmitted primarily by sexual contact. In the United States, condylomata acuminatum is the most common sexually transmitted viral disease. It is the most common anorectal infection of men who have sex with men (MSM) and is particularly prevalent in HIV-positive patients. The disease is not limited to men or women who practice anoreceptive intercourse. In women, the virus may track down from the vagina, and in men, it may track from the base of the scrotum. A recent study found that 16% of asymptomatic heterosexual men tested positive for anal HPV. In addition to causing anal warts, HPV infection is the primary cause of anal dysplasia and anal squamous cell cancer. While HPV strains HPV-6 and HPV-11 cause benign warts, HPV-16 and HPV-18 are the two HPV strains with the highest risk of anal cancer. Despite the high prevalence of HPV infection, most HPV-infected individuals will not develop cancer due to the response of the immune system against the virus. Immunocompromised individuals such as patients with HIV or transplant recipients have an increased HPV-related cancer risk. Recently a vaccine has been developed that prevents cancer, precancer, and most types of warts.

► Clinical Findings

Patients with condylomata acuminata present with wart-like growth around the anus and in the anal canal. The presence of warts is associated with discomfort, irritation, and possibly some occasional rectal bleeding. Due to HPV's high prevalence in MSM and its risk of causing cancer, primary care physicians, infectious disease clinics, and HIV clinics often screen for HPV with anal pap smears. Patients with positive anal pap smears are referred for further evaluation. The appearance of condylomata acuminata and HPV disease can be quite variable. Wart-like growths are typical but flat patches of warty growth can also be seen. Other HPV changes cannot be seen without the assistance of high-resolution anoscopy (HRA). HRA involves applying acetic acid to the anal canal and using a colposcope to look for HPV-related changes in the anoderm and rectal mucosa. Laboratory and radiographic studies are rarely utilized in the evaluation of patients with condylomata acuminata. Thus, evaluation of patients with HPV-related condylomata acuminata requires careful external examination, anoscopy, and possibly HRA to determine the extent of disease.

► Differential Diagnosis

Because of the variable appearance of condyloma acuminata, hemorrhoids, skin tags, and fibroepithelial polyps among many other anal skin conditions can mimic condylomata acuminata. Due to the large differential diagnosis for perianal and anal canal skin changes, it is important that a biopsy is taken of all anal canal lesions in order to make an accurate diagnosis.

► Prevention

A quadrivalent HPV vaccine against HPV-6, -11, -16, and -18 has been recently developed and has been shown to prevent cancer, precancer, and most types of warts. The vaccine is best given prior to any sexual activity but also has efficacy after the initiation of sexual activity. In uninfected individuals, the efficacy of the vaccine against the development anal dysplasia and anal cancer was 75% whereas in patients with known HPV infections the efficacy was 50%.

► Treatment

Condylomata acuminata are treated in the office or the operating room. Significant external disease or any internal anal canal disease is probably best treated in the operating room. Isolated external disease can be safely treated in the office. Condylomata acuminata are treated using a variety of excisional and destructive methods. In the office, anal warts can be excised after injecting local anesthesia or destroyed with bichloroacetic acid, podophyllin, liquid nitrogen, infrared coagulation, or electrocautry. In the operating room,

excision and destruction using electrocautery is commonly used. All excised specimens are sent for pathologic analysis. If highly suspicious lesions are excised during an operation, their location should be specified in the case that the pathology is unfavorable, and re-excision is required. Unless a patient has a significant burden of disease, all lesions are either excised or destroyed in the operating room. Some surgeons will use HRA in the office and operating room in order to identify and treat all HPV-related changes. After surgery pain medication and stool softeners are prescribed, and patients are given appropriate follow-up.

► Complications and Prognosis

While some bleeding, pain, and rarely infection may occur after excision of condylomata, the most common complication is recurrence. Patients should be informed prior to surgery that the recurrence rate is high (30%-80%) but that often small areas of recurrence can be treated in the office. Patients should also understand that close follow-up is necessary for early detection of recurrence. This close follow-up is important in order to avoid reoperation and the development of malignancy.

A relatively rare variant of condylomata acuminatum is the locally aggressive but benign giant condylomata acuminatum known as a Buschke–Lowenstein tumor. Treatment is radical excision for palliation or cure. In some patients, surgery has been combined with adjuvant chemotherapy and radiation therapy with success.

After excision of condylomata acuminatum patients should be informed of their pathology results. If an area of squamous cell cancer has been excised on the anal margin, re-excision of this area may need to be performed if the margins were positive. If squamous cell cancer has been identified in the anal canal or from an unknown location around the anus, then the patient should be treated with chemoradiation (Nigro protocol). On the other hand, pathologic analysis may not reveal cancer but rather anal intraepithelial neoplasia (AIN). Anal intraepithelial neoplasia is graded from I (most benign) to III (most ominous and closest to cancer). Many surgeons would return to the operating room to reevaluate and excise areas of AIN-III if there is any question about the completeness of excision at the initial operation. In HIV-positive patients, some grade of AIN is a very common finding. Most surgeons would follow patients with higher grades of AIN at more frequent intervals.

The prognosis of patients with condylomata acuminata is excellent as despite the presence of anal warts and HPV, anal cancer is still quite rare. Further, the prognosis of anal cancer is excellent if located on the anal margin and completely excised. Prognosis of anal canal squamous cell cancer is also good as treatment with chemoradiation is very successful for most localized anal canal squamous cell cancers. Salvage

abdominoperineal resection for recurrence of squamous cell cancer after chemoradiation is unusual.

PILONIDAL DISEASE

Pilonidal disease is a chronic gland infection in the depths of the gluteal cleft. While the glands and resulting pits can occur anywhere along the gluteal cleft, they occur most often in the superior gluteal cleft over the sacrum. The pathogenesis of pilonidal disease is thought to be a process in which the follicles in the midline gluteal cleft get blocked, infected, and then drain leaving open midline pits. In the depths of the gluteal cleft these pits have a vacuum effect on loose hair and hair is literally sucked into these pits. During surgery, tufts of hair can be found in the pits and chronic abscess cavity. Thus, while the hair does not cause pilonidal disease, the presence of hair in the pits and glands acts as a foreign body and causes the infection and drainage to persist. Pilonidal disease usually occurs in men (3:1 male to female ratio) between the ages of 15 and 40 with the peak incidence between 16 and 20 years. Although pilonidal disease is typically chronic with recurrent drainage and inflammation, it often regresses with time and is rare after 40 years of age. The pathogenesis and natural history of pilonidal disease is important to remember when recommending treatment. Given its natural history that involves disease regression with time, conservative treatment, and minimal surgery is recommended for most patients.

► Clinical Findings

Patients with pilonidal disease present in three main ways—acute abscess, chronic draining pits or complex, recurrent disease after previous surgery. Patients with an acute pilonidal abscess will have pain and possibly swelling in or along the gluteal cleft. Given the relatively fixed nature of the tissues in this region and how deep a typical pilonidal abscess is located, swelling and cellulitis are often absent, and physical examination often underestimates the size of the abscess. Patients with chronically draining midline pits will have one or more pits in the midline with drainage and recurrent inflammation. Often hair will be seen protruding from the pits. Patients with complex disease after previous surgery such as pilonidal cystectomy will have chronic, nonhealing wounds in the midline of the gluteal cleft. History and physical examination are sufficient to make the diagnosis of pilonidal disease regardless of the type of presentation. Laboratory and imaging studies play no role in the evaluation of patients with pilonidal disease.

► Differential Diagnosis

Pilonidal disease occurs in the superior gluteal cleft and is usually relatively easy to diagnose. Pilonidal disease occurring inferior in the gluteal cleft and close to the anus may be difficult to distinguish from an anal fistula. An examination under anesthesia may be required in order to differentiate pilonidal pit and cyst from an anal fistula. Further, pilonidal disease off the midline may mimic hidradenitis. Usually, hidradenitis will occur elsewhere and will not be just limited to the gluteal cleft like pilonidal disease.

► Treatment

Patients with an acute abscess related to pilonidal disease should undergo incision and drainage of their abscess. Antibiotics are not necessary unless the patient has significant infection, sepsis, or is immunocompromised. The abscess is nearly always located deep to the midline gluteal cleft. Because incisions in the midline heal poorly, an acute abscess should be drained through a lateral incision at least 2 cm off midline. A generous lateral incision allows for adequate drainage of pus and hair from the pilonidal cyst. Shaving a wide area around the gluteal cleft is important to help prevent further accumulation of hair in the cyst. After abscess drainage, patient should be followed to insure healing, but further operative intervention is usually not necessary.

Patients with chronically draining pilonidal pits should be treated conservatively. The whole gluteal cleft and surrounding gluteal skin should be shaved, and all hair in the pits removed. Patients are instructed to bend over in the shower and allow the water to blast the gluteal cleft to help prevent accumulation of hair in the pits. Patients should

undergo repeat shaving and hair removed from the pits every week or 2 until resolution of symptoms. If symptoms recur, conservative treatment with shaving and removal of pit hair should be resumed. Patients with persistent drainage and inflammation despite 2-3 months of conservative treatment are candidates for surgery. Traditionally, surgical treatment of pilonidal disease involved pilonidal cystectomy which meant complete removal of the midline chronic abscess cavity. This procedure is associated with wound breakdown and possible development of a nonhealing midline wound that may in fact be more debilitating than the disease prior to surgery. Given this possibility, midline incisions are absolutely avoided. Rather, a minimally invasive operation entitled lateral incision and pit closure is performed. After a lateral incision is made, the abscess cavity in the midline is accessed via this lateral incision to remove all pus, hair, and granulation tissue. Next, the pits in the midline are excised and the minimal 2-3 mm wounds closed with nylon suture. The lateral incision is left open for drainage. If the excised midline pit wounds heal, the pilonidal disease is eliminated, and the lateral incision will heal readily over 2-4 weeks.

Patients with complex, recurrent pilonidal disease with large, nonhealing midline wounds need complex flap surgery to resolve their symptoms. Many types of flaps have been used to close these wounds and all flaps involving incisions in the midline or that cross the midline are plagued by poor healing in the midline. Due to poor midline healing, the Bascom cleft closure flap procedure that not only avoids the midline but eliminates the gluteal cleft is a very good option for these patients. In this procedure, the open wound is excised and the excision is extended laterally off the midline on one side leaving an asymmetric wound. The skin and subcutaneous tissues of the gluteal cleft and cheek of the opposite side are then mobilized and advanced across the midline to the side with the lateral excision. This flap accomplishes two important goals—the flap closure incision is off the midline facilitating healing (and there is no midline portion of the incision) and the gluteal cleft is eliminated as the cleft is mobilized and advanced to the opposite side. Without a gluteal cleft, further pilonidal disease is unheard of.

► Complications & Prognosis

Patients with pilonidal disease are young, active adults, and often desire a quick fix for their symptoms. It is important to counsel patients regarding the natural history of the disease. Patients need to understand the chronic nature of the disease but also that it naturally regresses with time. With understanding, patients will more readily participate in conservative treatment and understand the goals of minimally invasive surgery such as lateral incision and pit closure. Overall, the prognosis of patients with pilonidal disease is excellent.

ANAL STENOSIS

Anal stenosis is a relatively unusual condition that is most commonly associated with either previous surgery, malignancy, or Crohn disease. Patients often are successful at self-treating their stenosis by keeping their stools soft with stool softeners and laxatives. Complete anal canal obstruction is rare. Identification of the etiology of the anal stenosis is key to successful treatment.

► Clinical Findings

Patients with anal stenosis complain of difficult evacuation and possibly rectal bleeding. The history is important to determine the etiology of their symptoms. The most common cause of anal stenosis is previous anorectal surgery particularly hemorrhoid surgery. Since stenosis often occurs years to decades after hemorrhoid surgery, patients should be specifically questioned regarding prior anorectal surgery. Patients with anal stenosis related to Crohn disease usually have a relatively long history of anorectal Crohn disease. This may include treatment of abscesses, fistulas, and anal canal ulcers. Patients with malignancy may have a history of anal condyloma but often will have no antecedent history. Physical examination reveals a narrowed anal canal. Digital examination is still possible in patients with a mild anal stenosis. Moderate to severe anal canal stenosis does not allow digital examination. Due to the severity of stenosis, it may be difficult to determine if the stenosis is due to a mass or tumor. Laboratory and imaging studies play no role in the evaluation of patients with anal stenosis. Flexible endoscopy is important in all patients with anal stenosis. In those patients with moderate to severe stenosis, flexible endoscopic evaluation may be impossible prior to treatment and is done after the stenosis is corrected.

► Treatment

Mild anal stenosis can be treated with stool softeners and laxatives with good results. Patients with persistent symptoms

despite treatment and those patients with moderate to severe stenosis require endoscopic or surgical intervention. Because malignancy is always a possibility even after hemorrhoid surgery or in patients with Crohn disease, a biopsy of the anal canal stenosis is mandatory. Of course any patient diagnosed with malignancy needs treatment specific for the malignancy which usually involves chemoradiation (anal cancer) and possibly surgery (if rectal cancer). For patients without malignancy, the choice of a surgical procedure is dictated by the etiology of the anal stenosis.

Patients with Crohn disease can undergo endoscopic balloon dilatation of their anal stricture or operative anal stricturoplasty. During anal stricturoplasty, longitudinal incisions are made through the stricture at one to three locations around the anal canal. Recurrent stricture can be treated with repeat balloon dilatation or operative anal stricturoplasty.

Patients with postsurgical anal stenosis have a deficiency of anoderm related to their previous operation and subsequent scarring. Due to their deficiency of anoderm, these patients are not appropriate candidates for stricturoplasty but rather are better served with a local advancement flap into the anal canal to correct their anoderm deficiency. Many local advancement flaps have been described and used successfully such as the V-Y, Y-V, and the anal houseflap. During the anal houseflap operation the patient is placed in the prone position and the anal canal is visualized. Standard operative anosopes will not fit into the anal canal of patients with moderate to severe stenosis and thus use of a nasal speculum is necessary. With the anal canal visualized, the anoderm is divided longitudinally for the length of the strictured anal canal. Transverse incisions are then made at the proximal and distal aspects of this incision converting the incision wound into a rectangular defect. A house-shaped flap of anal margin skin and subcutaneous tissue is developed and advanced into the anal canal. The flap is then sutured into place, and the donor site closed. In some cases, two or three separate houseflaps around the anus are necessary to adequately correct the anal stenosis. Thus, the advancement of anal margin skin into the anal canal corrects the deficiency of anoderm and relieves the anal stenosis.

The results following anal advancement flap treatment of anal canal stenosis are very good. Potential complications include bleeding, infection, flap necrosis, and flap retraction. If an advancement flap fails it can be repeated in another quadrant around the anus.

PRURITUS ANI

Pruritus ani is a challenging dermatologic disorder characterized by intense itching of the perianal skin. Diagnosis of this problem is typically not straightforward and, subsequently, patients are seen by a variety of specialists including, gastroenterologists, dermatologists, and colorectal surgeons. The incidence of pruritus ani ranges from 1% to 5% in adults and typically has a male predominance (ratio 4:1).

Pruritus ani is broadly classified either as primary (idiopathic) or secondary. Up to 90% of cases are considered idiopathic while the remaining secondary cases are caused by a variety of local and systemic conditions.

► Clinical Findings

Patients typically present with complaints of an unpleasant perianal burning, which usually starts insidiously. As the condition becomes more chronic, this burning is replaced by varying degrees of itching that can become intolerable. Careful history uncovers that symptoms are often more pronounced at night.

Physical findings on examination can be varied. In the early stages the skin may appear normal; however, as the patient continues to scratch, the local inflammation worsens, resulting in erythematous, excoriated, and macerated skin. In the chronic stage, the skin is often lichenified with coarse ridges and ulcerations.

► Differential Diagnosis

Identifying the primary etiology of pruritus ani can be very challenging; therefore, a careful history and physical examination is required. Information on diet, medications, synchronous skin conditions, common anorectal disorders, bowel function and stool consistency, as well as prior anorectal procedures should be ascertained. A thorough examination of the perianal skin and anoscopy are essential. Skin scrapings, cultures, and biopsy of suspicious lesions are important adjuncts to elucidate the underlying etiology. The routine use of endoscopy and radiologic studies is unnecessary unless there is a high index of suspicion for a colorectal cause. Some of the established causes of secondary pruritus ani are summarized in Table 31–5.

► Treatment

The goal of treatment should be directed toward establishing clean and dry perianal skin that is free of ulcerations. If pruritus is found to be secondary to one of the aforementioned causes then treatment should be directed towards that specific pathology. The management of idiopathic pruritus is more challenging, often requiring intensive patient education and behavior modification. A high-fiber diet should be encouraged while eliminating foods that may precipitate pruritus. If symptoms improve, then these foods

Table 31–5. Common causes of secondary pruritus ani.

Diet	Dermatologic Conditions
Coffee, tea, caffeinated beverages, alcohol, chocolate, spicy foods, tomatoes (ketchup), dairy products	Psoriasis, contact dermatitis, lichen sclerosis/planus
Local Irritants	Local Malignancies
Topical medications, soaps, detergents, fabric	Bowen disease, Paget disease, squamous cell cancer
Anorectal Diseases	Perianal Infections
Hemorrhoids, fistula, rectal prolapse, fecal incontinence/soiling, skin tags	Bacterial (<i>Staphylococcus</i> or <i>Streptococcus</i>), fungal, viral (eg, herpes simplex, HPV), parasitic
Systemic Diseases	Psychological
Diabetes mellitus, liver disease, thyroid disorder, renal disease, leukemia	Anxiety, depression, stress

may be slowly reintroduced in order to identify the offending product.

Meticulous perianal hygiene should be stressed as the first step in management. Patients should discontinue use of all topical medications and should clean the perineum only with water, avoiding soaps and other potential irritants. In cases of more severe skin excoriation, skin barrier creams may provide symptomatic relief. A brief trial of topical steroids (hydrocortisone 0.5%-1%) is also often a useful adjunct but should not be used for prolonged periods as it results in thinning of the perianal skin. Topical hydrocortisone 1% has been shown in a double-blinded, randomized, placebo-controlled to reduce daily visual analog score (VAS) for severity of itch by 68% and weekly Dermatology Life Quality Index (DLQI) scores by 75%.

In patients with refractory symptoms, topical capsaicin can be considered. A randomized, placebo-controlled, trial comparing topical capsaicin (0.006%) with placebo (1% menthol) in patients with chronic pruritus ani found that of 44 patients, 31 (70%) had relief of their symptoms. Intradermal injection of methylene blue (1%) has also been described with limited success. Skin necrosis from inappropriate infiltration has been described.

► Prognosis

The successful identification and treatment of secondary causes of pruritus ani often yields good results. However, relapses can be common with idiopathic pruritus. Every attempt should be made to continue to reinforce patient education.

PROCTITIS & ANUSITIS

Proctitis and anusitis are general terms referring to inflammation within the anal canal or rectum secondary to infectious pathogens or inflammatory causes. Sexually transmitted diseases are an increasingly common cause of proctitis with an incidence exceeding 15 million new cases annually in the United States. The differential diagnosis can be quite broad with a variety of bacteria and viruses; therefore, a systematic approach is important. The diagnosis and management of these conditions depends primarily on the underlying etiology.

1. Herpes proctitis—The Herpes Simplex Virus (HSV) is a DNA virus that is the most prevalent STD in the United States. The majority of anogenital infections are caused by the HSV-2 serotype, accounting for approximately 80%-90% of infections. Anorectal infections typically result from auto-inoculation or direct contact with infected partners. The virus travels along peripheral nerves and has a variable incubation period (days to weeks). Prodromal symptoms may consist of burning, irritation, fever, and myalgia. This typically escalates to more intense, painful proctitis, and tenesmus. The characteristic lesions are small vesicles with surrounding erythema, which eventually coalesce and rupture forming painful ulcerations. Additionally, patients may develop tender inguinal adenopathy.

Evaluation of the rectum with a proctoscope will demonstrate erythematous and friable mucosa with ulcerations and mucopurulent discharge. Tzanck smear of the discharge reveals the characteristic multinucleated giant cells with intranuclear inclusion bodies. Viral cultures of the discharge from these vesicles are also highly positive in acute infections.

HSV infections are usually self-limited in the absence of superimposed bacterial infections; therefore, initial treatments, such as sitz baths and oral analgesics are aimed at controlling symptoms. There is no cure for active infections but Acyclovir, Valacyclovir, and Famciclovir will shorten the duration of symptoms and may be used for suppressive therapy in patients with frequent recurrences.

2. Anorectal syphilis—Syphilis is caused by the spirochete, *Treponema pallidum*, which typically has an incubation period of 2-6 weeks. This disease was once on the verge of elimination but the incidence has been increasing steadily, especially young black men.

Acute anorectal infection is characterized by a small papule (chancre) on the anal margin or within the anal canal, which eventually ulcerates and may be mistaken for a routine anal fissure. This eventually regresses spontaneously in 3-4 weeks and is followed by a secondary stage 2-10 weeks later. Secondary syphilis may consist of fever, malaise, arthralgia, a maculopapular rash on the palms and soles of the feet, tenesmus, mucoid discharge, rectal pain, and inguinal adenopathy.

There are several methods for diagnosis. Dark-field microscopy will reveal the spirochetes, which have a corkscrew-shaped appearance. Biopsy shows spirochetes on a Warthin–Starry silver stain. There are also two serologic tests, RPR and VDRL.

Treatment consists of a single dose of penicillin intramuscularly in the early phase. If identified later, three doses are given 2 weeks apart.

3. Gonococcal proctitis—Gonococcal proctitis is caused by the organism, *Neisseria gonorrhoeae*, which is an intracellular gram-negative diplococcus. It is estimated that there are approximately 3 million people infected yearly worldwide; however, there is a large population of asymptomatic carriers. Anorectal infection results from contiguous spread from the genital area in women and from receptive anal intercourse in men.

The incubation period varies but can last up to 2 weeks. Symptoms then include pruritus, tenesmus and a thick, purulent discharge, which can be expressed from the anal crypts. Proctitis of the mid to distal rectum can be identified on proctoscopy. Standard Gram stains of the discharge are generally unreliable; however, culture on Thayer–Martin medium increases the positive yield.

The first-line treatment of anorectal gonorrhea includes a single intramuscular dose of ceftriaxone. Penicillin is no longer recommended given the high rate of resistance. Infected patients and partners should also be treated for concomitant Chlamydia infection, which is very common.

4. Chlamydial proctitis and lymphogranuloma venereum—*Chlamydia trachomatis* is the most common sexually transmitted infection worldwide and the most frequently reported

STD in the United States. This intracellular bacteria has several serotypes that have an incubation period up to 2 weeks. Serotypes D-K are responsible for proctitis and genital infections while serotypes L1-L3 are responsible for lymphogranuloma venereum (LGV).

A large portion of patients will be asymptomatic; however, when present, symptoms of an active anorectal infection include rectal pain, tenesmus, and fever. Similar anorectal complaints are present in patients with LGV but the inguinal adenopathy is often more prominent with large matted nodes with overlying erythema.

Diagnosis of active infections can be challenging with routine culture given the intracellular location of the bacteria. Often patients with suggestive symptoms of proctitis that have a Gram stain demonstrating leukocytes without detectable gonococci are presumed to have a Chlamydia infection and treated accordingly. Cell culture is also possible using a sucrose phosphate media. Treatment consists of a single oral dose of Azithromycin or Doxycycline twice daily for 7 days. Treatment with Doxycycline is extended to 21 days for LGV. Sexual partners should be treated as well to prevent reinfection.

5. Condyloma acuminata—*Condyloma acuminata*, caused by the human papilloma virus, have a recognizable raised, cauliflower-like appearance and are located on the anal margin, within the anal canal, or surrounding the genitalia. This presents one of the most common STDs in the United States for which consultation with a colorectal surgeon is sought. There are more than 60 subtypes of this latent virus with types 6 and 11 producing benign exophytic lesions. Types 16 and 18 are noted to be more aggressive, often causing lesions with high-grade dysplasia that may progress to cancer if left untreated.

Patients are often asymptomatic but may present with complaints of bleeding, itching, or anal discomfort due to the growths. Once present, there is no way to eradicate the infection surgically. The goal of treatment is to remove the macroscopic burden of disease with excisional biopsies and electrocautery. Recurrences are common; therefore, surveillance of these patients is extremely important. Bichloroacetic acid, trichloroacetic acid, and Imiquimod are topical agents that have been used with reasonable success.

6. Chancroid—Chancroid is a rare sexually transmitted disease in the United States caused by the gram-negative bacteria, *Haemophilus ducreyi*. Globally, the incidence is higher in developing countries.

The infection manifests itself days after transmission with painful inguinal adenopathy and erythematous papules around the genitalia that eventually ulcerate. Diagnosis is typically made with routine culture of the fluid from the ulcers. Treatment consists of single doses of Azithromycin (orally) or Ceftriaxone (intramuscularly).

7. Inflammatory proctitis—Inflammatory proctitis refers to a general mild to moderate inflammation of the rectum that is unrelated to an underlying infection or sexually transmitted disease. Symptoms include rectal bleeding, urgency, tenesmus, and often diarrhea. Examination of the rectum is characterized by a continuous erythematous, friable mucosal surface. If applicable, cultures should be taken to elucidate any infectious etiology and biopsies should be taken to rule out Crohn disease.

This condition can be self-limited but persistent cases typically respond to short courses of steroid enemas. Additionally, mesalamine enemas are efficacious. If there is no improvement after a few weeks of treatment, the patient should be reevaluated.

8. Radiation proctitis—Radiation proctitis is an unfortunate byproduct of pelvic irradiation that typically occurs in two phases. Acute injury occurs during or shortly after the administration of pelvic radiation. This is characterized by vascular congestion and friable mucosa. Symptoms include rectal bleeding, urgency, tenesmus, and diarrhea. The late phase of injury occurs months to years after the completion of treatment and is characterized histologically by fibrosis that can manifest clinically with strictures, fistulas to the urinary tract or vagina, and telangiectasias. Symptoms include bleeding, change in bowel habits, recurrent urinary tract infections, and vaginal discharge. Evaluation should include flexible sigmoidoscopy or colonoscopy and biopsy to make the diagnosis and rule out malignancy.

The initial treatment of acute radiation proctitis incorporates medications that manage symptoms, including bulking agents, antidiarrheals, and antispasmodics. Enemas of steroids, mesalamine, or short-chain fatty acids have been shown to improve proctitis as well. Refractory cases can be treated topical application of 4% formalin to the rectal mucosa. Radiation proctitis complicated by fistulas is best managed surgically with interposition of normal, healthy tissues.

RECTOVAGINAL FISTULA

Rectovaginal fistulas can be congenital or acquired and are generally characterized by their abnormal connection between the epithelialized mucosal surfaces of the rectum and the vagina. Distal fistulas arising from the anal canal are appropriately termed, anovaginal fistulas. Acquired rectovaginal fistulas are generally caused by obstetric injuries, inflammatory bowel disease, trauma, or infection.

► Clinical Findings

A. Symptoms and Signs

The diagnosis of a rectovaginal fistula is typically straightforward based on an accurate history; however, in some instances, patients can be asymptomatic. Commonly, patients will present with complaints of the passage of air or feces from the vagina. The degree of distress often depends of the size of the fistulous opening. With smaller fistulas, more subtle complaints of a foul vaginal discharge, recurrent vaginitis, or dyspareunia may be more common while the feculent drainage from larger fistulas may be confused with fecal incontinence. If the etiology of the fistula is due to inflammatory bowel disease then rectal complaints such as tenesmus or bloody diarrhea may predominate.

On digital rectal examination, the fistula can often be identified as a dimpling or pit in the anterior rectal mucosa, which can be easily be confirmed by anoscopy. Inspection of the vagina will reveal staining of the mucosa with stool and the hyperemic mucosa of the fistula opening contrasting with the normal pink background of the vaginal mucosa. Occasionally, the identification of the fistula can be more challenging despite very suggestive symptoms. In these instances, a thorough examination under anesthesia may be indicated. With a saline-filled vagina, air can be instilled per rectum via a proctoscope. Air bubbles may help identify fistulas that are not readily apparent. Alternatively, diluted methylene blue can be instilled per rectum with a tampon in place in the vagina. Staining of the tampon with methylene blue will confirm the presence of a fistula.

B. Laboratory Studies and Imaging

Adjunct studies are sometimes necessary to identify the fistula location and to determine the quality of the surrounding tissue. Retrograde contrast enemas and CT scans with rectal contrast may identify contrast extravasation into the vagina. CT scans have the added benefit of identifying any associated inflammatory changes. MRI and endorectal ultrasound have also been used with varying results. Endoscopy is a valuable diagnostic tool to assess any underlying inflammatory conditions such as Crohn disease and to exclude underlying malignancy. Biopsies should be performed on any abnormal mucosa in the rectum or around the fistula orifice.

► Differential Diagnosis

The most common cause of rectovaginal fistulas is obstetrical trauma accounting for 70%-80% of cases. These fistulas may present immediately but more frequently they manifest weeks after delivery, typically after third- and fourth-degree lacerations. In the Western hemisphere, the incidence has been estimated at up to 0.1% of all vaginal deliveries. Other etiologies include—inflammatory bowel disease—primarily Crohn disease, postoperative trauma, radiation, malignancy, and infection.

► Treatment

The management of rectovaginal fistulas primarily depends on its complexity, as determined by the location, etiology, and the quality of the surrounding tissue. Simple fistulas are typically small in diameter, low on the rectovaginal septum, and are secondary to either traumatic injury or infection. On the other hand, complex fistulas are larger in diameter, higher on the rectovaginal septum, and are associated with underlying inflammatory bowel disease, radiation, neoplasm, or previous failed repairs. There are several well-described operative approaches that can generally be divided into transanal, transvaginal, transperineal, and transabdominal repairs.

Common transanal repairs include fistula excision with layered closure, endorectal advancement flap, and rectal sleeve advancement. The mucosal advancement flap is appropriate for simple, low fistulas. During this procedure, a flap composed of mucosa, submucosa, and a portion of internal sphincter muscle is mobilized proximally and used to cover the fistula defect. The base of the flap should be wider than the apex in order to ensure adequate perfusion of the flap. The muscle is then reapproximated in the midline—closing the fistula. The flap is then advanced into the anal canal and secured with absorbable sutures. Success rate are varied in literature, ranging from 50% to 100%.

Rectal sleeve advancement is a reasonable approach for rectovaginal fistulas with extensive stenosis and anal ulcerations due to Crohn disease. Starting at the dentate line, a circumferential incision is made and extended cephalad. The dissection becomes full thickness above the anorectal ring and is extended until the distal rectum is adequately mobilized. The rectum is then pulled down through the anal canal and the diseased rectum is transected. The fistula opening in the vaginal is closed and the rectum is sutured to the dentate line. This repair is often done with a protective diverting ostomy.

Perineoproctectomy is a perineal technique that essentially converts a RVF into a fourth-degree laceration. The vaginal mucosa, sphincter muscles, and the rectum are divided between the fistula openings and reapproximated in layers, ultimately obliterating the fistula tract.

Tissue interpositions are also typically performed through the perineal approach and include the gracilis muscle flap

and the Martius (bulbocavernosus muscle) flap. The fundamental concept in these procedures is that normal, healthy tissue is placed between the fistula openings after dissecting the plane between the rectum and the vagina. Successful closure with these procedures has been reported as high as 80% and is an ideal repair for RVF that have failed previous repairs or with abnormal surrounding tissues.

Rectovaginal fistulas that are higher in the rectovaginal septum are usually approached through an abdominal approach. There are several potential procedures, ranging from simple fistula division and closure with interposition of pedicled omentum, to proctectomy with colorectal or coloanal anastomosis. The choice of procedure depends on the quality of surrounding tissues, location, and the etiology of the fistula.

Finally, the last decade has seen increasing use of bio-prosthetic plugs and sheets in the management of RVFs. Small series have shown promising results but there is still a paucity of long-term data.

► Prognosis

The prognosis for rectovaginal fistulas relates to its overall complexity. Simple, low fistulas can be approached with relatively straightforward transanal or perineal techniques with good results. Fistulas that are higher or associated with inflammatory bowel disease, radiation, or neoplasm are understandably more challenging, often requiring multiple repairs.

ANAL & PERIANAL NEOPLASMS

► General Considerations

Neoplasms of the anus and surrounding skin are uncommon—accounting for only about 3% of all colorectal

malignancies. Approximately 5200 cases are diagnosed annually in the United States, resulting in more than 700 deaths. The overall management of these lesions depends primarily on the histology, the size, and location of the lesion. While the definitions can be confusing, the anal canal is commonly defined, by surgeons, as the region extending from the anal verge to the anorectal ring at the top of the sphincter complex. The lymphatic drainage in this area is variable but clinically important. Proximal to the dentate line, the lymphatic system drains to the internal iliac and inferior mesenteric nodes while distal to the dentate line, drainage is typically to the inguinal nodes. It is important to realize that lesions in this area may not be completely visualized on routine inspection of the perineum. The anal margin is generally defined as the perianal skin extending circumferentially within 5 cm of the anal verge. Lesions in this area are easily visible on examination.

► Tumors of the Anal Margin

A. Squamous Cell Carcinoma

The majority of malignant neoplasms of the anal margin are squamous cell cancers (SCC). They have similar presentation to SCCs that occur elsewhere on the skin and are subsequently staged similarly based on size, which has been shown to correlate with lymph node positivity. The American Joint Committee on Cancer (AJCC) staging system is summarized in Table 31–6. The overall incidence of anal margin cancers is low and the prognosis is often more favorable than squamous cell carcinoma of the anal canal. These lesions are typically well differentiated, indolent, and are rarely associated with distant metastasis.

Lesions in this location may present with pain, bleeding, pruritus, tenesmus, or incontinence if locally advanced. On examination, there are rolled, everted edges often with central ulceration. Palpable lymph nodes may be identified in the inguinal region.

The management of anal margin SCC consists of wide local excision for T1 and early T2 lesions that can be easily resected with a 1-cm margin without compromising sphincter function. Poorly differentiated tumors, T3, or T4 cancers should be treated with chemoradiation, including the inguinal and pelvic nodes in the field of treatment. Abdominoperineal resection (APR) should be reserved for recurrent disease, residual disease after radiation, or bulky tumors that are invading the sphincter complex.

B. Basal Cell Carcinoma

Basal cell cancers (BCC) of the anal margin are exceedingly rare, accounting for 0.2% of anorectal cancers. They typically present in older men and approximately one-third of patients will have a history of BCC or a synchronous lesion

Table 31–6. American joint committee on cancer (AJCC) TNM staging of squamous cell cancer.

	Anal Margin	Anal Canal
Tumor (T)		
Tis	Carcinoma <i>in situ</i>	Carcinoma <i>in situ</i>
T1	Tumor ≤ 2 cm in greatest dimension	Tumor ≤ 2 cm in greatest dimension
T2	Tumor 2-5 cm in greatest dimension	Tumor 2-5 cm in greatest dimension
T3	Tumor > 5 cm in greatest dimension	Tumor > 5 cm in greatest dimension
T4	Tumor invades deep structures	Tumor invades deep structures (not including the sphincters)
Nodal Status (N)		
N0	No regional lymph node metastasis	No regional lymph node metastasis
N1	Regional lymph node metastasis present	Perirectal lymph node metastasis present
N2		Unilateral internal iliac or inguinal lymph node metastasis present
N3		N1 and N2 and/or bilateral internal iliac or inguinal lymph node metastasis present
Distant Metastasis (M)		
M0	No distant metastasis	No distant metastasis
M1	Distant metastasis present	Distant metastasis present

elsewhere. The appearance of these lesions is similar to that of other areas of the body with irregular, raised, pearly edges with superficial plaques or ulcers. Local I invasion and metastatic potential are both typically low.

Wide local excision with an adequate margin is the treatment of choice for small lesions. Local recurrence is fairly uncommon and can usually be re-excised. Larger, bulky lesions can be treated with abdominoperineal resection or radiation.

C. Bowen Disease

Historically, the term Bowen disease referred to squamous cell carcinoma *in situ*. This term as well as anal intraepithelial neoplasia (AIN) II and III have largely been replaced

by the classification of high-grade squamous intraepithelial lesion (HSIL), which has similar histologic features. Human papilloma virus infection is common. Patients may complain of itching or pain and examination reveals scaly, erythematous, and sometimes pigmented lesions.

Traditionally, these lesions have been treated wide local excision, often with complex reconstructions for larger lesions. This approach has been plagued by high recurrence rates and generally very morbid. More recent data suggest that HSIL can be adequately treated with targeted biopsy with high-resolution anoscopy, ablation, and close surveillance every 3-6 months. The application of topical Imiquimod (Aldara) or topical 5-FU have been proposed to minimize recurrence, but are generally limited by local skin irritation.

D. Verrucous Carcinoma

Perianal verrucous carcinoma is often referred to as a Buschke-Lowenstein tumor or Giant Condyloma, given its exophytic, cauliflower-like appearance. These lesions can vary in size but are generally slow growing and locally invasive. Histologically, they are considered benign but larger lesions may certainly encompass underlying malignancy—usually invasive squamous cell carcinoma. Patients frequently present with complaints of an anal mass but may also describe pain, fistulas, or abscesses. Wide local excision is recommended for the majority of these lesions and, if large, the resulting defects may require more complex closure with plastic surgeons. More advanced cases with invasion into the sphincter complex may require APR.

E. Paget Disease

Paget disease is a rare condition characterized by an intraepithelial adenocarcinoma of the perianal skin. The most common presenting complaint is intolerable pruritus and examination typically reveals a well-demarcated, erythematous, eczematous rash. Diagnosis is made after a full-thickness biopsy, which shows the pathognomonic Paget cell with a pale vacuolated cytoplasm and peripheral nucleus. These lesions often are associated with synchronous gastrointestinal malignancies, so a complete evaluation of the intestinal tract should be performed.

In the absence of invasive disease, wide local excision is the treatment of choice. It is important to obtain intraoperative frozen sections to ensure negative margins. Large defects can be covered with skin grafts or adjacent tissue transfers. Patients with invasive disease have a poor prognosis and should be considered for radical resection with abdominoperineal resection. Inguinal lymphadenectomy should be added for clinically positive nodal involvement. The role of chemoradiation is not well defined but has been used as an adjunct in invasive and recurrent disease.

TUMORS OF THE ANAL CANAL

1. Epidermoid Carcinoma

► Clinical Findings

Tumors of the anal canal are rare, accounting for about 2% of all colorectal malignancies. Of these, epidermoid carcinomas are the most common. The term epidermoid carcinoma encompasses several histological subtypes including squamous cell, basaloid, mucoepidermoid, and transitional cancers.

The clinical manifestation of anal canal tumors can be quite variable and many patients are initially diagnosed with benign anorectal conditions. They are typically slow growing and the resulting mass commonly causes pain and bleeding. Digital rectal examination and anoscopy are important tools for an accurate diagnosis, during which the size, location, consistency, and degree of fixation should be noted. Additionally, the presence of any palpable inguinal adenopathy should be documented. A biopsy of the lesion confirms the diagnosis and provides the specific subtype. The staging of anal tumors is summarized in Table 31-6. Endoanal ultrasound, MRI, and PET/CT are important adjuncts that aid in defining that degree of distant spread, local invasion, and surrounding adenopathy.

► Treatment

Since its introduction in 1974, radiation and chemotherapy with 5FU and mitomycin C (Nigro Protocol) have largely replaced surgery in the treatment of anal cancer. There is ample data that demonstrates equivalent local control, survival rates with preservation of sphincter function. Approximately 30% of patients have persistent or recurrent disease after chemoradiation for anal SCC. Salvage abdominoperineal resection is reserved for recurrent or residual pelvic disease after chemoradiation.

The management of inguinal node disease is variable. Due to the high morbidity rate, prophylactic groin dissection

is not recommended. Clinically significant inguinal adenopathy can be included in the field of radiation.

The overall response to chemoradiation should be assessed clinically at about 8 weeks after the completion of treatment. At this point, up to 85% of patients will have complete clinical response. Those with good partial response may be observed closely to ensure that complete response does occur. Any lesions suspicious for residual disease or progression of disease should be biopsied at that time. For those patients with complete clinical response, surveillance entails DRE and examination of inguinal nodes every 3-6 months for the first 2 years and annually thereafter up to 5 years. There is no consensus on the routine use of imaging in surveillance, but it is often practiced.

► Prognosis

Complete response rates approach 90% for smaller tumors with 5-year survival that ranges between 70% and 90%. Residual or recurrent disease confers a poorer prognosis with 5-year survival rates between 24% and 58% after salvage APR.

2. Melanoma of the Anal Canal

The anorectum is the third most common site overall for melanoma, but it is the most common site of primary melanoma of the gastrointestinal tract—making it an exceedingly rare condition. It accounts for up to 2% of all melanomas and 2%-4% of all anorectal tumors.

► Clinical Findings

Pain, bleeding, and a palpable mass are the most consistent clinical findings with melanoma of the anal canal. Patients may also present with tenesmus, change in the caliber of stools, and weight loss. Like its cutaneous counterpart, anal melanoma are raised and pigmented; however, it is important to note that these lesions may be amelanotic, which may mimic more benign disease.

► Treatment

For localized disease, surgery offers the only chance for cure, as there has been no proven benefit for chemotherapy or radiation. Both radical resection with APR and wide local excision have been advocated. Abdominoperineal resection does not confer a survival advantage and is associated with high morbidity rates, subsequently, wide local excision is recommended as the initial surgical approach for localized disease. Large, bulky tumors that involve the sphincter complex will require radical resection.

► Prognosis

The prognosis for anorectal melanoma is universally poor because many patients present with advanced disease.

Survival rates generally range from 6% to 28% in the literature. The overall 5-year survival for large, deeply invading, or metastatic disease is less than 10% with a median survival of 12-18 months.

NORMAL FUNCTION OF THE ANOECTUM

Anorectal physiology is very complex. It requires coordination between the pelvic nerves, pelvic floor muscles, the rectum, and the sphincter complex that results in normal, controlled evacuation of intestinal waste.

Like the colon, the rectum is comprised of two layers of smooth muscle—an inner circular layer and an outer longitudinal layer. It varies in length between 12 and 18 cm and is predominantly confined within the bony pelvis. The peritoneum covers the upper two-thirds of the rectum anteriorly, the upper third laterally, and the lower third of the rectum is extraperitoneal. The rectum is very distensible and, as such, has the capacity to hold large volumes, which is ideal since it primarily functions as a reservoir for stool prior to defecation. Alterations in rectal sensation or compliance by infection, inflammation, or fibrosis will result in urgency.

The anal canal begins at the anal verge, extending cephalad to the anorectal ring, and is surrounded by the levator ani muscles as well as the internal and external sphincter complex. The internal anal sphincter (IAS) muscle, which accounts for approximately 85% of the resting anal pressure, is an involuntary muscle that is the downward continuation of the circular, smooth muscle of the rectum. The IAS is approximately 3 cm in length and supplied by both sympathetic and parasympathetic nerves (S2-4). It is a constant state of contraction due to intrinsic slow-wave impulses. The IAS muscle is surrounded by the striated muscles of the external anal sphincter (EAS), which is a voluntary muscle but also contributes in small part to the overall resting tone. The EAS is supplied by the pudendal nerves.

The pelvic floor (levator ani muscles) is composed of symmetrical sheets of striated muscles with a central ligamentous attachment—the pubococcygeus, the iliococcygeus, and the puborectalis. These muscles surround and support

the rectum, vagina, and urethra as they pass through to the perineum. The puborectalis, which wraps around the anorectal junction posteriorly and inserts on the pubic ramus anteriorly, is particularly important to overall continence by increasing the acute angle between the rectum and anal canal, known as the anorectal angle.

Normal defecation is an intricate sequence of events that relies on proper relaxation of these muscles and a few key anorectal reflexes. The stimulus for initiating defecation is distention of the rectum, which stimulates pressure receptors in the pelvic floor muscles, also known as accommodation. This in turn triggers two key reflexes: (1) relaxation of the internal sphincter, the rectoanal inhibitory reflex (RAIR) and (2) contraction of the external sphincter, the rectoanal excitatory reflex. This process allows sampling of the rectal contents that come into contact with the upper anal canal. This allows us to discriminate between gas, liquid, or solid stools. Once the decision has been made to evacuate the rectum, the puborectalis muscle relaxes, allowing straightening of the anorectal angle. Intra-abdominal pressure increases and the EAS relaxes allowing passage of contents through the anus.

In conjunction with a careful history, there are several useful modalities that are employed to investigate evacuation dysfunction. Anal manometry, defecography, endorectal ultrasound, and pudendal nerve terminal motor latency testing can be integral in the diagnosis of fecal incontinence, pelvic dyssynergia, constipation, rectocele, and intussusception, to name a few. A thorough understanding of the anatomy and the available testing modalities is imperative for diagnosis and treatment.

FECAL INCONTINENCE

► General Considerations

Complete anal continence results from the complex interactions between stool consistency, rectal capacity and compliance, the sphincter complex, and underlying neurological function. Impairment in one or all of these components results in varying degrees of fecal incontinence, which is generally defined as the recurrent, involuntary loss feces or gas through the anus.

The true incidence of fecal incontinence is difficult to determine due to lack of standard definitions and underreporting; however, rates up to 20% have been reported in literature, depending on the study population. Female patients predominate in most series of major incontinence but men and women are affected equally with minor incontinence. Higher rates have been reported in the elderly and patients with certain neurologic disorders.

There are numerous causes of fecal incontinence; however, the most common is related to obstetric injury. The incidence of obstetric tears with vaginal deliveries has been reported in up to 10% of cases. Additionally, occult injuries have identified by ultrasound in up to 35% of cases; therefore presentation with symptoms of incontinence or leakage may be delayed. Other causes include—congenital anomalies, neurologic disorder (eg, spinal cord injury), pelvic floor denervation (stretch-induced injury of the pudendal nerves), conditions causing poor rectal compliance (eg, Crohn disease, ulcerative colitis, radiation proctitis), functional bowel disorders (diarrhea or fecal impaction with overflow incontinence), and iatrogenic injuries (eg, anorectal surgeries).

► Clinical Findings

A. Symptoms and Signs

A detailed history of the presenting symptoms is required to differentiate the patient's ability to control gas, liquid and solid stools. Frank incontinence must be differentiated from fecal urgency or soiling which may be associated with other treatable anorectal disorders. Information on diet, activity, medications, obstetric and anorectal surgical history should also be gathered to provide more complete picture. This is understandably and potentially devastating disorder, so attempts should also be made to ascertain the overall level of impact of these symptoms on the patient's daily activities. To aid in this characterization, there are several validated scoring systems, including the Fecal Incontinence Severity Index score, the Cleveland Clinic Florida Incontinence score, and the Fecal Incontinence Quality of Life score, which can provide an objective baseline of these symptoms and can be used to track progress throughout treatment.

Physical evaluation should begin with inspection of the anus and perineum, to document any scars from previous obstetric or anorectal procedures. Benign anorectal conditions, such as fistulas, prolapse, and hemorrhoids may also be readily excluded. Perineal descent during straining is another important finding which indicates an abnormal laxity of the pelvic floor muscles. Finally, digital rectal examination provides useful initial information on the resting sphincter tone and maximum squeeze pressure.

B. Imaging Studies

Further testing for fecal incontinence often require an integrated approach. Anal manometry, endoanal ultrasound,

MRI, defecography, and pudendal nerve latency studies have all been employed in the evaluation of the patient with fecal incontinence.

Anal manometry provides an objective assessment of resting sphincter pressure, maximum squeeze pressure, inherent anorectal reflexes, as well as anorectal sensation and compliance. Resting pressure is in large part a reflection of internal sphincter muscle function while maximum squeeze pressure reflects external sphincter function.

While it may be limited by the operator, endoanal ultrasound is an extremely useful tool in the evaluation of these patients. It is an inexpensive office-based procedure that allows visualization of the length and width of the sphincter complex as well as any defects that may be present.

Defecography has a more limited role in the evaluation of incontinence. The study allows visualization of the process of defecation, including the anorectal angle, pelvic floor descent, and internal intussusception.

Pudendal nerve motor latency testing provides information about potential nerve damage to the pelvic floor. It measures the time from nerve stimulation to the onset of response of the pelvic floor muscles. Prolonged times are indicative neuropathy. The degree of denervation does not influence the severity of incontinence but does seem to provide some prognostic information about the outcomes of surgical repairs.

► Treatment

The initial management of patients with fecal incontinence should include nonoperative measures. These include diet modification, fiber supplementation, and biofeedback training. If these measures fail, then consideration should be given to surgical repair. Options include sphincteroplasty, sacral nerve stimulation, injectable bulking agents, artificial bowel sphincter, and fecal diversion.

Anterior sphincteroplasty involves direct repair, either in an overlapping or end-to-end fashion, of the external sphincter muscle if a segmental defect is identified on preoperative evaluation. This technique has good short-term with up to 80% of patients experiencing improvement in function; however, at 5-10 years of follow up, function does tend to deteriorate. In literature, diminished success rates have been associated with age, duration of symptoms, and pudendal neuropathy.

Sacral nerve stimulation has recently been approved for the treatment of fecal incontinence and has been shown to be safe and effective. It provides the unique advantage of a temporary evaluation phase before permanent implantation. A temporary electrode is placed with the aid of fluoroscopy into the sacral foramen (usually the third) and the patient is subsequently stimulated for 2-3 weeks. If there is at least a 50% reduction in symptoms then a permanent stimulator is implanted. The precise mechanism of action of SNS is still

unknown, but the short-term results have been promising. In many series more than 75% of study participants report greater than 50% improvement in continence episodes and 41%-75% of patients reported complete continence to liquid and solid stool. A recent randomized trial demonstrated that SNS was significantly better than best supportive measures including pelvic floor exercises, bulking agent, and dietary manipulation. Data with long-term follow up is still evolving.

The artificial bowel sphincter is another modality that is approved for treatment of incontinence but is not widely used. The device, which is surgically placed around the sphincter complex, is connected to a tunneled reservoir and pump that inflates and deflates the cuff to allow controlled defecation. This procedure has been limited by infectious complications and device erosion; therefore, is typically reserved for end-stage incontinence in patients without other alternatives except colostomy.

Passive fecal incontinence caused by internal sphincter dysfunction has been shown to respond favorably to injection of bulking agents. Small series have reported the injection of silicone biomaterial into the intersphincteric plane or submucosa with short-term improvement in continence.

If conservative and other surgical options have failed then a diverting colostomy becomes a reasonable solution that can restore a patient's quality of life.

► Prognosis

Fecal incontinence is a treatable condition; however, appropriate management requires careful evaluation and proper patient selection. Surgical intervention should be preceded by an initial trial of conservative measures if indicated. Sphincteroplasty has good short-term results with initial success rates of approximately 75%; however, success diminishes over time. Sacral nerve stimulation has been an exciting new surgical development for fecal incontinence with greater than 80% of patients maintaining more than 50% reduction of symptoms after 1-2 years of permanent implantation. Complications requiring explantation of the device are uncommon.

PELVIC FLOOR DYSFUNCTION

► General Considerations

Pelvic floor dysfunction is a global term that can encapsulate several presentations including dysfunctional urinary and bowel evacuation symptoms, sexual dysfunction, as well as pain syndromes. Alternative terms, such as pelvic dyssynergia, obstructed defecation, and paradoxical puborectalis, have also been used further confounding the understanding of the topic. Functional disorders of the pelvic floor are marked by symptoms of obstructed defecation without an anatomic abnormality in the surrounding muscles. As outlined earlier, the process of defecation is intricate. It requires coordination of the pelvic nerves, the rectum, and the surrounding muscles, including the puborectalis and the remaining levator muscles. During normal defecation these muscles relax, allowing the rectum to empty; however, patients with pelvic floor dysfunction have uncoordinated activity that impairs evacuation of intestinal waste.

Understandably, this can be a debilitating problem affecting a large number of patients, which are predominantly women. In the United States, approximately 24% of women report at least one pelvic floor disorder, which seems to increase with age, parity, and obesity.

► Clinical Findings

A. Symptoms and Signs

Symptoms of pelvic floor dysfunction tend to develop slowly and insidiously; therefore, a careful history is paramount to establishing a working diagnosis and developing a strategy for diagnostic testing. Patients commonly describe constipation, straining with bowel movements, or the sense of incomplete evacuation. The residual soft stool in the rectal

vault may cause soiling of the anoderm triggering the feeling of incontinence. Attention should be paid to diet as well as obstetric, urologic, and surgical histories. While these symptoms do not impose risk to the patient's health, they do interfere with the overall quality of life. At the time of presentation patients have often tried a plethora of medications and laxatives.

A focused physical examination should start with inspection of the anus and perineum. Profound perineal descent with straining is an indication of laxity of the pelvic floor, which is common with increasing age and multiparity. Digital rectal examination is important and should be performed to rule out rectal masses, to assess pain with palpation of the puborectalis, assess sphincter tone, and contraction/relaxation of the levator muscles. Specifically, paradoxical contraction of the puborectalis with simulated straining should be assessed.

B. Laboratory and Imaging Studies

A colonoscopy and colon transit study should generally be performed to exclude an underlying malignancy and slow-transit constipation, respectively. Additional adjuncts include anal manometry with balloon expulsion and defecography. Anal manometry should assess resting and maximum squeeze pressure as well as the presence of the RAIR. Patients with pelvic floor dysfunction will typically be unable to expel a balloon, which is inserted into the rectum.

Defecography offers a more dynamic view of the rectum, pelvic floor muscles, and anal sphincters. During this examination, the rectum is filled with contrast and the patient is asked to simulate defecation. Vaginal and oral contrast materials are also usually given to provide additional information about the neighboring structures. Defecography is useful in identifying rectoceles, internal and external rectal prolapse, enteroceles, as well as a nonrelaxing pelvic floor.

► Differential Diagnosis

Symptoms of constipation and defecation problems are quite common and may be due to a myriad of causes. Anatomic disorders, such as anal or rectal cancers, rectoceles, rectal prolapse, internal intussusception, and enteroceles, should be distinguished from functional disorders like a non-relaxing puborectalis.

► Treatment

A. Medical Treatment

Patients with pelvic floor dysfunction due to a nonrelaxing puborectalis should be referred for pelvic floor retraining, also known as biofeedback, which has become an integral part of treatment. During these sessions with the physical therapist, patients are instructed on how to properly relax the pelvic muscles with the aid of visual feedback. This neuromuscular

training program is typically instrument-based employing manometry-, or electromyography-based biofeedback.

B. Surgical Treatment

Patients with obstructed defecation due to anatomic causes are candidates for surgery if they have failed initial conservative therapy with fiber supplementation and laxatives.

Rectocele repair is indicated for large rectoceles that have demonstrated failure to empty on defecography. Several approaches have been employed with varying success, including transvaginal, transrectal, and transperineal. A newer technique that has shown some initial short-term success is the stapled Trans-Anal Rectal Resection (STARR) procedure, which uses two circular staplers to produce a circumferential transanal full-thickness resection of the lower rectum. Its widespread use is limited by the lack of data on long-term outcomes and the potential for devastating complications such as pelvic sepsis and fistulas.

Internal rectal prolapse (intussusception) can be present in up to 50% of asymptomatic individuals; therefore, the surgical treatment of internal prolapse associated with obstructed defecation symptoms remains controversial. Rectopexy without concomitant resection has been advocated by some and the STARR procedure has been used by others. Results have been varied in the literature.

► Prognosis

Biofeedback has been the mainstay of treatment for nonrelaxing pelvic floor dysfunction. It is minimally invasive and repeatable with good results for those that complete the program. Improvement in symptoms has varied between 40% and 90% in several trials.

ABNORMAL RECTAL FIXATION

► General Considerations

Abnormal rectal fixation is a general term for a group of diseases in which the attachment of the rectum to its

surrounding structures has developed more laxity, allowing the rectum to, completely or incompletely, protrude through the anal canal. The exact pathophysiology is unknown but, in large part, this is related to chronic straining with defecation. Common anatomic variations may include a patulous anus, redundant sigmoid colon, diastasis of the levator ani muscles, and a deep cul-de-sac.

Rectal prolapse is characterized by an intussusception of the rectum. There are three general categories that ultimately influence symptoms and overall management: (1) internal prolapse (intussusception), which does not extend beyond the anal canal, (2) mucosal prolapse, and (3) complete prolapse, which involves full-thickness protrusion of the rectum through the anus.

In adults, older women are six times more likely to develop rectal prolapse, accounting for 80% to 90% of the patient populations. The peak incidence is after the fifth decade.

► Clinical Findings

A. Symptoms and Signs

Symptoms can vary with the degree of rectal prolapse, but typical complaints include a perianal mass that protrudes with straining, mucoid or bloody discharge, incomplete evacuation, incontinence, pain if the rectum becomes incarcerated.

On examination, a patulous anus or exaggerated perineal descent may be initial clues to the diagnosis if prolapsing rectal tissue is not evident. Digital rectal may reveal diminished or absent tone with complete prolapse but may suggest a mass with straining for internal intussusception. The diagnosis is most easily made with the patient straining in the seated position, which should reproduce the rectal prolapse, identified by the concentric folds of mucosa.

B. Laboratory and Imaging Studies

If the diagnosis remains elusive, defecography should be able to clearly demonstrate either internal or complete prolapse as well as other associated abnormalities such as cystoceles, enteroceles, and rectoceles. In patients who also present with complaints of longstanding constipation, anorectal manometry, and colon transit studies are also crucial. Prior to any surgical intervention, these patients should also undergo colonoscopy.

► Differential Diagnosis

Complete rectal prolapse is often confused with prolapsing internal hemorrhoids; however, the two can easily be separated by close examination of the mucosa. Prolapsing internal hemorrhoids produce radial folds in the visible rectal mucosa, which contrasts with the concentric folds seen with rectal prolapse.

► Complications

The most dreaded complication for rectal prolapse is incarceration, which may lead to tissue ischemia and necrosis. Chronic reducible rectal prolapse may also impair fecal continence due to the repeated stretching of the sphincter muscles.

► Treatment

A. Medical Treatment

A trial of fiber supplementation and diet modification may prove to be beneficial for mild cases of internal intussusception. Biofeedback, rectopexy, and the STARR procedure have been reported in refractory cases but their use remains controversial.

B. Surgical Treatment

Surgical treatment is indicated in patients with full-thickness rectal prolapse. Surgical treatment is broadly divided into abdominal and perineal approaches, which are dictated by the patient's age and comorbidities as well as surgeon preference and experience. Perineal approaches generally result in reduced length of hospital stay and less perioperative morbidity and pain; however, they are plagued by higher recurrence rates.

Rectopexy, resection rectopexy, and mesh rectopexy are the three abdominal procedures that are most widely practiced. The principle component of each of these procedures is the posterior mobilization of the rectum down to the level of the levator muscles. The rectum is elevated from the deep pelvis and sutured to the presacral fascia at the level of the sacral promontory. The lateral ligaments are preserved, as this has been shown to decrease postoperative constipation. Sigmoid resection with tension-free anastomosis to the rectum is performed if excessive redundancy is encountered or if there has been a longstanding history of constipation. Mesh has also been used to fix the rectum to the presacral fascia and should be performed without a concomitant resection. Complications include bowel obstruction, erosion of the mesh, and fistulas. All of these abdominal procedures have been approached laparoscopically with similar results, while maintaining the benefits of a minimally invasive technique.

Perineal proctosigmoidectomy, also known as the Altemeier procedure, combines a perineal proctosigmoidectomy with an anterior levatoroplasty. A full-thickness, circumferential incision is made 1 cm proximal to the dentate line. The mesentery of the rectum and sigmoid colon is sequentially divided until no redundant bowel remains. The colon is transected at this level and an anastomosis is created between the colon and the anal canal with either sutures or a circular stapler. An anterior levatoroplasty is usually added to correct the laxity in the levator muscles commonly associated with this condition.

The Delorme procedure is ideal for short segment mucosal prolapse since it entails a mucosal sleeve resection starting at the dentate line. The excess mucosa is transected and the proximal and distal edges of the mucosa are approximated while the muscle is pliated with interrupted sutures placed circumferentially.

► Prognosis

The described abdominal approaches have been shown to be safe and efficacious with approximately a 10% recurrence rate. Perineal approaches are also well tolerated but are associated with higher recurrence rates of 20%-30%.

MULTIPLE CHOICE QUESTIONS

- All of the following are sites of perirectal abscesses, except
 - Ischiorectal
 - Perianal
 - Intermuscular
 - Infralevator
 - Submucous
- Anal bleeding can be commonly caused by
 - Diverticulitis
 - Anal condyloma
 - Anorectal abscess (undrained)
 - Anal fissure
 - Thrombosed external hemorrhoids
- Rectal prolapse
 - Can be distinguished from prolapsed hemorrhoids based upon imaging
 - Is an intussusception of the rectum
 - Cannot involve the muscular layers of the rectum due to fixation to the pelvic sidewalls
 - Is best evaluated by MRI
 - Is more common in men than women
- Epidermoid tumors of the anal canal
 - Are typically treated with a regimen of chemotherapy and radiation therapy after diagnosis
 - Are about as common as rectal cancers
 - Have a 25% response rate to initial therapy regimens
 - Typically require abdominoperineal resection for complete treatment
 - Rarely metastasize to regional lymph nodes
- Management of condyloma acuminata
 - Are rarely transmitted by sexual contact
 - Are often treated with antiviral therapy as first line treatment
 - Can include palliation of macroscopic lesions my operation
 - Do not carry any risk of dysplasia
 - Are asymptomatic

Hernias & Other Lesions of the Abdominal Wall*

Karen E. Deveney, MD

I. HERNIAS

An external hernia is an abnormal protrusion of intra-abdominal tissue through a fascial defect in the abdominal wall. Although most hernias (75%) occur in the groin, incisional hernias represent an increasing proportion (15%-20%), with umbilical and other ventral hernias comprising the remainder. Generally, a hernial mass is composed of covering tissues (skin, subcutaneous tissues, etc), a peritoneal sac, and any contained viscera. Particularly if the neck of the sac is narrow where it emerges from the abdomen, bowel protruding into the hernia may become obstructed or strangulated. If the hernia is not repaired early, the defect may enlarge and operative repair may become more complicated. The definitive treatment of hernia is operative repair.

A *reducible hernia* is one in which the contents of the sac return to the abdomen spontaneously or with manual pressure when the patient is recumbent.

An *irreducible (incarcerated) hernia* is one whose contents cannot be returned to the abdomen, usually because they are trapped by a narrow neck. The term “incarceration” does not imply obstruction, inflammation, or ischemia of the herniated organs, though incarceration is necessary for obstruction or strangulation to occur.

Though the lumen of a segment of bowel within the hernia sac may become obstructed, there may initially be no interference with blood supply. Compromise to the blood supply of the contents of the sac (eg, omentum or intestine) results in a *strangulated hernia*, in which gangrene of the contents of the sac has occurred. The incidence of strangulation is higher in femoral than in inguinal hernias, but strangulation may occur in any hernia.

An uncommon and dangerous type of hernia, a *Richter hernia*, occurs when only part of the circumference of the

bowel becomes incarcerated or strangulated in the fascial defect. A strangulated Richter hernia may spontaneously reduce and the gangrenous piece of intestine be overlooked at operation. The bowel may subsequently perforate, with resultant peritonitis.

HERNIAS OF THE GROIN

► Anatomy

All groin hernias protrude through the myopectineal orifice of Fruchaud, a weakness or defect in the transversalis fascia, an aponeurosis located just outside the peritoneum. External to the transversalis fascia are found the transversus abdominis, internal oblique, and external oblique muscles, which are fleshy laterally and aponeurotic medially. Their aponeuroses form investing layers of the strong rectus abdominis muscles above the semilunar line. Below this line, the aponeurosis lies entirely in front of the muscle. Between the two vertical rectus muscles, the aponeuroses meet again to form the linea alba, which is well defined only above the umbilicus. The subcutaneous fat contains the Scarpa fascia—a misnomer, since it is only a condensation of connective tissue with no substantial strength.

In the groin, an indirect inguinal hernia results when obliteration of the processus vaginalis, the peritoneal extension accompanying the testis in its descent into the scrotum, fails to occur. The resultant hernia sac passes through the internal inguinal ring, a defect in the transversalis fascia halfway between the anterior iliac spine and the pubic tubercle. The sac is located anteromedially within the spermatic cord and may extend partway along the inguinal canal or accompany the cord out through the subcutaneous (external) inguinal ring, a defect medially in the external oblique muscle just above the pubic tubercle. A hernia that passes fully into the scrotum is known as a *complete hernia*. The sac and the spermatic cord are invested by the cremaster muscle, an extension of fibers of the internal oblique muscle.

*See Chapter 43 for further discussion of hernias in the pediatric age group and Chapter 21 for a discussion of internal hernias.

Other anatomic structures of the groin that are important in understanding the formation of hernias and types of hernia repairs include the *conjoined tendon*, a fusion of the medial aponeurotic transversus abdominis and internal oblique muscles that passes along the inferolateral edge of the rectus abdominis muscle and attaches to the pubic tubercle. Between the pubic tubercle and the anterior iliac spine passes the inguinal (Poupart) ligament, formed by the lowermost border of the external oblique aponeurosis as it rolls on itself and thickens into a cord.

Just deep and parallel to the inguinal ligament runs the iliopubic tract, a band of connective tissue that extends from the iliopsoas fascia, crosses below the deep inguinal ring, forms the superior border of the femoral sheath, and inserts into the superior pubic ramus to form the lacunar (Gimbernat) ligament. The lacunar ligament is about 1.25 cm long and triangular in shape. The sharp, crescentic lateral border of this ligament is the unyielding noose for the strangulation of a femoral hernia.

The Cooper ligament is a strong, fibrous band that extends laterally for about 2.5 cm along the iliopectineal line on the superior aspect of the superior pubic ramus, starting at the lateral base of the lacunar ligament.

The Hesselbach triangle is bounded by the inguinal ligament, the inferior epigastric vessels, and the lateral border of the rectus muscle. A weakness or defect in the transversalis fascia, which forms the floor of this triangle, results in a direct inguinal hernia. In most direct hernias, the transversalis fascia is diffusely attenuated, though a discrete defect in the fascia may occasionally occur. This funicular type of direct inguinal hernia is more likely to become incarcerated, since it has distinct borders.

A femoral hernia passes beneath the iliopubic tract and inguinal ligament into the upper thigh. The predisposing anatomic feature for femoral hernias is a small empty space between the lacunar ligament medially and the femoral vein laterally—the femoral canal. Because its borders are distinct and unyielding, a femoral hernia has the highest risk of incarceration and strangulation of groin hernias.

Surgeons must be familiar with the pathways of the nerves and blood vessels of the inguinal region to avoid injuring them when repairing groin hernias. The iliohypogastric nerve (T12, L1) emerges from the lateral edge of the psoas muscle and travels inside the external oblique muscle, emerging medial to the external inguinal ring to innervate the suprapubic skin. The ilioinguinal nerve (L1) parallels the iliohypogastric nerve and travels on the surface of the spermatic cord to innervate the base of the penis (or mons pubis), the scrotum (or labia majora), and the medial thigh. This nerve is the most frequently injured in anterior open inguinal hernia repairs. The genitofemoral (L1, L2) and lateral femoral cutaneous nerves (L2, L3) travel on and lateral to the psoas muscle and provide sensation to the scrotum and anteromedial thigh and to the lateral thigh, respectively.

These nerves are subject to injury during laparoscopic hernia repairs. The femoral nerve (L2-L4) travels from the lateral edge of the psoas and extends lateral to the femoral vessels. It can be injured during laparoscopic or femoral hernia repairs.

The external iliac artery travels along the medial aspect of the psoas muscle and beneath the inguinal ligament, giving off the inferior epigastric artery, which borders the medial aspect of the internal inguinal ring. The corresponding veins accompany the arteries. These vessels can be injured during hernia repairs of all types.

► Causes

Nearly all inguinal hernias in infants, children, and young adults are indirect inguinal hernias. Although these “congenital” hernias most often present during the first year of life, the first clinical evidence of hernia may not appear until middle or old age, when increased intra-abdominal pressure and dilation of the internal inguinal ring allow abdominal contents to enter the previously empty peritoneal diverticulum. An untreated indirect hernia will inevitably dilate the internal ring and displace or attenuate the inguinal floor. The peritoneum may protrude on either side of the inferior epigastric vessels to give a combined direct and indirect hernia, called a pantaloon hernia.

In contrast, direct inguinal hernias are acquired as the result of a developed weakness of the transversalis fascia in the Hesselbach area. There is some evidence that direct inguinal hernias may be related to hereditary or acquired defects in collagen synthesis or turnover. Femoral hernias involve an acquired protrusion of a peritoneal sac through the femoral ring. In women, the ring may become dilated by physical and biochemical changes during pregnancy.

Any condition that chronically increases intra-abdominal pressure may contribute to the appearance and progression of a hernia. Marked obesity, abdominal strain from heavy exercise or lifting, cough, constipation with straining at stool, and prostatism with straining on micturition are often implicated. Cirrhosis with ascites, pregnancy, chronic ambulatory peritoneal dialysis, and chronically enlarged pelvic organs or pelvic tumors may also contribute. Loss of tissue turgor in the Hesselbach area, associated with a weakening of the transversalis fascia, occurs with advancing age and in chronic debilitating disease.

INDIRECT & DIRECT INGUINAL HERNIAS

► Clinical Findings

A. Symptoms

Most hernias produce no symptoms until the patient notices a lump or swelling in the groin, though some patients may describe a sudden pain and bulge that occurred while lifting or straining. Frequently, hernias are detected in the course of routine physical examinations such as preemployment

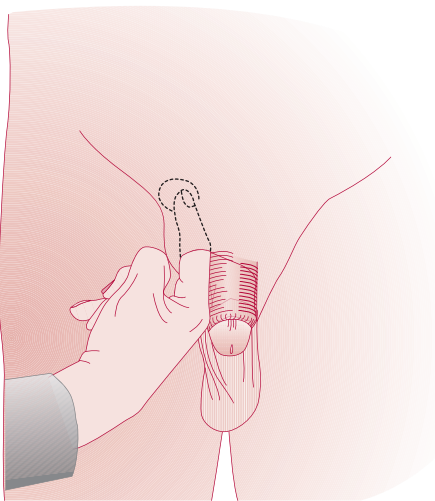

examinations. Some patients complain of a dragging sensation and, particularly with indirect inguinal hernias, radiation of pain into the scrotum. As a hernia enlarges, it is likely to produce a sense of discomfort or aching pain, and the patient must lie down to reduce the hernia.

In general, direct hernias produce fewer symptoms than indirect inguinal hernias and are less likely to become incarcerated or strangulated.

B. Signs

Examination of the groin reveals a mass that may or may not be reducible. The patient should be examined both supine and standing and also with coughing and straining, since small hernias may be difficult to demonstrate. The external ring can be identified by invaginating the scrotum and palpating with the index finger just above and lateral to the pubic tubercle (Figure 32-1). If the external ring is very small, the examiner's finger may not enter the inguinal canal, and it may be difficult to be sure that a pulsation felt on coughing is truly a hernia. At the other extreme, a widely patent external ring does not by itself constitute hernia. Tissue must be felt protruding into the inguinal canal during coughing in order for a hernia to be diagnosed.

Differentiating between direct and indirect inguinal hernia on examination is difficult and is of little importance, since most groin hernias should be repaired regardless of type. Nevertheless, each type of inguinal hernia has specific features more common to it. A hernia that descends into the scrotum is almost certainly indirect. On inspection with the patient erect and straining, a direct hernia more commonly appears as a symmetric, circular swelling at the external

▲ **Figure 32-1.** Insertion of finger through upper scrotum into the external inguinal ring.

ring; the swelling disappears when the patient lies down. An indirect hernia appears as an elliptic swelling that may not reduce easily.

On palpation, the posterior wall of the inguinal canal is firm and resistant in an indirect hernia but relaxed or absent in a direct hernia. If the patient is asked to cough or strain while the examining finger is directed laterally and upward into the inguinal canal, a direct hernia protrudes against the side of the finger, whereas an indirect hernia is felt at the tip of the finger.

Compression over the internal ring when the patient strains may also help to differentiate between indirect and direct hernias. A direct hernia bulges forward through Hesselbach triangle, but the opposite hand can maintain reduction of an indirect hernia at the internal ring.

These distinctions are obscured as a hernia enlarges and distorts the anatomic relationships of the inguinal rings and canal. In most patients, the type of inguinal hernia cannot be established accurately before surgery.

► Differential Diagnosis

Groin pain of musculoskeletal or obscure origin occurs primarily with vigorous physical exertion (so-called “sports hernia”) and may be difficult to distinguish from a true hernia, even with thorough physical examination. MRI may be helpful in identifying the problem as inflammation, edema, or a muscle or tendon tear or strain.

Herniation of preperitoneal fat through the inguinal ring into the spermatic cord (lipoma of the cord) is commonly misinterpreted as a hernia sac. Its true nature may only be confirmed at operation. Occasionally, a femoral hernia that has extended above the inguinal ligament after passing through the fossa ovalis femoris may be confused with an inguinal hernia. If the examining finger is placed on the pubic tubercle, the neck of the sac of a femoral hernia lies lateral and below, while that of an inguinal hernia lies above.

Inguinal hernia must be differentiated from hydrocele of the spermatic cord, lymphadenopathy or abscesses of the groin, varicocele, and residual hematoma following trauma or spontaneous hemorrhage in patients taking anticoagulants. An undescended testis in the inguinal canal must also be considered when the testis cannot be felt in the scrotum.

The presence of an impulse in the mass with coughing, bowel sounds in the mass, and failure to transilluminate are features that indicate that an irreducible mass in the groin is a hernia.

► Treatment

Although inguinal hernias have traditionally been repaired electively to avoid the risks of incarceration, obstruction, and strangulation, asymptomatic or mildly symptomatic hernias may be safely observed in elderly, sedentary patients or those with high morbidity for operation. The annual risk

of hernia incarceration is not precisely known but has been estimated at fewer than 2/1000 patients per year. However, a high percentage of patients become symptomatic while being observed expectantly. All symptomatic groin hernias should be repaired if the patient can tolerate surgery.

Even elderly patients tolerate elective repair of a groin hernia very well when other medical problems are optimally controlled and local anesthetic is used. Emergency operation carries a much greater risk for the elderly than carefully planned elective operation.

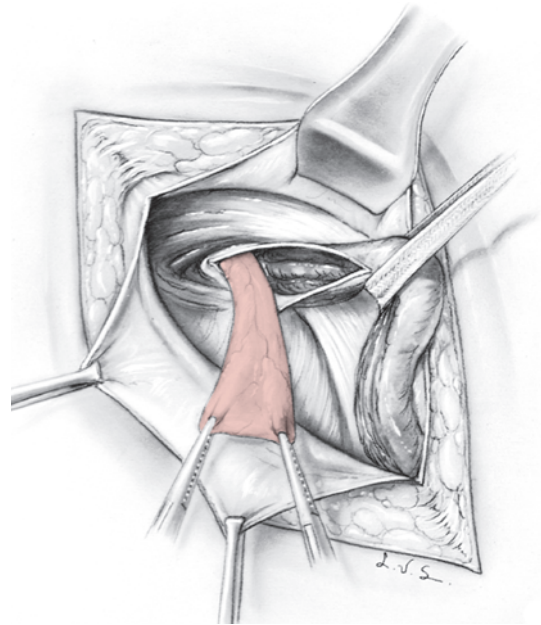

If the patient has significant prostatic hyperplasia, it is prudent to solve this problem first, since the risks of urinary retention and urinary tract infection are high following hernia repair in patients with significant prostatic obstruction.

Although most direct hernias do not carry as high a risk of incarceration as indirect hernias, the difficulty in reliably differentiating them from indirect hernias makes the repair of all symptomatic inguinal hernias advisable. Direct hernias of the funicular type, which are particularly likely to incarcerate, should always be repaired.

Because of the possibility of strangulation, an incarcerated, painful, or tender hernia usually requires an emergency operation. Nonoperative reduction of an incarcerated hernia may first be attempted. The patient is placed with hips elevated and given analgesics and sedation sufficient to promote muscle relaxation. Repair of the hernia may be deferred if the hernia mass reduces with gentle manipulation and if there is no clinical evidence of strangulated bowel. Though strangulation is usually clinically evident, gangrenous tissue can occasionally be reduced into the abdomen by manual or spontaneous reduction. It is therefore safest to repair the reduced hernia at the earliest opportunity. At surgery, one must decide whether to explore the abdomen to make certain that the intestine is viable. If the patient has leukocytosis or clinical signs of peritonitis or if the hernia sac contains dark or bloody fluid, the abdomen should be explored.

A. Principles of Operative Treatment of Inguinal Hernia

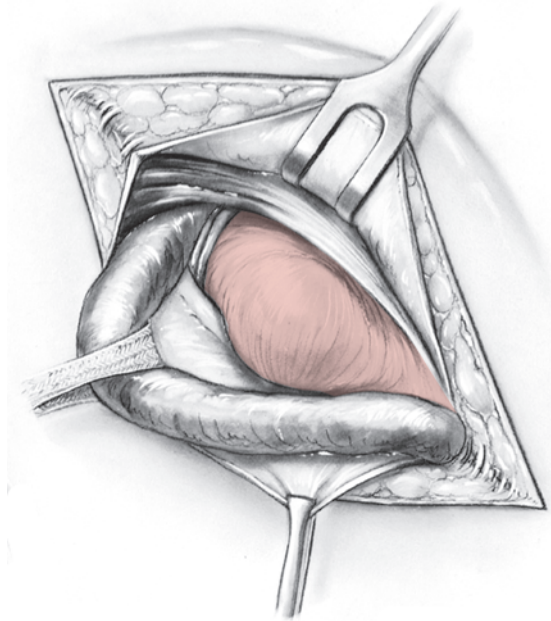

1. Durable repair requires that any correctable aggravating factors be identified and treated (chronic cough, prostatic obstruction, colonic tumor, ascites, etc) and that the defect be reconstructed without tension.
2. An indirect hernia sac should be anatomically isolated, dissected to its origin from the peritoneum, and ligated (Figure 32-2). In infants and young adults in whom the inguinal anatomy is normal, repair can usually be limited to high ligation, removal of the sac, and reduction of the internal ring to an appropriate size. For most adult hernias, the inguinal floor should also be reconstructed. The internal ring should be reduced to a size just adequate to allow egress of the cord structures.

▲ **Figure 32-2.** Indirect inguinal hernia. Inguinal canal opened, showing spermatic cord retracted medially and indirect hernia peritoneal sac dissected free to above the level of the internal inguinal ring.

In women, the internal ring can be totally closed to prevent recurrence through that site.

3. In direct inguinal hernia (Figure 32-3), the inguinal floor is usually so weak that a primary repair using the patient's own tissues would be under tension. Although a vertical relaxing incision in the anterior rectus abdominis sheath was traditionally used, most hernia repairs are now performed using mesh so that a tension-free repair can be accomplished.
4. Even though a direct hernia is found, the cord should always be carefully searched for a possible indirect hernia as well.
5. In patients with large hernias, bilateral repair has traditionally been discouraged under the assumption that greater tension on the repair would result and therefore would increase the recurrence rate and surgical complications. If open mesh repair or laparoscopic methods are used, however, bilateral repairs can be done with low risk of recurrence. In children and young adults with small hernias, bilateral hernia repair is usually recommended because it spares the patient a second anesthetic.
6. Recurrent hernia within a few months or a year of operation usually indicates an inadequate repair, such as

▲ **Figure 32-3.** Direct inguinal hernia. Inguinal canal opened and spermatic cord retracted inferiorly and laterally to reveal the hernia bulging through the floor of the Hesselbach triangle.

overlooking an indirect sac, missing a femoral hernia, or failing to repair the fascial defect securely. Any repair completed under tension is subject to early recurrence. Recurrences 2 or more years after repair are more likely to be caused by progressive weakening of the patient's fascia. Repeated recurrence after careful repair by an experienced surgeon suggests a defect in collagen synthesis. Because the fascial defect is often small, firm, and unyielding, recurrent hernias are much more likely than unoperated inguinal hernias to develop incarceration or strangulation, and they should nearly always be repaired again.

If recurrence is due to an overlooked indirect sac, the posterior wall is often solid and removal of the sac may be all that is required. Occasionally, a recurrence is discovered to consist of a small, sharply circumscribed defect in the previous hernioplasty, in which case closure of the defect suffices.

B. Types of Operations for Inguinal Hernia

The goal of all hernia repairs is to reduce the contents of the hernia into the abdomen and to close the fascial defect in the inguinal floor. Traditional repairs approximated native tissues using permanent sutures. More recently, synthetic mesh has supplanted tissue repairs because multiple prospective,

randomized studies have shown lower recurrence with tension-free mesh repairs than traditional primary tissue repair.

Over the past 20 years, increased experience has been gained with minimally invasive techniques for hernia repair. Laparoscopic approaches offer less pain and more rapid return to work or normal activities. Multiple randomized trials have compared open and laparoscopic hernia repairs. Although details of specific studies vary, long-term recurrence rates of open and laparoscopic repairs are similar. The success of laparoscopic approaches is dependent on experience of the surgeon, as is also true for open repair.

Although repairs today overwhelmingly employ prosthetic material, the presence of infection or need to resect gangrenous bowel may make use of nonbiologic mesh unwise. In these situations, primary tissue repairs may still be a preferable option. For this reason, surgeons need to know the traditional techniques even though they are rarely used today.

Among the traditional autologous tissue repairs, the Bassini repair is the most widely used method. In this repair, the conjoined tendon is approximated to the Poupart ligament, and the spermatic cord remains in its normal anatomic position under the external oblique aponeurosis. The Halsted repair places the external oblique beneath the cord but otherwise resembles the Bassini repair. Cooper ligament (Lotheissen–McVay) repair brings the conjoined tendon farther posteriorly and inferiorly to the Cooper ligament. Unlike the Bassini and Halsted methods, McVay repair is effective for femoral hernia but always requires a relaxing incision to relieve tension. Recurrence rates after these open nonmesh repairs vary widely according to skill and experience of the surgeon but population studies show them to range from as low as 5%–10% to as high as 33%. Though the Shouldice repair has a lower reported recurrence rate, it is not widely used, perhaps because of the more extensive dissection required and a belief that the skill of the surgeons may be as important as the method itself. In the Shouldice repair, the transversalis fascia is first divided and then imbricated to the Poupart ligament. Finally, the conjoined tendon and internal oblique muscle are also approximated in layers to the inguinal ligament.

The open preperitoneal approach exposes the groin from between the transversalis fascia and peritoneum via a lower abdominal incision to effect closure of the fascial defect. Because it requires more initial dissection and is associated with higher morbidity and recurrence rates in less experienced hands, it has not been widely used. For recurrent or large bilateral hernias, a preperitoneal approach using a large piece of mesh to span all areas of potential herniation has been described by Stoppa.

A desire to decrease the recurrence rate of hernias prompted the increased use of prosthetic materials in repair of both recurrent and first-time hernias. Methods include “plugs” of mesh inserted into the internal ring and sheets of mesh to create a tension-free repair. The most widely used

technique is that of Lichtenstein, an open mesh repair that allows an early return to normal activities and a low complication and recurrence rate.

Virtually all laparoscopic approaches utilize mesh in the repair. Several methods have been explored, with two methods having emerged as most frequently employed—the transabdominal preperitoneal mesh technique (TAPP) and total extraperitoneal (preperitoneal) mesh placement (TEP). The high incidence of complications that occurred in early studies prompted revisions in the operative technique to avoid injury to lateral nerves. Several prospective randomized trials have subsequently been conducted comparing open with minimally invasive techniques and one type of minimally invasive technique with another. These studies have reported decreased pain and faster return to work with the minimally invasive techniques but increased operative time and cost. Laparoscopic procedures also require general anesthesia and therefore are not appropriate for all patients. Long-term hernia recurrence is equivalent with open and laparoscopic mesh repairs at approximately 4%. Specific situations in which laparoscopic procedures often lower recurrence include the repair of recurrent hernias after anterior open repairs, repair of bilateral hernias simultaneously, and repair in patients who must return to work particularly quickly. Although the percentage of hernias repaired laparoscopically has increased, its use varies considerably across different locales and still represents a minority of groin hernia repairs. The success of both open and laparoscopic repair of groin hernias is highly dependent upon the surgeon's skill and experience with the technique.

C. Nonsurgical Management (Use of a Truss)

The surgeon is occasionally called upon to prescribe a truss when a patient refuses operative repair or when there are absolute contraindications to operation. A truss should be fitted to provide adequate external compression over the defect in the abdominal wall. It should be taken off at night and put on in the morning before the patient arises. The use of a truss does not preclude later repair of a hernia, although it may cause fibrosis of the anatomic structures, so that subsequent repair may be more difficult.

► Preoperative & Postoperative Course

Although groin hernia repair is usually an outpatient procedure, a thorough preoperative evaluation should be completed before the day of surgery. The anesthetic may be general, spinal, or local. Local anesthetic is effective for most patients, and the incidence of urinary retention and pulmonary complications is lowest with local anesthesia. Recurrent hernias are more easily repaired with the patient under spinal or general anesthesia, since local anesthetic does not readily diffuse through scar tissue. A sedentary worker may return to work within a few days; heavy manual labor has

traditionally not been performed for up to 4-6 weeks after hernia repair, though recent studies document no increase in recurrence when full activity is resumed as early as 2 weeks after surgery, particularly when mesh has been used in the repair.

► Prognosis

In addition to chronic cough, prostatism, and constipation, poor tissue quality and poor operative technique may contribute to recurrence of inguinal hernia. Because tissue is often more attenuated in direct hernias, recurrence rates are slightly higher than for indirect hernias. Placing the repair under tension leads to recurrence. Failure to find an indirect hernia, to dissect the sac high enough, or to adequately close the internal ring may lead to recurrence of indirect hernia. Postoperative wound infection is associated with increased recurrence. The recurrence rate is considerably increased in patients receiving chronic peritoneal dialysis, cirrhotics with ascites, smokers, and patients on steroids or who are malnourished.

The current recurrence rate after hernia repair in adults is reported at best to be 4%. Reasons for recurrence include failure to identify a femoral or indirect hernia.

An underappreciated sequela of groin hernia repair is chronic groin pain, which may occur in as high as 10% of patients and is usually attributed to nerve entrapment or neuroma. Laparoscopic repair or prophylactic division of the ileoinguinal nerve in open repairs has been shown to decrease the incidence of chronic groin pain.

SLIDING INGUINAL HERNIA

A sliding inguinal hernia (Figure 32–4) is an indirect inguinal hernia in which the wall of a viscus forms a portion of the wall of the hernia sac. On the right side, the cecum is most commonly involved, and on the left side, the sigmoid colon. The development of a sliding hernia is related to the variable degree of posterior fixation of the large bowel or other sliding components (eg, bladder, ovary) and their proximity to the internal inguinal ring.

► Clinical Findings

Though sliding hernias have no special signs that distinguish them from other inguinal hernias, they should be suspected in any large hernia that cannot be completely reduced. Finding a segment of colon in the scrotum on contrast radiograph strongly suggests a sliding hernia. Recognition of this variation is of great importance at operation, since failure to recognize it may result in inadvertent entry into the lumen of the bowel or bladder.

▲ **Figure 32–4.** Right-sided sliding hernia seen in sagittal section. At arrow, the wall of the cecum forms a portion of the hernia sac.

► Treatment

It is essential to recognize the entity at an early stage of operation. As is true of all indirect inguinal hernias, the sac will lie anteriorly, but the posterior wall of the sac will be formed by colon, bladder, or retroperitoneal ileum.

After the cord has been dissected free from the hernia sac, most sliding hernias can be reduced by a series of inverting sutures (Bevan technique) and one of the standard types of inguinal repair performed. Very large sliding hernias may have to be reduced by entering the peritoneal cavity through a separate incision (La Roque technique), pulling the bowel back into the abdomen, and fixing it to the posterior abdominal wall. The hernia is then repaired in the usual fashion. Sliding hernias can also be repaired successfully by laparoscopic (TAPP or TEP) techniques in experienced hands.

► Prognosis

Sliding hernias have a higher recurrence rate than uncomplicated indirect hernias.

The surgical complication most often encountered during repair of a sliding hernia is entry into the bowel or bladder, usually due to failure to recognize that the hernia is a sliding hernia.

FEMORAL HERNIA

A femoral hernia descends through the femoral canal beneath the inguinal ligament. Because of its narrow neck, it is prone to incarceration and strangulation. Femoral hernia is much more common in women than in men, but in both sexes femoral hernia is less common than inguinal hernia. Femoral hernias comprise about one-third of groin hernias in women and about 2% of groin hernias in men.

► Clinical Findings

A. Symptoms

Femoral hernias are notoriously asymptomatic until incarceration or strangulation occurs. Even with obstruction or strangulation, the patient may feel discomfort more in the abdomen than in the femoral area. Thus, colicky abdominal pain and signs of intestinal obstruction frequently are the presenting manifestations of a strangulated femoral hernia, without discomfort, pain, or tenderness in the femoral region. The patient often has a history of previous repair of an inguinal hernia, lending credence to the concept that a

femoral hernia may be overlooked if a thorough search for a femoral hernia is not conducted during an operation for an inguinal hernia.

B. Signs

A femoral hernia may present in a variety of ways. If it is small and uncomplicated, it usually appears as a small bulge in the upper medial thigh just below the level of the inguinal ligament. Because it may be deflected anteriorly through the fossa ovalis femoris to present as a visible or palpable mass at or above the inguinal ligament, it can be confused with an inguinal hernia.

► Differential Diagnosis

Femoral hernia must be distinguished from inguinal hernia, a saphenous varix, and femoral adenopathy. A saphenous varix transmits a distinct thrill when a patient coughs, and it appears and disappears instantly when the patient stands or lies down—in contrast to femoral hernias, which are either irreducible or reduce gradually on pressure.

► Treatment

A femoral hernia can be repaired through an open or laparoscopic approach, with mesh or primary tissue repair. The traditional primary repair was the McVay (Cooper ligament) repair that employed a relaxing incision in the anterior rectus sheath. More recently, open repair with mesh or laparoscopic preperitoneal repair (TEP) have been used. No matter what the approach, the hernia is often difficult to reduce. Reduction may be facilitated by carefully incising the iliopubic tract, Gimbernat ligament, or even the inguinal ligament. Occasionally, a counterincision in the thigh is required to free attachments below the inguinal ligament. Irrespective of the approach used, successful femoral hernia repair must close the femoral canal.

If the hernia sac and mass reduce when the patient is given opiates or anesthesia and if bloody fluid appears in the hernia sac when it is exposed and opened, one must strongly suspect the possibility of nonviable bowel in the peritoneal cavity. In such cases, it is mandatory to explore the abdomen, an advantage of the laparoscopic approach.

► Prognosis

Recurrence rates are equivalent to that of inguinal hernia at 4%-5%.

OTHER TYPES OF HERNIAS

UMBILICAL HERNIAS IN ADULTS

Umbilical hernia in adults occurs long after closure of the umbilical ring and is due to a gradual yielding of the cicatricial tissue closing the ring. It is more common in women than in men.

Predisposing factors include: (1) multiple pregnancies with prolonged labor, (2) ascites, (3) obesity, and (4) large intra-abdominal tumors.

► Clinical Findings

In adults, umbilical hernia does not usually obliterate spontaneously, as in children, but instead increases steadily in size. The hernia sac may have multiple loculations. Umbilical hernias usually contain omentum, but small and large bowel may be present. Emergency repair is often necessary, because the neck of the hernia is usually quite narrow compared to the size of the herniated mass and incarceration and strangulation are common.

Umbilical hernias with tight rings are often associated with sharp pain on coughing or straining. Very large umbilical hernias more commonly produce a dragging or aching sensation.

► Treatment

Umbilical hernia in an adult should be repaired expeditiously to avoid incarceration and strangulation. Repairs utilizing mesh result in the lowest recurrence rate. The laparoscopic approach is associated with less postoperative pain and faster recovery than open techniques. Mesh should be used for all but the smallest umbilical hernias.

The presence of cirrhosis and ascites does not contraindicate repair of an umbilical hernia, since incarceration, strangulation, and rupture are particularly dangerous in patients with these disorders. If significant ascites exists, however, it should first be controlled medically or by transjugular intrahepatic portosystemic shunt (TIPS) if necessary, since mortality, morbidity, and recurrence are higher after hernia repair in patients with ascites, when the procedure must be performed as an emergency. Preoperative correction of fluid and electrolyte imbalance and improvement of nutrition also improve the outcome in these patients.

► Prognosis

Factors that lead to a high rate of complication and recurrence after surgical repair include large size of the hernia, old age or debility of the patient, obesity, and the presence of related intra-abdominal disease. In healthy individuals, surgical repair of the umbilical defects gives good results with a low rate of recurrence.

EPIGASTRIC HERNIA

An epigastric hernia (Figure 32–5) protrudes through the linea alba above the level of the umbilicus. The hernia may develop through one of the foramina of egress of the small paramidline nerves and vessels or through an area of congenital weakness in the linea alba.

About 3%-5% of the population have epigastric hernias. They are more common in men than in women and most common between the ages of 20 and 50. About 20% of epigastric hernias are multiple, and about 80% occur just off the midline.

▲ **Figure 32–5.** Epigastric hernia. Note closeness to midline and the presence in upper abdomen. The herniation is through the linea alba.

► Clinical Findings

A. Symptoms

Most epigastric hernias are painless and are found on routine abdominal examination. If symptomatic, their presentation ranges from mild epigastric pain and tenderness to deep, burning epigastric pain with radiation to the back or the lower abdominal quadrants. The pain may be accompanied by abdominal bloating, nausea, or vomiting. The symptoms often occur after a large meal and on occasion may be relieved by reclining, probably because the supine position causes the herniated mass to drop away from the anterior abdominal wall. The smaller masses most frequently contain only preperitoneal fat and are especially prone to incarceration and strangulation. These smaller hernias are often tender. Larger hernias seldom strangulate and may contain, in addition to preperitoneal fat, a portion of the nearby omentum and, occasionally, a loop of small or large bowel.

B. Signs

If a mass is palpable, the diagnosis can often be confirmed by any maneuver that will increase intra-abdominal pressure and thereby cause the mass to bulge anteriorly. The diagnosis is difficult to make when the patient is obese, since a mass is hard to palpate; ultrasound, CT, or tangential radiographs may be needed in the very obese patient.

► Differential Diagnosis

Differential diagnosis includes peptic ulcer, gallbladder disease, hiatal hernia, pancreatitis, and upper small bowel obstruction. On occasion, it may be impossible to distinguish the hernial mass from a subcutaneous lipoma, fibroma, or neurofibroma.

Another condition that must be distinguished from an epigastric hernia is diastasis recti, a diffuse widening and attenuation of the linea alba without a fascial defect. On examination, this condition appears as a fusiform, linear bulge between the two rectus abdominis muscles without a discrete fascial defect. Although this condition may be unsightly, repair should be avoided since there is no risk of incarceration, the fascial layer is weak, and the recurrence rate is high. If it is painful or unsightly, a diastasis is best repaired using a laparoscopic plication technique.

► Treatment

Most epigastric hernias should be repaired, since small ones are likely to become incarcerated and large ones are often symptomatic and unsightly. Small defects can usually be closed primarily, although mesh should be used for large hernias. Herniated fat contents are usually dissected free and removed. Intraperitoneal herniating structures

are reduced, but no attempt is made to close the peritoneal sac.

► Prognosis

The recurrence rate is 10%-20%, a higher incidence than with the routine inguinal or femoral hernia repair. This high recurrence rate may be partly due to failure to recognize and repair multiple small defects.

Palanivelu C et al: Laparoscopic repair of diastasis recti using the “Venetian blinds” technique of plication with prosthetic reinforcement: a retrospective study. *Hernia* 2009;13:287-292.

INCISIONAL HERNIA (VENTRAL HERNIA)

About 10% of abdominal operations result in incisional hernias. The incidence of this iatrogenic type of hernia is not diminishing in spite of an awareness of the many causative factors.

► Etiology

The factors most often responsible for incisional hernia are listed below. When more than one factor coexists in the same patient, the likelihood of postoperative wound failure is greatly increased.

1. Poor surgical technique. Inadequate fascial bites, tension on the fascial edges, or too tight a closure are most often responsible for incisional failure.
2. Postoperative wound infection. An infection in the wound increases the risk of hernia formation to as high as 80%, the greatest single risk factor for hernia.
3. Age. Wound healing is usually slower and the closure less solid in older patients.
4. General debility. Cirrhosis, carcinoma, and chronic wasting diseases are factors that affect wound healing adversely. Any condition that compromises nutrition increases the likelihood of incision breakdown.
5. Obesity. Obese patients frequently have increased intra-abdominal pressure. The presence of fat in the abdominal wound masks tissue layers and increases the incidence of seromas and hematomas in wounds.
6. Postoperative pulmonary complications that stress the repair as a result of vigorous coughing. Smokers and patients with chronic pulmonary disease are therefore at increased risk of fascial disruption.
7. Placement of drains or stomas through the primary operative fascial defect.
8. Intraoperative blood loss greater than 1000 mL.
9. Failure to close the fascia of laparoscopic trocar sites over 10 mm in size.
10. Defects in collagen or matrix metalloprotease.

► Treatment

Small incisional hernias should be treated by early repair since they may cause bowel obstruction. If the patient is unwilling to undergo surgery or is a poor surgical risk, symptoms may be controlled by an elastic binder.

Defects too large to close easily may be left without surgical repair if they are asymptomatic, since they are less likely to incarcerate bowel than smaller defects.

For only the very smallest incisional hernias (< 2 cm in diameter) should a direct fascia-to-fascia repair be considered. Interrupted or continuous closure may be used, but the sutures should be nonabsorbable. Sutures tied too tightly or tension on the repair will predispose to recurrence.

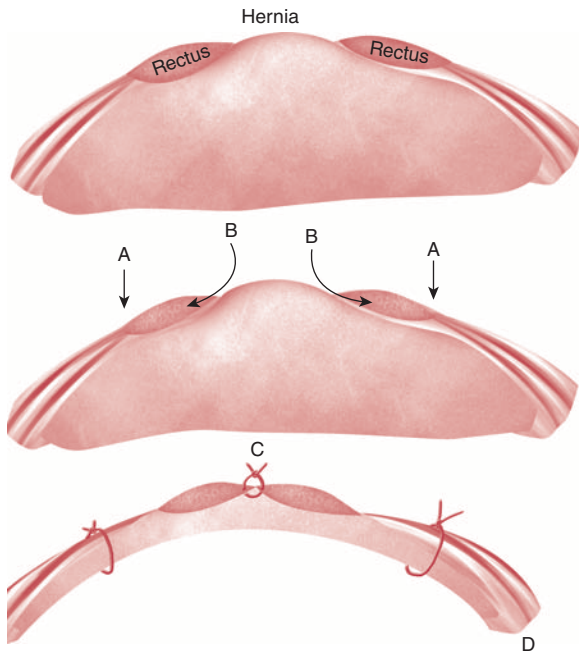

Although no specific diameter distinguishes a small from a large hernia, a hernia can be considered large when the fascial edges cannot be approximated without tension. Primary closure of a large defect is not advisable, since tension on the closure increases the risk of hernia recurrence. Increasingly, repair of large or recurrent defects is performed using non-absorbable mesh. Although a variety of techniques exist for placement of the mesh, a retrorectus underlay achieves a lower recurrence rate than an edge-to-edge or onlay placement. If a large dead space persists, a closed drainage system is usually employed in the space above the fascia. The lowest recurrence is achieved if native tissues can be approximated over the mesh underlay.

Laparoscopic techniques are increasingly being used to repair incisional hernias and perform adhesiolysis electively. A sheet of synthetic material is secured to the abdominal wall as an underlay graft; the intraperitoneal placement of the graft enhances the durability of the repair, though it also increases the risk of bowel adhesions or fistula formation.

Alternative methods to repair very large hernias that close the fascial defect using the patient's native tissue include component separation techniques that allow primary closure in the midline (Figure 32-6). These techniques are especially indicated when the procedure is infected or contaminated, making synthetic mesh an unwise choice. In a contaminated or infected field biologic mesh of human or animal origin is increasingly used as an underlay since infection risk is high with synthetic mesh. Best results are seen, when native tissue can be brought together over the biologic mesh.

► Prognosis

Results of randomized clinical trials show that mesh repair is superior to primary suture repair, even for small incisional hernias. Despite the increasing use of both open and laparoscopic mesh repairs, however, population-based studies show that incisional hernias continue to recur at a high rate after repair, and the recurrence rate increases with each subsequent reoperation for recurrence, reaching almost 40% on average after the third recurrence. Factors shown to increase risk of hernia recurrence include wound infection,

▲ **Figure 32-6.** Component separation technique to allow primary closure in the midline, usually over a mesh underlay. **A.** Division of the external oblique aponeurosis. **B.** Release of the rectus from the posterior rectus sheath. **C.** Closure of the rectus in the midline. **D.** Mesh underlay.

the presence of abdominal aneurysms, smoking, and poor nutrition. Recurrence rates are so high in smokers that many surgeons require patients to stop smoking for a month before the operation. If patients are able to stop smoking, complications and recurrence are cut in half. In all techniques employing mesh, the underlay technique with at least 3-4 cm of underlay of the mesh leads to the lowest recurrence rates. In addition to a high recurrence rate after operations, complications such as infected mesh, bleeding, seroma, and erosion of mesh into bowel causing a fistula occur in a small percentage of cases. Mesh infection is more likely after repair of a hernia occurring in a wound with a previous infection.

PARASTOMAL HERNIA

A parastomal hernia is a particularly troublesome hernia to repair successfully, since the stoma's course through the abdominal wall is, by its very nature, a hernia. Studies cite an incidence of up to 50% for this type of hernia. Traditional teaching advises that a stoma be placed through the rectus muscle rather than more laterally, but even perfect stoma placement can result in hernia formation when the fascial opening stretches and allows additional loops of intestine to protrude. Causes include collagen defects and anything that increases intra-abdominal pressure such as straining, heavy lifting, or obesity.

Parastomal hernias should be repaired if they interfere with stoma function or are difficult to reduce, as they can incarcerate and strangulate. If the hernia is asymptomatic or very large, repair is not mandatory. Many options for repair of a parastomal hernia are described. Primary repair and moving the stoma have particularly poor results. The lowest recurrence is found with mesh repair by open or laparoscopic approach, placing the mesh beneath the rectus or intraperitoneally in a keyhole fashion. Because of the high risk of this hernia's occurrence, some even advocate the prophylactic use of mesh when the stoma is placed, though this practice has not gained widespread acceptance.

VARIOUS RARE HERNIATIONS THROUGH THE ABDOMINAL WALL

► Littre Hernia

A Littre hernia is a hernia that contains a Meckel diverticulum in the hernia sac. Although Littre first described the condition in relation to a femoral hernia, the relative distribution of Littre hernias is as follows—inguinal, 50%; femoral, 20%; umbilical, 20%; and miscellaneous, 10%. Littre hernias of the groin are more common in men and on the right side. The clinical findings are similar to those of Richter hernia; when strangulation is present, pain, fever, and manifestations of small bowel obstruction occur late.

Treatment consists of repair of the hernia plus, if possible, excision of the diverticulum. If acute Meckel diverticulitis is present, the acute inflammatory mass may have to be treated through a separate abdominal incision.

► Amyand Hernia

An Amyand hernia is a groin hernia that contains the appendix. If the appendix is inflamed, it should be removed and the hernia repaired using native tissues or biologic mesh. If the appendix is normal and only an incidental finding in the hernia, it should be returned to the abdomen and a mesh repair employed.

Sharma H et al: Amyand's hernia: a report of 18 consecutive patients over a 15-year period. *Hernia* 2007;11:31-35.

► Spigelian Hernia

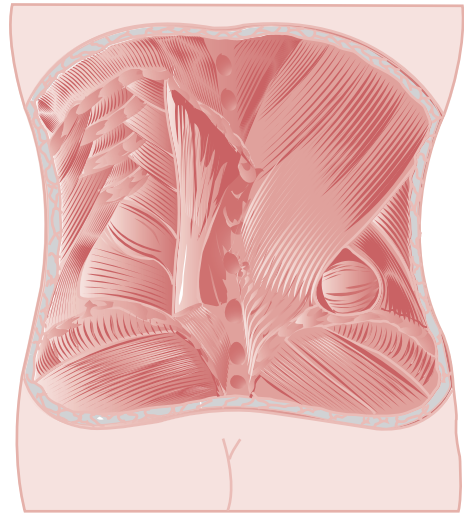

Spigelian hernia is an acquired ventral hernia through the linea semilunaris, the line where the sheaths of the lateral abdominal muscles fuse to form the lateral rectus sheath. Spigelian hernias are nearly always found above the level of the inferior epigastric vessels. They most commonly occur where the semicircular line (fold of Douglas) crosses the linea semilunaris.

The presenting symptom is pain that is usually localized to the hernia site and may be aggravated by any maneuver that increases intra-abdominal pressure. With time, the pain may become more dull, constant, and diffuse, making diagnosis more difficult.

If a mass can be demonstrated, the diagnosis presents little difficulty. The diagnosis is most easily made with the patient standing and straining; a bulge then presents in the lower abdominal area and disappears with a gurgling sound on pressure. Following reduction of the mass, the hernia orifice can usually be palpated.

Diagnosis is often made more difficult because the hernial defect may lie beneath an intact external oblique layer and therefore not be palpable. The hernia often dissects within the layers of the abdominal wall and may not present a distinct mass, or the mass may be located at a distance from the linea semilunaris. Patients with spigelian hernias should have a tender point over the hernia orifice, though tenderness alone is not sufficient to make the diagnosis. Both ultrasound and CT scan may help to confirm the diagnosis.

Spigelian hernias have a high incidence of incarceration and should be repaired. Small hernias may be repaired by primary aponeurotic closure though fascial defects larger than 2-3 cm should be repaired using mesh, preferable in an underlay, preperitoneal technique. Open or laparoscopic approach may be used according to the surgeon's experience, with laparoscopy affording an advantage in allowing the evaluation and treatment of bilateral hernia.

▲ **Figure 32-7.** Anatomic relationships of lumbar or dorsal hernia. On the left, lumbar or dorsal hernia into space of Grynfeltt. On the right, hernia into the Petit triangle (inferior lumbar space).

Bittner J et al: Mesh-free laparoscopic spigelian hernia repair. *Am Surg* 2008;74:713-720.

Saber A et al: Laparoscopic spigelian hernia repair: the scroll technique. *Am Surg* 2008;74:108-112.

► Lumbar or Dorsal Hernia

Lumbar or dorsal hernias (Figure 32-7) are hernias through the posterior abdominal wall at some level in the lumbar region. The most common sites (95%) are the superior (Grynfeltt) and inferior (Petit) lumbar triangles. A “lump in the flank” is the common complaint, associated with a dull, heavy, pulling feeling. With the patient erect, the presence of a reducible, often tympanitic mass in the flank usually makes the diagnosis. Incarceration and strangulation occur in about 10% of cases. Hernias in the inferior lumbar triangle are most often small and occur in young, athletic women. They present as tender masses producing backache and usually contain fat. Lumbar hernia must be differentiated from abscesses, hematomas, soft tissue tumors, renal tumors, and muscle strain.

Acquired hernias may be traumatic or nontraumatic. Severe direct trauma, penetrating wounds, abscesses, and poor healing of flank incisions are the usual causes. Congenital hernias occur in infants and are usually isolated unilateral congenital defects.

Lumbar hernias increase in size and should be repaired when found. Repair is by mobilization of the nearby fascia and obliteration of the hernia defect by precise fascia-to-fascia closure. The recurrence rate is very low.

Stamatiou D et al: Lumbar hernia: surgical anatomy, embryology, and technique of repair. *Am Surg* 2009;75:202-207.

► Obturator Hernia

Herniation through the obturator canal is more frequent in elderly women and is difficult to diagnose preoperatively. The mortality rate (13%-40%) of these hernias makes them the most lethal of all abdominal hernias. These hernias most commonly present as small bowel obstruction with cramping abdominal pain and vomiting. The hernia is rarely palpable in the groin, though a mass may be felt on pelvic or rectal examination. The most specific finding is a positive Howship–Romberg sign, in which pain extends down the medial aspect of the thigh with abduction, extension, or internal rotation of the knee. Since this sign is present in fewer than half of cases, diagnosis should be suspected in any elderly debilitated woman without previous abdominal operations who presents with a small bowel obstruction. Though diagnosis can be confirmed by CT scan, operation should not be unduly delayed if complete bowel obstruction is present.

The abdominal approach gives the best exposure; these hernias should not be repaired from the thigh approach. The Cheatle–Henry approach (retropubic) may also be used. Simple repair is most often possible, though bladder wall, pectineal muscle, peritoneum, or mesh has been used when the defect cannot be approximated primarily.

Petrie A et al: Obturator hernia: anatomy, embryology, diagnosis, and treatment. *Clin Anat* 2011;24:562-569.

Stamatiou D et al: Obturator hernia revisited: surgical anatomy, embryology, diagnosis, and technique of repair. *Am Surg* 2011;77:1147-1157.

► Perineal Hernia

A perineal hernia protrudes through the muscles and fascia of the perineal floor. It may be primary but is usually acquired following perineal prostatectomy, abdominoperineal resection of the rectum, or pelvic exenteration.

These hernias present as easily reducible perineal bulges and usually are asymptomatic but may present with pain, dysuria, bowel obstruction, or perineal skin breakdown.

Repair is usually done by an abdominal approach, with an adequate fascial and muscular perineal repair. Occasionally, polypropylene (Marlex) mesh or flaps using the gracilis, rectus abdominis, or gluteus may be necessary, when the available tissues are too attenuated for adequate primary repair.

► Interparietal Hernia

Interparietal hernias, in which the sac insinuates itself between the layers of the abdominal wall, are usually of an indirect inguinal type but, rarely, may be direct or ventral

hernias. Although interparietal hernias are rare, it is essential to recognize them, because strangulation is common and the mass is easily mistaken for a tumor or abscess. The lesion usually can be suspected on the basis of the physical examination provided it is kept in mind. In most cases, extensive studies for intra-abdominal tumors have preceded diagnosis. A lateral film of the abdomen will usually show bowel within the layers of the abdominal wall in cases with intestinal incarceration or strangulation, and an ultrasound or CT scan may be diagnostic.

As soon as the diagnosis is established, operation should be performed, usually through the standard inguinal approach.

► Sciatic Hernia

Sciatic hernia is the rarest of abdominal hernias and consists of an outpouching of intra-abdominal contents through the greater sciatic foramen. The diagnosis is made after incarceration or strangulation of the bowel occurs. The repair is usually made through the abdominal approach. The hernia sac and contents are reduced, and the weak area is closed by making a fascial flap from the superficial fascia of the piriformis muscle.

TRAUMATIC HERNIA

Abdominal wall hernias occur rarely as a direct consequence of direct blunt abdominal injury. The patient presents with abdominal pain. On examination, ecchymosis of the abdominal wall and a bulge are usually present. The existence of a hernia may not be obvious, however, and the patient may require CT scan to confirm it. Because of the high incidence of associated intra-abdominal injuries, laparotomy is usually required. The defect should be repaired primarily if possible.

II. OTHER LESIONS OF THE ABDOMINAL WALL

CONGENITAL DEFECTS

Congenital defects of the abdominal wall other than hernias or lesions of the urachus and umbilicus are rare. The important ones involving the urachus and umbilicus are discussed in Chapter 43.

TRAUMA TO THE ABDOMINAL WALL

► Rectus Sheath Hematoma

This is a rare but important entity that may follow mild trauma to the abdominal wall or may occur spontaneously in patients with disorders of coagulation, blood dyscrasia, or degenerative vascular diseases.

Abdominal pain localized to the rectus muscle is the presenting symptom. The pain may be sudden and severe in onset or slowly progressive. The key to diagnosis is the physical examination. Careful palpation will reveal a tender mass within the abdominal wall. When the patient tenses the rectus muscles by raising the head or body, the swelling becomes more tender and distinct on palpation, in contrast to an intra-abdominal mass or tenderness that disappears when the rectus muscles are contracted (Fothergill sign). In addition, there may be detectable discoloration or ecchymosis. If the physical signs are not diagnostic, ultrasound or CT scan will demonstrate the hematoma in the abdominal wall.

The condition does not commonly require operation. Coagulation abnormalities should be corrected if possible. The acute pain and discomfort usually disappear within 2-3 days, although a residual mass may persist for several weeks. Rarely bleeding persists, requiring embolization by interventional radiology.

PAIN IN THE ABDOMINAL WALL

A number of conditions are characterized by pain in the abdominal wall without a demonstrable organic lesion. Pain from a diaphragmatic, supradiaphragmatic, or spinal cord lesion may be referred to the abdomen. Herpes zoster (shingles) may present as abdominal pain, in which case it will follow a dermatomal distribution.

Scars may be sensitive or painful, particularly in the first 6 months after surgery.

Entrapment of a nerve by a nonabsorbable suture may cause persistent incisional pain, sometimes quite severe. Hyperesthesia of the skin over the involved dermatome may provide a clue to the cause. If local anesthetic nerve block relieves the pain, nerve block with alcohol or nerve excision may be performed.

In all cases of localized pain in the abdominal wall, careful search should be made for a small hernia—MRI or CT scan may be helpful to rule out a hernia.

ABDOMINAL WALL TUMORS

Tumors of the abdominal wall are not unusual, but most are benign, eg, lipomas, hemangiomas, and fibromas. Musculoaponeurotic fibromatoses (desmoid tumors), which often occur in abdominal wall scars or after parturition in women, are discussed in more detail in Chapter 44.

Endometriomas may also occur in the abdominal wall, particularly in the scars from gynecologic procedures and Caesarian sections. Most malignant tumors of the abdominal wall are metastatic. Metastases may appear by direct invasion from intra-abdominal lesions or by vascular dissemination. The sudden appearance of a sensitive nodule anywhere in the abdominal wall that is clearly not a hernia should arouse suspicion of an occult cancer, the lung and pancreas being the more likely primary sites.

MULTIPLE CHOICE QUESTIONS

- The most important principle for successful repair of a groin hernia in an adult is
 - Approximation of the conjoined tendon and inguinal ligament
 - High ligation of the hernia sac
 - A vertical relaxing incision in the anterior rectus sheath
 - A tension free repair
 - Reduction in the size of the internal inguinal ring
- All of the following are features of a femoral hernia repair *except*
 - Complete excision of the hernia sac
 - Use of a relaxing incision in the anterior rectus sheath when a tissue repair is done
 - Elimination of the defect in the transversalis fascia
 - Use of Cooper's ligament or iliopubic tract
 - Use of the inguinal ligament in the repair
- Randomized trials of groin hernia repair show
 - Equivalent recurrence rate of open and laparoscopic hernia repairs with mesh in the hands of experienced surgeons
 - Lower operative complication rate with a laparoscopic extraperitoneal repair
 - A greater rate of recurrence with open mesh repairs than laparoscopic repairs
 - Less chronic pain and numbness with open mesh repairs than laparoscopic repairs
 - Laparoscopic extraperitoneal repair had the lowest recurrence rate
- Of the following, the greatest risk for incisional hernia after an abdominal operation is found in patients who
 - Are more than 65 years old
 - Have coronary artery disease
 - Develop a wound infection
 - Have diabetes
 - Have COPD
- Of the following, the most durable method of repairing a large incarcerated incisional hernia containing strangulated bowel is
 - Open primary repair
 - Open inlay synthetic mesh
 - Open biologic mesh inlay
 - Laparoscopic synthetic mesh
 - Underlay of biologic mesh with primary tissue brought to midline

33

Adrenals

Quan-Yang Duh, MD

Chienying Liu, MD

J. Blake Tyrrell, MD

Operations on the adrenal glands are performed for primary hyperaldosteronism, pheochromocytoma, hypercortisolism (Cushing disease or Cushing syndrome), and adrenocortical carcinoma. These conditions are usually characterized by hypersecretion of one or more of the adrenal hormones. Less commonly, surgery may also be performed for nonfunctioning tumors or metastases.

ANATOMY & SURGICAL PRINCIPLES

The normal combined weight of the adrenals is 7-12 g. The right gland lies posterior and lateral to the vena cava and superior to the kidney (Figure 33-1). The left gland lies medial to the superior pole of the kidney, just lateral to the aorta and immediately posterior to the superior border of the pancreas. An important surgical feature is the remarkable constancy of the adrenal veins. The right adrenal vein, 2-5 mm long and several millimeters wide, connects the anteromedial aspect of the adrenal gland with the posterolateral aspect of the vena cava. The left adrenal vein is several centimeters long and travels inferiorly from the lower pole of the gland, joining the left renal vein after receiving the inferior phrenic vein. Variant venous drainage (multiple or anomalous veins) occurs in about 5% of glands and are more common for pheochromocytomas and larger tumors. The adrenal arteries are small, multiple, and inconstant. They usually come from the inferior phrenic artery, the aorta, and the upper pole branch of renal artery.

With the exception of rare nonsecreting cancers, indications for adrenal surgery result from hypersecretory states. Diagnosis and treatment begin with confirmation of a hypersecretory state (ie, measurement of excess cortisol, aldosterone, or catecholamines in blood or urine). In order to determine whether the problem originates in the adrenal, levels of the trophic hormone in question (ie, adrenocorticotrophic hormone [ACTH] or renin) must be measured. If levels of the trophic hormone are suppressed

but hormone secretion is excessive, autonomous secretion is proved. The next step, except in pheochromocytoma, is to determine the degree of autonomy, a process that usually distinguishes hyperplasias (which respond to most but not all controlling mechanisms) from adenomas and adenomas from cancers. In general, cancers are under little if any feedback control. If the primary problem is not in the adrenal, as in Cushing disease, treatment must be directed elsewhere when possible.

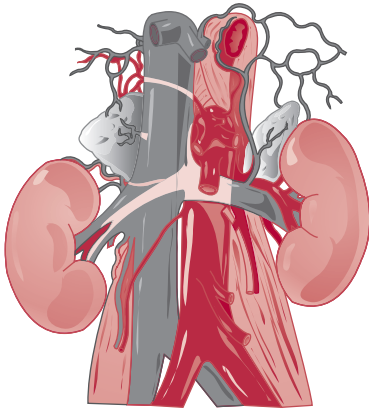

The major principles of adrenal surgery are as follows:

- Whenever possible, the surgeon must be certain of the diagnosis and the location of the lesion before undertaking the operation.
- The patient must be thoroughly prepared so he or she can withstand any metabolic problems caused by the disease or by the operation.
- The surgeon and consultants must be able to detect and treat any metabolic crisis that occurs during or after operation.

SURGICAL APPROACHES

Currently, almost all adrenal tumors are identified preoperatively by localization studies such as CT and MRI, so very few operations require general exploration of the abdomen. This permits the use of minimally invasive surgery. Almost all adrenal tumors can be removed laparoscopically. Traditional open adrenalectomy is necessary only when the tumor is especially large (eg, > 8-10 cm, depending on the surgeon's experience) or for locally invasive adrenocortical cancer where resection of lymph nodes or adjacent organs may be required.

Laparoscopic adrenalectomy can be performed using a transabdominal or retroperitoneal approach. Transabdominal laparoscopic adrenalectomy involves medial rotation of the spleen and pancreas (on the left) or

▲ **Figure 33–1.** Anatomy of the adrenals, showing venous return.

the liver (on the right), using gravity to drop the viscera away from the adrenal. Retroperitoneal adrenalectomy involved the use of high insufflation pressure to maintain the space for dissection and to decrease bleeding during dissection. Although transabdominal approach is more suitable for larger tumors and the retroperitoneal approach better for bilateral adrenalectomy and for patients with abdominal adhesions, surgeon preference usually dictate the choice of surgical approach.

The traditional open surgical approach is used when laparoscopic expertise is not available or when required by the size and invasiveness of the tumor. The advantages of laparoscopic operation are so great that it is strongly preferred.

The open anterior approach (midline, subcostal, or “L” incision) allows wide exposure for large tumors but causes more pain and wound complications, and it requires longer hospitalization. The open posterior approach through the bed of the 11th or 12th rib has been superseded by the laparoscopic approach. Thoracoabdominal incision may be used for large or invasive tumors.

DISEASES OF THE ADRENALS

PRIMARY ALDOSTERONISM

ESSENTIALS OF DIAGNOSIS

- ▶ Hypertension with or without hypokalemia.
- ▶ Elevated aldosterone secretion and suppressed plasma renin activity.
- ▶ Metabolic alkalosis, relative hyponatremia.
- ▶ Weakness, polyuria, paresthesias, tetany, cramps due to hypokalemia.

▶ General Considerations

Aldosterone, the most potent mineralocorticoid secreted by the adrenal cortex, regulates the body’s electrolyte composition, fluid volume, and blood pressure. Excess aldosterone increases total body sodium, decreases potassium levels, increases extracellular fluid volume (without edema), and increases blood pressure. Under normal conditions, aldosterone secretion is regulated by the renin-angiotensin system in a feedback fashion and is also stimulated transiently by ACTH.

In primary aldosteronism, aldosterone levels are elevated and renin levels are suppressed. In secondary hyperaldosteronism, increased aldosterone is due to increased renin secretion. Examples of secondary hyperaldosteronism include renovascular disease, renin-secreting tumors, and cirrhosis with low intravascular volume or diuretic use. Among the subtypes of primary aldosteronism, aldosterone-producing adenoma (APA, aldosteronoma) and idiopathic hyperaldosteronism (IHA) with adrenal hyperplasia are the most common types. Unilateral primary adrenal hyperplasia, aldosterone-producing adrenocortical carcinoma, and familial hyperaldosteronism (FH) (eg, FH type I-glucocorticoid-remediable hyperaldosteronism and FH type II) are rare. Surgery is beneficial only in patients with APAs and in patients with unilateral primary adrenal hyperplasia.

Primary aldosteronism in its classic form is characterized by hypertension, hypokalemia, increased aldosterone secretion, and suppressed plasma renin activity (PRA). However, hypokalemia is not required to make the diagnosis; recent studies have shown that many patients have a normal potassium level. Primary aldosteronism was once thought to be present in about 1% of patients with hypertension, but its prevalence has increased to 5%-13% based on various studies when plasma aldosterone concentration (PAC)-to-PRA was used to screen for hyperaldosteronism in patients with hypertension who were not hypokalemic. Although rare, normotensive primary aldosteronism has been described.

Aldosteronomas are usually solitary and small (0.5-2 cm). They have a characteristic golden-yellow color when sectioned. Tumor cells typically have heterogeneous cytomorphology, resembling those of all three zones of the adrenal cortex, including hybrid cells having cytologic features of the zona glomerulosa and zona fasciculata. Hyperplasia is also often seen in glands harboring adenomas.

▶ Clinical Findings

Aldosterone facilitates the exchange of sodium for potassium and hydrogen ions in the distal nephron. Therefore, when aldosterone secretion is chronically increased, serum potassium and hydrogen ion concentrations fall (hypokalemia and alkalosis), total body sodium rises, and hypertension results.

A. Symptoms and Signs

Symptoms, if present, are usually those of hypokalemia and depend on the severity of potassium depletion. Patients complain of a sense of malaise, muscle weakness, polyuria, polydipsia, cramps, and paresthesias. Tetany and hypokalemic paralysis occur rarely. Headaches are common. Hypertension is usually moderate to severe and may be refractory to medical therapy, but advanced retinopathy is rare. Although extracellular fluid volume is increased, edema is not seen unless renal failure occurs.

B. Laboratory Findings

1. Screening test—Primary aldosteronism should be suspected in patients with hypertension and hypokalemia—either spontaneous or following the administration of diuretics—and in patients with refractory hypertension. The diagnostic evaluation should start with screening tests. A simple ambulatory test determines the ratio of PAC, in nanograms per deciliter, to PRA, in nanograms per milliliter per hour, performed in the morning in a seated ambulant patient. A ratio greater than 20 with a PAC greater than 15 ng/dL suggests primary aldosteronism and warrants confirmatory biochemical studies. Hypertensive individuals without primary aldosteronism usually have ratios of less than 20. If the patient is taking an aldosterone receptor antagonist spironolactone or eplerenone, the data are uninterpretable, and estrogens increase PACs by increasing angiotensinogen. These agents should be discontinued for 6 weeks before the workup.

Many medications affect PAC and PRA. For example, PAC is decreased by angiotensin-converting enzyme inhibitors (ACE inhibitors), angiotensin receptor blockers (ARBs), central alpha-2 agonists such as clonidine, dihydropyridine (DHP) calcium channel antagonists such as amlodipine, and beta-blockers. PRA is increased by ACE inhibitors, ARBs, and DHP-calcium channel antagonists. These medications should be discontinued for 2 weeks if necessary. Peripheral α -adrenergic blockers such as doxazosin, terazosin, prazosin, hydralazine, and non-DHP calcium channel blocker such as verapamil are the preferred antihypertensive agents during evaluation. In many patients, it is unwise to withdraw antihypertensive medications, and one must be content with imperfect data.

2. Confirmatory test—If the screening test is positive, failure to suppress aldosterone secretion with sodium loading will confirm the diagnosis of primary aldosteronism in most patients. Normally aldosterone can be suppressed by oral salt loading or intravenous sodium chloride infusion. The patient should consume a high-sodium diet (5000 mg of sodium for 3 days) or be supplemented with NaCl tablets (2-3 g with each meal) if necessary. A 24-hour urine sample is collected for aldosterone and sodium on the third day.

Serum potassium should be monitored because the high-salt diet increases kaliuresis, and potassium chloride should be supplemented to avoid hypokalemia, which interferes with the test results by decreasing aldosterone secretion and may cause cardiac arrhythmias. Urinary aldosterone excretion higher than 12-14 $\mu\text{g}/24$ h distinguishes most patients with primary aldosteronism from those with essential hypertension on a high-salt diet, as confirmed by urinary sodium excretion exceeding 200 mEq/24 h. Alternatively, a PAC higher than 10 ng/mL after an infusion of 2 L of normal saline over 4 hours is also consistent with primary aldosteronism.

► Differential Diagnosis

Once the diagnosis is established, the surgically correctable forms—APA (aldosteronoma), constituting approximately 35% of primary aldosteronism, and the rare unilateral primary adrenal hyperplasia—should be distinguished from IHA, comprising approximately 65% of primary aldosteronism, due to bilateral adrenal hyperplasia, for which medical therapy is the best management. Aldosteronoma and IHA are the most common subtypes. Compared with those with IHA, patients with aldosteronoma have more severe hypertension, more severe hypokalemia, higher aldosterone secretion (> 20 ng/dL), higher 18-hydroxycorticosterone concentrations (> 100 ng/dL), and are younger. Interestingly more than one third of aldosteronomas have a somatic KCNJ5 gene mutation.

Glucocorticoid-remediable hyperaldosteronism (FH type I) is inherited in an autosomal dominant fashion. The genetic defect results in a chimeric gene. The mutated gene juxtaposes the promoter for expression of the 11-hydroxylase gene, which is ACTH-responsive, with the coding sequence of the aldosterone synthase gene. This leads to aldosterone production under ACTH stimulation in the zona fasciculata. Glucocorticoid therapy reverses this type of hyperaldosteronism. These patients have a family history of onset of hypertension at an early age. The diagnosis can be established by genetic testing. Measurement of 24-hour urine 18-hydroxycortisol and 18-oxocortisol levels is less reliable. The molecular basis for FH type II is not clear although it is also inherited in an autosomal dominant fashion.

Aldosterone-secreting adrenocortical carcinoma is rare and should be suspected if the tumor is larger than 4 cm, especially if it also secretes cortisol and intermediate metabolites.

► Tumor Localization

An APA can frequently be demonstrated by high-resolution CT or MRI scanning. Small aldosteronomas can be missed, and in such cases, a patient with a small aldosteronoma not seen on CT may be misdiagnosed as having adrenal hyperplasia. Aldosteronomas that coexist with nonfunctional

adenomas can be mislabeled as adrenal hyperplasia because of multinodularity or bilateral masses on CT. Small abnormalities on CT scans may represent hyperplasia rather than true aldosteronomas. Therefore, unless an unequivocal unilateral tumor, preferably larger than 1 cm, is present on the CT scan and the contralateral gland is normal, the diagnosis and localization of aldosteronoma is not certain. When in doubt, adrenal vein sampling should be done. Blood is sampled from the adrenal veins and the inferior vena cava for aldosterone and cortisol levels at baseline and after ACTH infusion. Proper catheter placement is confirmed by finding high cortisol levels in adrenal venous blood compared with the inferior vena cava. Corrected aldosterone levels are calculated from the ratio of aldosterone to cortisol in each venous sample. A lateralization ratio of the corrected aldosterone level higher than 4 indicates unilateral aldosterone secretion, thereby confirming a diagnosis of aldosteronoma in most patients. Adrenal vein sampling is invasive and requires considerable skill and experience. The success rate for cannulating both adrenal veins is about 90% (60%-95% depending on experience of radiologists). Complication of venous sampling, such as adrenal hemorrhage can occur in 1% of patients. Some recommend adrenal vein sampling to be done routinely regardless of CT findings. Whereas others advocate using it selectively when CT scan findings are uncertain (no tumor, bilateral tumors, or small tumor < 1 cm in diameter).

► Complications

Uncontrolled hypertension can lead to renal failure, stroke, and myocardial infarction. Severe hypokalemia can cause weakness, paralysis, and arrhythmia, especially in patients taking digitalis.

► Treatment

The goal of therapy is to prevent the complications of hypertension and hypokalemia. Unilateral adrenalectomy is recommended for patients with aldosteronoma and medical therapy for those with IHA or those with aldosteronoma who are poor candidates for surgery.

A. Surgical Treatment

1. Preoperative preparation—Blood pressure and hypokalemia should be controlled before surgery. Spironolactone, a competitive aldosterone antagonist, has been the drug of choice. It blocks the mineralocorticoid receptor, promotes potassium retention, restores normal potassium concentrations, and reduces the extracellular fluid volume, thereby controlling blood pressure. Furthermore, it reactivates the suppressed renin-angiotensin-aldosterone system in the contralateral adrenal gland, reducing the risk of postoperative hypoaldosteronism. The medication should be continued to the day of operation. For additional information and

medical regimens for preoperative preparation, see Medical Treatment section.

2. Surgery—Because aldosteronomas are almost always small and benign, laparoscopic adrenalectomy is the procedure of choice. It can be performed safely and with equally good results by several approaches. The lateral transabdominal approach uses gravity to help medially rotate the viscera (liver on the right and spleen and pancreas on the left) and exposes the adrenal gland. It is the most versatile approach since the anatomy is familiar to most abdominal surgeons. The posterior retroperitoneal approach is best in patients with prior upper abdominal operations, but the working space is more limited. Although some surgeons perform a subtotal resection for aldosteronoma, most excise the whole adrenal gland with the tumor. The surrounding adrenal tissue frequently appears hyperplastic. Small aldosteronomas may not be visible intraoperatively. Bilateral adrenalectomy is not indicated, since hypocortisolism will require steroid-replacement treatment. Patients with IHA should be treated medically.

3. Postoperative care—Occasional patients may develop transient aldosterone deficiency because of suppression of the contralateral adrenal gland by the hyperfunctioning adenoma. This is rare in patients treated with spironolactone preoperatively. Symptoms include postural hypotension and hyperkalemia. Adequate sodium intake is usually sufficient for treatment; rarely, short-term fludrocortisone replacement (0.1 mg/d orally) is required.

B. Medical Treatment

The goal is to control hypertension and hypokalemia. Spironolactone, a competitive aldosterone antagonist, has been the drug of choice. Initial dosages of 200-400 mg/d may be required to control hypokalemia and hypertension. Once blood pressure is normalized and hypokalemia is corrected, the dose can be tapered and maintained at about 100-150 mg/d. Spironolactone may have antiandrogenic side effects, such as impotence, gynecomastia, menstrual irregularity, and gastrointestinal disturbances. These potential side effects may make this medication less desirable for some patients. Unlike spironolactone, which also blocks androgen and progesterone receptors, eplerenone is a selective mineralocorticoid receptor antagonist and has fewer endocrine side effects. It has been approved for treatment of hypertension and for heart failure after myocardial infarction. Eplerenone may become the treatment of choice for primary aldosteronism because of its decreased side effects if it is proven as efficacious as spironolactone, in spite of its increased cost. Amiloride, 20-40 ng/d, a potassium-sparing diuretic, may be used alternatively or as a supplement to spironolactone. Other medications, such as ACE inhibitors, calcium-channel blockers, and diuretics, may be required to control hypertension.

► Prognosis

Primary aldosteronism usually follows a prolonged and subtly changing course. Untreated hypertension may cause stroke, myocardial infarction, or renal failure.

Removal of an aldosteronoma normalizes potassium levels in nearly 100% of the patients, but hypertension is cured in about 50% of the patients. Persistent hypertension after operation is more common in overweight men who preoperatively required more than three antihypertensive medications for more than 6 years, but residual hypertension is usually easier to control than before the operation. Essential hypertension and atherosclerosis due to chronic hypertension are contributing factors. Although patients with IHA should be treated medically, adrenalectomy is indicated for those with aldosteronoma because side effects of the medications and compliance make long-term medical treatment undesirable. The low morbidity, short hospitalization, and high success rate of laparoscopic adrenalectomy have made surgery preferable to long-term medical therapy.

► General Considerations

Pheochromocytomas are tumors of the adrenal medulla and related chromaffin tissues elsewhere in the body (paragangliomas) that secrete epinephrine or norepinephrine, resulting in sustained or episodic hypertension and other symptoms of catecholamine excess.

Pheochromocytoma is found in less than 0.1% of patients with hypertension and accounts for about 5% of adrenal tumors incidentally discovered by CT scanning. Most pheochromocytomas occur sporadically without other diseases, but about one third are associated with various familial syndromes such as MEN2, NF1, VHL, and familial paraganglioma syndromes. Patients with multiple endocrine neoplasia (MEN)2A may have medullary thyroid carcinoma, pheochromocytoma, and hyperparathyroidism. Those with MEN2B have medullary thyroid carcinoma, pheochromocytoma, mucosal neuromas, marfanoid habitus, and ganglioneuromatosis. Patients with neurofibromatosis type I have café au lait spots, neurofibromatosis, and pheochromocytoma. Patients with von Hippel-Lindau disease may have retinal hemangioma, hemangioblastoma of the central nervous system, renal cysts and carcinoma, pheochromocytoma, pancreatic cysts or neuroendocrine tumors, and epididymal cystadenoma. Familial paraganglioma syndromes are caused by mutations of the succinate dehydrogenase genes *SDHx* (*SDHB*, *SDHD*, *SDHC*, *SDHA*, and *SDHAF2*). All are associated with extra-adrenal paragangliomas. *SDHB* is particularly associated with malignant pheochromocytomas. These syndromes should be considered especially in young patients and in patients with multifocal, extra-adrenal, malignant, or recurrent tumors. Other genetic mutations associated with pheochromocytomas are *TMEM127* and *MAX*. Because of the higher than previously expected prevalence of hereditary pheochromocytoma, all patients with pheochromocytoma should be considered for genetic counseling and testing. The specific genes tests should depend on clinical and biochemical findings and family history. Family members of patients who have been diagnosed with these syndromes also need screening to determine whether they are gene carriers and are at risk for developing the various tumors, including pheochromocytoma.

On pathologic examination, pheochromocytoma appears reddish-gray and frequently has areas of necrosis, hemorrhage, and sometimes cysts. The usual size is about 100 g, or 5 cm in diameter, but they can be as small as 2-3 cm or as large as 12-16 cm. Cells are pleomorphic, showing prominent nucleoli and frequent mitoses. Cytologic findings cannot be used to determine whether a pheochromocytoma is malignant or benign. The veins and capsules may also be invaded even in clinically benign tumors. Malignancy can only be diagnosed in the presence of metastases in non-chromaffin cell bearing tissues or invasion into surrounding tissues.

PHEOCHROMOCYTOMA

ESSENTIALS OF DIAGNOSIS

- Hypertension, frequently sustained, with or without paroxysms.
- Episodic headache, excessive sweating, palpitation, and visual blurring.
- Postural tachycardia and hypotension.
- Elevated urinary catecholamines or their metabolites, hypermetabolism, hyperglycemia.

► Clinical Findings

A. Symptoms and Signs

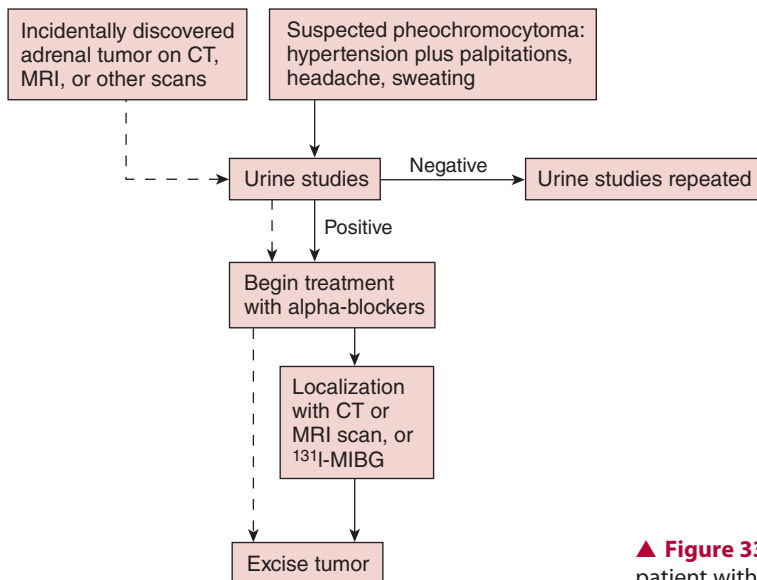

The clinical findings of pheochromocytoma are variable, and almost half of them come to attention because of an incidental finding of an adrenal tumor (incidentaloma) on CT or MRI scans performed to evaluate other diseases. Classically, the patient has episodic hypertension associated with the triad of palpitation, headache, and sweating. The patient may also complain of anxiety, tremors, weight loss, dizziness, nausea and vomiting, abdominal discomfort, constipation, and visual blurring. Rarely pheochromocytomas can secrete VIP causing severe diarrhea or ACTH causing Cushing syndrome. The physical examination may be unremarkable except during an attack, when pallor and excess sweating may be observed. Tachycardia, postural hypotension, and hypertensive retinopathy are other signs.

Hypertension, the most common feature of pheochromocytoma, occurs in 90% of patients. More than half have sustained hypertension, which may be mild to moderate, with or without other signs and symptoms of catecholamine excess, and the diagnosis may be missed. In some cases, basal blood pressure may not be elevated, and severe hypertension occurs only while the patient is under stress, such as general anesthesia or trauma. Patients with diastolic hypertension and postural hypotension who are not receiving antihypertensive medications may have pheochromocytoma. Hyperglycemia may occur because epinephrine raises blood glucose and norepinephrine decreases insulin secretion.

In children, hypertension is less prominent, and about 50% have multiple or extra-adrenal tumors. Paragangliomas due to *SDHB* mutations are more likely to metastasize. Pheochromocytomas occur in 40%-50% of patients with MEN2; they tend to be bilateral and multiple but are rarely extra-adrenal or malignant. Biochemical screening for gene carriers of hereditary pheochromocytoma should be performed routinely. Measurement of plasma free metanephrines (metanephrine and normetanephrine) is the most sensitive test for pheochromocytoma in familial syndromes.

B. Laboratory Findings

The diagnosis of pheochromocytoma is best confirmed either by 24-hour urinary fractionated catecholamines and metanephrines measured in the same collection or by plasma free metanephrines. Both tests have high diagnostic sensitivity and specificity (Figure 33–2). Plasma free metanephrines is more sensitive than the urine test, but it has a higher false-positive rate, especially in elderly patients. Urinary output of metanephrines and/or free catecholamines is elevated in more than 95% of patients with pheochromocytoma. In 80% of patients, the level exceeds twice normal. Measurement of urinary vanillylmandelic acid (VMA) is less sensitive, and this test should no longer be used. Assays using high-performance liquid chromatography (HPLC) reduce interference by drugs and diets, but HPLC assays differ among various testing labs, and many drugs and diets can potentially interfere with certain HPLC assays or affect the secretion and metabolism of catecholamines. Examples

▲ **Figure 33–2.** Scheme for evaluation of a patient with suspected pheochromocytoma.

include acetaminophen, labetalol, vasodilators (nitroglycerin and nitroprusside), nifedipine, theophylline, stimulants (amphetamine, caffeine, nicotine, methylphenidate), many antipsychotics, antidepressants (especially tricyclic antidepressants), buspirone, prochlorperazine, and methyl dopa. Interpretation of the study may also be affected by coffee, ethanol, bananas, radiographic dyes, drugs that contain catecholamines, and withdrawal from clonidine. These agents should be discontinued for 2 weeks before measuring urinary catecholamines and metanephrines. The interfering substances vary depending on the specific assays used, so a list and protocol for preparing the patient should be obtained from the specific laboratory. Liquid chromatography-tandem mass spectrometry is a newer assay that has been shown to minimize drug interferences in the measurement of plasma and urinary metanephrines and may improve its diagnostic accuracy.

Overnight urinary collection and short collection periods following a paroxysm, indexed to creatinine, have also been used. Measuring plasma free metanephrines is 96%-100% sensitive and 85%-89% specific. Depending on the particular assay, caffeic acid found in coffee, acetaminophen, phenoxybenzamine, and tricyclic antidepressants may cause false-positive results. Provocative tests—using glucagon, histamine, or tyramine—are not accurate and are potentially dangerous; they are no longer used. Clonidine suppression tests are rarely used.

C. Tumor Localization

Localization studies should be performed only after biochemical studies have confirmed the diagnosis of a catecholamine-secreting tumor. Ninety percent of pheochromocytomas are found in the adrenal glands and most are larger than 3 cm in diameter. Of the extra-adrenal pheochromocytomas (also called paragangliomas), 75% are in the abdomen, 10% in the bladder, 10% in the chest, 2% in the pelvis, and 3% in the head and neck. Both CT and MRI can localize most pheochromocytomas. CT scan is less expensive and gives better anatomic details for the surgeons, but MRI avoids radiation exposure. Pheochromocytoma usually has a characteristic bright appearance on T2-weighted MRI. ^{123}I -MIBG scanning should be considered when searching for extra-adrenal, multiple, malignant, or metastatic pheochromocytomas. MIBG is more specific but less sensitive compared with CT or MRI for localization. PET-CT scans using various PET tracers have been studied. Compared to CT, MRI, and MIBG, 18F-fluoro-2-deoxy-D-glucose (18F-FDG) PET-CT is more sensitive for localizing metastatic paragangliomas in patients with *SDHB* mutations. Arteriography and fine-needle aspiration biopsy can precipitate a hypertensive crisis. They do not contribute to the diagnosis and are not indicated. Venous sampling for catecholamines is not indicated and can be misleading.

► Differential Diagnosis

The differential diagnosis includes all causes of hypertension. Hyperthyroidism and pheochromocytoma have many features in common (weight loss, tremor, and tachycardia). The diagnosis of pheochromocytoma is easier if episodic hypertension is present. Acute anxiety attacks mimic the symptoms and may precipitate hypertensive episodes, but anxiety alone rarely produces severe hypertension. Carcinoid syndrome causing episodes of flushing may also be mistaken for pheochromocytoma. Urinary 5-HIAA level is usually markedly elevated, and CT scan may show liver metastases in patients with carcinoid syndrome. Labile essential hypertension is not associated with elevated catecholamine levels.

Pheochromocytoma in pregnancy, if not recognized, will kill half of the fetuses and nearly half of the mothers. Hypertension in pregnancy is usually ascribed to preeclampsia-eclampsia. The diagnosis of pheochromocytoma requires the same biochemical studies; MRI is indicated to localize the tumor when a biochemical diagnosis has been established. CT or MIBG is not used to avoid radiation exposure. α -Adrenergic and β -adrenergic blockers are well tolerated. Timing of the operation is individualized. If recognized early, the tumor is best removed early in the second trimester. Otherwise, α -adrenergic blockade is continued. A planned cesarean section at term is followed by laparoscopic adrenalectomy a few weeks postpartum.

Pheochromocytoma crisis may develop in patients with pheochromocytoma, usually precipitated by trauma, certain medications, surgery, or other procedures. It can also be triggered by glucocorticoids. Crisis usually occurs when α -adrenergic blockade has not been instituted. These patients may develop multisystem failure, especially cardiovascular complications. If pheochromocytoma crisis is not recognized, death is the usual result. Once pheochromocytoma is diagnosed, the patient should be stabilized and α -adrenergic blockade started. After adequate blockade (10-14 days), the pheochromocytoma can be resected either during the same hospitalization or the patient may be stabilized, discharged, and electively readmitted. Emergent operation is rarely necessary.

► Complications

Pheochromocytoma causes complications because of hypertension, cardiac arrhythmia, and hypovolemia. The sequelae of hypertension are stroke, renal failure, myocardial infarction, and congestive heart failure. Sudden death can result from ventricular tachycardia or fibrillation. α -Adrenergic stimulation by the catecholamines causes vasoconstriction and a low total blood volume. The patient is therefore unable to compensate for a sudden loss of blood volume (bleeding) or catecholamines (tumor removal) and is at risk of cardiovascular collapse. Preoperative α -adrenergic

blockade and restoration of blood volume can prevent these complications.

► Treatment

A. Medical Treatment

Treatment with α -adrenergic blocking agents should be started as soon as the biochemical diagnosis is established. The aims of preoperative therapy are (1) to restore the blood volume, which has been depleted by excessive catecholamines; (2) to prevent a severe crisis, with its potential complications; and (3) to allow the patient to recover from cardiomyopathy. Close control of hypertension is necessary in order to keep blood volume normal.

Phenoxybenzamine, a nonselective α -adrenergic antagonist, has a long duration of action and is the preferred drug. It should be started at a dosage of 10 mg/12 h, and the dose should be increased by 10-20 mg every 2-3 days—as postural hypotension allows. Usual doses are 100-160 mg/d; however, dosages as high as 300 mg/d may be necessary. Most patients require 10-14 days of treatment, as judged by stabilization of blood pressure and reduction of symptoms. Nasal stuffiness is usually present when alpha blockade is well established. Calcium-channel blockers and competitive selective α -adrenergic blocking agents such as doxazosin and prazosin may also be effective. Metyrosine inhibits tyrosine hydroxylase and reduces catecholamine synthesis, and can be added to phenoxybenzamine as preoperative therapy.

β -Adrenergic blocking agents are often used to treat arrhythmias and tachycardia but should only be given after alpha blockade has been achieved. Otherwise, a hypertensive crisis may be precipitated because of the unopposed α -adrenergic effect of the catecholamines. Opioids should be avoided because they may stimulate histamine release and precipitate a crisis.

B. Surgical Treatment

The definitive treatment of pheochromocytoma is excision after preoperative localization and alpha-adrenergic blockade.

Smaller (< 5-6 cm) adrenal pheochromocytomas can be safely resected by laparoscopic adrenalectomy. Larger (> 8-10 cm), locally invasive and extra-adrenal tumors are technically more difficult and may require open resection.

During surgery, an arterial line is necessary for continuous blood pressure monitoring. Monitoring of pulmonary artery pressure is usually not necessary in patients who are well blocked.

Nitroprusside should be immediately available to treat sudden hypertension and beta-blockers to treat the cardiac dysrhythmias that may occur when the tumor is manipulated. Manipulation of the gland is less with laparoscopic adrenalectomy, which minimizes fluctuations in plasma catecholamine levels.

Very large malignant tumors may require a thoracoabdominal incision. Malignant pheochromocytomas may invade the adrenal vein or vena cava. Extra-adrenal pheochromocytomas (paragangliomas) are usually found along the abdominal aorta and in the organ of Zuckerkandl near the aortic bifurcation around the inferior mesentery artery. However, tumors have been found in widely scattered sites such as the bladder, the vagina, the mediastinum, the neck, and even skull base and pericardium. In general, extra-adrenal tumors should be localized with MIBG, CT, MRI, or PET-CT preoperatively to avoid a blind exploration.

In patients with MEN2 or VHL and bilateral pheochromocytomas, cortical-sparing subtotal adrenalectomy on the side of the smaller tumor may avoid postoperative adrenal insufficiency, though it increases the risk for recurrence. In patients with a known hereditary pheochromocytoma syndrome and a unilateral pheochromocytoma, prophylactic resection of the contralateral normal-appearing adrenal gland is not indicated, since bilateral adrenalectomy leads to lifelong hypoadrenalism requiring cortisol replacement. These patients should be followed with biochemical evaluations, and the contralateral adrenal gland should be resected only if pheochromocytoma develops.

Patients undergoing resection of pheochromocytoma who are not adequately prepared preoperatively may have hypertensive crises, cardiac arrhythmia, myocardial infarction, or acute pulmonary edema. In addition, these patients may experience intractable hypotension and die in shock after tumor removal. If the patient has been properly prepared with alpha-blockers, the changes in blood pressure will not be severe. Otherwise, intravenous infusion of large amounts of saline and vasopressors may be necessary to maintain blood pressure after the tumor is removed. Hypoglycemia may develop after tumor removal so blood glucose level should be checked until the patient is eating.

► Prognosis

Patients with untreated pheochromocytoma are at high risk for complications from hypertensive crisis and cardiovascular disease, whereas the operative mortality rate is 0%-3%. Mild to moderate essential hypertension may persist after surgery. Second tumors in the remaining adrenal or metastatic tumors can occur years after excision of the primary pheochromocytoma; long-term follow-up is mandatory. Patients with pheochromocytoma should be offered genetic counseling and when appropriate tested for hereditary causes of pheochromocytoma. Long-term prognosis may depend on the mutation present (eg, risk for malignant pheochromocytoma in *SDHB* mutation gene carriers). Metastatic or recurrent malignant pheochromocytoma should be resected if possible to reduce the catecholamine load. Treatment with high-dose ^{131}I -MIBG may be helpful in these patients.

HYPERCORTISOLISM (CUSHING DISEASE & CUSHING SYNDROME)

ESSENTIALS OF DIAGNOSIS

- ▶ Facial plethora, dorsocervical fat pad, supraclavicular fat pad, truncal obesity, easy bruisability, purple striae, acne, hirsutism, impotence or amenorrhea, muscle weakness, and psychosis.
- ▶ Hypertension, hyperglycemia, and osteopenia or osteoporosis.

General Considerations

Cushing syndrome is due to chronic glucocorticoid excess. It may be caused by excess ACTH stimulation or by adrenocortical tumors that secrete glucocorticoids independently of ACTH stimulation. Excess ACTH may be produced by pituitary adenomas (Cushing disease) or extrapituitary ACTH-producing tumors (ectopic ACTH syndrome). Cushing syndrome not dependent on ACTH is usually caused by primary adrenal diseases such as adrenocortical adenoma and micronodular or macronodular hyperplasia or carcinoma.

The natural history of Cushing syndrome depends on the underlying disease and varies from a mild, indolent disease to rapid progression and death.

Clinical Findings

A. Symptoms and Signs

See Table 33–1. The classic description of Cushing syndrome includes truncal obesity, hirsutism, moon facies, acne, buffalo hump, purple striae, hypertension, and diabetes, but other signs and symptoms are common. Weakness and

Table 33–1. Frequency of manifestations of hypercortisolism.

depression are striking features. Weakness and other features are also seen after prolonged and excessive administration of adrenocortical steroids.

In children, Cushing syndrome is most commonly caused by adrenal cancers, but adenomas and nodular hyperplasia have been described. Cushing syndrome in children also causes growth retardation or arrest.

B. Pathologic Examination

The pathologic features of the adrenal gland depend on the underlying disease. Normal adrenal glands weigh 7–12 g combined. The hyperplastic adrenal glands in patients with Cushing disease weigh less than 25 g combined. In ectopic ACTH syndrome, the combined adrenal weight is greater—from 25 to 100 g.

Adrenal adenomas in Cushing syndrome range in weight from a few grams to over 100 g, usually over 3 cm in diameter, and are larger than APAs. The typical cells usually resemble those of the zona fasciculata. Variable degrees of anaplasia are seen, and differentiation of benign from malignant tumors is often difficult on the basis of cytology alone. These adrenal adenomas occur more frequently in women. Adrenal cancers are frequently very large—almost always over 5 cm in diameter. They are undifferentiated, invade the surrounding tissues, and metastasize via the blood stream.

Rare forms of ACTH-independent Cushing syndrome include ACTH-independent macronodular adrenal hyperplasia, which in some cases is due to aberrant expression of

receptors in the adrenals that respond to stimuli other than ACTH. In these cases, the adrenal glands can be massively enlarged. Primary pigmented nodular adrenal disease or micronodular hyperplasia is associated with the syndrome of Carney complex that also includes cardiac myxoma and lentiginos.

Rarely, ectopic adrenal tissue can be the source of excessive cortisol secretion. It has been found in various locations, most commonly near the abdominal aorta.

Cushing disease is caused by pituitary adenomas.

Ectopic ACTH syndrome is usually caused by small-cell lung cancer and neuroendocrine tumors (carcinoid tumors) of the pancreas, thymus, thyroid, prostate, esophagus, colon, and ovaries. Pheochromocytoma and malignant melanoma may also secrete ACTH.

C. Laboratory Findings

Since no single test is specific, a combination of tests must be used.

Normal subjects have a circadian rhythm of ACTH secretion that is paralleled by cortisol secretion. Levels are highest in the early morning and decline during the day to their lowest levels in the late evening. In Cushing syndrome, the circadian rhythm is abolished, and total secretion of cortisol is increased. In mild cases, the plasma cortisol and ACTH levels may be within the normal range during much of the day but abnormally high in the evening.

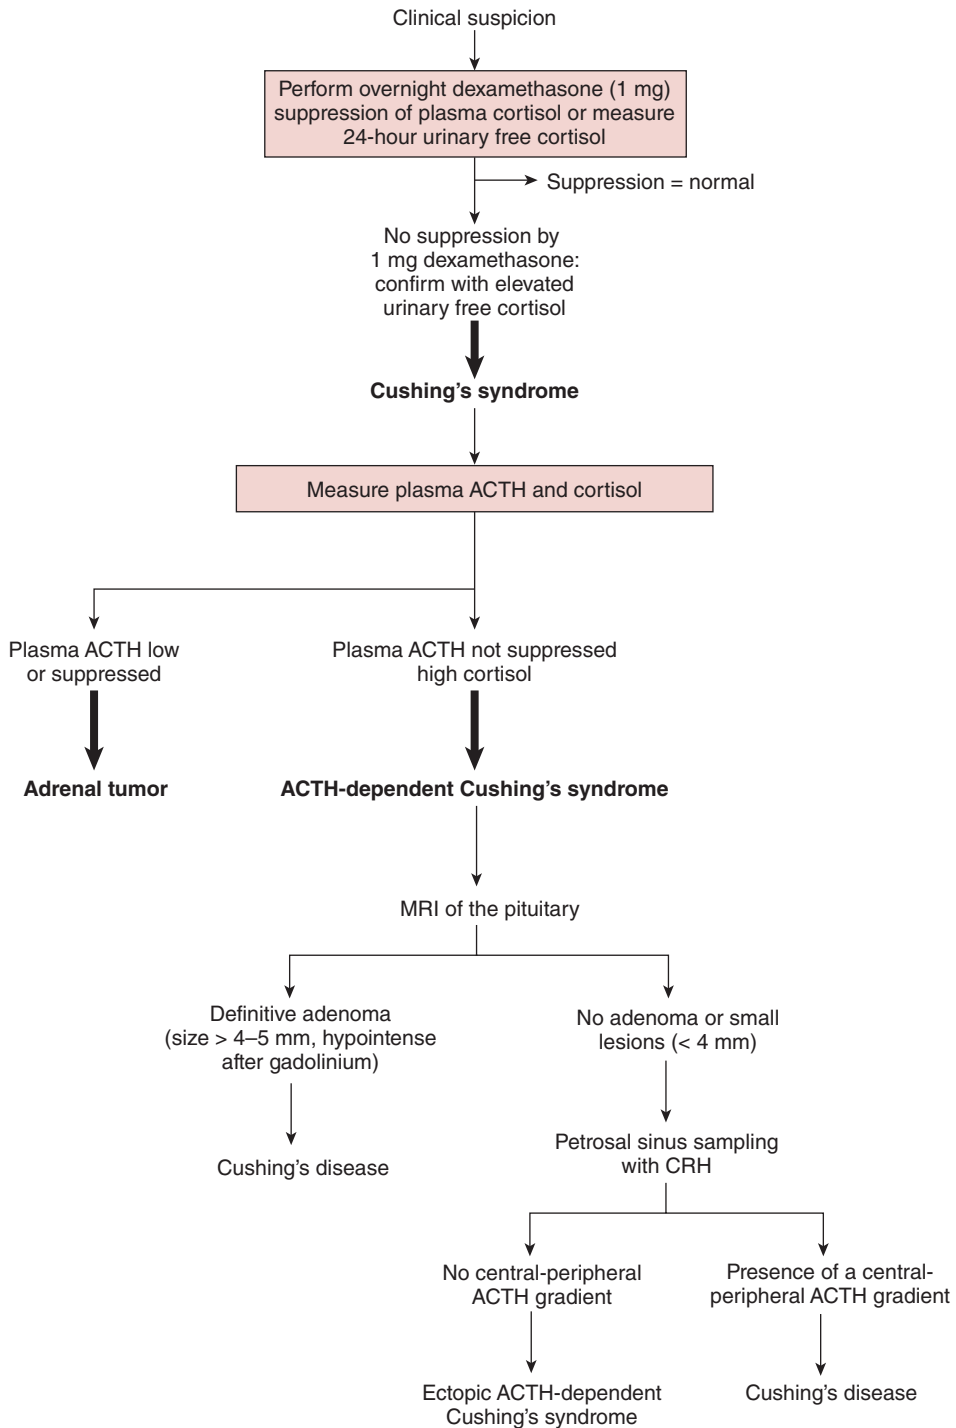

When Cushing syndrome is suspected, the first objective is to establish the diagnosis; the second is to establish the cause. An algorithm for the diagnosis is presented in Figure 33-3. When hypercortisolism is suspected, three tests are available as the initial tests to establish the diagnosis: overnight dexamethasone suppression test, measurement of 24-hour urinary free cortisol, and late night salivary cortisol sampling. Dexamethasone, 1 mg orally will suppress ACTH secretion and stop cortisol production in most healthy individuals. This low-dose dexamethasone, however, will not suppress excessive cortisol production from autonomous adrenocortical tumors or adrenals that are being stimulated by excess ACTH. Since dexamethasone does not cross-react in the assay for plasma cortisol, suppression of endogenous circulating cortisol is easily demonstrated. The test is done as follows: At 11 PM, the patient is given 1 mg of dexamethasone by mouth. A fasting plasma cortisol is measured the following morning between 8 and 9 AM. Suppression of plasma cortisol to 1.8 $\mu\text{g/dL}$ (50 nmol/L) or less excludes Cushing syndrome. Higher cutoff levels have been recommended, but some patients with mild ACTH-dependent Cushing syndrome may be suppressed easily; thus, the response is falsely negative and the diagnosis of Cushing syndrome is missed. On the other hand, this low cutoff level increases the likelihood of a false-positive result. False-positive results are more common in patients with depression, alcoholism,

physiologic stress, marked obesity, obstructive sleep apnea, or renal failure and in those taking estrogens or drugs that accelerate dexamethasone metabolism, such as phenytoin, rifampin, and phenobarbital. Estrogens increase cortisol-binding globulin and elevate total plasma cortisol concentrations. In these situations, measurement of 24-hour urinary free cortisol or salivary cortisol is preferred. Twenty-four-hour urinary cortisol directly measures the physiologically active form of circulating cortisol, integrates the daily variations of cortisol production, and is very sensitive and specific for the diagnosis of Cushing syndrome.

Late night salivary cortisol sampling can also assist in establishing the diagnosis of Cushing syndrome. The procedure involves chewing a cotton tube for 2-3 minutes between 11 PM and 12 AM. Salivary cortisol levels correlate highly with plasma and serum-free cortisol levels. One positive initial screening test result should be confirmed by a second initial screening test to establish the diagnosis. *Once the diagnosis of Cushing syndrome is established*, the next step is to determine the cause. Plasma ACTH measurement by immunoradiometric assay is the most direct method. A normal to elevated ACTH level is diagnostic of hypercortisolism due to pituitary adenoma or ectopic ACTH secretion. Suppressed ACTH levels are diagnostic of hypercortisolism due to a primary adrenal cause such as adenoma, carcinoma, or nodular hyperplasia.

The differential diagnosis of ACTH-dependent Cushing syndrome can be challenging. No test is perfect, and a combination of tests may be necessary. Since 90% of patients have Cushing disease, pituitary MRI is the first test to identify the source of ACTH secretion. However, 10% of normal adults have incidental pituitary lesions 3-6 mm in diameter on MRI, and many patients with Cushing disease have no detectable lesions. Lesions smaller than 3-4 mm are more likely to represent normal variation, artifacts, volume averaging, incidental nonfunctional adenomas, or cysts. An unequivocal pituitary lesion (ie, > 4-5 mm in diameter with decreased signal intensity on gadolinium) strongly suggests Cushing disease.

If the pituitary MRI does not show a definite lesion, the next step is inferior petrosal sinus sampling with corticotropin-releasing hormone (CRH) stimulation. Compared with other biochemical tests, such as high-dose dexamethasone suppression or CRH stimulation, petrosal sinus sampling is the most accurate way to identify an ACTH-secreting pituitary adenoma; the diagnostic accuracy is close to 100%. The test requires simultaneous bilateral venous sampling from the inferior petrosal sinuses. The inferior petrosal sinus connects the cavernous sinus to the jugular bulb and drains the pituitary. A central-to-peripheral ACTH ratio of 2 or greater without CRH stimulation is diagnostic of Cushing disease. CRH, 100 μg given intravenously as a bolus injection, can increase the diagnostic sensitivity to 100%; a peak central-to-peripheral ACTH ratio of 3 or greater is diagnostic of

▲ **Figure 33-3.** Cushing syndrome: diagnosis and differential diagnosis.

Cushing disease. The lack of a central-to-peripheral ACTH gradient is diagnostic of an ectopic ACTH-secreting tumor.

In Cushing syndrome caused by primary adrenal diseases, the plasma ACTH level is suppressed. Adenomas are usually 3-5 cm in diameter and secrete only cortisol. Adrenal carcinomas are typically larger than 5 cm in diameter, are usually rapidly progressive, and may cosecrete other hormones, such as adrenal androgens, deoxycorticosterone, aldosterone, and estrogens.

D. Imaging Studies

For Cushing syndrome caused by primary adrenal diseases, thin-section CT or MRI is able to detect virtually all of the adrenal tumors and hyperplasia. MRI of the sella is the imaging study of choice for pituitary adenomas. If a definitive adenoma is not seen, inferior petrosal sinus sampling with CRH stimulation can differentiate Cushing disease from ectopic Cushing syndrome. For ectopic Cushing syndrome, CT or MRI of the chest and abdomen may detect ACTH-secreting tumors. Bronchial carcinoids may be very small and difficult to find; high-resolution thin-cut CT of the chest is indicated. Occasionally, the source of an ectopic ACTH-secreting tumor cannot be determined (occult ectopic ACTH syndrome).

► Complications

Severe or lethal complications may result from sustained hypercortisolism, including hypertension, cardiovascular disease, stroke, thromboembolism, infection, severe debilitating muscle wasting, and weakness. Psychosis is common. Death may also be caused by the underlying tumors, such as adrenal carcinoma, small cell lung cancer, and others causing ectopic ACTH syndrome.

The truncal obesity and muscle weakness in patients with Cushing syndrome predispose them to postoperative pulmonary complications. Atrophic skin and easy bruisability also predict poor wound healing.

Nelson syndrome, the progression of an ACTH-secreting pituitary adenoma following bilateral adrenalectomy for Cushing disease, occurred in as many as 30% of patients in the era when bilateral adrenalectomy was used as primary therapy. However, since transsphenoidal resection has become the initial procedure of choice for Cushing disease, and because MRI now allows accurate diagnosis of pituitary adenomas larger than 5 mm, Nelson syndrome occurs in less than 5% of patients.

These tumors in patients with Nelson syndrome are among the most aggressive of pituitary tumors, causing sellar enlargement and extrasellar extension. Plasma ACTH levels are markedly elevated. Patients are frequently hyperpigmented and hypopituitary, with symptoms of mass effects including headaches, visual field deficits, and even

blindness from optic nerve compression. Removal of feedback control from hypercortisolism at the pituitary level probably explains the aggressiveness of these tumors.

► Treatment

Resection is the best treatment for cortisol-producing adrenal tumors or ACTH-producing tumors. Other treatment options may be necessary to temporarily control hypercortisolism—or for patients not cured by resection or when complete resection is impossible.

A. Excision of Pituitary Adenoma

Patients with Cushing disease are usually treated by transsphenoidal microsurgical excision of the pituitary adenomas. Relief of symptoms is rapid, and the prognosis for adequate residual pituitary-adrenal function is good. Total or subtotal hypophysectomy may be performed in older patients if a discrete tumor is not found. Pituitary procedures fail in about 15%-25% of patients because of failure to find the adenoma, pituitary hyperplasia, or recurrence of adenoma. When pituitary surgery fails, the disease may respond to pituitary irradiation. In some patients, medical therapy or total adrenalectomy will be necessary. Because of the effectiveness of pituitary microsurgery, radiotherapy is usually not recommended as primary treatment for Cushing disease.

B. Adrenalectomy

Compared with patients with other adrenal tumors, those with severe Cushing syndrome are at a higher risk for postoperative complications such as wound infection, hemorrhage, peptic ulceration, and pulmonary embolism. Adrenalectomy, however, is usually successful in reversing the devastating effects of hypercortisolism.

Laparoscopic adrenalectomy causes less morbidity than open adrenalectomy and is preferred for benign hyperplasia or adenomas. Laparoscopic adrenalectomy for adrenocortical carcinoma is technically challenging. If necessary, the operation should be converted to laparotomy to achieve complete tumor resection without breaching the capsule. Local recurrence may be more common after laparoscopic resection for large and invasive cancer, especially if the capsule is breached during dissection.

Unilateral adrenalectomy is indicated for adrenal adenomas or carcinomas that secrete cortisol. The contralateral adrenal gland and the hypothalamic-pituitary-adrenal axis will usually recover from the suppression 1-2 years after the operation. Subtotal resection is not indicated because adenoma and carcinoma may not be readily distinguishable.

Total bilateral adrenalectomy is indicated for selected patients with Cushing disease or ectopic ACTH syndrome in whom the ACTH-secreting tumor cannot be found or resected. It is also indicated for patients with bilateral

primary adrenal disease, such as pigmented micronodular hyperplasia or massive macronodular hyperplasia.

Bilateral adrenalectomy can almost always be accomplished by the laparoscopic approach.

Subtotal resection is not recommended in patients with Cushing syndrome, because it usually leaves inadequate adrenocortical reserve initially, and the disease frequently recurs with continuing ACTH stimulation. Total bilateral adrenalectomy with adrenal gland autotransplantation is rarely successful and offers little advantage over pharmacologic replacement.

C. Medical Treatment

Drugs are mainly used as adjuvant therapy. Hypercortisolism may be controlled with ketoconazole, metyrapone, or aminoglutethimide, all of which inhibit steroid biosynthesis. Ketoconazole is usually the first choice. A combination of drugs may be necessary to control hypercortisolism and to decrease dose-related side effects.

Mifepristone (RU 486), a progesterone and glucocorticoid receptor antagonist, is also effective, but it raises cortisol and ACTH levels, making it difficult to monitor the patient. Experience with the medication is still limited.

Mitotane is a dichlorodiphenyltrichloroethane derivative that is toxic to the adrenal cortex. It has been used with modest success in the treatment of adrenal hypersecretory states, especially adrenocortical carcinoma. Unfortunately, serious side effects are common at effective doses.

Pasireotide, a somatostatin analog, and cabergoline, a dopamine receptor (type 2) agonist, may be effective in controlling hypercortisolism in small subsets of patients with Cushing disease. Frequently, a combination of drugs is needed.

D. Postoperative Maintenance Therapy

For patients who require total adrenalectomy, lifelong corticosteroid maintenance therapy becomes necessary after total adrenalectomy. The following schedule is commonly used: no cortisol is given until the adrenals are removed during surgery. On the first day, give 50 mg of hydrocortisone intravenously every 6-8 hours. On the second day, give 25 mg every 6-8 hours. Thereafter, the dose should be tapered as tolerated. The same tapering process is used after excision of a unilateral cortisol-secreting adenoma, because the remaining adrenal may not function normally for months.

As the hydrocortisone dose is reduced below 50 mg/d, it is often necessary to add fludrocortisone (a mineralocorticoid), 0.1 mg daily orally if patients had bilateral adrenalectomy. The usual maintenance doses are about 15-20 mg of hydrocortisone and 0.1 mg of fludrocortisone daily. More than half the hydrocortisone dose is given in the morning.

Patients who have had a total bilateral adrenalectomy and are on maintenance therapy can develop Addisonian crisis

when under stress, such as general anesthesia or infection. Adrenal insufficiency causes fever, hyperkalemia, abdominal pain, and hypotension, and should be promptly recognized and treated with saline infusion and cortisol.

► Prognosis

The prognosis is good after resection of benign adrenal adenomas, pituitary adenomas, or benign ACTH-secreting tumors. Patients with Cushing disease in remission after pituitary surgery have reversal of excess mortality. Symptoms and signs of hypercortisolism resolve, usually over months. Short-term adrenal insufficiency after surgery requires cortisol replacement. Cushing disease can recur after excision of a pituitary adenoma. An occult ACTH-secreting tumor may become apparent later and require removal.

Residual adrenal tissue or embryonic rests are present in up to 10% of patients after total adrenalectomy. Cushing syndrome can then recur if stimulation with ACTH continues.

The prognosis is extremely poor in patients with adrenocortical carcinoma and in those with malignant tumors causing ectopic ACTH syndrome.

VIRILIZING ADRENAL TUMORS

In adults, hormonally active benign adrenal adenomas usually secrete aldosterone or cortisol. Virilizing tumors in women are more likely to be caused by ovarian tumors. Virilizing adrenal tumors are rare, and virilization is usually due to hypersecretion of adrenal androgens, mainly dehydroepiandrosterone (DHEA), its sulfate derivative (DHEAS), and androstenedione, all of which are converted peripherally to testosterone and 5-dihydrotestosterone. Very rarely, virilizing adrenal tumors secrete only testosterone.

The differentiation of benign from malignant adrenocortical tumors may be difficult when based on histologic features; some patients with histologically benign tumors may develop metastases, and others with histologically malignant

tumors may never have recurrent disease. Malignancy is only definitely diagnosed from local or distant spread. Seventy percent of virilizing adrenal tumors exhibit malignant behavior. Adrenocortical carcinomas are usually large tumors with local spread or distant metastases. They often secrete multiple steroids, most commonly cortisol and androgens, leading to Cushing syndrome and virilization.

In children, adrenocortical tumors are rare, but virilization with or without hypercortisolism is the most frequent feature. Virilizing adrenal tumors are less likely to be malignant in children than in adults. Histologic features of malignancy do not always predict malignant behavior. Large tumors (> 100 g) have a worse prognosis.

Signs and symptoms of virilization include hirsutism, male-pattern baldness, acne, deep voice, male musculature, irregular menses or amenorrhea, clitoromegaly, and increased libido. Rapid linear growth with advanced bone age is common in children.

CT and MRI are used to image virilizing adrenal tumors. Resection is the only successful treatment.

Virilization can also be caused by congenital adrenal hyperplasia, an autosomal recessive disorder. The mutated genes encode enzymes essential for cortisol and mineralocorticoid synthesis. 21-Hydroxylase deficiency accounts for 90% of cases. The inhibition of cortisol synthesis leads to stimulated ACTH secretion, accumulation of precursors, and overproduction of androgens. Administration of glucocorticoids is the mainstay of treatment in patients with classic congenital adrenal hyperplasia. Mineralocorticoid replacement is also required. Corrective surgery may be needed in female infants born with ambiguous genitalia. The combination of antiandrogens, aromatase inhibitors, and lower dose glucocorticoid replacement to minimize the effect of excess androgen is being investigated. Adrenalectomy with lifelong steroid replacement is another approach in the most severely affected patients.

FEMINIZING ADRENAL TUMORS

Estrogens are not normally synthesized by the adrenal cortex. Feminizing adrenal tumors are extremely rare and are almost always carcinomas. They are usually seen in men with feminization or in girls with precocious puberty. Vaginal bleeding may be the presenting symptom in adult women. Feminizing adrenal carcinomas frequently hypersecrete other hormones. The diagnosis is based on a finding of increased plasma estrogens. Ovarian tumors and administration of exogenous estrogen should be ruled out.

Definitive treatment is excision of the tumor. The prognosis is guarded.

Cavlan D et al: Androgen- and estrogen-secreting adrenal cancers. *Semin Oncol* 2010;37:638.

ADRENOCORTICAL CARCINOMA

Adrenocortical carcinomas are rare. More than half of patients have symptoms related to hypersecretion of hormones, most commonly Cushing syndrome and virilization. Feminizing and purely aldosterone-secreting carcinomas are rare. In some cases, hormone hypersecretion is subclinical and only found by biochemical studies. The adrenal mass may be palpable. The mean diameter of adrenal carcinoma is 12 cm (range, 3-30 cm). Adrenocortical carcinoma invades the surrounding tissues, and about half of the patients have metastases (lung, liver, and elsewhere) at the time of diagnosis. In those without local spread or distant metastases, a diagnosis of carcinoma based on cytologic features may be wrong.

The median survival is 25 months, and 5-year actuarial survival is 25%. Tumor stage at the initial operation predicts the prognosis. Surgery is the only treatment that potentially provides a cure; however, beneficial outcomes are confined to patients with localized disease. When grossly complete resection is possible, the 5-year survival is 50%. Thus, recurrence is common despite apparent complete resection due to micrometastases at initial presentation. Laparoscopic adrenalectomy is technically more difficult for adrenocortical carcinomas than for other adrenal tumors because the tumor is fragile and adjacent organs may have to be removed. Where the adrenal tumor is small, malignancy is uncertain, and the surgeon is technically capable, starting the operation laparoscopically is acceptable. However, the surgeon should have a low threshold for converting to open or hand-assisted adrenalectomy if a better operation could be accomplished that way. For local recurrent disease, reoperation is indicated and may prolong life. Patients with distant metastases at initial presentation usually die within 1 year. Resecting the adrenal tumor in these patients does not improve survival.

Mitotane, an adrenolytic agent, has been used as an adjuvant to surgery in patients with advanced adrenocortical carcinoma. It controls endocrine symptoms in 50% of patients, and the tumor regresses in some. Some cases of prolonged remission have been reported.

In patients who underwent complete primary resection, older reports of routine adjuvant mitotane therapy postoperatively did not confer definitive benefits. However, a recent large retrospective study showed that mitotane improved recurrence-free survival. Dose-related side effects (eg, gastrointestinal symptoms, weakness, dizziness, and somnolence) may limit its use. A variety of other chemotherapeutic agents has been tried with limited success. A recently completed international multicenter prospective randomized study showed combination chemotherapy of etoposide, doxorubicin, and cisplatin plus mitotane improved the rates of response and progression-free survival over that of mitotane plus streptozocin.

The role of radiation is limited and usually is for palliation, especially for bony metastases.

INCIDENTALOMAS

Adrenal tumors have traditionally been diagnosed after presentation with clinical symptoms of excess hormone secretion. However, the increased use of ultrasonography, CT, and MRI for various diseases in the abdomen has led to the discovery of what are referred to as adrenal incidentalomas. Most are small nonfunctioning adrenal cortical adenomas; some are functioning adenomas or pheochromocytomas with subclinical secretion of hormones; and some are adrenocortical carcinomas or metastases.

Incidentalomas are found in 4% of CT scans and 6% of random autopsies. The incidence increases with age. Based on a review of 10 studies, subclinical Cushing syndrome and Cushing syndrome account for 6.4% of incidentalomas, pheochromocytoma 3.1%, adrenocortical carcinoma 1.8%, metastatic carcinoma 0.7%, and aldosteronoma for 0.6% (Table 33–2). Thus, 90% of the patients have presumed nonfunctioning cortical adenomas. Simple adrenal cysts, myelolipomas, and adrenal hemorrhages can be identified by the CT characteristics alone. Adrenal cysts can be large but are rarely malignant. Adrenal hemorrhage may occur in preexisting adrenal tumors.

The major issues in managing a patient with an incidentaloma is to determine whether the tumor is hormonally

active and whether it is a cancer; either would be an indication for resection. All functioning tumors should be excised. Large nonfunctioning tumors also should be excised because of the increased risk of cancer. Small nonfunctioning tumors are almost always benign adenomas; they can be followed with serial CT scans checking for changes in size. Since most incidentalomas are nonfunctioning adenomas, the workup should be selective to avoid unnecessary expense and procedures.

The workup should include a complete history and physical examination with specific reference to a history of previous malignancy and signs and symptoms of Cushing syndrome or pheochromocytoma. Hyperaldosteronism, pheochromocytoma, and virilizing or feminizing adrenocortical carcinoma should be investigated. Further laboratory studies may be indicated depending on the clinical presentation.

All patients—even those who do not have hypertension—should have a 24-hour urine collection for fractionated catecholamines and metanephrines or plasma free metanephrines to search for pheochromocytoma; the risk of unrecognized pheochromocytoma is high, and the hypertension may be absent or episodic. Most pheochromocytomas are over 2 cm in diameter and characteristically bright on T2-weighted MRI. *Almost half of pheochromocytomas are found incidentally because of CT or MRI scans obtained for other indications.*

Subclinical Cushing syndrome refers to autonomous cortisol secretion in patients without typical signs and symptoms of Cushing syndrome. Autonomous cortisol secretion is best assessed by overnight 1 mg dexamethasone suppression test.

Patients with subclinical Cushing syndrome may experience an Addisonian crisis if the tumor is resected and glucocorticoid replacement is not adequate.

Patients who are hypertensive should also have plasma aldosterone and PRA measured to screen for primary hyperaldosteronism.

If the above studies show that the tumor is nonfunctional, the size and imaging characteristics of the tumor and the patient's overall medical condition should determine the appropriate treatment. Nonfunctioning adrenal tumors larger than 5 cm in diameter should usually be removed because of higher risk of cancer. Nonfunctioning adrenal tumors smaller than 3 cm that are homogeneous and have low density on CT or MRI are unlikely to be cancers and can be safely followed. The patient's age and overall medical condition and the CT scan findings will usually determine whether a tumor 3–5 cm in size should be resected. High density, delayed wash out of contrast, irregular borders, and heterogeneity make pheochromocytoma, adrenocortical carcinoma, and metastases more likely.

In patients with a previously treated malignancy such as lung or breast cancer, the chance of an adrenal tumor being

Table 33–2. Adrenal incidentalomas.¹

Tumor Types	Percentage (%)
Subclinical Cushing/Cushing	6.4
Pheochromocytoma	3.1
Adrenocortical carcinoma	1.9
Metastatic carcinoma	0.7
Aldosterone-producing adenoma	0.6
Presumed nonfunctional adenoma	89.9
Total	100

¹Based on data reported in *Eur J Endocrinol* 2009;161:513.

metastatic is greater than 50% and even greater if the adrenal mass is larger than 3 cm. CT-guided fine-needle aspiration biopsy is rarely necessary, but can be used to diagnose metastatic cancer if it will change management of the patient. Fine-needle aspiration of an adrenocortical cancer may not be diagnostic, and breaching the capsule risks local spread of cancer. Needle biopsy of an unexpected pheochromocytoma can precipitate pheochromocytoma crisis. Biochemical screening for pheochromocytoma should be performed prior to biopsy. Resection of a solitary adrenal metastasis from a primary lung cancer may improve long-term survival (to about 25% at 5 years) if there are no other clinically obvious metastases. Patients with a metachronous solitary adrenal metastasis are more likely to benefit from adrenalectomy than are those with a synchronous metastasis. Patients with adrenal metastases from melanoma or renal cell carcinoma also benefit from resection even when there are other foci of metastases. Adrenal metastasis can be resected laparoscopically with minimal risk of local recurrence.

MULTIPLE CHOICE QUESTIONS

- The most common approach to resect a 3-cm functioning adrenal tumor is via
 - Laparoscopy
 - Laparotomy
 - Flank incision
 - Posterior incision
 - Thoracoabdominal incision
- The most sensitive and specific test for diagnosis of pheochromocytoma is
 - Plasma free catecholamines
 - 24-hour urinary VMA
 - 24-hour urinary catecholamines
 - Plasma free metanephrines
 - Plasma free VMA
- The workup of an adrenal incidentaloma includes the following, except
 - Measurement of 24-hour urinary fractionated metanephrines
 - Measurement of 24-hour urinary cortisol and creatinine
 - Fine-needle biopsy of the adrenal tumor
 - Plasma aldosterone level and renin activity
 - Obtain family history of adrenal disease
- Laparoscopic adrenalectomy is usually NOT indicated for
 - An aldosteronoma
 - A feminizing tumor
 - A pheochromocytoma
 - A metastasis from melanoma
 - A symptomatic myelolipoma
- Adrenal tumors can secrete the following, except
 - Normetanephrine
 - Aldosterone
 - Cortisol
 - DHEAS
 - 5-HIAA

Arteries

Joseph H. Rapp, MD
Warren Gasper, MD

Arterial disease can be broadly classified into two categories: occlusive and aneurysmal. The major sequelae of arterial obstruction are tissue ischemia and necrosis, while those of aneurysmal disease are rupture and hemorrhage in the aortic position and thrombosis and embolization in the peripheral arteries.

ARTERIAL OCCLUSIVE DISEASE

Although atherosclerosis is the dominant cause of arterial occlusive disease in Western countries, other etiologies such as congenital and anatomical anomalies, auto immune diseases, and remote thromboembolism can also result in arterial obstruction. Symptoms of occlusive vascular disease primarily are end-organ dysfunction and, in the muscle beds, pain with exercise and tissue necrosis.

ATHEROSCLEROSIS

Atherosclerosis can occur in any artery, with plaques most commonly developing in areas of low shear stress, such as at arterial branch points. Lesions are usually symmetrically distributed, although the rate of progression may vary. Early lesions are confined to the intima. In advanced lesions, both intima and media are involved, but the adventitia is spared. Preservation of the adventitia is essential for the vessel's structural integrity and is the basis for all cardiovascular interventions.

When the hemodynamically significant disease affects a major artery, a parallel system of collateral vessels may preserve flow to the peripheral runoff bed. Collateral vessels are smaller, more circuitous, and always have a higher resistance than the original unobstructed artery. The stimuli for collateral development include abnormal pressure gradients across the collateral system and increased flow velocity through intramuscular channels that connect to reentry vessels. Adequate collateral vessels take time to develop but

often maintain tissue viability in patients with chronic major arterial occlusions.

Generally, arterial insufficiency occurs in medium-sized and large arteries with at least a 50% reduction in arterial diameter. This correlates with a 75% narrowing of cross-sectional area and enough resistance to decrease downstream flow and pressure. Early in the process, compensatory dilation of the vessel wall may preserve lumen diameter as the atherosclerotic lesion develops, but with continued growth, lesions overcome this adaptation and result in flow limiting stenoses. If there is adequate collateral flow, single stenoses or even occlusions are reasonably well-tolerated. Severe ischemia occurs when there are inadequate collaterals or there are multiple levels of disease.

CHRONIC LOWER EXTREMITY OCCLUSIVE DISEASE

General Considerations

Peripheral arterial insufficiency is predominantly a disease of the lower extremities. Upper extremity arterial lesions are uncommon and confined mostly to the subclavian arteries. Even when present, upper extremity atherosclerosis rarely produces symptoms due to abundant collateral pathways. In the lower extremities, however, obstructive lesions are distributed widely, with lesions of the superficial femoral and iliac arteries the most common (Figure 34-1). Symptoms are related to the location and number of obstructions.

Peripheral arterial disease affects at least 20% of individuals older than 70 years with the incidence increasing with

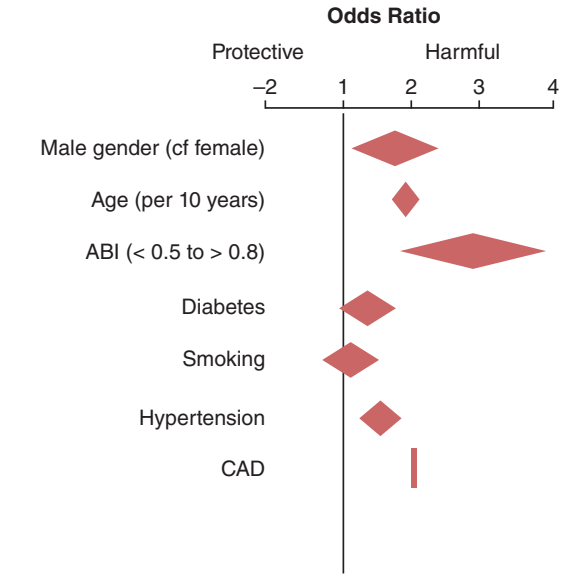

▲ **Figure 34-1.** Common sites of stenosis and occlusion of the visceral and peripheral arterial systems.

the increasing incidence of diabetes. Although most patients with this disorder do not develop gangrene or require amputations, adverse outcomes of systemic atherosclerosis, including myocardial infarction and/or stroke, are common. Even after adjustment for known risk factors, individuals with peripheral arterial disease exhibit a several-fold higher risk of mortality than the nonaffected population. A low ankle-brachial index (ABI) is one of the strongest risk factors for all-cause mortality. Peripheral arterial disease is more a marker of a more virulent form of atherosclerosis and early death from cardiovascular or cerebrovascular disease than an indicator of imminent limb loss; thus, identifying and treating associated atherosclerotic risk factors is essential (Figure 34-2).

► **Clinical Findings**

A. Symptoms

1. Intermittent claudication—Intermittent claudication refers to pain in muscles of the lower extremity associated with walking and relieved by rest. Because tissue perfusion is adequate at rest, tissue loss is not present and the risk of amputation is low unless there is progression of disease. Claudication is derived from the Latin word meaning “to limp”; therefore, the term should be used only for symptoms in the lower extremities. The pain is a deep-seated ache usu-

▲ **Figure 34-2.** Odds ratios for risk factors for all-cause mortality. ABI, ankle-brachial index; CAD, coronary artery disease. (Reproduced, with permission, from TASC Working Group: Dormandy JA et al. Management of peripheral arterial disease: epidemiology, natural history, risk factors. *J Vasc Surg.* 2000 Jan;31[1 Pt 2]:S1-S296.)

ally in the calf muscle, which gradually progresses until the patient is compelled to stop walking. Patients occasionally describe “cramping” or “tiredness” in the muscle. Typically, symptoms are completely relieved after 2–5 minutes of inactivity. Claudication is distinguished from other types of pain in the extremities in that it does not occur at rest and some period of exertion is always required before it appears, it generally occurs after a relatively consistent distance traveled, and it is relieved by cessation of walking. Relief of symptoms is not dependent upon sitting or other positional change. The severity of claudication is traditionally expressed in terms of city blocks.

Regardless of which arterial segment is involved, claudication most commonly involves the calf muscles because of their high workload with the mechanics of normal walking. Occlusions proximal to the origin of the profunda femoris can extend the pain to involve the thigh. Gluteal pain indicates lesions in or proximal to the hypogastric arteries and is often accompanied by impotence. **Leriche syndrome** occurs in men with aortoiliac disease and includes claudication of calf, thigh, and buttock muscles; erectile dysfunction; and diminished or absent femoral pulses. Occasionally, patients describe transient numbness of the extremity accompanying the pain and fatigue of claudication as nerves as well as muscles become ischemic.

The two conditions that most often mimic claudication are osteoarthritis of the hip or knee and neurospinal compression due to congenital or osteophytic narrowing of the lumbar neurospinal canal (spinal stenosis). Osteoarthritis can be differentiated from claudication because pain occurs predominantly in joints, the amount of exercise required to elicit symptoms varies, symptoms are characteristically worse in the morning and upon initiating exercise, rest does not relieve symptoms promptly, the severity of symptoms changes from day to day, and anti-inflammatory agents may relieve the pain. Impingement on the spinal canal or nerve root produces neurospinal compression symptoms; therefore, the pain is typically burning in nature and symptoms may occur with sitting or standing. Neurospinal pain often follows a dermatomal distribution, a key factor in differentiating this from claudication.

Uncommon conditions such as coarctation of the aorta, chronic compartment syndrome, popliteal artery entrapment, and vasculitis can mimic symptoms of atherosclerotic arterial insufficiency. Age at presentation and associated findings may aid in diagnosing these conditions.

The correct diagnosis of vascular claudication should be easily established by determining the location of pain with exercise (calf), the quality of the pain (aching or cramping), the length of time required for relief of symptoms after stopping exercise (immediate), the reproducibility of the distance walked before symptoms begin (initial claudication distance), and most importantly, the reduction or loss of pulses with exercise.

2. Critical limb ischemia—With extensive disease, patients develop ischemic rest pain and/or ulceration. Ischemic rest pain, a grave symptom caused by ischemic neuritis, indicates advanced arterial insufficiency that carries a risk of gangrene and amputation if arterial reconstruction cannot be performed. The pain is severe and burning, usually confined to the forefoot distal to the metatarsals. It may be localized to the vicinity of an ischemic ulcer or pregangrenous toe. It is aggravated by elevation of the extremity or by bringing the leg to the horizontal position. Thus, it appears at bed rest (hence the name) and may prevent sleep. Because gravity aids the delivery of arterial blood, classically, the patient with rest pain can obtain relief by simply hanging the leg over the side of the bed. This simple maneuver will differentiate ischemic rest pain from peripheral neuropathy, which is associated with diabetes and is the most common cause of foot pain at rest. In patients who must keep the foot constantly dependent to relieve pain, the leg and foot may be swollen, causing some confusion in diagnosis. The ischemic neuritis of rest pain is severe and resistant to opioids for relief.

Patients with rest pain may give a history of claudication, but rest pain also may occur de novo in diabetics with distal tibial disease, embolic occlusion of the distal tibial arteries, and patients whose walking is limited by other conditions.

Differentiating ischemic rest pain from neuropathy in diabetics is critical and may require vascular testing to clarify the diagnosis.

3. Nonhealing wounds or ulcers—Patients with severe lower extremity arterial insufficiency often develop ulcers or wounds on the feet even from seemingly trivial trauma. These lesions are most commonly located on the distal foot and toes, but on occasion they can be in the upper foot or ankle. Typically, the wounds are excruciatingly painful, deep, and devoid of any evidence of healing such as contraction or formation of granulation tissue.

4. Erectile dysfunction—Inability to attain or maintain an erection may be produced by lesions that obstruct blood flow through both hypogastric arteries and is commonly found in association with narrowing of the terminal aorta, common iliac, or hypogastric arteries. Vasculogenic erectile dysfunction is less common than that due to other causes.

5. Sensation—Although the patient may report numbness in the extremity, sensory abnormalities are generally absent on examination. If decreased sensation is found in the foot, peripheral neuropathy should be suspected.

B. Signs

Physical examination is of paramount importance in assessing the presence and severity of vascular disease. The physical findings of peripheral atherosclerosis are related to changes in the peripheral arteries and to tissue ischemia.

1. Arterial palpation—Decreased amplitude of the pulse denotes proximal obstructions to flow. The pulse examination can help localize disease. For example, an absent femoral pulse usually signifies aortoiliac disease. It is unusual for collateral flow to be sufficient to produce a pulse distal to an occluded artery.

2. Bruits and thrills—A bruit is the sound produced by dissipation of energy as blood flows through a stenotic arterial segment. With extremely high flows, the energy may vibrate the artery, creating a “thrill.” The bruit or thrill is transmitted distally along the course of the artery. Thus, when a bruit is heard through a stethoscope placed over a peripheral artery, stenosis is present at or proximal to that level. The pitch of the bruit rises as the stenosis becomes more marked, until a critical stenosis is reached or the vessel becomes occluded, when the bruit may disappear. Thus, absence of a bruit does not indicate insignificant disease.

3. Response to exercise—Exercise in a normal individual increases the pulse rate without producing arterial bruits or reduction in pulse amplitude. In an individual who complains of claudication, there may be minimal findings at rest, but exercise will produce decreased pulse strength, decreased distal arterial pressure, and possibly an audible

bruit unmasking a significant stenosis. Exercise is best used in conjunction with noninvasive vascular testing.

4. Integumentary changes—Chronic ischemia commonly produces loss of hair over the dorsum of the toes and foot and may be associated with thickening of the toenails (onychomycosis) due to slowed keratin turnover. With more advanced ischemia, there is atrophy of the skin and subcutaneous tissue so that the foot becomes shiny, scaly, and skeletonized.

5. Pallor—Pallor of the foot on elevation of the extremity to approximately 40 cm with a complete absence of capillary refill indicates advanced ischemia. Pallor on elevation does not occur unless advanced ischemia is present. It is always present with ischemic rest pain.

6. Reactive hyperemia—When pallor is produced with elevation, the ischemia results in maximum cutaneous vasodilation. When the extremity is returned to a dependent position, blood returning to the dilated vascular bed produces an intense red or possibly ruborous color in the foot, called reactive hyperemia, and denotes advanced disease. The delay in the appearance of color when the extremities return to a dependent position is proportionate to the impairment in circulation.

7. Rubor—In advanced atherosclerotic disease, the skin of the foot displays a characteristic dark red/cyanotic color on dependency. Because of low inflow, the blood in the capillary network of the foot is relatively stagnant, oxygen extraction is high, and the capillary blood becomes the color of the venous blood. The concurrent vasodilation due to ischemia causes blood to suffuse the cutaneous plexus, imparting a purple color to the skin. The purple discoloration due to severe chronic venous insufficiency does not give way to pallor on elevation.

8. Skin temperature—With chronic ischemia, the temperature of the skin of the foot decreases. Coolness can best be detected by palpation with the back of the examiner's hand with comparison to the contralateral foot.

9. Ulceration—Ischemic ulcers are usually very painful and accompanied by rest pain in the foot. They occur in toes or at a site where minor trauma can initiate the injury. The margin of the ulcer is sharply demarcated or punched-out, and the base is devoid of healthy granulation tissue. The surrounding skin is pale and mottled, and signs of chronic ischemia are invariably present.

10. Atrophy—Moderate to severe degrees of chronic ischemia produce gradual soft tissue and muscle atrophy and loss of strength. Joint mobility and gait may be altered due to muscle atrophy. Subsequent changes in foot structure and gait increase the possibility of developing foot ulceration.

11. Necrosis—Severe tissue ischemia may progress to necrosis with minor injuries, infection, or swelling. Necrosis halts proximally at a line where the blood supply is sufficient to maintain viability and results in dry gangrene. If the necrotic portion is infected (wet gangrene), necrosis may extend into tissues that would normally remain viable.

C. Noninvasive Vascular Laboratory Tests

Noninvasive assessment is helpful to determine the severity of hypoperfusion and the sites of hemodynamically significant stenoses or occlusions.

The **ankle-brachial index** is a quick screening test and the cornerstone of the diagnosis of peripheral vascular disease. The ABI is determined by dividing the systolic pressure obtained by Doppler insonation at the ankle by the brachial arterial pressure. Normally, the ABI is 1.0 or greater; a value below 1.0 indicates occlusive disease proximal to the point of measurement. The ABI correlates roughly with the degree of ischemia (eg, claudication occurs with a value less than 0.7 and rest pain usually appears when the ratio is 0.3 or lower). Elderly patients or patients with diabetic vascular disease may have artificially elevated ABI values due to calcified, noncompressible arteries, and toe-to-brachial pressure ratios should be substituted.

Blood pressures can be measured at rest and after exercise in the ankle, and the effect of exercise can be monitored. **Exercise testing** confirms and quantitates the diagnosis of claudication. To perform exercise testing, the patient walks on a treadmill at a standard speed and grade until claudication pain is experienced or a time limit is reached. With significant arterial occlusive disease, there will be a decrease in the ABI with exercise, usually measured 1 minute after cessation of walking. If the pain is not due to arterial stenosis, no fall in pressure will occur. This test is particularly useful in differentiating neurogenic pain with walking from claudication.

D. Imaging Studies

Color duplex ultrasound imaging is a mainstay of vascular imaging. It is a painless, relatively inexpensive, and (in experienced hands) accurate method for acquiring anatomic and functional information (eg, velocity gradients across stenoses). Although the accuracy of this study is operator dependent, it can supply sufficient information to permit intervention in selected cases.

CT angiography (CTA) is useful for imaging the arterial tree and has the advantage of visualizing cross-sections of the vessel lumen. In many instances, this allows for more accurate determination of vessel diameter and stenosis severity than conventional angiography. It does require the administration of nephrotoxic contrast dye, it is less useful for tibial disease, and its images may be obscured by the presence of calcification or metallic implants. **MR angiography (MRA)**

also can be used to obtain images similar in quality to angiography in most cases. MRA does not show calcifications and gives better visualization of tibial vessels than CTA. MRA also can reveal details of composition of atherosclerotic plaque. Gadolinium-associated nephrogenic fibrosing dermopathy limits its use in patients with renal insufficiency. The integrated use of computer workstations with CT and MR image data can provide three-dimensional (3D) images that can be useful in visualizing patient anatomy and planning interventional procedures.

Conventional arteriography provides detailed anatomic information about peripheral arterial disease. It is reserved for patients warranting invasive intervention such as percutaneous transluminal angioplasty (often shortened to PTA) or vascular surgery. Complications of angiography are related to technique and contrast media. Technical complications such as puncture site hematomas, arteriovenous fistulas, and false aneurysms are rare (1%). Contrast agents may precipitate allergic reactions (0.1%). Patients with renal failure, proteinuria, diabetes, and dehydration are at increased risk for contrast-induced renal failure. Adequate hydration of patients before and after angiography, acetylcysteine, and periprocedural infusions of sodium bicarbonate infusions may reduce the incidence of this complication.

► Treatment & Prognosis

The objectives of treatment for lower extremity occlusive disease are relief of symptoms, prevention of limb loss, and maintenance of bipedal gait.

A. Nonoperative Treatment

In general, patients with peripheral vascular disease have shortened life expectancies because of their severe atherosclerotic disease. Nondiabetic patients with ischemic disease of the lower extremity have a 5-year survival rate of 70%. The survival rate is 60% in patients with associated ischemic heart disease or cerebrovascular insufficiency. Patients with peripheral vascular disease and renal failure have a 2-year survival rate of less than 50%. Most deaths are due to myocardial infarctions and strokes. Only 20% of deaths are due to nonatherosclerotic causes.

Nonoperative treatment consists of (1) medical management of cardiovascular risk factors, (2) exercise rehabilitation, (3) foot care, and (4) pharmacotherapy.

1. Reduction of cardiovascular risk factors—See Table 34–1. Cigarette smoking is the single most important risk factor for peripheral vascular disease, and all patients should stop smoking. At high levels of consumption, 2–3 packs per day, claudicants will experience immediate improvement in walking distance.

In the past, elevated lipids were not usually associated with peripheral vascular disease. Hyperlipidemia, however, is often present, especially in patients with early onset of disease. Elevated triglyceride levels and low high-density

Table 34–1. Summary of risk factor modification in peripheral vascular disease.

Risk Factor	Therapy	Clinical Effect
Tobacco use	Counseling Pharmacotherapy Nicotine replacement Bupropion, varenicline	Reduced overall mortality Reduced cardiovascular events
Antiplatelet	Aspirin Clopidogrel (Plavix)	Antiplatelet therapy gives > 20% reduction in MI, stroke, or vascular death
Hyperlipidemia	Statin Lipid goals in PAD patients: LDL < 100 mg/dL	20–30% reduction in cardiovascular and all-cause mortality in CAD patients
Hypertension	Target BP < 140/90 in PAD patients Beta-blocker ACE inhibitor	Beta-blocker and ACE inhibitors each associated with > 20% reduction in cardiovascular mortality
Diabetes	Goal hemoglobin A1c < 7%	Benefits in vascular disease unproven
Lifestyle	Daily aerobic exercise Weight loss Healthy, low-fat diet	Reduced lipid levels Reduced cardiovascular events

ACE, angiotensin converting enzyme; BP, blood pressure; CAD, coronary artery disease; LDL, low-density lipoprotein; MI, myocardial infarction; PAD, peripheral artery disease.

lipoprotein (HDL) cholesterol levels are more prevalent than elevated levels of low-density lipoprotein (LDL) cholesterol. Reduction of elevated lipid levels is associated with stabilization or regression of arterial plaques. Statins are extremely effective in reducing LDL cholesterol, and goals of therapy for patients with peripheral vascular disease are to maintain cholesterol levels at less than 100 mg/dL (2.6 mmol/L). Statins have other pleiotropic effects that may reduce inflammation, stabilize plaques, and independently increase walking distance in claudicants. Other antihyperlipidemic medications, including niacin and fibrates (gemfibrozil), may be used to lower hypertriglyceridemia, which can increase HDL cholesterol.

Both type 1 and type 2 diabetes increase the prevalence and severity of cardiovascular disease. Intensive glycemic control reduces the incidence of nephropathy, neuropathy, and retinopathy in diabetes, but it does not correlate with the severity or progression of peripheral arterial disease. In order to reduce all-cause mortality, however, it is recommended

that fasting blood sugars should be controlled with hemoglobin A1c levels less than 7%.

2. Exercise rehabilitation—For claudicants, exercise ranging from unsupervised walking to formal supervised exercise on a treadmill significantly improves walking ability. A 21-study meta-analysis of exercise programs showed an average 180% increase in initial claudication distance and a 120% increase in maximal walking distance achieved through exercise. The precise mechanism behind this improvement is not firmly established. Collateral development seems unlikely because ankle pressures and limb flow do not increase substantially. Possible explanations include improved metabolic capacity and conditioning of the muscles.

Since patients with claudication are at a twofold to fourfold greater risk of dying from complications of generalized atherosclerosis than people without claudication, an additional benefit of exercise in these patients is that an improvement in walking distance as part of an aggressive risk factor modification regimen results in an overall decrease in cardiovascular risk.

3. Foot care—The feet of patients with neuropathy or with critical limb ischemia should be inspected and washed daily and kept dry. Mechanical and thermal trauma to the feet should be avoided. Toenails should be trimmed carefully, and corns and calluses should be attended to promptly. Even minor foot infections or injuries should be treated aggressively. Educating the patient to understand neuropathy, peripheral vascular insufficiency, and the importance of foot care is a central aspect of treatment.

4. Pharmacotherapy—The Antiplatelet Trialists Collaboration found an overall 25% decrease in fatal and nonfatal myocardial infarctions, strokes, and vascular deaths in those treated with antiplatelet agents. Aspirin at dosages ranging from 75 to 350 mg/d is the first-line antiplatelet agent recommended, though clopidogrel, which blocks the activation of platelets by adenosine diphosphate (ADP), may be useful in aspirin-intolerant patients. Clopidogrel is also an important adjunctive therapy in reducing thrombogenicity at locations of endovascular arterial treatment. All patients with cardiovascular disease, whether symptomatic or asymptomatic, should be considered for antiplatelet therapy to reduce the risk of cardiovascular morbidity and mortality.

Two drugs have been approved by the FDA for treatment of intermittent claudication. Pentoxifylline produces a small improvement in both initial claudication distance (about 20%) and absolute claudication distance (about 10%). Cilostazol is a phosphodiesterase III inhibitor with vasodilator, antiplatelet, and antilipid activity. Randomized, placebo-controlled, blinded trials have shown an increase of about 50% in absolute claudication distance in patients treated with cilostazol. Quality-of-life assessments also improved

significantly. Gene therapy for cardiovascular disease is being investigated, but conclusions regarding safety and efficacy are premature.

B. Operative Treatment

Interventional procedures, open or endovascular, are performed both for limb salvage and for incapacitating claudication. The choice of operative procedure depends on the location and distribution of arterial lesions and the patient's comorbidities. Recognition of coexistent cardiopulmonary disease is particularly relevant, because many patients with peripheral vascular disease also have ischemic heart disease and/or chronic lung disease associated with tobacco use. Preoperative cardiac functional assessment is sometimes necessary, but preoperative myocardial revascularization is not beneficial in patients with reasonable cardiac reserve. All patients undergoing vascular surgery should have preoperative risk assessment. Randomized trials have shown that

▲ **Figure 34-3.** Endovascular gear. **A:** Sheath. Inserted using Seldinger technique into access vessel. Wires, catheters, and devices pass through the sheath. Sheaths provide stable working access points and protect artery. **B:** Catheter. Variable length, stiffness, coating, and shape (examples: B.1, cobra; B.2, pigtail; B.3, mesenteric selective). Catheters help steer wires through vasculature and also maintain access in vessel. **C:** Guidewire. Variable diameter, length, stiffness, and shape. perioperative β -blocker, angiotensin-converting enzyme (ACE) inhibitor, and statins may reduce cardiac morbidity in patients undergoing vascular surgery. Evidence is also emerging demonstrating the importance of maintaining statin therapy throughout the perioperative period.

1. Endovascular therapy—Endovascular therapy consists of image-guided techniques to treat diseased arterial segments from within the lumen of the vessel. Access to the arterial system is established by the insertion of valved sheaths, usually percutaneously, into the access vessel, often the common femoral artery. Steerable wires and catheters are then passed through the vasculature under fluoroscopic guidance to the target lesion (Figure 34-3). Once the target lesion is accessed, therapeutic maneuvers, such as angioplasty, or devices, such as stents, can be delivered. In many arterial beds, endovascular therapy is more commonly utilized than open surgical therapy because of its minimally invasive nature and reduction of short-term morbidity and mortality. However, many questions remain concerning the long-term durability of endovascular repairs, and open surgery still plays a major role in the treatment of patients with arterial disease.

2. Percutaneous transluminal angioplasty—with or without placement of an intravascular stent, is often the

treatment of choice when stenoses or even occlusions are relatively short and localized. As the angioplasty balloon expands, it stretches the adventitia, fracturing and compressing plaque, expanding the artery to widen the lumen. Energy losses associated with a stenosis are inversely proportionate to the fourth power of the radius; therefore, even small increases in radius can result in substantial increases in blood flow, although durability of the procedure is improved with the reestablishment of a normal lumen. Concomitant stenting is frequently performed to improve luminal expansion and the arteriographic appearance of the lesion. Stent grafts (stents with fabric covering) may also be used in selected cases or to repair the inadvertent rupture of an artery during angioplasty (Figure 34-4).

Both stents and stent grafts are commonly used from the aortic bifurcation to the distal popliteal artery. Stenting is performed less commonly below the knee, but angioplasty of tibial disease is now common with the use of small catheters and wires. As in the coronaries, drug eluting stents may significantly improve patency rates. Percutaneous mechanical and laser atherectomy are other options in removing obstructing lesions in lower extremity atherosclerotic occlusive disease.

For short, stenotic segments in larger, more proximal vessels, the results of endovascular therapies are good with 1-year success rates of 85% in common iliac disease and 70%

▲ **Figure 34–4.** Aortoiliac occlusive disease. **A:** Aorta. **B:** Severely stenotic/occluded iliac arteries. **B.1:** Widely patent iliac arteries following balloon angioplasty and stenting (**C**).

in external iliac disease. The results with superficial femoral and popliteal lesions are lower (Figure 34–5). The success of endovascular therapy for lower extremity occlusive disease is inversely related to the complexity of the lesion, defined by the number and length of stenoses treated.

Close follow-up of patients post endovascular therapy is required since disease may recur more frequently after angioplasty than after bypass surgery. The patient should be closely followed using noninvasive tests. Repeat angioplasty or stenting may be indicated for recurrent disease, but the improvement in morbidity and mortality of endovascular

interventions may be offset by the need for multiple repeat procedures. In general, minimally invasive percutaneous treatment of lower extremity occlusive disease is best used in patients of high operative risk and severe, limb-threatening ischemia (Figure 34–6).

C. Surgical treatment

1. Aortoiliac reconstruction—Open operations are indicated for aortoiliac occlusive disease in younger patients with low operative risk or patients with severe disease not amenable to endovascular therapy. To completely bypass

▲ **Figure 34–5.** Superficial femoral artery occlusion, angioplasty, and stent-graft. **A:** Common femoral artery. **B:** Occluded superficial femoral artery. **B.1:** Recannalized, stent-grafted superficial femoral artery. **C:** Profunda femoris artery. **D:** Stent-graft.

▲ **Figure 34-6.** Comparison of outcomes for surgical and endovascular intervention in lower extremity occlusive disease.

the aortoiliac segment, an inverted Y-shaped prosthesis is interposed between the infrarenal abdominal aorta and the femoral arteries, creating an **aortofemoral bypass**. The goal of operation is restoration of blood flow to the common femoral artery or, when occlusive disease of the superficial femoral artery is present, to the profunda femoris artery. The clinical results of aortofemoral reconstruction are excellent, although the mortality and morbidity clearly are higher than for endovascular therapy. The operative death rate is 5%; early patency rate, 95%; and late patency rate (5-10 years postoperatively), about 80%. Late complications may be as high as 10% and include graft-intestinal fistula formation, anastomotic aneurysm formation, renal failure, and erectile dysfunction.

Lower risk procedures may be preferable in high-risk patients. If the clinically important lesions are confined to one side, a femoral-femoral or iliofemoral bypass graft can be used. A graft from the axillary to the femoral artery (ie, axillofemoral graft) can be used for bilateral disease. Unfortunately, these “extra-anatomic” methods of arterial reconstruction are more prone to late occlusion than are direct reconstructions.

2. Femoropopliteal reconstruction—When disease is confined to the femoropopliteal segment of the SFA, **femoropopliteal bypass** is used. The principal indication for these operations is limb salvage. In patients with claudication

alone, the indications for femoropopliteal bypass are more difficult to define but must include substantial disability from claudication. For limited lesions of the superficial femoral artery, endovascular therapy is often attempted first, with surgery reserved for extensive disease or angioplasty failure.

The best conduit for femoropopliteal bypass is an autologous greater saphenous vein. The saphenous vein may be left in situ or removed and reversed. Expanded polytetrafluoroethylene (PTFE) may also be used as a conduit, particularly for bypass to the supragenicular popliteal artery. Below the knee, PTFE conduits produce much lower patency rates than saphenous veins. Operative death rates are low (2%), and 5-year patency rates range from 60% to 80%. Limb salvage rates are higher than graft patency rates.

The profunda femoris artery perfuses the thigh and acts as an important source of collateral flow when the superficial femoral artery is diseased. When there is a stenosis of the profunda, **profundoplasty** alone can be performed for limb salvages with success rates of 80% when the supragenicular popliteal artery is patent and 40%–50% when the popliteal artery is occluded. Isolated profundoplasty is rarely helpful for treating claudication.

3. Tibioperoneal arterial reconstruction—Reconstruction of tibial arteries (ie, **distal bypass** to the tibial, peroneal, or pedal vessels) is performed only for limb salvage. Advancing technology allows better endovascular therapy in the tibial vessels, with decreased short-term morbidity and mortality, and similar gains in limb salvage when compared to bypass surgery. However, bypass still remains an important mode of therapy for these patients. Autogenous saphenous veins are preferred because prosthetic conduits have high failure rates. Due to smaller vessel size, extensive disease, and probably the length of the bypass conduit, these grafts are not as durable as femoropopliteal bypass, so the limb salvage rate is substantially higher than graft patency. The operative death rate for these procedures is about 5 due to extensive comorbidities.

4. Amputation—Amputation of the limb is necessary within 5-10 years in only 5% of patients presenting with claudication. Amputation is more common if patients continue to smoke cigarettes. Patients with multiple risk factors for atherosclerosis and short-distance claudication are also at increased risk for eventual limb loss. Of patients who present with ischemic rest pain or ulceration, 5%–10% require amputation as initial therapy, and most eventually will require amputation if not revascularized. Successful revascularization results in lower costs than primary amputation and an infinite improvement in quality of life. Occasionally, primary amputation may be preferable to revascularization if the likelihood of successful bypass is low, extensive foot infection is present, or the patient is nonambulatory. Amputation levels, options, and the special needs

of amputees are covered in the section on Lower Extremity Amputation.

ACUTE LOWER EXTREMITY OCCLUSIVE DISEASE

► General Considerations

Sudden occlusion of a previously patent artery is a dramatic event characterized by the abrupt onset of severe pain and absent pulses in the involved extremity. Tissue viability depends on the extent to which flow is maintained by collateral circuits. When ischemia persists, motor and sensory paralysis and muscle infarction become irreversible in a matter of hours.

Acute major arterial occlusion may be caused by an embolus, primary arterial thrombosis, trauma, or dissection. The heart is the source of embolus in 80%–90% of episodes, with the remainder from proximal arterial lesions. Aortic aneurysms often contain thrombus, but this material rarely causes symptomatic emboli. In contrast, femoral and particularly popliteal aneurysms embolize frequently. Ulceration in atherosclerotic plaques also can lead to formation of thrombus, which may fragment. Miscellaneous infrequent sources of emboli include cardiac tumors (including cardiac myxoma) and paradoxical emboli (venous thrombi migrating through a patent for-

men ovale). Up to 5%–10% of spontaneous emboli originate from a source that remains unidentified despite thorough diagnostic interrogation.

It may be difficult to differentiate between sudden thrombosis of an atherosclerotic peripheral artery and embolic occlusion. The former patients usually have preexisting atherosclerotic stenosis and low blood flow, which predisposes to stagnation and thrombosis. One should also keep in mind the clinical setting and a history of preexisting symptoms such as atrial fibrillation (embolus) or claudication (primary thrombosis).

► Clinical Findings

The Five Ps

- Pain
- Pallor
- Pulselessness
- Paresthesias
- Paralysis

Acute arterial occlusion is characterized by the five Ps: pain, pallor, pulselessness, paresthesias, and paralysis. Severe sudden pain is present in 80% of patients, and its onset usually indicates the time of vessel occlusion. Pain is absent in some patients because of prompt onset of anesthesia and paralysis and portends a poor prognosis.

On examination, the key finding is a lack of palpable pulses in a diffusely painful extremity. It is important to determine if sensitivity to light touch is maintained. These fibers are highly susceptible to ischemia, and their dysfunction heralds the beginning of irreversible ischemic changes. The onset of motor paralysis implies impending gangrene. Early intervention is critical. Swelling with acute tenderness of a muscle belly—usually in the calf following acute femoral artery occlusion—generally denotes irreversible muscle infarction. Skin and subcutaneous tissues have greater resistance to hypoxia than nerves and muscles, which may demonstrate irreversible histological changes after 3 hours or less of ischemia.

► Treatment & Prognosis

A. Embolism and Thrombosis

Immediate anticoagulation by intravenous heparin slows the propagation of thrombus and allows time for assessment of adequacy of collateral flow and preparation for operation. If light touch is intact, arteriography may be performed to define the anatomy and assist in planning the operation. Diagnosis of acute embolic occlusion is based on an abrupt block of the artery with little accompanying arterial disease; conversely, acute in situ thrombosis is associated with extensive atherosclerosis and a well-established collateral network. The operative treatment for

an embolus, embolectomy, differs from that of preexisting atherosclerosis, which may require bypass. Nonoperative management is rarely indicated except in debilitated patients and patients with emboli to major arteries in the upper extremities, which generally have good collateral circulation.

Therapeutic options include catheter-directed thrombolysis, percutaneous mechanical thrombectomy, and surgical embolectomy. For patients with severe acute ischemia, operative therapy is preferable because it is usually associated with the least delay in reestablishing perfusion. Surgical embolectomy may be performed through an arteriotomy at the site of the embolic occlusion or, most commonly, by clot extraction with a balloon (Fogarty) catheter inserted through a remote arteriotomy. Successful embolectomy requires removal of the embolus and the “tail” of thrombus that extends distally or proximally from it. If operation is not performed within the first few hours, the clot may become adherent, and subsequent revascularization is less successful. Intraoperative infusion of thrombolytic agents is often a useful adjunct to embolectomy.

In patients who will tolerate a delay in revascularization (ie, those who do not have neural changes on examination), intra-arterial thrombolysis should be considered. The usual regimen involves selective intra-arterial infusion of low doses of thrombolytic agent (eg, tissue plasminogen activator) directly into the clot. This activates thrombus plasminogen more efficiently, allows high concentrations in the clot while limiting systemic effect, and has acceptable complication rates. In cases of thrombosis on preexisting atherosclerotic lesions, thrombolysis reveals the underlying lesions that will require treatment to prevent recurrent thrombosis.

If revascularization is successful, a reperfusion injury may develop with significant swelling requiring fasciotomy to treat the compartment syndrome that may accompany the reperfusion injury. Renal insufficiency from myoglobin release should be anticipated after reperfusion of ischemic muscle. Treatment consists of vigorous hydration and alkalization of the urine. Administration of free radical scavengers such as Mannitol may be helpful in this disorder.

Patients with clearly irreversible limb ischemia should undergo amputation without an attempt at revascularization, as revascularization may expose the patient to the serious hazards of reperfusion caused by release of acidic and hyperkalemic venous blood from the dying extremity.

▶ B. Traumatic Arterial Occlusion

Traumatic arterial occlusion must be corrected within a few hours to avoid development of gangrene. Repair of arterial injury is usually performed in conjunction with repair of

other injuries. Occasionally, temporary shunts are used to restore flow to the injured extremity while other injuries are addressed and repaired.

PERIPHERAL MICROEMBOLI

Microemboli are most dramatic when they occlude a digital artery perfusing a toe or finger. This causes sudden pain, cyanosis, and coldness or numbness in the affected digit. These changes characteristically improve over several days. If there are multiple emboli, these symptoms may reappear in a different area of the hand or foot. In the lower extremity, this clinical entity has been called **blue toe syndrome** or trash foot. The sudden onset of pain and purple discoloration of a toe in the presence of palpable pulses is recognized as a potentially limb-threatening arterial problem. With each succeeding episode, recovery is slower and less complete.

The most common source of microembolization is cardiac valvular disease. However, if no cardiac valvular lesions are found, a careful examination of the proximal arterial tree must be done to identify an arterial source shedding atheroemboli.

Sudden onset may differentiate peripheral microembolism from other causes of blue toes, such as vasculitis, thromboangiitis obliterans, trauma, or chronic ischemia. If a single toe is affected, it is more likely to be the result of emboli, while multiple cyanotic toes are more likely to be vasculitis or chronic ischemia. It is important to remember that a patent proximal artery is required to serve as a conduit for the embolus, so pulses are intact. Furthermore, a normal blood supply is present in adjacent tissue segments. The appearance of a normally perfused foot with a cyanotic toe is characteristic. However, the waxing and waning symptoms of repeated emboli can make the diagnosis difficult. Unless the syndrome is recognized, alternative diagnoses investigated, and the lesion of origin corrected, survival of the foot or hand may be in peril.

Dean SM: Atypical ischemic lower extremity ulcerations: a differential diagnosis. *Vasc Med* 2008;13:47.

DIABETIC VASCULAR DISEASE

Atherosclerotic arterial disease in patients with diabetes mellitus is more diffuse and more severe than in nondiabetics. In diabetic patients, the tibioperoneal vessels frequently contain atherosclerotic changes, and the vessels are often heavily calcified. The degree of ischemia may be severe and extensive, and noninvasive tests (ABIs) may be falsely elevated. Fortunately, in many diabetics, the small arteries in the foot are relatively spared, making distal bypass to

these arteries possible and allowing foot salvage in cases of threatened limb loss.

Diabetic patients also have a high incidence of neuropathy and are more apt to ignore minor foot injuries, which can develop into ulcerations. Daily foot inspections are essential to avoid progression of minor injuries into limb threatening lesions. Neuropathy is also responsible for loss of tone of intrinsic foot muscles that leads to subluxation of the metatarsal phalangeal joints, resulting in a “rocker-bottom” foot and ultimately producing complete joint destruction termed a Charcot foot. These architectural changes also make skin breakdown more likely to occur and require referral to a foot and ankle clinic.

NONATHEROSCLEROTIC DISORDERS CAUSING LOWER LIMB ISCHEMIA

▶ Thromboangiitis Obliterans

Thromboangiitis obliterans (Buerger disease) is characterized by multiple segmental occlusions of obliterating tibial and pedal arteries. The most distal arteries are affected making bypass impossible. Migratory phlebitis may be present. In contrast to atherosclerosis, which involves the intima and media, thromboangiitis obliterans is manifested by infiltration of round cells in all three layers of the arterial wall. The disease occurs almost exclusively in young male smokers. Fortunately, the incidence appears to be decreasing. It is essential that the patient stop smoking to avoid progression of the disease. Patients with Buerger disease may have specific cellular immunity against arterial antigens, specific humoral antiarterial antibodies, and elevated circulatory immune complexes, but a precise diagnosis can be made only by tissue histology. Arteriographic findings are distinctive but not pathognomonic. Sympathectomy decreases arterial spasm and is useful in some patients. Amputation is indicated for persistent pain or gangrene and can be performed adjacent to the line of demarcation with satisfactory primary healing.

The disease may become dormant if the patient can stop smoking. Unfortunately, smoking cessation seems particu-

larly difficult in these patients, and many ultimately require multiple amputations.

▶ Popliteal Artery Entrapment Syndrome

This rare cause of popliteal artery stenosis or occlusion occurs as a result of an anomalous course of the popliteal artery. The popliteal artery normally passes between the two heads of the gastrocnemius muscle as it enters the lower leg. In the entrapment syndrome, the artery passes medial to both heads of the gastrocnemius, causing compression of the popliteal artery when the knee is extended. There are five anatomic variants of popliteal artery entrapment, but all produce similar clinical effects. Fibrous thickening of the intima occurs at the site of compression and gradually progresses to total occlusion. Symptoms vary from calf claudication to those of more severe ischemia depending on lesion severity and embolization. Popliteal artery entrapment should be considered when a young, otherwise healthy patient presents with calf claudication. Until the artery becomes occluded, the only finding is a decrease in strength of the pedal pulses, most evident when using provocative maneuvers like foot dorsiflexion and plantar flexion. MRI and CT studies are most useful in confirmation of the diagnosis. Atherosclerotic changes are notably absent. Treatment consists of returning the popliteal artery to its normal anatomic course or bypass with saphenous vein.

▶ Cystic Degeneration of the Popliteal Artery

Arterial stenosis is produced by a mucoid cyst in the adventitia, usually located in the middle third of the artery. Calf claudication is the most common symptom, and the only finding is a decrease in the strength of the peripheral pulses. Rarely, a mass can be palpated. Arteriography shows a sharply localized zone of popliteal stenosis with a smooth concentric tapering. Ultrasound or CT scans can be used to demonstrate the cyst within the vessel wall. The stenosis may be missed on conventional anteroposterior films and may appear only on lateral exposures. The cyst and the affected artery should be excised and bypassed because of recurrence with evacuation of the cyst only.

▶ Abdominal Aortic Coarctation

Coarctations of the thoracic or abdominal aorta are rare. They may be congenital or may result from an inflammatory large vessel arteritis such as Kawasaki or Takayasu disease. These rare disorders may produce symptoms of lower extremity, mesenteric, or renal ischemia depending on the location of the constriction. The congenital variant of this condition is best managed surgically when it is recognized; autogenous repair may be preferable to the use of prosthetic grafts. Surgical repair in the presence of ongoing inflammation is not recommended because those patients do poorly.

However, if the disease is quiescent with a normal sedimentation rate, standard surgical operations appear to produce satisfactory results.

LOWER EXTREMITY AMPUTATION

General Considerations

More than 90% of the 110,000 amputations performed in the United States each year are for ischemic disease or infective gangrene. More than half of lower extremity amputations are performed for complications of diabetes mellitus, and 15%–50% of diabetic amputees will lose a second leg within 5 years. This risk is about two times higher for men than for women. Other indications for amputations are nondiabetic infection with ischemia (15%–25%); ischemia without infection (5%–10%); osteomyelitis (3%–5%); trauma (2%–5%); and frostbite, tumors, neuromas, and other miscellaneous causes (5%–10%).

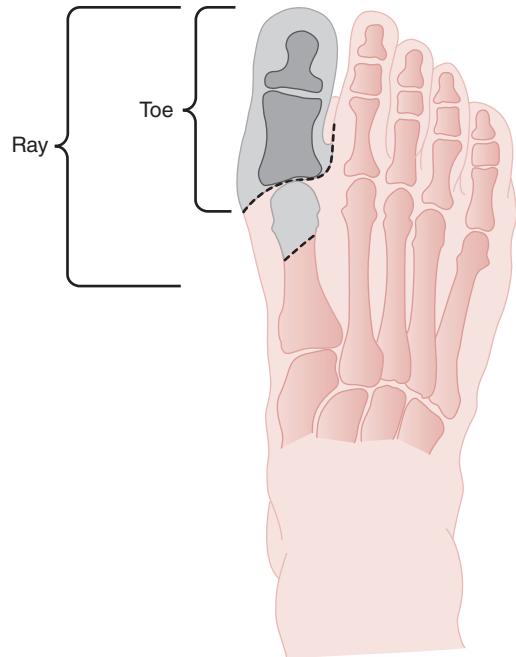

Many patients facing amputation are near the end of life because of systemic cardiovascular disease. Approximately 20%–30% of patients undergoing major amputation (below-knee or above-knee) will be dead within 2 years. The prevalence of many comorbidities in this population is also reflected in the perioperative mortality rates for major amputation, ranging from 5% to 10% for below-knee amputations to 10% or higher for above-knee amputations.

The level of amputation is determined by assessing the likelihood of healing of the limb in association with the functional potential of the patient. Compared with normal walking, energy expenditure is increased 10%–40% with a below-knee prosthesis, 50%–70% with an above-knee prosthesis, and 60% with crutches. The clinical conundrum in patients with limb ischemia is twofold: (1) determining which limbs have adequate blood supply to heal at the below-knee level and (2) determining which patients with vascular disease have reasonable rehabilitation potential. The best predictions are based on clinical assessment by an experienced surgeon, assisted by one of the several techniques such as Laser Doppler or transcutaneous measurement of oxygen tension.

Lower Extremity Amputation Levels

Lower extremity amputations are done most commonly at one of the following levels: toe (called digit amputations, which may be extended to include resection of the metatarsal and called ray amputations), transmetatarsal, below-knee, and above-knee. Amputations at other levels (Syme amputation, Chopart amputation, knee disarticulation, and hip disarticulation) are infrequently performed, usually to treat conditions other than vascular disease.

1. Toe and ray amputations—Toe amputations are the most frequently performed amputation (Figure 34–7). Over two thirds of amputations in diabetics involve the toes and

▲ **Figure 34–7.** Toe and ray amputations.

forefoot. A guiding principle is midphalangeal or metatarsal resection to ensure that all cartilaginous articular surfaces are removed because this material has no blood supply. The indications include gangrene, infection, neuropathic ulceration, frostbite, and osteomyelitis limited to the middle or distal phalanx. Good blood flow is required. Contraindications to digit amputation include indistinct demarcation, infection at the metatarsal level, pallor on elevation, or dependent rubor indicating ischemia of the forefoot.

For dry, uninfected gangrene of one or more toes, autoamputation may be allowed to occur. During this process, epithelialization occurs beneath the eschar, and the toe spontaneously detaches, leaving a clean residual limb at the most distal site. Although preferable in many patients (and especially frostbit patients), autoamputation sometimes requires months to complete.

Ray, or wedge, amputation includes removal of the toe and metatarsal head; occasionally, two adjacent toes may be amputated by this method. As with toe amputation, there is modest cosmetic deformity and a prosthesis is not required. Ray amputation of the great toe leads to unstable weight bearing and some difficulty with ambulation resulting from loss of the first metatarsal head.

Complications that may require amputation at higher levels include infection, osteomyelitis of remaining bone, and nonhealing of the incision. These complications have been reported in up to one third of diabetic patients.

2. Transmetatarsal amputation—Transmetatarsal fore-foot amputations preserve normal weight bearing. The principal indication is gangrene of several toes or the great toe, with or without soft tissue infection or osteomyelitis. Good blood supply is needed because the incision creates a generous plantar flap. There is no dorsal flap. On the plantar surface, the incision is continued medially to laterally just proximal to the metatarsophalangeal crease. The metatarsal bones are divided with the medial and lateral shafts cut shorter than those in the middle to preserve the normal architecture of the foot and assist with orthotic fitting postoperatively, and the tendons are pulled down and transected as high as possible.

Transmetatarsal amputation produces an excellent functional result. Walking requires no increase in energy expenditure, and the gait is usually smooth. A prosthesis is not mandatory, but to achieve optimal gait, the shoes must be modified.

3. Major leg amputations—An attempt at performing a below-knee amputation is warranted in almost any patient who appears to be a potential candidate for rehabilitation. This may explain why up to one third of patients having below-knee amputations require reamputation.

A. Below-knee amputation—The most common procedure for below-knee amputation is the Burgess technique, which utilizes a long posterior flap (Figure 34–8). The blood supply to a posterior flap is generally better than the supply to an anterior flap or to sagittal flaps, because the sural arteries (which supply the gastrocnemius and soleus muscles) arise high on the popliteal artery, an area not often diseased. The use of rigid dressings and immediate postoperative prostheses has proved advantageous. Application of a rigid cast bandage has several potential advantages: (1) it controls postoperative edema, which may reduce pain; (2) it protects the stump from trauma, particularly when a patient falls during attempts at mobilization; and (3) it allows the patient to be ambulatory with a temporary prosthesis much sooner.

▲ **Figure 34–8.** Below knee amputation.

B. Above-knee amputation—Absolute indications for primary above-knee amputation include contracture at the knee joint (observed in debilitated patients with longstanding extremity pain who have been in a prolonged withdrawal posture with the knee flexed) and nonviable calf muscle or skin for creation of the below-knee flap. The frequent failure of healing of below-knee amputation, the higher perioperative morbidity and mortality in this population (making secondary operations more dangerous), and the modest functional benefit of preserving the knee joint are the major arguments in favor of primary above-knee procedures in nonambulatory patients.

Above-knee amputation may be performed at several levels, including knee disarticulation. Although it is advantageous to preserve as long a lever arm as possible, knee disarticulation is technically more demanding than transfemoral amputation at a higher level. The technique is straightforward. Short anterior and posterior flaps, sagittal flaps, or a circular incision may be used. The bone is divided substantially higher than the skin and soft tissue to avoid tension when the wound is closed and later when the muscles of the thigh atrophy. A simple dressing is then applied.

SPECIAL PROBLEMS OF AMPUTEES

► Thromboembolism

The amputee is at great risk for deep venous thrombosis (15%) and pulmonary embolism (2%) postoperatively because (1) amputation often follows prolonged immobilization during treatment of the primary disease and (2) the operation involves ligation of large veins, causing stagnation of blood, a situation that predisposes to thrombosis. If immediate-fit prosthetic techniques are not employed, an additional period of inactivity follows the operation, further increasing the risk of thromboembolism.

► Rehabilitation After Amputation

The rehabilitation goals following amputation are highly variable. Younger patients universally want to regain ambulatory status and frequently return to work. Elderly patients with significant comorbid conditions may remain wheelchair-bound, and much of their rehabilitation is focused on providing wheelchair access in their living situations and working on independent transfers. It is important to understand that amputation in an elderly patient is frequently an event that occurs near the end of life. For these people, relief of pain and provision for modest function may be the most appropriate outcome in the limited amount of time they have left.

The length of the residual limb correlates well with regaining the ability to walk. Cardiopulmonary disease and physical weakness make walking an overwhelming effort for

some patients; this emphasizes the importance of preserving a below-knee amputation if possible, so that walking will require the least possible amount of energy.

► Pain & Flexion Contracture

Physical Therapy consultation is an important adjunct to prevent flexion contractures of the knee or hip occur rapidly in the painful limb because of the natural tendency to assume a flexed posture. Measures to prevent contracture are indicated preoperatively, and application of a rigid dressing postoperatively decreases the incidence of this complication.

► Phantom Pain

Persistent sensations in a residual limb are almost universal. Unfortunately, phantom limb pain also is common. Treatment is difficult; improvement has been reported using tricyclic antidepressants, transcutaneous electrical nerve stimulation (TENS), and calcitonin. The incidence and severity of phantom limb pain are increased if there was prolonged ischemia before amputation and decreased if postoperative rehabilitation is rapid.

► Ischemia in the Residual Limb

Progressive vascular disease results in ischemia of about 8% of above-knee amputations and 1% of below-knee amputations. Operations are often required to improve arterial flow when gangrene develops in a residual limb. The mortality rate of this condition is high.

CEREBROVASCULAR DISEASE

► General Considerations

Unlike in the other vascular beds, symptoms of extracranial carotid disease are most often caused by embolization. Arterial emboli account for approximately one quarter of strokes in Europe and North America, and 80% of these

originate from atherosclerotic lesions in a surgically accessible artery in the neck. The most common lesion is at the bifurcation of the carotid artery. Transcranial Doppler studies have shown that emboli are seen in approximately 20% of patients with moderate (> 50% stenosis) lesions at the carotid bifurcation and even higher rates with more than 70% stenoses. The incidence and frequency of emboli is increased in recently symptomatic patients. It would appear that transient deficits and strokes from emboli may not be single events but the result of multiple small emboli that temporarily or permanently obliterate the collateral reserve of the cerebral cortex.

The neurologic dysfunction associated with microemboli may appear as sudden “short-lived,” or transient, neurologic symptoms that may include unilateral motor and sensory loss, aphasia (difficulty finding words), or dysarthria (difficulty speaking due to motor dysfunction). These are termed **transient ischemic attacks (TIA)**. Most TIAs are brief (minutes). By convention, 24 hours is the arbitrary limit of a TIA. If the symptoms persist, it is a stroke, or **cerebrovascular accident (CVA)**. An embolus to the ophthalmic artery, the first branch of the internal carotid artery, produces a temporary monocular loss of vision called amaurosis fugax or permanent blindness. Atherosclerotic emboli may be visible as small bright flecks (Hollenhorst plaques) lodged in arterial bifurcations in the retina.

Characteristically, lesions of atherosclerosis in the internal carotid artery occur along the wall of the carotid bulb opposite to the external carotid artery origin (Figure 34–9). The enlargement of the bulb just distal to this major branch point creates an area of low wall shear stress, flow separation, and loss of unidirectional flow. Presumably, this allows greater interaction of atherogenic particles and the vessel walls at this site and accounts for the localized plaque at the carotid bifurcation.

The accessibility of this localized atheroma allows effective removal of the plaque and a dramatic reduction in stroke risk. Without treatment, 26% of patients with TIAs and more than 70% with carotid stenosis will develop permanent neurologic impairment (CVA) from continued embolization at 2 years. The risk of CVA can be reduced to 9% with plaque removal. The risk of CVA is lower for patients presenting with amaurosis fugax.

► Clinical Findings

A. Symptoms

Patients with cerebrovascular disease can be grouped into five categories based on symptoms at presentation.

1. Asymptomatic disease—An audible bruit heard in the neck may be the only manifestation of cerebrovascular disease. Severe carotid stenosis may also occur in the absence of a bruit with markedly reduced blood flow. Ultrasound screening also can identify these patients.

▲ **Figure 34–9.** Cerebrovascular circulation anatomy.

2. Transient neurologic episodes—Sudden onset of a neurologic deficit in the distribution of the anterior or middle cerebral arteries requires investigation of the carotid arteries. Symptoms depend on the ischemic area of the brain, the size of the embolus, and the condition of collaterals to the affected area. Hypoperfusion rarely causes transient neurologic and visual attacks. In symptomatic patients, stroke risk after TIA correlates with the severity of internal carotid artery stenosis.

3. Acute unstable neurologic deficits—Patients in this category have multiple (crescendo) TIAs, stroke in evolution, or waxing and waning neurologic deficits and high-grade stenoses. These patients must be treated urgently, because even with anticoagulation, their deficits may become permanent within hours.

4. Stroke (CVA)—Intervention is indicated for patients after stroke that have either complete recovery or mild to moderate deficits, because up to one half will suffer another stroke with further loss of neural function. The timing of intervention is controversial. If the infarct is large and the stenosis severe, a healing period prior to revascularization may be advisable to prevent hemorrhage into the necrotic area with restoration of systemic pressure. In stroke patients, the perioperative risk of additional neurologic deficit is higher than in patients post-TIA.

5. Vertebrobasilar disease—In the posterior circulation, emboli are less common and hypoperfusion is the dominant pathology. Reduction of flow in the vertebral and basilar arteries may cause drop attacks, clumsiness, and a variety of sensory phenomena. Frequently, the symptoms are bilateral. Vertigo, diplopia, or dysequilibrium occurring individually is rarely due to vertebrobasilar disease, but when these symptoms occur in combination, the diagnosis becomes more likely. It is unusual for dizziness alone to be due to cerebrovascular disease.

B. Signs

Auscultation of the carotid and subclavian arteries may delineate the sites of hemodynamically significant disease. However, bruits are nonspecific findings correlating more with overall risk for cardiovascular disease than with stroke.

C. Imaging

1. Doppler ultrasound—The most useful test for the diagnosis of extracranial carotid artery disease is the duplex ultrasound. As the stenosis encroaches on the lumen of the vessel, the velocity of blood increases in the area of the stenosis to maintain distal flow. Doppler spectral velocity analysis determines the flow rate rapidly and with reasonable accuracy and thereby gives an estimate of the degree of stenosis. Ultrasound can also display plaque morphology but with less reproducibility than stenosis.

2. CTA and MRA—CTA and MRA are often used for confirmation of duplex findings and planning interventional procedures (Figure 34–10). Both types of angiography can assess the degree of stenosis at the carotid bifurcation, providing information on the configuration of the aortic arch and identifying additional disease in the proximal supra-aortic trunk and intracerebral vessels. These studies also delineate regions of ischemic damage in the brain. Diffusion-weighted MRI of the brain is particularly sensitive and will define areas of injury as well as areas of infarction.

3. Arteriography—Cerebral arteriography is occasionally performed in patients with symptomatic or asymptomatic cerebrovascular disease. It is most useful for cases in which noninvasive studies are in disagreement or in those patients who are candidates for carotid angioplasty and stenting (CAS). Cerebral diagnostic arteriography is invasive and has a low but significant risk of stroke (0.5%–1.0%).

► Treatment

Stroke risk is highest immediately after a TIA, returning to baseline at approximately 6 months. Consequently, in symptomatic patients with carotid stenosis, early intervention is mandatory. Antiplatelet therapy, usually in the form of aspirin or clopidogrel, is particularly important in cerebrovascular patients, although clopidogrel should not be initiated in

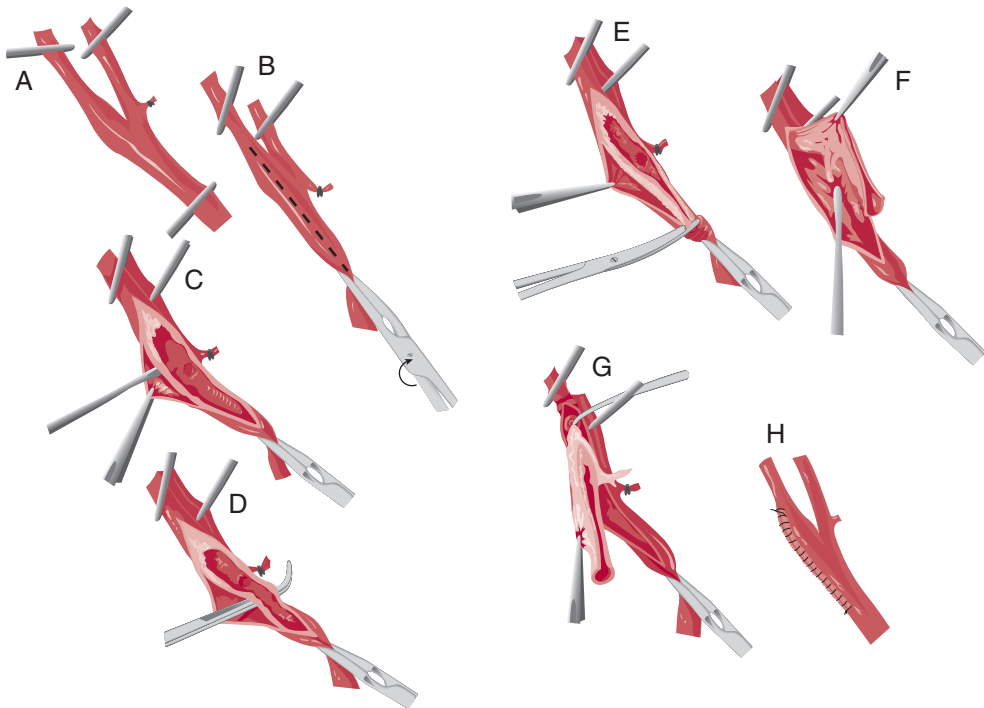

▲ **Figure 34–10.** Carotid bifurcation occlusive disease. **A:** 3D CT angiogram of neck demonstrating carotid bifurcation stenosis. **B:** Axial CT view demonstrating the lesion.

a patient who is scheduled to have a carotid endarterectomy because of the increased risk of bleeding. Cardiovascular risk factor modification is also imperative in reducing stroke and overall mortality. After a completed stroke, caution must be exercised when planning an intervention.

A. Carotid Endarterectomy

Carotid endarterectomy, the removal of the atherosclerotic lesion at the carotid bifurcation, is the primary operation performed (Figure 34–11). In the North American Symptomatic

▲ **Figure 34–11.** Technique of carotid endarterectomy.

Carotid Endarterectomy Trial (NASCET), carotid endarterectomy was shown to reduce incidence of ipsilateral stroke from 26% to 9% at 2 years in patients presenting with either TIA or stroke and carotid lesions of 70% stenosis or greater. The results also favored surgery in patients with moderate carotid stenosis (50%–69%), but less dramatically. The 5-year risk of ipsilateral stroke was 15.7% among patients treated surgically ($n = 1108$) and 22.2% among those treated medically ($n = 1118$; $P = .045$). Patients with stenoses of less than 50% did not significantly benefit from surgery.

Large clinical trials have also shown a benefit of surgery for asymptomatic carotid stenosis. Both the Asymptomatic Carotid Atherosclerosis Study (ACAS) in North America and the Asymptomatic Carotid Surgery Trial (ACST) in Europe showed that stroke incidence is halved (12%–6%) by carotid endarterectomy versus best medical therapy, which included antiplatelet agents and statins in the ACST, in patients with substantial carotid narrowing at 5 years of follow-up. While ACAS did not show a benefit for endarterectomy in women, the larger European study did.

Carotid endarterectomy cannot be performed when the internal carotid artery is completely occluded, because complete thrombectomy is difficult and residual clot may embolize, creating additional lesions.

B. Carotid Angioplasty and Stenting

Early studies of carotid angioplasty and stenting (CAS) (Figure 34–12) suggested similar morbidity and mortality

rates to carotid endarterectomy. Because of the higher rate of emboli with stenting, cerebral protection devices, either filters placed in the internal carotid or devices that allow a washout of atherosclerotic debris, should always be used. Poststenting, clopidogrel is prescribed for 6 weeks to limit late embolization from the stent.

Two large randomized studies found more strokes after CAS than after endarterectomy, the International Carotid Stent Study (ICSS) and the Carotid Revascularization Endarterectomy versus Stenting Trial (CREST). Conversely, there were more myocardial infarctions after endarterectomy. All women and men over age 70 did worse with CAS. Younger men did well with CAS. Current practice reserves CAS for occlusive lesions of the origins of the arch vessels and for recurrent stenosis after treatment. It is also chosen over endarterectomy in patients with hostile neck anatomy due to prior radiation or “high” lesions not accessible via a neck incision and in patients pre-op for CABG as they are at prohibitive risk for surgery.

C. Treatment Results

The main complication of cerebrovascular interventions is stroke, which occurs in 2%–7% of patients depending on the operative indications and cerebrovascular anatomy. Higher stroke rates occur in the setting of symptomatic stenosis or contralateral carotid occlusion. Lower stroke rates occur with asymptomatic stenosis. The operative death rate for all extracranial cerebrovascular interventions is less than 1%.

▲ **Figure 34–12.** Carotid angioplasty and stenting. **A:** Conventional arteriogram demonstrating diffuse occlusive disease of common and internal carotid arteries. **B:** Completion arteriogram following angioplasty and stenting of the lesions.

Transient cranial nerve injury occurs in about 10% of cases after endarterectomy and may cause tongue weakness, hoarseness, mouth asymmetry, earlobe numbness, and dysphagia. Less than 2% of peripheral nerve deficits are permanent, although this number goes up with surgery for recurrent disease, making stenting attractive for this indication.

Restenosis or occlusion is uncommon after carotid endarterectomy (5%–10% at 5 years) and appears to be equally uncommon after carotid stenting. For endarterectomy, using a prosthetic patch for closure of the arteriotomy can reduce restenosis.

► Subclavian Steal Syndrome

The subclavian steal syndrome is characterized by reversal of flow through the vertebral artery due to a more proximal occlusion or stenosis of the subclavian artery (ie, the vertebral artery serves as a collateral to supply blood to the arm). While this anatomic arrangement is often demonstrated on angiograms, clinical sequelae are rare. Symptoms of effort fatigue in the involved extremity are more common than neurologic complaints. When necessary, treatment consists of bypass grafting from the common carotid to the subclavian artery distal to the lesion or transposition of the subclavian artery beyond the lesion to the side of the nearby common carotid artery.

► Concomitant Coronary & Cerebrovascular Disease

When patients have coexistent severe coronary and carotid atherosclerosis requiring treatment, there has been controversy as to which lesion should be addressed first. Since most strokes during cardiac procedures are from atheromatous emboli from the aortic arch, not from low flow through a carotid stenosis, our policy has been to perform combined procedures only in patients with simultaneous symptomatic carotid and coronary disease, with critical bilateral asymptomatic stenoses, or with extremely high-grade (99%) unilateral stenosis. We have initiated a program of stenting the carotid stenoses 1 day prior to coronary artery bypass graft and have found this to be quite satisfactory.

► Other Causes of Cerebrovascular Symptoms

Other than atherosclerosis, primary disease of the extracranial arteries is rare.

A. Takayasu (Giant Cell) Arteritis

Takayasu arteritis is an obliterative arteriopathy principally involving the aortic arch vessels that often affects young women. The pararenal abdominal aorta and pulmonary arteries also may be affected. High-dose corticosteroids and cyclophosphamide have been shown to arrest and in some cases reverse the progress of the disease. Operative

treatment of nonspecific arteritis should be avoided when the arteritis is active, but it may be successful in quiescent disease.

B. Dissecting Aortic Aneurysms

Dissecting aortic aneurysms may extend into the arch branches, producing obstruction and cerebral symptoms. These are discussed in Chapter 19, Part I.

C. Internal Carotid Dissection

Classically occurring in exercising young adults, dissection originating in the internal carotid artery and localized to its extracranial segment occurs as an acute event that may narrow or obliterate the internal carotid lumen. The primary lesion is an intimal tear at the distal end of the carotid bulb. It may also follow various types of neck trauma or severe hypertension.

Cerebral symptoms are the result of ischemia in the ipsilateral hemisphere. Acute neck pain in association with localized cervical tenderness adjacent to the angle of the mandible is a frequent finding.

Arteriography shows a characteristic pattern of tapered narrowing at or just beyond the distal portion of the carotid bulb. The lumen beyond this point may be obliterated or may persist as a barely visible narrow shadow. If the lumen persists, it resumes a normal caliber beyond the bony foramen.

Because thrombus tends to form in and around the dissected vessel, anticoagulation is the treatment of choice for this disorder. In many patients, the intramural clot will be resorbed, restoring a normal lumen. Intervention is indicated for patients with recurrent TIAs. Stenting is the procedure of choice and will restore the normal carotid contour. If stenting is not successful and symptoms persist, ligation can be performed if the carotid back-pressure exceeds 65 mm Hg. Extracranial to intracranial bypass will be needed if the pressure is low.

D. Fibromuscular Dysplasia

Fibromuscular dysplasia is a nonatherosclerotic angiopathy of unknown cause that affects specific arteries chiefly in young women. Symptoms of cerebrovascular disease can occur when the carotid artery is affected. It is usually bilateral and involves primarily the middle third of the extracranial portions of the internal carotid artery. Several pathologic variants of the disease have been described, but in most of them, the primary lesion is overgrowth of the media in a segmental distribution, producing irregular zones of arterial narrowing. The most common result is a series of concentric rings, producing the radiologic appearance of a string of beads in a long internal carotid artery. Approximately one third

of patients are also hypertensive due to renal artery involvement.

The prevalence of fibromuscular dysplasia and the portion of patients who develop symptoms are not known. Once symptoms develop, transient neurologic events are the most common manifestation. However, more than 20% of patients have had a stroke by the time of presentation. Because of the high incidence of neurologic disability, the lesion should be corrected by angioplasty with distal protection when patients develop symptoms. Surgery with dilation of the carotid with graduated dilators or balloon dilation has given excellent results.

Atherosclerosis characteristically produces stenosis at the orifice of the main renal artery. The lesion usually consists of aortic atheroma that protrudes over the renal artery orifice. Less commonly, the atheroma arises in the renal artery itself. Renal artery stenosis is more common in men over age 45 years and is bilateral in about 95% of cases.

Fibromuscular dysplasia usually involves the middle and distal thirds of the main renal artery and may extend into the branches. Medial fibroplasia is the most common variety of fibromuscular dysplasia, accounting for 85% of these lesions. It is bilateral in 50% of cases. Concentric rings of hyperplasia that project into the arterial lumen cause the arterial stenoses. Renal artery aneurysms frequently coexist. Fibromuscular dysplasia occurs mainly in young women, with onset of hypertension usually occurring before age 45 years. It is the causative disorder in 10% of children with hypertension. Developmental renal artery hypoplasia, coarctation of the aorta, and Takayasu aortitis are other vascular causes of hypertension in childhood.

Hypertension due to renal artery stenosis results from the kidney's response to reduced blood flow. Cells of the juxtaglomerular complex secrete renin, which acts on circulating angiotensinogen to form angiotensin I, which is rapidly converted to angiotensin II by ACE. This octapeptide constricts arterioles, increases aldosterone secretion, and promotes sodium retention. Due to the excess aldosterone, hypertension becomes volume-dependent. Over time, pathologic changes occur in the uninvolved kidney, and the hypertension may not be sensitive to ACE inhibition. With sodium restriction and volume reduction (diuretics), the hypertension may once again become sensitive to ACE inhibition. If both kidneys have renal artery stenoses, or if the disease exists in a solitary kidney, renal insufficiency may occur with ACE inhibitor administration with a loss of pressure in the glomerulus due to a reduction of angiotensin II constriction of the efferent arteriole.

► Clinical Findings

A. Symptoms and Signs

Most patients are asymptomatic, but irritability, headache, and emotional depression are seen in a few. Persistent elevation of the diastolic pressure is usually the only abnormal physical finding. A bruit is frequently audible to one or both sides of the midline in the flank or upper abdomen. Other signs of atherosclerosis may be present when this is the cause of the renal artery disease.

Other clues to the presence of renovascular hypertension include absence of a family history of hypertension, early onset of hypertension (particularly during childhood or during early adulthood), marked acceleration of the degree of hypertension, resistance to control with antihypertensive drugs, and rapid deterioration of renal function.

RENOVASCULAR HYPERTENSION

► General Considerations

More than 23 million people in the United States have hypertension, and renovascular disease is a causative factor in 2%–7% of cases. Atherosclerosis of the aorta and renal artery (two thirds of cases) and fibromuscular dysplasia are the two primary causes of renovascular hypertension. Less common causes of hypertension include renal artery emboli, renal artery aneurysms, renal artery dissection, hypoplasia of the renal arteries, and stenosis of the suprarenal aorta.

One should suspect renovascular hypertension if initial diastolic pressure is greater than 115 mm Hg or if renal function deteriorates while a patient is being given ACE inhibitors. Sudden onset of pulmonary edema with severe hypertension also is highly suggestive of renovascular hypertension.

B. Diagnostic Studies

In the past, several diagnostic tests were devised to diagnose renovascular hypertension. Divided urinary excretion studies, selective renin determinations from renal vein samples, and captopril renal scintigraphy are now rarely used.

Noninvasive or minimally invasive imaging of the renal arteries is justified when the patient has a precipitous drop in blood pressure, decreased renal function with an ACE inhibitor, difficult-to-control hypertension, or unexplained deteriorating renal function.

C. Imaging Studies

In experienced hands, duplex ultrasound scanning has an overall agreement with angiography of over 90%. Renal artery stenosis is characterized by peak systolic velocities in the range of 180–200 cm/s, and the ratio of these velocities to those in the aorta approaches 3.5. CTA or MRA may provide high-resolution images of diseased renal arteries, although must be used with caution in patients with renal insufficiency. The contrast required with CTA is nephrotoxic and gadolinium has been associated with systemic nephrogenic fibrosis in patients with reduced renal clearance.

Renal arteriography is the most accepted method for delineating the obstructive lesion. Since atherosclerotic disease most often involves the origins of the renal arteries, a midstream aortogram should be obtained in addition to selective renal artery catheterization. The presence of collateral vessels circumventing a renal artery stenosis suggests a hemodynamically significant renal artery lesion.

Nonionic contrast agents should be used and the patient should be prepared with overnight hydration. Administration of N-acetylcysteine and periprocedural sodium bicarbonate infusion may give added protections but aggressive hydration remains the primary treatment to reduce the incidence of acute tubular necrosis with angiography and should be used routinely.

► Treatment

A. Medical Management

Patients with renovascular hypertension require aggressive management of modifiable risk factors. If hypertension responds well to medical therapy and the renal function

is stable, no intervention on the renal artery stenosis is needed.

B. Percutaneous Transluminal Angioplasty and Stenting

Percutaneous transluminal angioplasty (PTA) and stenting is the preferred procedure for most patients (Figure 34–13). Although clearly valuable for some patients, the overall results of percutaneous interventions for renal artery stenosis have been mixed, and large randomized clinical trials suggest that medical treatment with angiotensin receptor blockers may be as effective as stenting in most cases. Patients with fibromuscular dysplasia typically respond to angioplasty alone.

C. Surgical Treatment

In the very young, surgery is still the primary mode of treatment due to concern regarding the long-term durability of angioplasty and stenting. Surgical repair also is required for failed angioplasty and stenting, renal revascularization during a procedure on the aorta, and lesions that are in branch vessels. As with any operation, the indications for arterial reconstruction are influenced by the extent of disease, the patient's life expectancy, and the anticipated morbidity associated with operation. Nephrectomy may be considered when arterial repair is impossible or especially hazardous and the disease is unilateral.

Options include endarterectomy, which is most easily accomplished through an incision into the adjacent aorta, or bypass using prosthetic or autogenous conduits. An alternative is “nonanatomic” bypass such as a hepatorenal or splenorenal procedure. The celiac and splenic arteries often have coexistent occlusive atherosclerotic disease that mandates preoperative arteriographic assessment of these vessels.

Extracorporeal techniques have been developed for distal branch aneurysms or extensive fibromuscular dysplasia. These require removal of the kidney from the abdomen (ex vivo arterial reconstruction), continuous cold perfusion of its vascular tree, and microvascular techniques for arterial replacement. The kidney is then either returned to a site near its original position or transplanted to the ipsilateral iliac fossa.

► Prognosis

Procedures for revascularization of the renal artery are successful in lowering blood pressure in over 90% of patients with fibromuscular hyperplasia. Operation for atherosclerotic stenosis results in improvement or cure of hypertension in about 60%. The results for angioplasty and stenting are not as good, perhaps because of atheroembolization to the kidney during angioplasty.

▲ **Figure 34–13.** Renal artery occlusive disease. **A:** Aortogram demonstrating ostial lesion in left renal artery. **B:** Renal stent constrained on delivery catheter over wire positioned across lesion. **C:** Arteriogram demonstrating widely patent renal artery following balloon angioplasty and stent placement.

The results of intervention for salvage of renal function are better than those for treatment of hypertension. The procedural mortality rate of operative renovascular surgery in children is almost nil, whereas it increases to 2%–8% in adults with diffuse atherosclerosis. Stenting of the renal arteries is also very well tolerated.

MESENTERIC ISCHEMIA SYNDROMES

► General Considerations

The celiac axis and the superior and inferior mesenteric arteries are the principal sources of blood supply to the stomach and intestines, with the inferior mesenteric artery and internal iliac arteries supplying flow to the distal colon (Figure 34–14). The anatomic collateral interconnections between these arteries are numerous. Single or even multiple visceral artery lesions are generally well tolerated, because collateral flow is readily available (Figure 34–15).

Atherosclerosis is the cause of obstructive lesions in the visceral arteries in the vast majority of cases. Vasculitis (eg, lupus erythematosus, Takayasu disease) is much less common. When atherosclerosis is the cause, the usual lesion

▲ **Figure 34–14.** Visceral arterial circulation and interconnections.

is a collar of plaque spilling over from the aorta that creates a proximal stenosis or occlusion. Associated atherosclerosis in the aorta and its other branches is common.

CHRONIC MESENTERIC ISCHEMIA

► Clinical Findings

The principal complaint is postprandial abdominal pain, which has been labeled abdominal or visceral angina. Pain characteristically appears 15–30 minutes after the beginning of a meal and lasts for an hour or longer. Pain is occasionally so severe and prolonged that opiates are required for relief. Pain occurs as a deep-seated, steady ache in the epigastrium, occasionally radiating to the right or left upper quadrant. Weight loss results from reluctance to eat. Although mild degrees of malabsorption can occur, gastrointestinal absorption studies are not helpful. Diarrhea and vomiting have been described. An upper abdominal bruit may be heard.

Ultrasound can be diagnostic in experienced hands but CTA or arteriography in the anteroposterior and especially the lateral projections demonstrate both the arterial lesion and the patterns of collateral blood flow. Patients should be well hydrated before these procedures because they can precipitate hypercoagulability and osmotic diuresis with dehydration, vascular occlusion, and bowel infarction.

▲ **Figure 34–15.** Three-dimensional CT angiogram demonstrating a critical superior mesenteric artery stenosis (arrow) and collateral vessel enlargement originating at the inferior mesenteric artery (arrowhead).

► Treatment

Percutaneous transluminal angioplasty (PTA) and stenting has gained acceptance as a first line of therapy for mesenteric ischemia. Results are best for focal, nonirreversible stenoses. Embolization to the gut is a rare but potentially fatal complication of instrumentation of these lesions.

Surgical revascularization of the superior mesenteric and celiac axes may be performed by either endarterectomy or graft replacement. During endarterectomy, a sleeve of aortic intima and the orifice lesions in the celiac or superior mesenteric arteries are removed. The operation is performed by a retroperitoneal approach to the aorta through a left thoracoabdominal incision. Alternatively, Dacron grafts may be brought antegrade from the lower thoracic aorta or retrograde from the iliac arteries to the celiac axis or superior mesenteric artery—operations that are performed from within the abdomen.

Operation should be avoided in patients with acute vasculitis as the underlying cause of mesenteric ischemia; high-dose steroids and immunosuppressive agents are indicated instead.

► Prognosis

Opening flow to the mesenteric vascular bed almost always results in relief of symptoms. The limited durability of endovascular therapy necessitates close follow-up and reintervention if symptoms recur.

ACUTE MESENTERIC ISCHEMIA

Acute mesenteric ischemia is a highly morbid disorder. Patients classically present with excruciating diffuse abdominal pain with a surprising absence of physical findings such as abdominal tenderness or distention—unless actual bowel perforation produces a surgical abdomen. Symptoms of chronic mesenteric ischemia may precede this catastrophic event, or the onset may be sudden if the cause is embolic occlusion of the superior mesenteric artery. The diagnosis can be difficult, and its recognition is often delayed, resulting in irreversible bowel ischemia. The mortality rate from acute mesenteric ischemia remains high. Patients who require massive bowel resection rarely survive or, if they survive, can develop incapacitating short-gut syndrome. The prognosis improves dramatically if revascularization can be achieved prior to intestinal infarction. This obviously requires early diagnosis, which will only occur if the practitioner has a high index of suspicion.

CELIAC ARTERY COMPRESSION

External compression of the celiac artery, or median arcuate ligament syndrome, is an unusual cause of visceral ischemia. It generally affects young adults, with women more often affected than men, and is commonly associated with rapid weight loss. The classic sign is a loud epigastric bruit with exhalation as the crus of the diaphragm descends to compress the artery. The artery is scarred and must be repaired in conjunction with release of the compressing ligament. The diagnosis is difficult to make with certainty because some compression of the celiac artery by the arcuate ligament is common. Surgery should be advised only after an unsuccessful search for other causes of postprandial pain.

Patients with median arcuate ligament compression respond favorably to operation in most cases; however, some of these patients are not improved even though a technically adequate operation is performed.

ARTERIAL ANEURYSMS

► General Considerations

An aneurysm is defined as a localized dilation of an artery to at least 1.5 times its normal diameter. The expanding vessel

elongates as well as dilates. A true aneurysm involves primary dilation of the artery, including all vessel wall layers (intima, media, and adventitia). A false aneurysm, also called pseudoaneurysm, is characterized by a disruption of the artery wall, does not include all layers of the wall, and may actually be a pulsatile hematoma not contained by the artery wall but by a fibrous capsule. A false aneurysm caused by infection is called a mycotic aneurysm.

False aneurysms of the femoral artery secondary to catheterization are the most numerous of all aneurysms. Infrarenal abdominal aortic aneurysms (AAA) are the most common of the true aneurysms. In descending order, other arteries affected are the iliac arteries, the popliteal artery, the arch and descending portions of the thoracic aorta (including dilation after aortic dissection), the common femoral artery, the carotid arteries, and other peripheral arteries. Other rare causes of true aneurysms include Marfan syndrome, Ehlers–Danlos syndrome, Behçet disease, and cystic medial necrosis.

ABDOMINAL AORTIC ANEURYSMS

AAA are found in 2% of the elderly male population, and the incidence may be increasing. In selected groups, the incidence is higher—5% of patients with coronary artery disease and as many as 50% of patients with femoral or popliteal aneurysms have aortic aneurysms. Men are four times as likely to be affected as women. Ruptured aortic aneurysms are a cause of death of men age greater than 65 years in the United States, resulting in 15,000 deaths per year.

Numerous mechanisms have been proposed for the cause of AAA. Structural issues may contribute; reductions in the number of elastic lamellae and virtual absence of vasa vasorum in the media of the distal abdominal aorta compared with the thoracic aorta may favor aneurysmal degeneration. Excessive protease activity or local reductions in the concentration of protease inhibitors have been implicated in aneurysm formation, allowing for the enzymatic destruction of the two principal structural elements of the aorta, elastin, and collagen. There may be hemodynamic factors as well, owing to large pulsatile stresses because of tapering geometry, increased stiffness, and reflected pressure waves from branch vessels in the infrarenal aorta. Genetic factors influencing connective tissue metabolism and structure also have been associated with AAA development. Indeed, a positive family history of aortic aneurysms infers a 20% chance that a first-degree family member will have an aneurysm.

In terms of risk factors, cigarette smoking has a powerful influence on developing an aortic aneurysm, with an 8:1 preponderance of AAA in smokers compared with nonsmokers. The excess prevalence associated with smoking accounted for 78% of all AAA that were 4 cm or larger in the Veterans Administration ADAM study sample.

Hypertension is present in 40% of patients with AAA but did not correlate with enlargement in the ADAM study. Surprisingly, diabetics appear to have a lower incidence of aortic aneurysm formation.

Ninety percent of aneurysms of the abdominal aorta occur between the takeoff of the renal arteries and the aortic bifurcation but may include variable portions of the common iliac arteries. Rupture with exsanguination is the major complication of AAA. Unfortunately, neither the expansion rate nor the rupture risk is predictable. Tension on the aneurysm wall is governed by the law of Laplace. Thus, rupture risk is related to diameter. While relating this to an individual's risk is not possible, population-wide risks have been established. Because most aneurysms cause no symptoms prior to rupture, the number of deaths due to ruptured AAA has not changed significantly in the past 20 years. This has prompted a recommendation for ultrasound screening of smoking males over the age of 65 years.

► Clinical Findings

A. Symptoms and Signs

The vast majority of unruptured aneurysms are asymptomatic. Rarely, intact AAAs produce back pain due to pressure on nerves or erosion into vertebral bodies. Severe pain in the absence of rupture characterizes the rare inflammatory aneurysm that is surrounded by 2-4 cm of perianeurysmal retroperitoneal inflammatory reaction.

Eighty percent of 5 cm AAAs are palpable as a **pulsatile abdominal mass** in the mid-abdomen just above and to the left side of the umbilicus. Physical examination for an AAA is less reliable in obese patients. The aneurysm may be slightly tender to palpation. Extreme tenderness suggests a “symptomatic aneurysm” and is found in inflammatory aneurysms or if the aneurysm has recently expanded. A truly noninflammatory, symptomatic (tender) aneurysm demands urgent surgery.

B. Imaging Studies

Plain films of the abdomen reveal calcification in the outer layers of only 20% of abdominal aneurysms.

Ultrasound is the least expensive method for measuring the size of infrarenal aortic aneurysms. Repeated ultrasound examinations are cost effective for observing small AAAs and may be used to follow resolution of the aneurysm after endovascular repair. However, ultrasound examinations do not delineate adjacent structures as well as CT or MR and are less reliable in obese patients.

CT scan or MRI with 3D reconstructions are both accurate methods for assessing aneurysm diameter, although the ADAM trial showed that there can be substantial inter-reader variability in size determinations (Figure 34-16). An important source of error occurs when the course of the aneurysmal aorta is diagonal to the cross-sectional

▲ **Figure 34-16.** CT showing the typical position of a 5.5-cm abdominal aortic aneurysm and its proximity to the abdominal wall.

image. This creates an elliptical image of the AAA and a falsely elevated diameter in the larger dimension. CT scans provide valuable information about aneurysm location and size as well as important adjacent structures that affect AAA repair, such as horseshoe kidneys or other renal abnormalities, and venous anomalies, including retroaortic renal veins, circumaortic renal veins, and left-sided or duplicated vena cavae, which may have important surgical implications. If the patient has a multiplanar CT scan, aortograms, once routine studies in planning operative management of AAAs, are not needed.

C. Natural History

Most aneurysms continue to enlarge and will eventually rupture if left untreated. The average expansion rate for an AAA is 0.4 cm per year. The rate of expansion correlates with continued smoking, initial aneurysm diameter, and the degree of obstructive pulmonary disease. An expansion of 0.5 cm in 6 months or 1 cm over 12 months qualifies as rapid enlargement and suggests the aneurysm is unstable and should be repaired.

Aneurysm size is currently the best determinant of rupture risk. About 40% of aneurysms 5.5-6 cm or larger in diameter will rupture within 5 years if untreated, and the average survival of an untreated patient is 17 months. In contrast, the ADAM study found a 0.5% per year rupture rate in AAAs 4-5.4 cm, an overall rate remarkably similar to a comparable trial in the United Kingdom. Thus, *surgery is recommended for aneurysms 5.5 cm or more in size*, but small aortic aneurysms can be safely followed. Regardless of size, repair is mandatory for an aneurysm that is symptomatic or enlarging rapidly.

D. Treatment

1. Endovascular repair—Endovascular repair, introduced in 1991, is achieved with a synthetic graft to which metal stents have been attached (Figure 34–17). Endovascular repair requires that the aorta proximal to the aneurysm have a cylindrical configuration ideally 1.5 cm to allow for adequate sealing and iliac arteries of sufficient size and limited tortuosity so that the device can be introduced from the femoral arteries. Devices for endovascular repair of AAAs are delivered using a system of guidewires and delivery systems with large-bore sheaths. Several devices are available with unique design features. In series of comparable patients, patients with endovascular repair have less operative blood loss, shorter hospital stays, and reduced operative morbidity compared to those undergoing conventional repair.

The most important intermediate or long-term adverse outcome of endovascular repair is persistent perfusion of the aneurysm (“endoleak”). These are divided into types denoting clinical importance. A type 1 endoleak denotes ineffective proximal or distal sealing with pressurization of the aneurysm sac and should be fixed immediately. A type 2 endoleak results in persistent flow through the aneurysm between small aortic branches, usually from the inferior

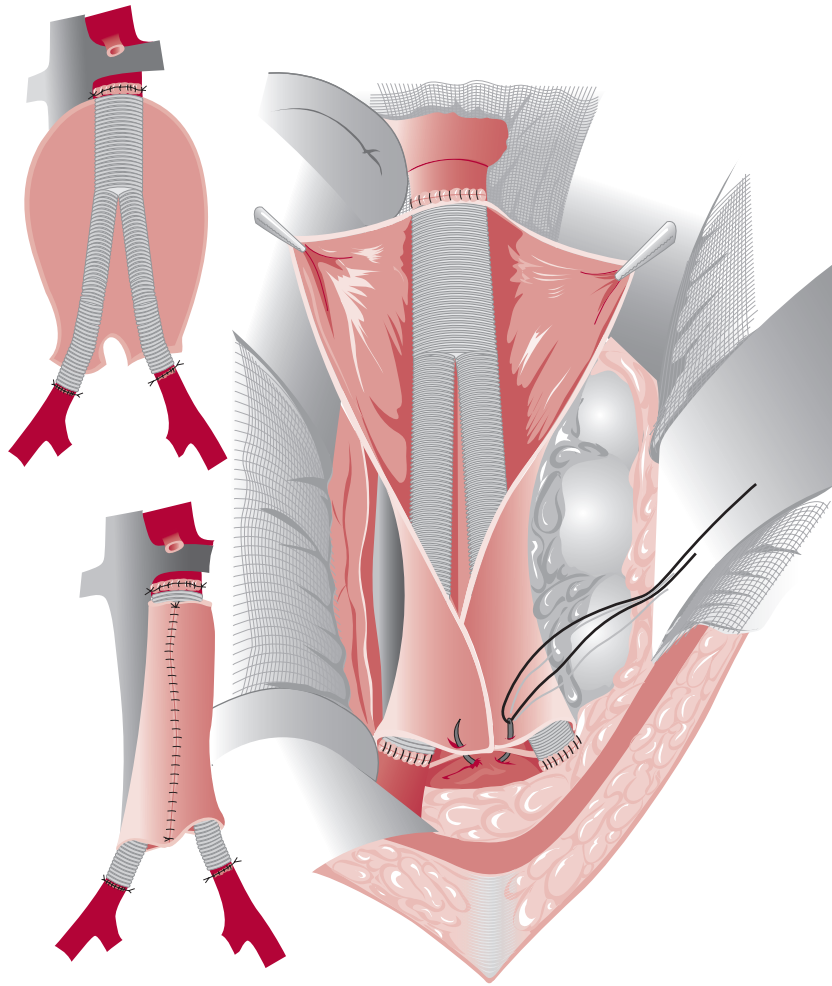

mesenteric artery to a patent lumbar artery. These have relatively low pressures and, unless the aneurysm is enlarging, are not treated. Pressurization of the aneurysm through the graft itself is a type 3 endoleak. The graft should be repaired or replaced if the aneurysm continues to enlarge over time due to a type 2 or type 3 leak.

Rupture has occurred after endovascular aortic aneurysm repair. The rate of late ruptures is low but underscores that patients need extended follow-up to ensure the durability of endovascular aneurysm repair. Endograft repair is more expensive than open repair in spite of the lower perioperative morbidity and shorter hospital stays. The devices are expensive (\$10,000–15,000), and there is further cost due to the extended follow-up with imaging studies to identify graft movement or endoleak.

2. Open repair—Conventional open operative AAA repair consists of replacing the aneurysmal segment with a synthetic fabric graft (Figure 34–18). Tubular or bifurcation grafts of Dacron or PTFE are preferred. The proximal anastomosis is made to the aorta above the aneurysm. The site of the distal anastomosis is determined by the extent of aneurysmal involvement of the iliac arteries. Traditionally, a transperitoneal approach via midline laparotomy has been

▲ **Figure 34–17.** **A:** Three-dimensional CT angiogram reconstruction of abdominal aortic aneurysm. White arrow points to aortic flow lumen at same level as that in panel B. **B:** Axial CT view. White arrow points to flow lumen, black arrow points to thrombus within aneurysm sac. Notice only aortic flow lumen visualized on CT angiogram, just as in conventional angiography. Total diameter of the aorta, including area containing thrombus, is used in predicting rupture risk and determining need for intervention. **C:** Three-dimensional CT angiogram following aortic stent graft repair.

▲ **Figure 34-18.** Replacement of an aortic aneurysm with a synthetic bifurcation graft. The laminated clot within the aneurysm has been removed, and the outer wall is closed over the graft.

used for AAA repair, but retroperitoneal operations via flank incision may decrease perioperative pulmonary and gastrointestinal complications.

Elective infrarenal abdominal aneurysmectomy has a 2%–4% operative death rate and a 5%–10% rate of complications, such as bleeding, renal failure, myocardial infarction, graft infection, limb loss, bowel ischemia, and erectile dysfunction. Paraplegia is a very rare complication due to involvement of an abnormally low artery of Adamkiewicz, a major collateral of the anterior spinal artery. Malignant tumors are encountered unexpectedly in about 4% of cases, although that rate is now dwindling with the routine use of multiplanar CT scans. If gastrointestinal malignancy is encountered during an aneurysm resection, the aneurysm

repair should be done first unless there is impending bowel obstruction.

Long-term results of open aneurysmectomy are excellent: graft failure rate is low and false aneurysm formation at the anastomoses is rare. The long-term survival of these patients is determined principally by their extent of coronary artery disease.

ILIAC ANEURYSMS

Iliac artery aneurysms generally occur in conjunction with AAAs. Isolated iliac aneurysms are unusual, but in some cases, the iliac segment of the aneurysmal artery may enlarge at a greater rate than the aortic segment and is the primary

reason for repair. As with aortic aneurysms, most iliac aneurysms are asymptomatic. However, they may present with symptoms related to compression or erosion of surrounding structures, such as obstructive uropathy with ureteral obstruction, neuropathy from compression of local nerves, and unilateral leg swelling from compression of the adjacent iliac vein.

Physical examination can suggest the diagnosis of large (> 4 cm) iliac artery aneurysms if the physician is alert to that possibility. Most symptomatic iliac aneurysms can be palpated as pulsatile masses on abdominal or rectal examinations. However, iliac aneurysms are usually found incidentally on ultrasound or CT.

Similar to aortic aneurysms, iliac aneurysms tend to enlarge and rupture unpredictably, but size is the most important determinant of rupture risk. Iliac aneurysms that are less than 3.5 cm in size should be followed up with serial imaging. Those that enlarge to 4 cm should be repaired in patients without serious operative risk factors.

The challenge of iliac aneurysm repair is in preserving flow to the pelvis through at least one internal iliac artery to prevent pelvic ischemia that can present as buttock claudication, impotence, or ischemia of the distal colon. Open repair of isolated iliac arteries is well tolerated and can be done through a retroperitoneal approach. If the ipsilateral hypogastric artery is also aneurysmal, repair will require opening the sac and ligating the branches from within the aneurysm, taking care not to injure the iliac veins surrounding the aneurysm.

SUPRARENAL AORTIC ANEURYSMS

Aneurysms of the segment of aorta between the diaphragm and the renal arteries account for only 10% of AAAs, with 6% being pararenal and 4% involving the visceral vessels. Resection and graft replacement of the upper abdominal aorta is an operation of far greater magnitude and risk than operations on the infrarenal aorta. Involvement of the renal arteries doubles operative mortality with substantial additional risk for involvement of the visceral vessels. Renal failure and bowel ischemia are much more common after repair of these aneurysms than after repair of infrarenal aortic aneurysms. There is also a risk of paraplegia if flow is interrupted to the artery of Adamkiewicz. An extended incision is usually necessary, and provisions must be made for revascularization of the celiac axis and the superior mesenteric and renal arteries. The use of perfusion catheters for the visceral and renal arteries has improved results, and left heart bypass is used in true thoracoabdominal aneurysms.

Because of the mortality and morbidity of repair of suprarenal aneurysms, there has been considerable interest in endovascular repair of these aneurysms using branched systems. Initial experience from selected centers, including our own, has shown dramatic reduction in morbidity and

mortality from these technically demanding endovascular procedures. In patients judged to be high risk for open repair, branched graft repair has equaled the best reported results for open repair.

RUPTURED AORTIC ANEURYSMS

► General Considerations

With increasing aneurysm size, lateral pressure within the aneurysm will eventually lead to spontaneous rupture of the aneurysm wall. Although immediate exsanguination may ensue, there is often an interval of several hours between the first episode of bleeding and death from exsanguination when the initial bleed is contained in the retroperitoneal tissues, a “contained rupture.” When the periaortic tissue can no longer contain the expanding hematoma, “free rupture” occurs with exsanguination into the free peritoneal cavity.

► Clinical Findings

The patient presents with sudden, severe abdominal pain that usually radiates into the back and occasionally into the inguinal region. Lightheadedness or syncope results from blood loss. Pain may lessen and lightheadedness may disappear after the first hemorrhage, only to reappear and progress to shock if bleeding continues. When bleeding remains contained in the periaortic tissue, a discrete, pulsatile abdominal mass may be felt. In contrast with an intact aneurysm, the ruptured aneurysm at this stage is painful to palpation. Signs of an acute abdomen may be present. As bleeding continues, usually into the retroperitoneum, the discrete mass is replaced by a poorly defined mid-abdominal fullness, often extending toward the left flank.

Shock can be profound, manifested by peripheral vasoconstriction, hypotension, and anuria. Unfortunately, the classic triad of pain, a pulsatile abdominal mass, and hypotension is not always present, and precious time may be lost while confirming the diagnosis. An abdominal ultrasound performed in the emergency room will confirm the presence of an aortic aneurysm but may not disclose hemorrhage. CT scans reliably confirm hemorrhage from an aneurysm, but in unstable patients, the delay in progressing to the operating room precludes their use. It is best to follow the adage that a patient with an AAA, signs of an acute abdomen, and hypotension belongs in the operating room.

► Treatment & Prognosis

Repair should be performed as soon as intravenous fluids have been started, the airway has been secured, and blood has been sent for cross-matching. Surgical control of the aorta proximal and distal to the aneurysm must be obtained immediately and should be attempted from the abdomen. Attempts to control the proximal aorta through the chest have been associated with poor outcomes. A successful

outcome of the operation is related to the patient's condition on arrival, the promptness of diagnosis, and the speed of operative control of bleeding and blood replacement. The operative death rate is between 30% and 80%, with an average of approximately 50%. Because many patients with ruptured aneurysms die before reaching the hospital, the overall death rate approaches 80%. Without operation, the outcome is uniformly fatal. Many centers are now treating ruptured AAA using endovascular stent grafts; morbidity and mortality remain high and abdominal compartment syndrome has been a complication requiring evacuation of the retroperitoneal hematoma.

INFLAMMATORY ANEURYSMS

Inflammatory aneurysms are degenerative aneurysms that elicit a unique inflammatory response adjacent to the external calcified layer of the aneurysm wall. Although similar to retroperitoneal fibrosis, the inflammation is usually confined to the anterior aorta and iliac arteries. The aneurysm may be responsible to chronic abdominal pain and is tender to palpation. One fourth of patients have some degree of ureteral obstruction. CT scanning reliably demonstrates the characteristic thickened wall and confirms the diagnosis. Characteristic pathologic changes include infiltration of the aortic wall by lymphocytes, plasma cells, occasional multinucleated giant cells, and lymphoid follicles with germinal centers. Inflammation resolves in most cases after successful repair. Inflammatory aneurysms are easily recognized at operation by the dense, shiny, white, fibrotic material that envelops the adjacent viscera, especially the duodenum, left renal vein, and inferior vena cava. Those structures are therefore especially vulnerable to operative injury. Endovascular repair is ideal and is the procedure of choice for inflammatory aneurysms. After repair, the inflammatory tissue usually regresses.

INFECTED (MYCOTIC) ANEURYSMS

The confusing term "mycotic aneurysm" is commonly used to denote infected aneurysms in general, which are rarely fungal. The aneurysm is secondary to a microbial aortitis in which virulent bacteria infect the aorta and destroy the aortic wall. Historically, salmonella infection was the most common cause. In the current era, staphylococcus is the more common infection due to intravenous drug use. These organisms may involve every major artery, but aortic involvement predominates.

The typical patient presents with a rapidly enlarging, tender pulsatile mass that may feel warm, if palpable. Fever is present, and half the patients have positive blood cultures. Alternatively, the aneurysm may be discovered late, after successful treatment of the infection. Angiography of these

patients may show a saccular false aneurysm. Treatment consists of excision and remote bypass grafting if possible. Liberal application of muscle flap coverage techniques facilitates healing. Direct repair has been successful when done after a course of antibiotics. A prolonged course of antibiotics should be given to guard against recurrence.

PERIPHERAL ARTERIAL ANEURYSMS

General Considerations

Popliteal artery aneurysms account for 70% of peripheral arterial aneurysms. Like aortic aneurysms, they are silent until critically symptomatic. However, unlike aortic aneurysms, they rarely rupture. The presenting manifestations are due to peripheral embolization and thrombosis, possibly due to movement of the artery with knee flexion. Popliteal aneurysms may embolize repetitively over time and occlude distal arteries. Due to the redundant parallel arterial supply to the foot, ischemia does not occur until a final embolus occludes flow to the remaining tibial/peroneal artery. Acute ischemia caused by popliteal aneurysms has a poor prognosis because of the chronicity of the process. The results of both chemical and mechanical thrombolysis may be disappointing because of clot age and adherence to the artery wall. After presentation with acute ischemia, approximately one third of patients will require an amputation. To prevent embolization and thrombosis, popliteal artery aneurysms should be repaired electively if greater than 2 cm in diameter or at any size if lined with thrombus.

Primary aneurysms of the femoral artery are much less common than aneurysms of the popliteal artery. However, pseudoaneurysms of the femoral artery following arterial punctures for arteriography and cardiac catheterization occur with an incidence ranging from 0.05% to 6%. Thrombosis and embolization are the main risks of femoral true or false aneurysms and, like popliteal aneurysms, should be repaired when greater than 2 cm in diameter.

Clinical Findings

A. Symptoms and Signs

Until progressive embolization or thrombosis occurs, peripheral artery aneurysms are usually asymptomatic. The patient may be aware of a pulsatile mass when the aneurysm is in the groin, but popliteal aneurysms are often undetected by the patient and physician. Peripheral aneurysms may produce symptoms by compressing the local vein or nerve, but this is unusual. In most patients, the first symptom is due to ischemia of acute arterial occlusion. The pathologic findings range from rapidly developing gangrene to moderate ischemia that slowly lessens as collateral circulation develops. Symptoms from recurrent embolization to the leg are often transient if they occur at all. Sudden ischemia may appear

in a toe or part of the foot, followed by slow resolution, and the true diagnosis may be elusive. The onset of recurrent episodes of pain in the foot, particularly if accompanied by cyanosis, suggests embolization and requires investigation of the heart and proximal arterial tree.

Because popliteal pulses are somewhat difficult to palpate even in normal individuals, a particularly prominent or easily felt pulse is suggestive of aneurysmal dilation and should be investigated by ultrasound. Since popliteal aneurysms are bilateral in 60% of cases, the diagnosis of thrombosis of a popliteal aneurysm is often aided by the palpation of a pulsatile aneurysm in the contralateral popliteal space. Approximately 50% of patients with popliteal aneurysms have an aneurysmal abdominal aorta.

B. Imaging Studies

Duplex color ultrasound is the most efficient investigation to confirm the diagnosis of peripheral aneurysm, to measure its size and configuration, and to demonstrate mural thrombus.

Arteriography may not demonstrate aneurysms accurately, because mural thrombus reduces the apparent diameter of the lumen. Three-dimensional imaging by CTA or MRA is required—especially when operation is considered—to define the anatomy and plan intervention.

C. Treatment

Early operation is indicated for an aneurysm that is greater than 2 cm in size associated with any peripheral embolization or an aneurysm with mural thrombus. Urgent operation is indicated when acute embolization or thrombosis has caused acute ischemia. Intra-arterial thrombolysis may be done in the setting of acute ischemia if examination (light touch) suggests that immediate surgery is not imperative to prevent tissue loss. Bypass with saphenous vein may include either excision or exclusion, depending on location. If exclusion rather than resection is performed, the geniculate “feeder” arteries within the aneurysm should be ligated or progressive enlargement can still occur.

Endovascular repair with covered stents can be used but are less durable than open repair and should be reserved for patients at high operative risk.

Acute pseudoaneurysms of the femoral artery due to arterial punctures can be successfully treated using ultrasound-guided compression and thrombin injections if the aneurysm is not large.

D. Prognosis

The long-term patency of bypass for femoral and popliteal aneurysms is generally excellent but depends on the adequacy of the outflow tract. Late graft occlusion is less common than in similar operations for occlusive disease.

UPPER EXTREMITY ANEURYSMS

▶ Subclavian Artery Aneurysms

Subclavian artery aneurysms are less common than aneurysms of the lower extremity, and most supraclavicular pulsatile masses represent tortuous vessels, not aneurysms. Pseudoaneurysms due to injections by drug addicts are becoming increasingly frequent. An anomaly, the aberrant right subclavian artery (incidence 0.5%), arises from the aorta distal to the left subclavian and courses behind the esophagus. As found in other aberrant arteries, enlargement is common and may compress the esophagus against the trachea, causing difficulty swallowing (termed dysphagia lusoria). This anomaly also is the most common cause of a nonrecurrent laryngeal nerve.

A true subclavian artery aneurysm is usually due to post-stenotic dilation in a patient with thoracic outlet syndrome or a large callous from a fractured clavicle. As with popliteal aneurysms, the most common manifestation is embolization with episodic hand ischemia and Raynaud’s phenomenon. The diagnosis is often missed. Sudden onset Raynaud’s, particularly with a history of waxing and waning digital ischemia, is indication for arterial imaging. Treatment consists of resection of the restricting structures at the time of arterial replacement.

▶ Radial Artery False Aneurysms

The incidence of radial artery false aneurysms has increased as a result of increasing use of radial artery catheters. Occasionally, the aneurysm is infected. If the Allen test is normal and adequate collateralization is confirmed with imaging, treatment consists of excision and ligation. If the ulnar collaterals are insufficient to preserve viability of the hand, excision and replacement with vein should be performed.

Small aneurysms of the palmar arch may be due to repetitive trauma. These aneurysms can be responsible for emboli to the digital arteries. The adage that hand ischemia requires angiography should be applied to ensure that all potentially reversible causes of hand ischemia, including these unusual aneurysms, be identified.

VISCERAL ARTERY ANEURYSMS

General Considerations

The etiology of this interesting group of aneurysms is generally unknown. Most often they occur as single lesions in a younger age group than those at risk for aortic aneurysms. Rupture is the primary danger and is one cause of “abdominal apoplexy.”

Splenic Artery Aneurysms

Aneurysms of the splenic artery account for more than 60% of splanchnic artery aneurysms. Women are affected four times more commonly than men and often during child-bearing years. Arterial fibrodysplasia and portal hypertension predispose to formation of splenic artery aneurysms. Rupture, the major complication, has been reported in less than 2% of splenic aneurysms; it rarely occurs with lesions smaller than 2–3 cm in diameter. Rupture during pregnancy tends to occur in the third trimester and is associated with a 75% maternal death rate and 90% fetal death rate. Diagnosis is most often made from plain x-ray films of the abdomen, showing concentric calcification in the upper left quadrant.

Intervention is indicated for patients with symptomatic aneurysms, aneurysms in pregnant women, and patients who have a low operative risk profile with aneurysms greater than 3 cm in diameter. Endovascular repair with covered stent grafts is ideal with the use of microcatheters developed for intracranial work, improving the ability to negotiate the often tortuous splenic artery. Laparoscopic ligation of the artery is also feasible.

Hepatic Artery Aneurysms

Hepatic artery aneurysms account for 20% of splanchnic artery aneurysms. There is a 2:1 male-to-female ratio, and the frequency of reported rupture is about 20%. Aneurysm rupture is associated with a 35% mortality rate. Rupture into the biliary tree producing hemobilia is as frequent as intraperitoneal rupture. The symptom triad of intermittent abdominal pain, gastrointestinal bleeding, and jaundice strongly suggests the diagnosis and is present in about one third of patients. Surgery is usually required to control bleeding. If the common

hepatic artery is involved, the artery may be safely ligated if collateral flow through the gastroduodenal artery has been demonstrated. Aneurysms in other portions of the artery usually require vascular reconstruction. Endovascular placement with a covered stent is preferred if the anatomy is suitable.

Superior Mesenteric Artery Aneurysms

Aneurysms of the proximal superior mesenteric artery account for 5% of all splanchnic artery aneurysms. Unlike splenic or hepatic aneurysms, 60% of superior mesenteric artery aneurysms are mycotic. The aneurysm may involve the origin or branches of the artery. Symptoms include nonspecific abdominal pain. The diagnosis can be made on CT scan.

Operative therapy for mycotic superior mesenteric artery aneurysms includes ligation if there are adequate collaterals or replacement with a segment of autogenous vessel. Endovascular stent graft placement is not advisable in an acute infection. However, it is valuable for true aneurysms as long as critical branches can be avoided. For distal branch aneurysms, bowel resection may be necessary.

RENAL ARTERY ANEURYSMS

This uncommon aneurysm occurs in less than 0.1% of the population and is often associated with hypertension. The aneurysm is usually saccular and located at a primary or secondary bifurcation of the renal arteries. Women are affected slightly more frequently than men. There are three principal categories: (1) idiopathic, (2) aneurysms associated with medial fibrodysplastic disease, and (3) arteritis-related microaneurysms.

Renovascular hypertension may occur because of distortion of the involved or nearby vessels by the aneurysm. Spontaneous rupture of renal artery aneurysms is rare except during pregnancy. CT scans or digital subtraction angiography should be performed to monitor enlargement. Operation is indicated in women of childbearing age or in patients with associated renal artery disease, uncontrolled hypertension, or large aneurysms. Most renal artery aneurysms can be repaired in situ, but ex vivo repair is occasionally required. Endovascular options are usually limited due to the involved vessel size and the aneurysm's proximity to artery branch points.

VASOCONSTRICTIVE DISORDERS

General Considerations

Vasoconstrictive disorders are characterized by abnormal activity of the sympathetic nervous system that reduces peripheral blood flow, causing tissue ischemia.

Raynaud's Disease/Phenomenon

Raynaud's disease/phenomenon consists of sequential pallor, cyanosis, and rubor of fingers or toes after exposure to cold. Excessive vasoconstriction, sluggish flow, and reflex vasodilation produce the characteristic white-blue-red color changes.

In Raynaud's disease, this response, due to spasm alone without underlying arterial lesions, is quite common and benign.

Sudden onset or progression of symptoms suggests underlying arterial lesions that exaggerate the normal reduction in blood flow caused by vasoconstriction. This is termed Raynaud's phenomenon, a more virulent entity associated primarily with immunologic and connective tissue disorders (eg, scleroderma, systemic lupus erythematosus, polymyositis, or drug-induced vasculitis). However, repeated embolization, occupational trauma (vibration injury, cold injury), and other disorders (cold agglutinins, chronic renal failure, and neoplasia) also have been reported.

Hyperreactivity to cold stimuli may be the initial presentation of arterial pathology. In new onset or severe cases of Raynaud's-type symptoms, a search for underlying pathology is required. All patients with Raynaud syndrome should avoid cold exposure, tobacco, oral contraceptives, β -adrenergic blocking agents, and ergotamine preparations. Calcium-channel blockers are generally prescribed but may cause hypotension. Transdermal prostaglandins, ketanserin, and cilostazol also have been used, with relief of symptoms in some patients. In rare cases, symptoms progress to tissue loss. Finger amputation is necessary once gangrene has developed.

► Acrocyanosis

Acrocyanosis is a common, chronic, benign vasoconstrictive disorder related to Raynaud syndrome that is largely restricted to young women. It is characterized by persistent cyanosis of the hands and feet. The changes disappear with exposure to a warm environment. Examination in a cool room shows diffuse symmetric cyanosis, coldness, and occasionally hyperhidrosis of the hands and feet. Cyanosis of the skin of the calf, thigh, or forearm usually displays a reticulated pattern and has been called livedo reticularis and cutis marmorata. The peripheral pulses may diminish in the cold but return to normal with rewarming.

THORACIC OUTLET SYNDROME

► General Considerations

Thoracic outlet syndrome refers to the variety of disorders caused by abnormal compression of arterial, venous, or neural structures in the base of the neck. Numerous mechanisms for compression have been described, including cervical rib, anomalous ligaments, hypertrophy of the anterior scalene muscle, and positional changes that alter the normal relation of the first rib to the structures that pass over it. Patients may describe a history of cervical trauma.

Symptoms rarely develop until adulthood. For this reason, it has been assumed that an alteration of normal structural relationships that occurs with advancing years is the primary factor. Even anomalous cervical ribs seem well tolerated during childhood and adolescence.

Transient circulatory changes may occur, but the primary cause of symptoms in most patients is intermittent compression of one or more trunks of the brachial plexus. Thus, neurologic symptoms predominate over those of ischemia or venous compression. When present, compression of the subclavian artery and vein in the thoracic outlet also can produce severe sequelae. Compression of the subclavian artery can produce stenosis and poststenotic dilation of the artery, leading to arterial occlusion or emboli, as discussed earlier. Compression of the vein between the anterior scalene, clavicle, and first rib can produce thrombosis, which can result in severe upper extremity pain and swelling. Compression may be exaggerated with exercise precipitating an occlusion. This syndrome is termed effort thrombosis or **Paget-Schroetter syndrome**.

► Clinical Findings

A. Symptoms and Signs

Neural symptoms consist of pain, paresthesias, or numbness in the distribution of one or more trunks of the brachial plexus (usually in the ulnar distribution). Most patients associate their symptoms with certain positions of the shoulder girdle. These may occur from prolonged hyperabduction, as in house painters, hairdressers, and truck drivers. Others may relate their symptoms to the downward traction of the shoulder girdle produced by carrying heavy objects. Numbness of the hands often wakes the patient from sleep. On physical examination, motor deficits are rare and usually indicate severe compression of long duration. Muscular atrophy may be present in the hand. Pulses can be weakened by abduction of the arm with the head rotated to the opposite side (Adson test), though pulse reduction by this maneuver often occurs in completely asymptomatic persons. Light percussion over the brachial plexus in the supraclavicular fossa may reproduce the symptoms in patients with chronic neurologic impingement.

Arterial symptoms are less common and often the result of emboli. A bruit may be heard over the subclavian artery with abduction of the arm, but this is not a specific finding. Venous occlusion results in unilateral arm swelling. There are good collaterals around the shoulder girdle, but symptoms may be debilitating in young active patients, the very patient in whom this is most likely to occur.

B. Diagnosis

Neurogenic thoracic outlet compression must be differentiated from other disorders that mimic this condition (eg, carpal tunnel syndrome and cervical disk disease). Cervical x-rays and peripheral nerve conduction studies are not diagnostic but are valuable to eliminate other possibilities. Unfortunately, there is no recognized objective study to unequivocally confirm the diagnosis of neurogenic thoracic outlet syndrome. Arteriograms may demonstrate subclavian or axillary artery stenosis when the arm is in abduction. This finding is not diagnostic, but poststenotic

dilation of the artery is distinctly abnormal and indicates a definite lesion.

► Treatment

Most patients with neurogenic TOS benefit from postural correction and a physical therapy program directed toward restoring the normal relation and strength of the structures in the shoulder girdle. Surgical techniques for decompression of the thoracic outlet are reserved for patients who have not responded after 3-6 months of conservative treatment. Some surgeons prefer transaxillary first rib resection, while others prefer a supraclavicular approach. With either operation, the anterior scalene muscle and any associated fibrous bands should be excised. Up to 90% of patients report cure or significant improvement.

Symptomatic arterial stenoses require decompression of the thoracic outlet in combination with arterial reconstruction. Effort thrombosis of the subclavian vein is usually best treated by catheter-directed thrombolysis of the venous occlusion followed by thoracic outlet decompression with or without operative venous reconstruction or angioplasty. Outcomes for these patients with vascular TOS symptoms are excellent with 80%–90% asymptomatic at 6 months.

ARTERIOVENOUS FISTULAS

Arteriovenous fistulas may be congenital, often called “malformations,” or acquired. Abnormal communications between arteries and veins occur in many diseases and affect vessels of all sizes and in many locations. In congenital fistulas, the systemic effect is often not great, because although the communications may be multiple, they are small. When a limb is involved, extensive arteriovenous communications may exist with increased flow and increased muscle mass and bone length. Surgical correction is rarely successful because of the numerous A-V connections. Massive swelling can be treated with ablation therapy but it also is rarely curative.

Acquired fistulas are usually the result of trauma, violent, or iatrogenic. These communications can have considerable flow, and high-output heart failure can occur. The third class of fistulas is surgically created fistulas for hemodialysis access.

Arteriovenous malformations in the gastrointestinal tract may cause hemorrhage. Osler-Weber-Rendu disease or syndrome (also termed hereditary hemorrhagic telangiectasia) is an autosomal dominant disorder characterized by gastrointestinal bleeding and epistaxis due to large arteriovenous anomalies in the gastrointestinal tract and lungs.

Pulmonary lesions cause recirculation with lower PO_2 , polycythemia, clubbing, and cyanosis.

Penetrating injuries either from trauma or iatrogenic ones from arterial punctures are the most common causes of acquired fistulas. Blunt trauma, erosion of an atherosclerotic or mycotic arterial aneurysm into adjacent veins, communication with an arterial prosthetic graft, or neoplastic invasion can all cause arteriovenous fistulas as well. When large vessels are involved, the presentation may be dramatic. For example, if an aortic aneurysm ruptures into the inferior vena cava, the fistula enlarges rapidly and can result in cardiac dilation and failure.

ARTERIOVENOUS FISTULA FOR HEMODIALYSIS

► General Considerations

A successful arteriovenous fistula for hemodialysis access requires a large vein (> 5 mm) that lies close to the skin for at least 20 cm. The cephalic vein is ideal for this purpose. A 3-mm vein will usually be able to dilate to 5-6 mm after arterializations. The radial artery to cephalic vein arteriovenous fistula (Cimino fistula) is the classic hemodialysis access fistula. If no suitable vein is available for an autogenous fistula, prosthetic grafts are used, most commonly PTFE. These are most commonly placed in a loop configuration. The poor patency rates of these grafts, 40% at 2 years, and potential for infection have driven national guidelines to encourage a higher rate of autogenous fistula formation. To maximize autogenous vein utilization, current practice includes transposing deep veins such as the basilic vein in the upper arm to the subcutaneous tissue. All veins used for access require dilation and “arterialization” of the wall, which takes at least 6 weeks prior to cannulization for dialysis. Transposed veins may take even longer to mature.

Flow rates of at least 300 cc/min are necessary for efficient dialysis. Patients with a newly created arteriovenous access should be watched carefully for arterial steal and distal extremity ischemia. Diabetics are the most vulnerable to this complication because of calcified proximal arteries or intrinsic arterial lesions of the arm. High-output cardiac failure occurs only rarely.

► Clinical Findings

A. Symptoms and Signs

A typical continuous machinery murmur can be heard over the arteriovenous fistulas and is often associated with a palpable thrill and locally increased skin temperature. Proximally, the arteries and veins dilate, and the pulse distal to the lesion diminishes. There may be signs of venous insufficiency, coolness, and hypertrophy distal to the communication on the involved extremity. Tachycardia occurs in some patients as a feature of increased cardiac output. The pulse rate slows (Branham sign) when the fistula is occluded by compression.

In contrast, venous malformations rarely produce hemodynamic effects. In this disorder, the presence of a mass, which may or may not be tender, is the principal finding. Because flow rates are low, bruits and thrills are absent.

B. Imaging Studies

MRI has become the imaging study of choice for the evaluation and follow-up of peripheral arteriovenous malformations, but CTA also gives excellent anatomic information. Precise delineation of arteriovenous fistulas can be done with selective angiography.

► Treatment

Not all arteriovenous connections require treatment. Most venous malformations should be treated conservatively. In addition, small peripheral fistulas may be observed and will often remain asymptomatic. Some are surgically inaccessible.

The indications for intervention include hemorrhage, local expansion, severe venous or arterial insufficiency, cosmetic deformity, and, rarely, heart failure. Most fistulas are now managed by embolization under radiographic control. The embolic material used includes blood clot, glass beads, and Gelfoam. Arteriovenous malformations of the head and neck and of the pelvis appear particularly well suited for this form of therapy. Direct injection of sclerosant compounds into venous malformations under fluoroscopic control also has been successful in at least temporarily reducing flow and swelling.

Surgical options are generally reserved for large acquired fistulas. When the fistulous connections involve substantial portions of an extremity, local ligation is invariably followed by recurrence, and only temporary palliation can be expected. Covered stent grafts are now being used for a variety of traumatic fistulas.

► Prognosis

The results of therapy vary according to the extent, location, and type of fistula. In general, traumatic fistulas have the most favorable prognosis. Congenital fistulas are more difficult to eradicate because of the numerous arteriovenous connections present.

Sidawy AN, Spergel LM, Besarab A, Allon M, Jennings WC, et al: The Society for Vascular Surgery: clinical practice guidelines for the surgical placement and maintenance of arteriovenous hemodialysis access. *J Vasc Surg* 2008;48:2S.

MULTIPLE CHOICE QUESTIONS

- Arterial occlusive disease
 - Occurs predominantly due to congenital abnormalities or anatomical anomalies
 - Includes disease caused by atherosclerotic plaques, which typically develop at arterial branch points of high shear stress
 - Is masked by collateral arterial circulation that typically has a lower resistance than the original unobstructed artery
 - Typically occurs with at least a 50% reduction in arterial diameter, which correlates with a 75% narrowing of cross-sectional area
 - Causes symptoms due to high pressure proximal to stenosis
- Intermittent claudication symptoms include all of these except
 - “Cramping” in a muscle
 - Deep-seated ache in the calf
 - Can be associated with walking
 - Pain occurs at rest
 - “Tiredness” in a muscle
- Acute lower limb ischemia
 - Usually is caused by increased muscular demand for blood flow in the distribution of an occluded artery
 - Can be caused by a major arterial dissection
 - Causes the five Ps: Pain, Petechiae, Pulselessness, Paresthesias, Paralysis
 - Is generally best managed by initial observation to allow recruitment of collaterals
 - Threatens skin loss before muscle or nerve damage
- Carotid endarterectomy
 - Cannot be performed when the carotid artery is completely occluded
 - Has not been shown to be beneficial for any patients in prevention of ipsilateral stroke
 - Is performed through a catheter placed in the ipsilateral femoral artery
 - Carries a 30% risk of transient cranial nerve injury
 - Has a restenosis rate of 35% at 5 years
- Arterial aneurysm
 - Management requires operative or catheter-based intervention in nearly all patients
 - Management should include urgent operation in most patients
 - Is defined as a localized dilation of an artery to at least 1.5 times its normal diameter
 - Is caused by a disruption of the artery wall and does not include all layers of the wall
 - Is most commonly a mycotic aneurysm

Thomas W. Wakefield, MD

I. THE VEINS

VENOUS ANATOMY

Veins of the lower extremity (Figure 35–1) consist of superficial and deep systems joined by venous perforators. The great and small saphenous veins are superficial—veins, the name “saphenous” aptly derived from the Greek word for “manifest, clear,” or “visible.” They contain many valves and show considerable variation in their location and branching points. The great saphenous vein may be duplicated in up to 10% of patients. Typically, it originates from the superficial arch of the foot and is found anterior to the medial malleolus at the ankle. As it ascends in the calf just beneath the superficial fascia, it is joined by two major tributaries: an anterior vein, which crosses the tibia; and a posterior arch vein, which arises posterior to the medial malleolus beside the posterior tibial artery. The great saphenous vein then enters the fossa ovalis in the groin to empty into the deep femoral vein.

The saphenofemoral junction is marked by four or five prominent branches of the great saphenous vein: the superficial circumflex iliac vein, the external pudendal vein, the superficial epigastric vein, and the medial and lateral accessory saphenous veins. Another important anatomic landmark is the relationship of the great saphenous vein to the saphenous branch of the femoral nerve; as it emerges from the popliteal space, the nerve follows a course parallel to the vein. Injury during saphenous vein harvest for bypass produces neuropathic pain or numbness along the medial calf and foot. The small saphenous vein arises from the superficial dorsal venous arch behind the lateral malleolus at the ankle and curves toward the midline of the posterior calf, ascending to join the popliteal vein behind the knee.

Deep veins of the leg parallel the courses of the arteries. Two or three *venae comitantes* accompany each tibial artery. At the knee, these paired high-capacitance veins merge to form the popliteal vein, which continues proximally as the

femoral vein. At the inguinal ligament, the femoral and deep (profunda) femoral veins join medial to the femoral artery to form the common femoral vein. Proximal to the inguinal ligament, the common femoral vein becomes the external iliac vein. In the pelvis, external and internal iliac veins join to form common iliac veins that empty into the inferior vena cava (IVC). The right common iliac vein ascends almost vertically to the IVC while the left common iliac vein takes a more transverse course. For this reason, the left common iliac vein may be compressed between the right common iliac artery and lumbosacral spine, a condition known as May–Thurner syndrome when thrombosis of the left iliac vein occurs.

Muscular sinusoids represent another component of the deep veins of the leg. These thin-walled, nonvalved venous lakes run longitudinally within soleus muscle bellies and then coalesce to join the posterior tibial and peroneal veins. Blood empties from these sinusoids during muscle contraction; inactivity leads to stasis and may contribute to the development of deep venous thrombosis (DVT).

Blood flow is directed from superficial to deep veins of the leg via valved perforating (communicating) veins. Perforators are located below the medial malleolus (infra-malleolar perforator), in the medial calf (Cockett perforators), at the level of the adductor canal (Hunterian perforator), and just above (Dodd perforator) and below (Boyd perforator) the knee.

Delicate bicuspid venous valves prevent reflux and direct the flow of blood from the foot and leg toward the heart and generally against gravity. Valves are more numerous in the distal part of the extremity, decrease in number proximally, and are virtually absent in the IVC itself.

The IVC ascends in the abdomen and ends at the right atrium. It lies to the right of the midline, lateral to the aorta, and receives a number of lumbar veins that connect with the vertebral and paravertebral venous plexuses. The IVC and its tributaries are derived in the 6th to 10th week of life from the fusion and obliteration of several paired embryonic veins:

the anterior and posterior cardinal veins, the subcardinal veins, the supracardinal veins, and the sacrocardinal veins. Because of this complex embryonic development, anomalies in the venous system are not uncommon. The most common abnormality is a circumaortic left renal vein (1.5%-8.7% incidence), followed by a retroaortic left renal vein (1.2%-3.4% incidence), duplication of the IVC (1%-3% incidence), azygos and hemiazygos continuation of the IVC (0.6%), and left-sided IVC (0.2%-0.5% incidence). An unsuspected retroaortic or circumaortic renal vein can be inadvertently injured during aortic cross-clamping. Most unusual is the congenital absence of the suprarenal IVC, which results from failure of the right subcardinal vein branches to join the veins of the embryologic liver. This ultimately results in the infrarenal segment of the IVC joining the azygos-hemiazygos veins to drain into the superior vena cava. The hepatic veins drain directly into the right atrium in patients with this unusual anomaly.

Veins of the upper extremity are also divided into superficial and deep groups, though direction of flow from superficial to deep is not as distinct as in the lower extremity. Dorsal veins of the hand empty into the cephalic vein ("intern vein") on the radial aspect and into the basilic vein on the ulnar aspect of the forearm. The cephalic vein ascends lateral to the biceps muscle into the deltopectoral groove, where it passes through the clavipectoral fascia to join the axillary vein. The cephalic vein is useful for arteriovenous fistulas, both at the wrist and in the upper arm, because it is superficial and lateral in the arm, allowing easy access for hemodialysis needles. The basilic vein, which runs medially in the arm to become the axillary vein, is deeper and thicker walled than the cephalic vein. Its many branches make it tedious to harvest, but it can be used for a bypass conduit or for a laterally tunneled upper-arm dialysis fistula (basilic vein transposition). The median cubital vein links the cephalic and basilic veins in the antecubital space.

Paired brachial veins comprise the deep system of veins. They accompany the brachial artery and join the basilic vein as it becomes the axillary vein. The axillary vein continues medially as the subclavian vein, which passes through a tight space anterior to the first rib and anterior scalene muscle and posterior to the clavicle. The subclavian vein and the internal jugular vein join behind the clavicular head to form the brachiocephalic vein, which empties into the superior vena cava.

VENOUS PHYSIOLOGY

Knowledge of lower extremity venous anatomy is essential to understanding the physiology of venous flow. The volume of blood in the lower extremities may increase by

one-half liter when an individual moves from a reclining to an erect position (Figure 35–2). Increased blood volume is accommodated by increased venous capacitance, which is regulated by smooth muscle contractility in the vein walls. Erect posture creates a vertical column of blood, exerting a hydrostatic pressure equal to the distance from the toes to the right atrium (about 100-120 mm Hg). The hydrostatic pressure must be overcome to avoid pooling of blood in the legs and to provide venous return to the heart. Several aspects of the venous system make it possible to move blood against the force of gravity. Because the circulation is a closed system, venous return is affected by arterial inflow and by the negative intrathoracic pressure created during inspiration. Functional valves assure unidirectional movement of blood from superficial to deep systems and from

▲ **Figure 35–1.** Anatomy of the superficial and perforating veins of the lower extremity. (Reproduced, with permission, from Mozes G, Gloviczki P et al: Surgical anatomy for endoscopic subfascial division of perforating veins, *J Vasc Surg.* Nov;24(5):800–808, 1996.)

▲ **Figure 35-2.** Pedal venous pressure measurements with exercise. The normal drop in pressure associated with ambulation is impaired by deep vein incompetence and proximal venous obstruction. the foot back to the heart. Hydrostatic pressure is dissipated by lack of simultaneous opening of the valves. Soleal venous sinusoids are another central component to the system. When the muscle contracts during exercise, blood empties from the sinusoid into the deep veins of the calf and leg. This high-velocity flow siphons blood from deep veins of the foot upward into the calf, analogous to smoke being drawn up a smokestack by wind blowing past the chimney (Venturi effect).

DISEASES OF THE VENOUS SYSTEM

VARICOSE VEINS

► General Considerations

Varicose veins are very common, afflicting 10%-20% of the world's population. Abnormally dilated veins occur in several locations in the body: the spermatic cord (varicocele), esophagus (esophageal varices), and anorectum (hemorrhoids). Varicosities of the legs were described as early as 1550 BC and in the 1600s AD were correlated with trauma, childbearing, and "standing too much before kings." Modern studies identify female sex, pregnancy, family history, prolonged standing, and a history of phlebitis as risk factors for varicose veins. In the Framingham Study, the highest incidence was found in women between 40 and 49 years of age.

Varicose veins are classified as either primary or secondary. Primary varicose veins are thought to be due to genetic or developmental defects in the vein wall that cause diminished elasticity and valvular incompetence. Most cases of isolated superficial venous insufficiency are primary varicose veins. Secondary varicose veins arise from destruction or dysfunction of valves caused by trauma, DVT, arteriovenous fistula, or nontraumatic proximal venous obstruction (pregnancy, pelvic tumor). When valves of the deep and perforating veins are disrupted, chronic venous stasis changes may accompany superficial varicosities. It is important to recognize that untreated, longstanding venous dysfunction from either primary or secondary varicose veins may cause chronic skin changes that lead to infection, non-healing venous ulceration, and chronic disability. To define the optimal method of treatment, the etiologic factors and distribution of disease must be clearly identified.

► Clinical Findings

The clinical presentation of patients with varicose veins can be quite variable. Many varicose veins are asymptomatic and come to medical attention because of aesthetic concerns. If symptomatic, varicose veins may be associated with localized pain, a burning sensation over the vein, a diffuse ache or "heaviness" in the calf (particularly with prolonged standing), or phlebitis. Mild ankle edema may occur. Symptoms generally improve with leg elevation.

The varicosities appear as dilated, tortuous, elongated veins predominantly on the medial aspect of the lower extremity along the course of the great saphenous vein. Overlying skin changes may be absent even in the presence of extensive large varicosities. Smaller flat, blue-green reticular veins, telangiectasias, and spider veins may accompany varicose veins and are further evidence of venous dysfunction. A cluster of telangiectasias below the inframalleolar perforator is termed a corona phlebectatica paraplantaris. Secondary varicose veins can cause symptoms characteristic of chronic venous insufficiency (CVI), including edema, hyperpigmentation, stasis dermatitis, and even venous ulcerations.

Physical examination begins with inspection of all extremities to determine the distribution and severity of the varicosities. Bimanual circumferential palpation of the thighs and calves is helpful. Palpation of a thrill or auscultation of a bruit indicates the presence of an arteriovenous fistula as a possible etiologic factor. Today, tourniquet tests have been virtually replaced by venous duplex ultrasound imaging, which is now used as the primary method with which to map the location and extent of reflux.

► Differential Diagnosis

Ulceration, brawny induration, and hyperpigmentation often indicate accompanying chronic deep venous insufficiency. This is important to recognize because the changes

generally do not resolve with saphenous vein stripping alone.

Klippel-Trenaunay syndrome (KTS) must be considered if extensive varicose veins are encountered in a young patient, especially if unilateral and in an atypical distribution (lateral leg). The classic triad of KTS is varicose veins, limb hypertrophy, and a cutaneous birthmark (port wine stain or venous malformation). Because the deep veins are often anomalous or absent, saphenous vein stripping can be hazardous. Standard treatment for patients with KTS is graduated support stockings, and a good program of intermittent leg elevation and exercise. Limited stab avulsion of symptomatic varices after thorough duplex ultrasound vein mapping, and occasional surgery for correction of limb length discrepancy may also be indicated.

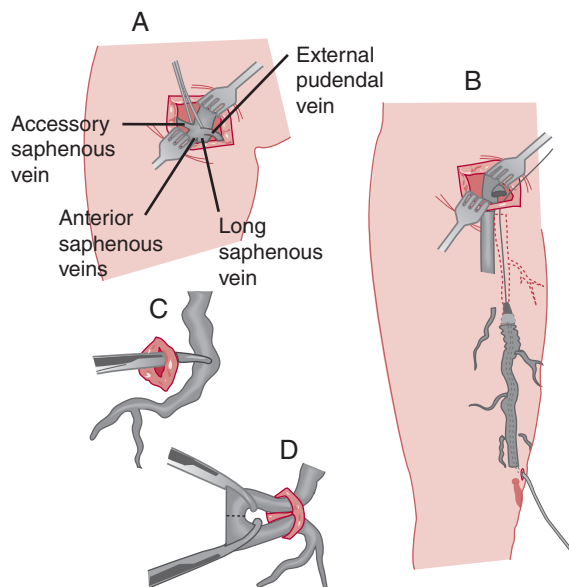

► Treatment

A. Nonsurgical Treatment

Treatment for both primary and secondary varicose veins initially involves a program directed at management of venous insufficiency, including elastic stocking support, periodic leg elevation, and regular exercise. Prolonged sitting and standing are discouraged. For most patients, knee-high or thigh-high gradient compression stockings of 20-30 mm Hg are sufficient, although some patients require 30-40 mm Hg pressure. The compression stockings are worn all day to diminish venous distention during standing and are removed at night.

B. Surgical Treatment

Traditionally, open surgical approaches have been the mainstay of treatment for saphenous vein disease. The preferred surgical option for saphenous veins remains high ligation with stripping or high ligation alone (Figure 35-3). High ligation and stripping of the saphenous system is performed for patients with an incompetent valve at the saphenofemoral junction and varicosities throughout the length of the great saphenous vein. This was traditionally performed by ligating the saphenofemoral junction and the major proximal saphenous vein branches through a small incision in the groin. Then the saphenous vein was removed to the point of clusters of varicosities. For the small saphenous vein, high ligation alone with short-length phlebectomy with local anesthesia is typically performed to minimize sural nerve injury. Epifascial veins may also be treated in an ambulatory setting, with phlebectomy performed under local anesthesia. Today, most open surgical approaches have been replaced with endovascular techniques (see next paragraph, C). A new treatment strategy called ASVAL (ambulatory selective varices ablation under local anesthesia) embraces the surgical treatment of epifascial veins while sparing the refluxing saphenous vein, minimizing the need to treat

▲ **Figure 35-3.** Technique of varicose vein stripping. (Reproduced, with permission, from Bergan JJ, Kistner RL: *Atlas of Venous Surgery*. Saunders, 1992.)

the saphenous vein in many cases. Although controversial, under the principle of antegrade reflux such that reflux spreads from epifascial to saphenous veins, the treatment of epifascial veins alone is said to correct saphenous reflux. Ongoing research has demonstrated that patients with primary varicose veins or less severe disease have done well with this approach.

C. Endovascular Treatment

In recent years, great advances have been made in endovascular techniques for treatment of varicose veins. Ablation techniques include thermal (radiofrequency and laser) and chemical ablation. Thermal ablation causes treated veins to collapse due to vein wall and lumen fibrosis. Vein reabsorption occurs over the course of several months. Both radiofrequency and laser ablation have been found to be safe and effective in the treatment of incompetent greater saphenous veins (GSVs), and the latest 2011 consensus opinion recommends thermal ablation to surgical or chemical ablation for GSVs. Its use has also been reported in successful treatment of perforator veins, though recent guidelines recommend against selective treatment of incompetent perforating veins in patients with simple varicose veins. However, in patients with “pathologic” perforating veins, subfascial endoscopic perforating vein surgery, ultrasonographically guided sclerotherapy, and thermal ablations remain viable options. Finally, advances have been made in chemical ablation techniques in the form of foam sclerotherapy. Compared to

liquid sclerotherapy, foam has increased time of endothelial contact as it expands to fill the vein. Given its ease of use, it is a suggested option for treatment of incompetent saphenous veins and a recommended option along with phlebectomy for treatment of varicose tributaries.

DEEP VEIN THROMBOSIS

► General Considerations

DVT and pulmonary embolism (PE) affect up to 900,000 people per year in the United States, and their incidence increases with age. Treatment is estimated to cost billions of dollars per year, not even including expenditures associated with long-term sequelae of this disease.

The Virchow triad (stasis, vascular injury, and hypercoagulability) should be the cornerstone for assessment of risk factors for DVT. In most cases, the cause is multifactorial.

Acquired risk factors include advanced age, cancer, surgery, trauma, immobilization, hormone replacement therapy, oral contraceptive use, pregnancy, neurologic disease, cardiac disease, and antiphospholipid antibodies. Approximately 30%-40% of patients with a new DVT (both upper and lower extremity) have been found to present with malignancy within 5 years. In men, pancreatic and colorectal cancers are most frequently associated with thrombotic risk, while hematological malignancies carry a lower risk. Cancers of the pancreas, ovary, and brain are mostly associated with thrombotic complications. Breast cancer, especially during its chemotherapy treatment, is also a risk factor. Most of these malignancies are associated with increased fibrinogen or thrombocytosis.

Endothelial injury can result from direct trauma (severed vein, venous cannulation, or transvenous pacing) or local irritation secondary to infusion of chemotherapy, previous

DVT, or phlebitis. Damaged endothelium leads to platelet aggregation, degranulation, and formation of thrombus as well as vasoconstriction and activation of the coagulation cascade. Thrombin activation from release of tissue factor and diminished fibrinolysis mediated by plasminogen activator inhibitor are intraoperative events that may be related to endothelial disruption.

Hypercoagulable states may also be inherited. Genetic causes include deficiencies of natural coagulation inhibitors (antithrombin III, protein C, protein S), factor V Leiden, prothrombin 20210A gene variant, blood group non-O, elevated homocysteine levels, plasminogen abnormalities, elevated levels of coagulation factors (such as factor VIII), and reduced heparin cofactor II activity. Hematologic disorders associated with DVT include disseminated intravascular coagulation, heparin-induced thrombocytopenia, antiphospholipid antibody syndrome, thrombotic thrombocytopenic purpura, hemolytic uremic syndrome, polycythemia vera, and essential thrombocythemia. Inflammatory bowel disease, systemic lupus erythematosus, and obesity are additionally associated with DVT.

DVT occurs most frequently in the calf veins, though it may arise in the femoral or iliac veins. Thrombi originate in soleal sinusoids or in valve sinuses, where there are flow eddies. Treatment of isolated calf vein thrombosis is controversial, as it is associated with a low risk of PE. However, a 2011 meta-analysis of studies spanning nearly 25 years demonstrated significant reductions both in progression to PE and in proximal thrombus propagation in patients treated with anticoagulation compared to patients who not receiving anticoagulation. While the studies were heterogeneous, the summation of the data indicated no statistical increased risk of bleeding in patients who received anticoagulation compared to the control arms. These observations and the improved safety profile of low-molecular-weight heparin (LMWH) are compelling practitioners to treat isolated calf DVTs aggressively. In the latest 2012 ACCP guidelines, it is recommended that “in patients with acute isolated distal DVT of the leg and without severe symptoms or risk factors for extension, we suggest serial imaging of the deep veins for 2 weeks over initial anticoagulation” while “in patients with acute isolated distal DVT of the leg and severe symptoms or risk factors for extension, we suggest initial anticoagulation over serial imaging of the deep veins.” The length of anticoagulation recommended is for 3 months.

► Clinical Findings

A. Symptoms and Signs

The diagnosis of DVT cannot be made solely on the basis of presenting symptoms and signs, as up to half of patients with acute thromboses have no abnormality detectable in the involved extremity. Homans sign (pain on passive dorsiflex-

ion of the ankle) is nonspecific and positive in only half of cases, and is unreliable. Some patients present with acute PE unaccompanied by leg edema or pain.

Symptomatic patients most often complain of a dull ache or pain in the calf or leg associated with mild edema. With extensive proximal DVT, there can be massive edema, cyanosis, and dilated superficial collateral veins. Low-grade fever and tachycardia occasionally occur. Iliofemoral venous thrombosis can result in phlegmasia. In phlegmasia alba dolens, the leg is pulseless, pale, and cool, which may progress to phlegmasia cerulea dolens, characterized by cyanosis of the limb and a precursor to gangrene.

B. Imaging Studies

Because DVT is difficult to diagnose on the basis of physical signs or symptoms, some objective diagnostic study is required before treatment is started. Historically, the standard for diagnosis was ascending phlebography, accomplished by fluoroscopic imaging during contrast injection into an intravenous line on the dorsum of the foot. The patient stands but is non-weight-bearing on the extremity studied. An abrupt cutoff of the contrast column indicates DVT. The complications of this procedure include risk of contrast allergy, contrast-induced nephropathy, and phlebitis.

Duplex ultrasound is now the best initial test to detect the presence of DVT. It is a noninvasive examination, does not expose the patient to radiation, is easily reproducible, and has specificity and sensitivity of greater than 95%. In this method, the transducer produces a two-dimensional image of the imaged vein and the surrounding tissue. Normally, veins collapse completely when compressed. Vein incompressibility is the primary ultrasonographic diagnostic criterion for acute lower limb DVT. Secondary diagnostic criteria include vein distention, echogenic thrombus within the vein lumen, absence of spectral or color Doppler signal from the vein lumen, and loss of venous flow phasicity and/or loss of response to Valsalva maneuver. Additionally, augmentation is expected in normal, compressible veins. When pressure is applied to the lower extremity distal to the area of evaluation, normally there is increased blood flow through the vein with compression. Lack of augmentation is suggestive of an occlusion in the segment of vein between the site of compression and the transducer. It is worth noting that direct thrombus visualization using B-mode imaging is variable depending on the age of the clot: fresh thrombus is anechoic and therefore not visible. Finally, while duplex ultrasound has a high accuracy for proximal DVT, it is less accurate in distal thrombosis and is highly operator dependent. Magnetic resonance venography shows promise as a diagnostic study for this disorder. The sensitivity and specificity of magnetic resonance venography are 100% and 96%, respectively. The injection of gadolinium is useful for

determining the age of the thrombus. Advances in magnetic resonance direct thrombus imaging with methemoglobin as an endogenous contrast allows for accurate diagnosis of femoropopliteal DVT with a sensitivity and specificity greater than 100%. This method allows for the paramagnetic properties of methemoglobin to provide a high signal on T1-weighted images against a background of flowing blood and fat. The thrombus may be directly visualized without administration of contrast, making it a viable option for patients with renal insufficiency. CT imaging, especially as part of a PE protocol CT image, may also be a good alternative to establish the diagnosis.

Measurement of D-dimer levels is too nonspecific for use alone and, when combined with a negative risk assessment, may be useful to rule out DVT but not to rule in the diagnosis of DVT. Radiolabeled fibrinogen is too sensitive in the pelvis for use in the acute clinical setting and carries with it a risk of transmission of infectious disease. It is no longer used. Older tests such as impedance plethysmography and venous pressure measurements do not achieve the same accuracy as duplex ultrasound and have been largely abandoned. Recent studies have demonstrated the potential for using soluble P-selectin as a marker for diagnosing DVT. P-selectin is a cell adhesion molecule that is the first upregulated glycoprotein on activated endothelial cells and platelets. As thrombosis and inflammation are interrelated, elevated levels of soluble P-selectin acts as an indicator or biomarker of inflammation. Consequently, a combination of soluble P-selectins with a Wells score has been shown to have a positive predictive value of approximately 90% with a negative predictive value greater than 95% for establishing the diagnosis of DVT.

► Differential Diagnosis

A variety of pathologies may mimic the symptoms of DVT. Lymphatic conditions such as adenopathies or lymphangitis can present with lower extremity pain and edema, but without flow on color Doppler images seen with DVTs. Vascular lesions such as hematomas and pseudoaneurysms secondary to catheterization of the common femoral artery may simulate DVTs. These can be differentiated from DVTs under evaluation by gray-scale images showing a delineation of the pseudoaneurysm or hematoma, or by color Doppler imaging which will illustrate the typical “yin-yang” sign of bidirectional flow. Muscular lesions of the thigh such as muscle strains, tears, and contusions may result in pain, stiffness, edema, and a mass. Cellulitis may cause edema, localized pain, and erythema. Unilateral leg swelling can also result from lymphedema, obstruction of the popliteal vein by Baker cyst, or obstruction of the iliac vein by retroperitoneal mass or idiopathic fibrosis. Bilateral leg edema suggests heart, liver, or kidney failure or IVC obstruction by tumor or pregnancy.

Treatment is aimed at reducing the incidence of complications associated with DVT. Short-term complications include recurrent DVT or pulmonary thromboembolism, while long-term complications include the development of varicose veins and chronic venous insufficiency. The primary treatment of DVT is systemic anticoagulation. This reduces the risk of PE and extension of venous thrombosis and also decreases the rate of recurrent DVT by 80%. Systemic anticoagulation does not directly lyse thrombi but stops propagation and allows natural fibrinolysis to occur. Heparin is initiated immediately and dosed to a goal partial thromboplastin time (PTT) of 1.5-2.5 times normal, or, more currently, LMWH, weight-based without monitoring. Achieving therapeutic heparinization within the first 24 hours after diagnosis is shown to reduce the rate of recurrent DVT.

Warfarin is started after therapeutic heparinization. The two therapies should overlap to diminish the possibility of a hypercoagulable state, which can occur during the first few days of warfarin administration, because warfarin also inhibits the synthesis of natural anticoagulant proteins C and S. For both acute lower extremity DVT and acute PE, guidelines recommend starting warfarin the same day as the start of parenteral anticoagulation over delayed initiation, with a continuation of parenteral anticoagulation for a minimum of 5 days until the INR is greater than 2.0 for more than 24 hours. Specifically, in patients with a PE or proximal DVT of the leg provoked by surgery, the recommended treatment is 3 months compared to a longer or shorter time period. Three months of anticoagulation is similarly recommended in patients with (i) PE/proximal DVT of the leg provoked by a nonsurgical transient risk factor, (ii) in patients with PE/an isolated distal DVT of the leg provoked by surgery or by a nonsurgical transient risk factor. In patients who have had an unprovoked PE or DVT of the proximal or distal leg, the recommended treatment is a minimum of 3 months' treatment followed by reevaluation of risk-benefit ratio of extended therapy. After a second episode of DVT, the usual recommendation is prolonged or lifelong warfarin in patients with a low or moderate bleeding risk. In patients with a high bleeding risk, the guidelines recommend 3 months of anticoagulation over extended therapy. The risk for recurrent venous thrombosis is increased markedly in the presence of homozygous factor V Leiden mutations, antiphospholipid antibody, antithrombin III, and protein C or protein S deficiencies, so lifelong anticoagulation is usually recommended for these conditions as well.

LMWH has been shown to be as safe and effective as standard unfractionated heparin (UFH) in the treatment of DVT. It is administered once or twice daily by subcutaneous injection. LMWH does not require monitoring of its anticoagulant effect because of its predictable dose-response relationship, and this feature of the drug has made feasible the outpatient treatment of DVT. Standard UFH inhibits

thrombin because it is large enough to make a three-way complex between thrombin, antithrombin, and itself. LMWHs are much smaller than standard heparin molecules and do not inhibit thrombin; their main therapeutic effect comes from inhibition of factor Xa activity. In patients with acute DVT of the leg or acute PE, the most recent 2012 ACCP guidelines suggest LMWH over both IV and SC forms of UFH. LMWH is suggested over vitamin K antagonist therapy for patients with PE or DVT of the leg and cancer. The advantages of LMWHs over standard heparin preparations include a lower risk of bleeding complications and thrombocytopenia, a lower risk of heparin-induced thrombocytopenia, lower recurrence of VTE, decreased mortality, less interference with proteins C and S, less complement activation, and a lower risk of osteoporosis. Moreover, recent randomized trials have shown regression of thrombus with LMWH. A disadvantage worth noting is that LMWH accumulates in patients with renal failure.

Recent studies evaluating specific factor Xa inhibitors and direct thrombin inhibitors have demonstrated significant promise. Fondaparinux is a synthetic pentasaccharide which binds to antithrombin and catalyzes the inhibition of factor Xa. It has more specific anti-Xa activity than low molecular weight heparin (LMWH), and has a longer half-life than LMWH. It is rapidly and almost completely bioavailable after subcutaneous injection, and does not require coagulation monitoring. However, due to its dependence on renal clearance, its use is contraindicated in patients with renal insufficiency. For the treatment of VTE, fondaparinux is administered at a fixed dose of 7.5 mg for patients weighing 50-100 kg, with the dose adjusted to 5 mg for patients weighing less than 50 kg and 10 mg for those weighing more than 100 kg. In orthopedic patients undergoing total hip or knee arthroplasty or hip fracture surgery (HFS), fondaparinux is among one of the recommended agents for use as prophylaxis by the current 2012 ACCP guidelines (grade 1C). In patients with acute VTE, ACCP guidelines recommend initial treatment with parenteral anticoagulation agents—among those—subcutaneous fondaparinux (grade 1B). For the treatment of VTE, fondaparinux was found to be equal to LMWH for treating DVT, and for PE, it was found as effective as UFH.

Dabigatran etexilate (Pradaxa) is an oral direct thrombin inhibitor. It has been approved for prophylaxis in total hip replacement and total knee replacement in Western Europe and Canada. It demonstrates a low risk for bleeding, offers fixed oral dosing without coagulation monitoring, and does not cause an increase in liver enzymes. When tested against LMWH given twice daily in DVT prophylaxis, it failed to meet the noninferiority target that was achieved when compared with LMWH once daily. Dabigatran was recently found to be as effective as warfarin for the treatment of DVT, and has now been approved by the FDA as an oral anticoagulant for treatment of nonvalvular atrial fibrillation. Another

oral agent, Rivaroxaban, has been studied as monotherapy for treatment of DVT and was found noninferior to standard therapy in the primary endpoint of symptomatic recurrent DVT and nonfatal or fatal PE, without any increase in bleeding. Finally, Apixaban is yet awaiting FDA approval, but it has been shown to be superior to warfarin in the treatment of atrial fibrillation in patients with that diagnosis and one additional risk factor for stroke.

The prevention of CVI after DVT can be divided into those measures that are useful with traditional anticoagulant treatment of DVT and measures that involve more aggressive interventions to lyse thrombus. Certain LMWHs decrease indices of CVI compared to standard therapy when used over an extended period of time. Associated with this traditional therapy, the rate and severity of the postthrombotic syndrome (PTS) after proximal DVT can be decreased by approximately 50% by the use of surgical compression stockings and ambulation without increasing the risk of PE.

The clinical outcome after DVT can be thought of as resulting in either valvular reflux, persistent venous obstruction, or their combination. Patients with both obstruction and valvular reflux often have the most severe postthrombotic symptoms. In order to limit these consequences, thrombus removal should be the best solution. The longer a thrombus is in contact with a vein valve, the more likely the valve will no longer function. Additionally, the thrombus initiates an inflammatory response in the vein wall, which may lead to vein wall and valve dysfunction. The most recent guidelines recommend early thrombus removal in patients with limb-threatening venous thrombosis (grade 1A), though recommend that patients with isolated femoropopliteal DVTs to be managed with only conventional anticoagulation therapy (grade 1C).

Techniques for early thrombus removal include catheter-directed thrombolytic therapy and open thrombectomy. In the treatment of acute iliofemoral DVTs, a systematic review and meta-analysis by Casey and colleagues reports that thrombectomy results in significantly decreased risk of developing PTS, venous reflux, and a trend for reduced venous obstruction when compared to systemic anticoagulation. Catheter-directed thrombolysis yielded similar results when compared to systemic anticoagulation, though there were insufficient data to directly compare outcomes of catheter-directed thrombolysis to thrombectomy. Following either therapy, it is currently recommended that patients wear knee-high compression stockings (30-40 mm Hg) for at least 2 years following the procedure.

► Prevention of VTE

Surgery increases the risk of DVT 21-fold. This disorder is a reported complication for approximately 20%-25% of patients admitted for a general surgical procedure, 20%-30% of those undergoing an elective neurosurgical procedure,

and 50%-60% of those undergoing hip or knee arthroplasty. These statistics emphasize the need for routine DVT prophylaxis in the surgical patient. The most commonly used measures are elastic stockings, pneumatic sequential compression devices, low-dose UFH (5000 units given by subcutaneous injection), or LMWH given at a prophylactic dose subcutaneously (either once or twice daily).

For general surgical patients, the incidence of DVT is high without prophylaxis, and the risk of PE is 1.6%, 0.9% fatal. Patients have been categorized into levels of risk in the current Chest guidelines based on their risk scoring via the Rogers or Caprini scoring system, placing a very low risk for VTE patient at more than 0.5%, low risk at approximately 1.5%, moderate risk at approximately 3%, and high risk at approximately 6%. In general surgery patients at very low risk for VTE, the recommended prophylaxis is simply early ambulation, with no pharmacologic or mechanical prophylaxis recommended. For patients at low risk, the guidelines suggest mechanical prophylaxis, preferably with intermittent pneumatic compression (IPC). Patients at moderate risk of VTE who are not at high risk for major bleeding complications are suggested LMWH, low-dose unfractionated heparin (LDUH), or mechanical prophylaxis. In those at moderate risk of VTE but at high risk for bleeding, the guidelines suggest mechanical prophylaxis. For high risk VTE patients who are not at high risk for major bleeding, the recommendation is pharmacologic prophylaxis with LMWH or LDUH, with the additional suggestion of mechanical prophylaxis. In the special case of high VTE risk patients with cancer who are not high risk for bleeding complications, the guidelines recommend IPC with LMWH for extended-duration pharmacologic prophylaxis (4 weeks) over a shorter duration.

For orthopedic patients having undergone major surgery including hip fracture surgery (HFS), total hip arthroplasty (THA), or total knee arthroplasty (TKA), an evaluation of the extended postoperative VTE risk (postoperative days 0-35) comparing no prophylaxis with LMWH found the total symptomatic VTE rate decreased from 4.3% to 1.8%, a greater than 60% reduction. These values represent a decrease in rates of PE from 1.5% to 0.55% and a decrease in rates of DVT from 2.8% to 1.25%. Therefore, the current guidelines suggest extending thromboprophylaxis for up to 35 days postoperatively (grade 2B). For patients undergoing THA or TKA, the use of LMWH is suggested over fondaparinux, apixaban, dabigatran, rivaroxaban, LDUH, adjusted-dose VKA, or aspirin. In patients undergoing HFS, LMWH is also the suggested agent, regardless of concomitant use of mechanical prophylaxis. If started preoperatively, LMWH is suggested to be administered ≥ 12 hours prior to surgery. In patients with increased risk of bleeding or contraindications to both pharmacologic and mechanical thromboprophylaxis, the guidelines suggest against using an IVC filter over no thromboprophylaxis.

For trauma patients, evidence is lacking, and randomized studies are needed. Trauma risk factors include lower extremity or pelvic fractures, surgical procedures, advanced age, femoral vein lines or major venous repairs, prolonged immobility, spinal cord injury, and prolonged duration of hospital stay. In major trauma patients, the guidelines suggest the use of LDUH, LMWH, or mechanical prophylaxis. For these patients at high risk for VTE, such as those with acute spinal cord injury or traumatic brain injury, mechanical prophylaxis is suggested in addition to pharmacologic prophylaxis. Because venous compression ultrasound detection and subsequent treatment of asymptomatic DVT in this population does not reduce the risk of PE or fatal PE, the guidelines do not suggest periodic surveillance with this modality. IVC filters are recommended in patients when anticoagulation is contraindicated, but are not suggested for use as primary prevention.

In neurosurgery, DVT and PE occur equivalent to rates in general surgery patients, and risk factors include intracranial surgery, prolonged surgery, malignant tumors, the presence of leg weakness, and increased age. The recommendations differ between craniotomy and spine surgery patients. In craniotomy patients, the suggested prophylaxis is mechanical or pharmacologic or no prophylaxis. However, in those craniotomy patients who are at very high risk for VTE, such as those with malignant disease, the guidelines suggest pharmacologic prophylaxis in addition to mechanical prophylaxis when it is safe to do so. For spinal surgery patients, mechanical prophylaxis is suggested over no prophylaxis, UFH, or LMWH. Similar to their counterparts, spinal surgery patients at very high risk for VTE are suggested to have both pharmacologic and mechanical prophylaxis when medically safe.

AXILLARY-SUBCLAVIAN VENOUS THROMBOSIS

▶ General Considerations

Thrombosis of the axillary or subclavian vein is a relatively uncommon event, accounting for less than 5% of all cases of DVT. Only 12% result in clinically apparent pulmonary thromboembolism, but the incidence is higher if all patients undergo diagnostic testing. Besides PE, the most common consequence of axillary-subclavian vein thrombosis is chronic edema and resultant disability. The effects of post-thrombotic syndrome (PTS) and recurrent thrombosis are not uncommon.

There are two major etiologies. Primary axillary-subclavian thrombosis, also known as Paget-Schroetter syndrome or “effort thrombosis,” occurs as a result of intermittent transient obstruction of the vein in the costoclavicular space during repetitive or strenuous activities involving the upper extremity (Figure 35-4). This condition was first described in independent reports by Paget and von Schroetter in the late 19th century. During strenuous repetitive movements of the upper extremity, the subclavian vein is compressed between the first rib and the anterior scalene muscle posteriorly and the clavicle—with underlying subclavius muscle and fibrous costocoracoid ligament—anteriorly. In many cases, the costoclavicular ligament congenitally inserts more laterally than normal, subjecting the anatomically tight space to further compression of the subclavian vein. Primary subclavian vein thrombosis can also occur in patients with hypercoagulable states such as antiphospholipid antibody syndrome or factor V Leiden mutation. Secondary subclavian vein thrombosis, which is increasing in incidence, results from venous injury by indwelling central venous catheters, external trauma, or pacemaker wires. These patients are less likely to be symptomatic than patients with primary subclavian vein thrombosis.

▲ **Figure 35-4.** **A:** Effort thrombosis in a 13-year-old wrestler. Arrow marks subclavian vein thrombosis refractory to rt-PA thrombolysis. **B:** Arm in abduction. Note disappearance of prominent venous collaterals. **C:** Immediate postoperative venogram following scalenectomy, first rib resection, and thrombectomy.

► Clinical Findings

A. Symptoms and Signs

Primary axillary-subclavian vein thrombosis usually occurs in healthy young athletes and people who perform repetitive activities that involve hyperabduction of the upper extremities. Most patients present with edema of the affected extremity, diffuse aching pain, and cyanosis of the upper extremity. As venous collaterals develop, dilated veins appear in the chest wall and shoulder region. In less pronounced presentations, patients become symptomatic only when their affected extremity is positioned in a way that predisposes it to vascular occlusion.

Paget-Schroetter syndrome may also be accompanied by symptoms of neurogenic thoracic outlet syndrome, often causing tingling, numbness, and pain in the hand and arm, sometimes in an ulna distribution indicating compression of the C-8/T-1 roots of the brachial plexus between hypertrophied or anomalous anterior and middle scalene muscles.

B. Imaging Studies

Upper extremity venous duplex ultrasound is a sensitive and reliable modality to diagnose axillary-subclavian vein thrombosis.

Magnetic resonance venography has demonstrated promise with greater than 97% sensitivity and specificity for diagnosis, but its cost and limited availability reduce its wide-spread use. While computed tomographic venography is widely available, its use exposes the patient to contrast dye. Venography, while invasive, remains the common next step in diagnosis, with a positive venogram indicating subclavian vein compression with the appearance of prominent collateral veins. Obtaining these images allows delivery of catheter-directed thrombolysis and allows for further planning of thoracic outlet decompression surgery.

Chest x-ray should be obtained on all patients to exclude the presence of cervical rib, which can also contribute to compression of the subclavian vein.

► Treatment

For patients with secondary axillo-subclavian thrombosis, any indwelling central venous lines or pacemaker wires in the thrombosed vein should be removed if possible. If not contraindicated, anticoagulation should be considered as well as arm elevation and pain control.

Patients who have primary venous thrombosis secondary to thoracic outlet compression should be considered for decompression because, if left untreated, the patients have a 35%-65% risk of PTS characterized by recurrent episodes of pain, swelling, and chronic venous insufficiency (CVI) secondary to venous hypertension and valvular damage.

The current standard of care is catheter-directed thrombolysis followed by surgical decompression of the thoracic

outlet in the majority of cases. Catheter-directed thrombolysis is beneficial to patients presenting early, and offers therapeutic value without the higher rates of bleeding complications seen in systemic fibrinolysis. As the success of thrombolysis decreases as time from onset of symptoms increases, the early initiation of treatment is paramount. Some have advocated a treatment window of two weeks, as there is progressive fibrosis of the vein and risk of extension of the thrombus distally into the arm with decreased chance of recovery. In patients who are more than six weeks from initial presentation of symptoms, thrombolytic agents were generally ineffective in completely removing the clot. Inflow is typically inadequate by the time patients present with chronic obstruction.

Because the etiology of venous thoracic outlet syndrome is compression of the vein between the first rib–anterior scalene muscle origin and the clavicle, surgery consists of anterior scalenectomy, first rib resection, and venolysis (release of the vein from any externally constricting scar). It is particularly important to resect the entire medial portion of the rib to the sternal junction when an anterior, or subclavicular, approach is used. Some prefer this to the transaxillary approach, as the transaxillary approach prevents full resection of the medial rib, and allows for intact subclavius tendons and costoclavicular ligaments, resulting in kinking of the vein on any of these residual structures. However, others find that the transaxillary dissection minimizes the exposure of the neurovascular structures, minimizing their injury. In either case, for patients presenting with acute occlusion, surgical resection of the anterior scalene and first rib with venolysis is preferred to thrombectomy, balloon venoplasty, and stenting.

For patients with chronic obstruction, Molina and colleagues report successful approaches based on length of the obstructed segment. For patients with short segment chronic obstruction, they have been successful with saphenous vein patch to the subclavian vein. In patients with a long segment of chronic obstruction, they have treated with either long vein patch with upper thigh saphenous vein or implantation of thoracic aortic homografts with subsequent balloon dilation and implantation of a stent for reobstruction. Venous bypass has also been successfully used in patients with residual stenosis after thoracic outlet decompression.

The need for and duration of anticoagulation for patients treated with catheter-directed thrombolysis followed by decompression is unclear. Some authors maintain that no anticoagulation is needed when good surgical outcomes are obtained, while others have anticoagulated for two to three months. All patients who present with primary venous thrombosis should undergo a workup for a hypercoagulable state, the most common of which are mutations in coagulation factor V, protein C and S deficiencies, and antithrombin III. Because of a 40%-60% rate of recurrent thrombosis, these patients are maintained indefinitely on warfarin.

► Prognosis

The prognosis after axillary-subclavian vein thrombosis is dependent on the cause of the condition. Most patients experience fairly rapid resolution of their initial presenting symptoms. For patients with secondary forms of this disease, the outcome is dependent on resolution of the underlying condition, such as a malignancy. For patients with Paget-Schroetter syndrome who undergo thoracic outlet decompression, excellent outcomes, characterized by continued venous patency and absence of symptoms of CVI, are typical. In contrast, chronic axillary-subclavian vein thrombosis with symptoms persisting for over 3 months does not often respond to thrombolysis, mechanical thrombolysis, or prolonged anticoagulation and may cause significant long-term disability.

PULMONARY THROMBOEMBOLISM

► General Considerations

Pulmonary thromboembolism is responsible for up to 50,000 deaths each year in the United States. It is the third-leading cause of death among hospitalized patients, yet only 30%-40% of those with pulmonary thromboembolism have suspected DVT at the time of diagnosis. Efforts directed at reduction in the mortality rate of pulmonary thromboembolism demand an aggressive approach to the prevention of DVT and diagnosis of pulmonary thromboembolism in patients identified to be at high risk.

Pulmonary thromboemboli arise from a number of sources. Air embolism can occur during the placement or removal of central venous catheters intraoperatively during operation on large venous vessels. Amniotic fluid emboli may occur during active labor. Fat emboli from long bone fractures cause a syndrome characterized by respiratory insufficiency, coagulopathy, encephalopathy, and an upper body petechial rash. Other less common causes of pulmonary emboli include septic emboli, tumor emboli from atrial myxoma or IVC extension of renal cell carcinoma, and parasitic emboli. However, DVT remains the most common source of pulmonary thromboemboli. Up to 60% of patients with untreated proximal lower extremity DVT may develop pulmonary thromboembolism.

Fewer than 10% of pulmonary thromboemboli will produce pulmonary infarction. The pathophysiology of PE

depends on the size and frequency of the emboli as well as the condition of the underlying lung. Obstruction of large pulmonary arteries results in increases in pulmonary artery pressure and acute right-ventricular failure, but many of the clinical manifestations of pulmonary thromboembolism result from release of vasoactive amines that cause severe pulmonary vasoconstriction. Vasoconstriction leads to increased physiologic dead space and systemic hypoxia from a right-to-left shunt. Reflex bronchial vasoconstriction is also common.

► Clinical Findings

A. Symptoms and Signs

Signs and symptoms associated with PE are notoriously vague. Dyspnea and chest pain are present in up to 75% of patients with pulmonary thromboembolism. However, these symptoms are nonspecific, especially in patients who may have underlying cardiopulmonary disease. Tachycardia, tachypnea, and altered mental status are highly suggestive findings in an at-risk population. The classic triad of dyspnea, chest pain, and hemoptysis is present in only 15% of patients with pulmonary thromboembolism. Pleural friction rub and the S1Q3T3 morphology on electrocardiography are even less common findings.

B. Imaging and Other Diagnostic Studies

Chest x-ray is most often normal but may show a pleural cap. Electrocardiography may reveal new-onset atrial fibrillation, evidence of right-heart strain, or ischemic changes, but in most cases only acute sinus tachycardia and nonspecific ST and T wave changes are identified. Arterial blood gas determination reveals hypoxia and often a respiratory alkalosis or increased arterial-alveolar oxygen gradient. Plasma D-dimer levels are elevated in the presence of both pulmonary thromboembolism and acute DVT, but this test lacks sufficient specificity to be of primary diagnostic value. In acute massive or submassive PE resulting in hemodynamic instability (systolic blood pressure < 90 mm Hg) and right heart strain leading to myocardial ischemia, cardiac troponins may be elevated. Plasma B-type natriuretic peptide may also be elevated in right heart strain, though it is similarly not specific enough to be used alone for diagnosis of PE.

CT angiography is now the preferred imaging modality used for the diagnosis of PE, due to its wide availability, sensitivity and specificity, characterization of vascular and nonvascular structures, and exceptional speed (Figure 35–5). CT angiograms (CTA) are more accurate than the previously commonly used ventilation-perfusion scan, and when compared to pulmonary angiography, CTAs are less invasive, less time consuming, and less expensive. For CTA, the patient presentation must match the results of the CTA, for the most accurate determination of the diagnosis of PE. For patients in whom massive PE is suspected but

contrast agent administration is undesirable, a bedside echocardiogram may be performed to evaluate for right heart dysfunction as an indication of hemodynamically significant PE. Intravascular ultrasound (IVUS) has also been used for bedside evaluation.

► Treatment

A. Anticoagulation

Rapid anticoagulation remains the mainstay of treatment of PE. Heparin, the pentasaccharide fondaparinux, or LMWH anticoagulation is started as soon as the diagnosis is made after initial stabilization with ventilatory support and vasopressor medications. While these drugs are not thrombolytic, they allow the body's fibrinolytic system to function unopposed. Thrombolysis is considered for large clot burden, severe respiratory compromise, hemodynamic instability, or right-heart failure. When compared with heparin alone, thrombolytic therapy speeds the resolution of pulmonary emboli in the first 24 hours. The disadvantages of lytic therapy include its greater cost and higher risk of significant bleeding complications.

B. Inferior Vena Cava Interruption

IVC interruption is considered in patients who have extension of venous thrombus on adequate anticoagulant therapy, patients in whom heparin anticoagulation is contraindicated, patients who have had a complication of anticoagulation, or patients who have had recurrent DVT or PE despite *therapeutic* anticoagulation. More recently, temporary or permanent IVC filters have been placed prophylactically in high-risk patients such as those with unresectable cancer or major trauma. Interestingly, as insertion of an IVC filter does not completely eliminate the risk of a PE, may increase the risk of DVT, and does nothing to prevent postthrombotic syndrome (PTS), the current guidelines suggest that patients who have an IVC filter should receive the standard course of anticoagulation if the contraindication to anticoagulation is no longer applicable.

Historically, IVC interruption was performed as an open surgical procedure, involving ligation or plication of the infrarenal vena cava or placement of a serrated clip to “strain” blood returning to the right atrium. The Greenfield filter, developed in 1973, was initially deployed by venous cutdown. Multiple devices are now available for fluoroscopically guided percutaneous placement through a range of sheath sizes from 6F to 12F and are introduced into the common femoral vein or, in cases of femoral thrombus, into the internal jugular vein. Diagnostic inferior venacavogram is essential prior to placing the filter to exclude the presence of a duplicated IVC because lower extremity DVT might still serve as a source of emboli. The presence of thrombus within the IVC, the diameter of the IVC, and identification of the level of the renal veins are also important to evaluate.

The development and increased use of retrievable IVC filters for both prophylaxis and therapy of VTE is largely driven by the results of the PREPIC study. This study remains the only prospective, randomized clinical trial comparing IVC filters to anticoagulation alone. At 8 years,

the study suggested a higher incidence of recurrent DVT in patients who were randomized to the IVC filter arm of the study compared to group who received anticoagulation only. This study suggested that patients with IVC filters in place had a significantly higher risk of recurrent DVT than patients treated with anticoagulation alone. There was no difference in the incidence of PTS between study groups but patients with IVC filters in place had significantly lower rates of PE over the course of the study compared to the anticoagulation group. While there is a multitude of devices available and many small observational studies that suggest that retrievable filters are safe and effective, no other prospective comparison studies have yet to be performed.

Additionally, alternative imaging modalities (other than venography) are successfully being used to place filters. Specifically, devices are being successfully and safely deployed under ultrasound guidance, both intravascular and transabdominal ultrasound. Kassavin and colleagues recently described the transition from combined use of IVUS-guided and traditional techniques (such as venography) for IVC filter placement to the use of IVUS as the primary road mapping tool had a learning curve of only approximately 20 cases. Compared to traditional placement, the use of IVUS for IVC filter deployment lacks the risks of prolonged radiation exposure and nephrotoxic contrast agents while diminishing the case duration and overall cost.

C. Surgical Treatment

Hemodynamically unstable patients in whom thrombolytic therapy has failed or cannot be instituted require percutaneous or open surgical extraction of the thrombus. Open surgical pulmonary embolectomy is reserved for patients who develop intractable hypotension, those who fail transcatheter pulmonary embolectomy, and those who have tumor or foreign body emboli. Catheter techniques involve mechanical thrombolysis or removal of intact pulmonary emboli using a suction embolectomy device.

► Prognosis

PE is one of the most frequent causes of preventable hospital death. Prevention by use of DVT prophylaxis and early diagnosis by selective testing of high-risk patients are essential steps to reducing the morbidity of this disease. The placement of IVC filters in selected patients can aid in prevention of pulmonary embolus but does nothing to treat the underlying disease process (venous thromboembolic disease) or prevent the long-term sequelae of DVT-PTS.

SUPERFICIAL THROMBOPHLEBITIS

► General Considerations

Superficial thrombophlebitis (SVT) may appear spontaneously in patients with varicose veins, in pregnant or postpartum women, or in patients with thromboangiitis obliterans or Behçet disease. It may also occur after intravenous therapy or in an area of localized trauma. The presence of superficial phlebitis, particularly if it occurs in a migratory manner, suggests the presence of an abdominal cancer such as carcinoma of the pancreas (Trousseau thrombophlebitis). The most common vein affected is the greater saphenous vein and its branches. In up to 40% of cases, a simultaneous DVT exists, and duplex imaging is a must in these situations. Pulmonary emboli are rare unless extension into the deep venous system occurs.

► Clinical Findings

The patient usually presents complaining of localized extremity pain and redness. Areas of induration, erythema, and tenderness correspond to dilated and often thrombosed superficial veins. Over time, a firm cord may develop. Generalized edema is absent unless the deep veins are involved. The presence of fever and shaking chills suggests septic or suppurative phlebitis, which occurs most commonly as a complication of intravenous cannulation.

► Differential Diagnosis

Superficial thrombophlebitis must be distinguished from ascending lymphangitis, cellulitis, erythema nodosum, erythema induratum, and panniculitis. Unlike these other disorders, superficial phlebitis tends to be well localized over a superficial vein.

► Treatment

The primary treatment of superficial venous thrombophlebitis is the administration of nonsteroidal anti-inflammatory drugs, local heat, elevation, and support stockings or elastic wraps. Ambulation is encouraged. In most cases, symptoms will resolve within 7-10 days. Excision of the involved vein is recommended for symptoms that persist over 2 weeks

despite treatment or for recurrent phlebitis in the same vein segment. If there is progressive proximal extension with involvement of the saphenofemoral junction or cephalic-subclavian junction, ligation and resection of the vein at the junction should be performed. More recently, cases in which endovenous thermal ablation was used in the treatment of superficial thrombophlebitis has been reported but not usually during the acute phase of the disease process. Alternatively, LMWH has been studied in the treatment of superficial thrombophlebitis given its anti-inflammatory and antithrombotic effects. In a randomized trial by Rathbun and colleagues comparing daily dalteparin versus ibuprofen three times daily for up to 14 days, dalteparin was found to be superior in preventing extension of superficial thrombophlebitis at 14 days with similar relief of pain.

The approach to treating SVT is variable, as there is no general consensus on ideal treatment. Reports of less than 10% to approximately 40% of presentation of SVT also presents with associated acute DVT. The occurrence of concomitant PE has been reported from 0.5% to 4% in symptomatic patients. Approximately 60%-80% of SVT cases involve the great saphenous vein and 10%-20% of cases involve the small saphenous veins, with involvement of the upper extremity veins occurring next in frequency. The association between SVT and both DVTs and PEs increases as the phlebitis extends toward the saphenofemoral junction. The treatment approach therefore depends on the location, presence of concomitant DVT, and the presence of additional risk factors such as hypercoagulable disorders. Involvement of the junction warrants aggressive treatment with LMWH to prevent further extension into the deep venous system. A recent Cochrane review involving 26 studies and 5521 participants assessed the current approach to patients with superficial thrombophlebitis of the legs. Fondaparinux at a prophylactic dose given for 45 days was associated with lower rates of recurrence and extension of superficial thrombophlebitis compared to placebo. Both NSAIDs and LMWH reduced extension or recurrence when compared to placebo. When comparing LMWH with surgical intervention (saphenofemoral disconnection), both were comparable in reduction of VTE events, though surgery was associated with a statistically insignificant lower risk of extension or recurrence. Alternatively, venous stripping plus elastic stockings demonstrated a lower, non-significant incidence of VTE compared with elastic stockings alone. In general, surgical treatment with ligation of the great saphenous vein at the saphenofemoral junction allows for superior symptomatic relief of pain, while medical management with anticoagulants appears superior for minimizing complications and preventing subsequent DVT/PE.

Septic thrombophlebitis requires treatment with broad-spectrum intravenous antibiotics. If rapid resolution of the cellulitis occurs, no treatment beyond a short course of antibiotics is required. However, if the patient becomes septic, excision of the entire infected vein is required. Catheter

removal is required in cases involving central venous catheter infection. In patients refractory to standard medical therapy yet poor candidates for invasive surgical therapy, endovascular treatment using thrombectomy devices, balloon angioplasty, and local intraluminal infusion of antibiotics has been reported. Thrombolytic therapy and mechanical thrombectomy remain options for the treatment of the thrombosed vein segment.

► Prognosis

Most episodes of uncomplicated superficial thrombophlebitis respond to conservative management. Cases in which extension into the deep venous system occurs can be associated with thromboembolism.

CHRONIC VENOUS INSUFFICIENCY

CVI can result from congenital venous valvular insufficiency or can result from previous venous thrombosis. In the former circumstance, it is called CVI while in the latter circumstance, it is called the PTS. Varicose veins (also a manifestation of venous insufficiency), CVI, and PTS occur in 76/100,000 person-years, and it has been estimated that 6-7 million Americans suffer from stasis pigmentation changes in the legs with another 400,000-500,000 patients with skin ulceration. Treatment costs are in the billion dollar range. The basic physiologic abnormality in patients with CVI is chronic elevation of venous pressure. The normal venous capacitance can accommodate large-volume changes that occur during exercise with only minimal changes in venous pressure. However, with calf muscle pump dysfunction and valvular reflux, blood pools in the lower extremities and venous hypertension occurs, leading to venous hypertension. Outflow obstruction from proximal obstruction can also produce venous hypertension, resulting in “venous claudication” as the deep venous system fills with blood during exercise. The leg becomes painful, swollen, and heavy (especially with exercise), mimicking arterial insufficiency. Severity of chronic venous disease has been associated with older age and higher body mass index.

Valvular incompetence of the deep veins can be congenital or result from damage following phlebitis, varicose veins, or DVT. The best estimate for the incidence of CVI is approximately 30% after 8-year follow-up. Chronic venous stasis

changes are centered in the “gaiter areas” around the ankles. This is the location of the commonly affected perforator veins and is a region with sparse soft tissue support to withstand elevated venous pressures. Brawny edema is produced by extravasation of plasma fluid, red blood cells, and plasma proteins. Lysis of red blood cells results in deposition of hemosiderin, which creates a brownish discoloration. Leukocytes become sequestered in the microcirculation, leading to capillary occlusion and release of superoxide radicals, proteolytic enzymes, and growth factors. Macrophages and T lymphocytes are primary mediators of this inflammatory response, which results in fibroblast activation and scarring and fibrosis of the subcutaneous tissues. Ultimately, this fibrosis results in compromised skin perfusion and ulceration.

► Clinical Findings

A. Symptoms and Signs

Both isolated saphenous vein incompetence and deep venous insufficiency can lead to venous varicosities and chronic venous stasis changes. One of the first symptoms to develop is usually ankle and calf edema. Involvement of the foot and toes suggests lymphedema. Typically, the edema is worse at the end of the day and improves with leg elevation. Additional symptoms may include aching, tingling, burning, muscle cramps, heaviness, sensations of throbbing, and leg fatigue. Longstanding disease is characterized by stasis dermatitis, hyperpigmentation, brawny induration, and ulceration. Venous stasis ulcers are large, painful, and irregular in outline. They have a shallow, moist granulation bed, occur in the gaiter area on the medial or lateral aspects of the ankle, and are often accompanied by stasis dermatitis and stasis pigmentation changes.

B. Imaging and Other Diagnostic Studies

Duplex ultrasound can identify the presence and location of incompetent superficial and deep veins and perforating veins and has been used to evaluate the function of individual venous valves. Current guidelines recommend selective scanning of perforating veins in patients with CVI. Duplex imaging has become the most important test of venous pathophysiology today and should be performed in every patient with CVI and PTS. However, it does not easily assess calf muscle pump function or the presence of proximal obstruction. These concerns are addressed with use of other tests, such as air plethysmography, which gives a quantitative assessment of venous reflux (by the venous filling index), calf muscle pump function (by the ejection fraction), and overall venous function (by residual volume function). These measurements help to stratify patients into treatment groups.

Determination of functional outflow obstruction requires venography with or without pressure measurement, although intravascular ultrasound (IVUS) is also

very useful to determine the presence or absence of venous obstruction. Descending phlebography involves injection of contrast media into the common femoral vein to test the valves during normal breathing and with a forced Valsalva maneuver. Using this technique, pathologic reflux can be identified in patients with postthrombotic damage. Such testing is reserved in anticipation of surgical correction of the venous pathology if duplex scanning does not provide definite information on pathophysiology.

► Differential Diagnosis

Congestive heart failure and chronic liver and kidney disease must be considered in the differential diagnosis of bilateral lower extremity edema. Lymphedema is characterized by nonpitting edema of the dorsum of the foot and toes as well as the calf and generally is not associated with skin pigment changes, dermatitis, or ulceration. Severe arterial insufficiency produces ulcers that are painful, well circumscribed, and located over pressure points on the distal end of the extremity and foot. Ulcers due to autoimmune diseases, erythema nodosum, and fungal infections are distinguished by appearance and distribution.

► Treatment

Venous insufficiency is an incurable but manageable problem. Most patients respond well to a conservative treatment program composed of intermittent leg elevation, regular exercise to improve calf muscle pump function, and the use of surgical elastic graduated compression stockings. Although the mechanism by which elastic compression improves the symptoms of CVI has not been clearly established, recent work suggests that external compression may restore competency of dilated valve cusps and affect venoarterial reflex. Most venous ulceration will improve with leg elevation, external compression, and local wound care. Compression can be achieved with an inelastic bandage such as an Unna boot, an occlusive wound dressing covered by elastic bandage wrapping, or surgical support stockings.

Surgery is indicated for a small percentage of patients with nonhealing ulcers or disabling symptoms refractory to conservative management. The three main categories of procedures include those ablative procedures on the superficial venous system in the face of superficial venous reflux, antireflux procedures, and bypass operations for obstruction. If superficial venous reflux is a significant component of the total venous reflux present, then superficial ablation is appropriate. Such ablation has been found successful in preventing recurrent venous ulceration and has also been found to improve patients' symptoms of both varicose veins and venous reflux. Ablation may be performed with traditional open surgical ligation and stripping or the more recent endovenous procedures such as radiofrequency ablation or endovenous laser therapy. The pathology must be accurately

characterized so that an appropriate operative strategy can be developed. The most common abnormality in patients with CVI is incompetence of the popliteal or tibial veins; 50%-60% of patients have incompetent perforators.

Perforating vein interventions are typically performed in patients with recurrent venous ulcers or demonstrated incompetence of perforating veins under the area of ulceration. Since its introduction in the 1980s to the late 2000s, subfascial endoscopic perforator vein surgery (SEPS) was the technique of choice for perforator ablation, as studies revealed that it resulted in a significant lower rate of wound infections and recurrent ulcers compared to the open Linton procedure. However, continued advancements in perforator ablation techniques in more recent years has led to increased use of percutaneous ablation of perforators (PAPS), radiofrequency ablation (RFA), endovenous laser ablation, and sclerotherapy in addition to SEPS. Current guidelines recommend against selective treatment of incompetent perforating veins in patients with simple varicose veins. However, in perforating veins which meet "pathologic" criteria (outward flow ≥ 500 ms duration, diameter ≥ 3.5 mm, located beneath healed or open venous ulcer), SEPS, ultrasound-guided sclerotherapy, or thermal ablations are suggested.

While minimally invasive techniques addressing superficial and perforator reflux have advanced, such treatment of deep reflux disease remains challenging. There are both non-thrombotic and postthrombotic etiologies, either of which contributes to the obstructive component of deep reflux disease. Previous surgical options included venous bypass and reconstruction procedures, patch venoplasty, and, specifically in the case of patients for whom iliac-femoral stenosis is confirmed through venography and intravenous ultrasonography (IVUS), venous stenting has been a successful endovascular treatment option. Alhalbouni and colleagues reported the majority of their patients experienced healing of their chronic venous stasis ulcers after stenting of stenotic lesions found by IVUS. Raju et al. describe 5-year continued freedom from venous ulcer after iliac stenting to near 90%, underscoring both the role of obstruction in the pathophysiology and the effectiveness of relieving such obstruction.

II. THE LYMPHATICS

LYMPHEDEMA

▶ General Considerations

Much less is known about the fluid dynamics of the lymphatic system than of the venous or arterial system. Most energy for lymph propulsion arises from the intrinsic lymphatic smooth muscle contractions that occur rhythmically. Lymphatic luminal pressures are usually 30–50 mm Hg and can exceed arterial pressure under special circumstances. The lymphatic system carries interstitial fluid and macromolecular proteins lost from the capillaries, as well as infectious agents and foreign material, back into the central circulation. Two to four liters a day of lymph drain into the subclavian vein.

The fundamental mechanism responsible for lymphedema formation is impaired lymph flow out of the extremity. Primary lymphedema includes idiopathic types of lymphedema without an identifiable etiology, and the more commonly recognized type due to abnormal lymphatic development, most often hypoplasia resulting in severe reduction in the number of lymphatics and the lymphatic diameters. It is classified by age at onset of the disease. Congenital lymphedema develops before 1 year of age, is usually bilateral, and affects men more than women; if familial, it is known as Milroy disease. More often, lymphedema develops during adolescence (lymphedema praecox) and is unilateral; there is a 10:1 female predominance. Lymphedema occurring after age 35 is referred to as lymphedema tarda.

Secondary lymphedema results from a wide variety of disease processes that cause obstruction to the lymphatic system. The most common of these is surgical excision and radiation to the axillary or inguinal lymph nodes as part of the treatment of breast cancer, cervical cancer, prostate cancer, melanoma, and soft tissue tumors. Many of these neoplasms tend to develop regional lymphatic metastases before progressing to distant metastatic disease, and their treatment commonly involves complete lymph node dissection of the involved territory. Of note, secondary lymphedema may arise at any time postoperatively, including years and decades after the operation. Less common causes of secondary lymphedema are bacterial and fungal infections, trauma, and lymphoproliferative diseases. In many developing countries, lymphatic obstruction due to filariasis is caused by three different parasites: *Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori*.

▶ Clinical Manifestations

A. Symptoms, Signs, and Assessment

The history of the disease process will usually define the cause of the lymphedema. Development of painless edema in an adolescent girl with a family history of lymphedema

would indicate primary lymphedema as a diagnosis. A history of lymph node dissection, irradiation, or the presence of a parasitic infection suggests secondary lymphedema.
