Lymphedema development is usually slowly progressive and painless. In the early stages, the edema is pitting, but as the disease progresses, chronic fibrosis occurs and the edema becomes nonpitting. The distribution of edema is also characteristic. It is usually centered on the ankle (Figure 35–6) and is most pronounced on the dorsum of the foot, producing a buffalo hump appearance. Unlike edema of venous stasis disease, lymphedema also often involves the toes. In the early stages, the skin is normal, but skin thickening and hyperkeratosis occurs with longstanding disease. A chronic eczematous dermatitis may ensue.

Objective assessment is most commonly performed by measuring the circumference of the extremities, with the difference threshold of greater than 2 cm to define lymphedema. Additionally, water displacement is used to assess limb volume. The difference between the two arms before and after surgery of over 200 mL has been used to identify secondary lymphedema.

▲ **Figure 35–6.** Acquired lymphedema. Edema is centered at the ankle and involves the foot and toes.

Rarely, lymphangiosarcoma or angiosarcoma may develop as a complication of chronic lymphedema. This neoplastic transformation of blood vessels and lymphatics is called Stewart–Treves syndrome.

B. Imaging Studies

Venous duplex scans are performed to rule out venous insufficiency and exclude venous obstruction. CT and MRI are useful tests in patients with suspected secondary lymphedema from unknown malignancy. Lymphangiography has largely been replaced by radionuclide lymphoscintigraphy, the gold standard for evaluation of lymphatic function. A subcutaneous injection of ^{99m}Tc -labeled substance is injected into the first and second web-space of the toes or fingers, and its movement, transition time, and activity are interpreted. Lymphoscintigraphy carries minimal risk, and its use in conjunction with duplex scans permits the detection of lymphatic dysfunction and lymph nodes and provides information on lymph transport and reflux.

► Differential Diagnosis

A variety of diseases can result in bilateral lower extremity edema. These include congestive heart failure, pulmonary hypertension, chronic renal or hepatic insufficiency, and hypoproteinemia. In patients with unilateral leg edema, differential diagnosis includes congenital vascular malformations, chronic venous insufficiency, and reflex sympathetic dystrophy.

► Treatment

Lymphedema is a chronic disease for which there is no complete cure. However, a variety of conservative measures can substantially reduce the risk of further complications and disability.

No drug therapy is effective. Use of benzopyrones (to increase lymphatic transport by macrophages) has shown some benefit. Diuretics can be useful for acute exacerbation of edema secondary to infection or for coexisting venous stasis disease, but these agents are not recommended for long-term use in lymphedema.

The mainstay of treatment is external compression and meticulous skin care. Mechanical reduction of lymphedema can best be achieved with a program of frequent leg elevation, manual lymphatic drainage massage, low-stretch wrapping techniques, and intermittent pneumatic compression (IPC). Decongestive lymphatic therapy (DLT) is traditionally the first line of treatment regardless of primary or secondary etiology. DLT is composed of manual lymphatic drainage, compression therapy with bandages and IPC, and movement exercises. Many different devices are available for use on the leg, and sleeves can be custom fit for patients with postmastectomy arm lymphedema. Graduated compression

stockings maintain the limb after reduction by pneumatic compression. Good skin care is imperative in order to prevent infection. Moisturizing lotions should be applied regularly, especially after showering or bathing. Drying and cracking of the skin can create portals of entry for bacteria. Infection is difficult to eradicate because of disordered lymphatic drainage and can be limb threatening.

The psychologic impact of chronic lymphedema cannot be underestimated. However, with appropriate patient education that results in the prevention of chronic infection or massive edema, this problem can be manageable.

Operation may be considered in rare cases of severe functional impairment and recurrent lymphangitis. The approaches are either reductive in nature to minimize bulk, or they are reconstructive to rebuild lymphatic channels. Indications for reductive therapies include massive, incapacitating extremities, and the failure of conservative therapy. The Charles procedure involves excision of all skin and subcutaneous tissue from the tibial tuberosity to the lateral head of the fibula and wound coverage by a split thickness skin graft. Due to unpredictable cosmetic outcomes and associated complications such as cellulitis and sepsis, many variations of this procedure now exist with reported decrease in morbidity. More recently, liposuction-circumferential suction-assisted lipectomy has been successful in treating upper-extremity lymphedema secondary to breast cancer therapy. In this scenario, fat is the primary cause of swelling and not fluid, thus lymph reconstruction and conservative measurements are ineffective.

The application of reconstructive techniques is most successful in early disease, when the lymphatics are relatively healthy. Lymphatic channels are rebuilt via microsurgical methods of lympho-venous or lympho-venous-lymphatic bypass anastomosis, lympho-lymphatic segmental interposition, or free lymph node transplantation. Campisi and colleagues present the largest series to date evaluating lymphatic reconstruction, with 1800 patients with primary and secondary lymphedema treated over 30 years with lymphatic-venous anastomoses. Their study demonstrates 87% of their subjects reported subjective improvement and 83% showed significant volume reduction. Notably, more than 90% of these patients were in Campisi stage II and III lymphedema with persistent edema, but still at a relatively early stage before the onset of fibrosis or severe limb deformation. As the disease progresses and irreversible damage inevitably results, there is little success in restoring flow or reducing fibrosclerotic tissue.

LYMPHANGITIS

► General Considerations

Lymphangitis is usually caused by a hemolytic streptococcal or staphylococcal infection that arises in an area of cellulitis near an open wound. Multiple long red streaks can be seen coursing toward the regional lymph nodes. Severe systemic manifestations include tachycardia, fever, chills, and malaise, which untreated can lead to sepsis and death.

► Clinical Findings

A. Symptoms and Signs

Pain at the site of the initial wound is present. High fevers develop rapidly. The streaks may be faint in appearance initially, especially in dark-skinned patients. Regional lymph nodes are often enlarged and tender.

B. Laboratory Findings

An elevated white blood cell count associated with a left shift is almost universally present. Blood and wound cultures should be obtained routinely.

► Differential Diagnosis

Lymphangitis should be distinguished from superficial thrombophlebitis, which is usually localized to a single venous segment often with a palpable cord. Patients with thrombophlebitis usually do not appear toxic, as do patients with lymphangitis. Cat-scratch fever should always be considered when lymphadenitis is present. It is also important to differentiate cellulitis and severe soft tissue infections from lymphangitis. In general, lymphangitis is characterized by its superficial location and the linear pattern of erythema.

► Treatment

The extremity should be elevated and warm compresses applied. Analgesics and intravenous antibiotics should be instituted immediately. Examination of the wound should be made to determine the need for debridement or incision and drainage of an abscess.

► Prognosis

Delayed or inadequate therapy can lead to overwhelming sepsis and death. Aggressive institution of appropriate antibiotic therapy and wound care will usually control the infection within 48-72 hours.

MULTIPLE CHOICE QUESTIONS

- Which statement regarding the treatment of varicose and perforator veins is true?
 - Surgical and chemical ablations are preferred compared to thermal ablation of the GSV
 - Selective treatment of incompetent varicose veins is recommended in patients with simple varicose veins
 - Thermal ablation is an effective approach to the treatment of saphenous veins
 - Vein reabsorption after thermal ablation occurs over the course of a few days
- Three months' anticoagulation is recommended for which of the following?
 - In patients with PE/an isolated distal DVT of the leg provoked by surgery
 - In patients with PE/proximal DVT of the leg provoked by a nonsurgical transient risk factor
 - All patients with DVT
 - A and B
- Which imaging study is an appropriate initial evaluation in patients with suspected axillary-subclavian vein thrombosis?
 - CT angiogram
 - CT venogram
 - Chest x-ray
 - Upper extremity venous duplex ultrasound
- Which of the following regarding superficial thrombophlebitis is true?
 - Generalized edema is almost always present
 - Up to 40% of presentations have associated acute DVT
 - Ambulation is discouraged due to the painful, inflammatory process
 - Most episodes of septic thrombophlebitis require surgical excision
- Lymphedema is a chronic condition for which no definitive cure is currently available. Which of the following is true?
 - The distribution of edema is exactly the same as that of venous stasis disease
 - The gold standard for evaluation of lymph function is CT
 - Venous duplex scans aid in ruling out venous insufficiency and venous obstruction
 - Diuretics are a mainstay of treatment of minimizing the edema

DIAGNOSIS & MANAGEMENT OF ALTERATIONS IN CONSCIOUSNESS

Kyle Sheehan, MD; George A. Mashour, MD, PhD

Alterations of consciousness and the related conditions of delirium, acute confusional state, and acute encephalopathy are among the most common mental disorders encountered in either surgical or medical patients. The prevalence of altered mental status in hospitalized patients is high, with reported rates up to 50%. These conditions are associated with increased mortality rates ranging from 10% to 65%, and excess annual health care expenditures in the billions. Given the high incidence of altered mental states, at least a basic understanding of the pathophysiology, diagnosis, and management of common etiologies is warranted for all medical practitioners.

DEFINITIONS

Consciousness is generally defined as the subjective experience of the environment and the self. It is comprised of two components: arousal, which is the state of wakefulness, and awareness, which is the state of phenomenal perception. This distinction is useful, since the two processes are dissociable. For example, a vegetative state is characterized by a patient that is awake (ie, the cortex is aroused), but not necessarily aware.

Arousal is generated by activity of the ascending reticular activating system, which is composed of neurons within the central mesencephalic brainstem, the lateral hypothalamus, and portions of the thalamus. Widespread projections of these nuclei synapse on neurons in the cerebral cortex and generate an arousal response. Arousal responses define the *level* of consciousness (eg, being awake vs. asleep vs. comatose). **Awareness** is thought to be generated through networks involving the thalamus and association cortices of the frontal, parietal, temporal, and occipital lobes. Processes

related to awareness define the *content* of consciousness (eg, seeing a blue circle vs. a red triangle).

Many terms are used to describe the levels of consciousness ranging from alert to comatose. The alert patient is awake and immediately responsive to all stimuli. Stupor is a condition in which the patient is less alert but still responds with stimulation. An obtunded patient appears to be asleep much of the time but still responds to noxious stimuli. A vegetative state is a state of arousal without awareness in which the patient may open his or her eyes, track objects, chew, and swallow, but not respond to auditory stimuli or appear to sense pain (although pain processing is now known to occur in the vegetative state). The comatose patient appears asleep and does not respond to stimuli. Often, terms used to describe states of consciousness lack consistent definitions, and a clear description of a patient's state of arousal and awareness results in more precise communication.

PATHOPHYSIOLOGY OF ALTERED CONSCIOUSNESS

In general, altered states of consciousness can arise from physiologic, pharmacologic, and pathologic causes. Before addressing pathologic causes (which can have structural or nonstructural etiologies), physiologic perturbations such as hypoglycemia, hypoxia, hypercarbia, hyponatremia, and hypothermia should be addressed. Pharmacologic etiologies, such as acute intoxication, overdose, and residual anesthesia from surgery, should also be considered and reversed when possible.

▶ Structural Pathology

The reticular activating system is excited by a wide variety of stimuli, particularly somatosensory stimuli. Given that its nuclei are highly concentrated in the midbrain, it can be damaged by central midbrain lesions, which can result in the loss of arousal and coma.

Less severe dysfunction of the reticular activating system results in an acute confusional state. The cardinal signs of an acute confusional state are somnolence, inattention, and disorientation. Additionally, perceptions may be distorted, leading to hallucinations, and the patient may be unable to organize and interpret a complex stimuli. Disordered perception results in dysfunctional learning, memory, and problem solving. Thought processes can be disorganized and tangential, and the confused patient may develop delusions. In some cases, the acute confusional state presents as delirium, which can, in its hyperactive form, be characterized by heightened arousal, disordered perception, agitation, delusions, hallucinations, and autonomic hyperactivity (diaphoresis, tachycardia, hypertension, and mydriasis). However, it is important to note that hypoactive delirium is the most common type to be manifested in the postoperative setting.

Neurons in the pons, midbrain, and hypothalamus are necessary for regulation of sleep-wake cycles. Therefore, lesions involving the pons may preserve consciousness but disturb sleep. This is in contrast to the typical vegetative state that results from diffuse destruction or injury of the bilateral cerebral cortices, secondary to global cerebral ischemia or anoxia with preservation of the reticular activating system and brainstem sleep centers. This leaves the patient with preserved sleep-wake cycles without the ability to interact with the environment.

Acute confusional states and coma may result from structural or metabolic causes. Structural lesions of the cerebral hemispheres such as hemorrhage (intracerebral, subdural, or epidural), large areas of ischemic infarction, abscesses, or neoplasms can expand over minutes or a few hours and result in significant elevation of the intracranial pressure (ICP).

► Nonstructural Pathology

Several nonstructural disorders that diffusely disturb brain function can produce a confusional state or, if severe, coma (Table 36–1). Acute toxic-metabolic encephalopathy (TME), which encompasses delirium and the acute confusional state, is an acute condition of global cerebral dysfunction in the absence of primary structural brain disease. Typically, TME is usually a consequence of systemic disease or secondary to drugs and metabolic toxins that are reversible, thus making prompt recognition and treatment critical.

Additionally, TME is common among critically ill patients and is probably underdiagnosed, especially when it occurs in patients who require mechanical ventilation. Risk factors for the development of TME include admission to an ICU, advanced age, preexisting primary neurodegenerative disease (dementia), nutritional deficiency, infection, temperature dysregulation, and failure of multiple organ systems.

Table 36–1. Etiology of altered state of consciousness.

Physiologic	Pathologic	Pharmacologic
Global cerebral ischemia	Trauma-associated subdural or epidural hematoma	Sedatives
Hepatic encephalopathy	Tumor	Narcotics
Hypoxia/hypercarbia	Infection—meningitis or encephalitis	Alcohol/illicit substances
Hyperosmolar state	Vascular (stroke)	Poisoning
Hypotension	Ischemic stroke (ie, basilar artery thrombosis)	
Hypo/hypercalcemia	Subarachnoid hemorrhage	
Hypo/hyperthermia	Intracerebral hemorrhage	
Hypo/hyperglycemia	Seizures	
Hypo/hyponatremia	Subclinical status epilepticus	
Hypothyroidism	Prolonged post-ictal state	
Thyrotoxicosis		
Uremia		

PATHOPHYSIOLOGY OF ELEVATED INTRACRANIAL PRESSURE

The skull encloses three major components: brain parenchyma, cerebrospinal fluid (CSF), and blood. The volumetric sum of these components is maintained at a constant. Given the nondistensible cranial vault and these three noncompressible substances, an increase in one component must be offset by a decrease in another or pressure will increase. This offset is normally accomplished by displacement of CSF into the contiguous subarachnoid space of the spinal cord, termed “spatial compensation.” This delicate balance, however, has physiologic limits. Once these compensatory limits are met, an increase in the volume of any component will lead to an exponential increase in ICP as illustrated by the intracranial elastance curve (Figure 36–1).

Normal ICP in adults is less than 10–15 mm Hg. The presence of tumor or blood, the impedance of CSF drainage (hydrocephalus), cerebral edema, and increased cerebral

▲ Figure 36–1. Intracranial compliance curve demonstrating the approximate relationship between ICP and an expanding intracranial mass.

blood flow (hyperemia as a response to head injury or hypoventilation causing hypercarbia and vasodilation) may raise the ICP to a dangerous level. The increased ICP may lead to reduced cerebral perfusion and ischemia and a mass effect progressing to shifting of the brain parenchyma and devastating herniation.

SIGNS & SYMPTOMS OF INCREASED ICP

Increased ICP is often accompanied by altered mental status, headache, vomiting (without nausea), and papilledema on fundoscopic examination. Cushings triad may be seen in patients with severely increased ICP and consists of hypertension, bradycardia, and respiratory irregularity. Obtundation, focal neurologic findings including unilateral pupillary dilation from pressure or traction exerted on the third cranial nerve (ie, the “blown” pupil), and hemodynamic instability are late findings and indicate pending uncal herniation.

► Cerebral Herniation Syndromes

Cerebral herniation occurs when increased ICP results in a portion of the brain shifting from one intracranial compartment to another. These shifts may lead to vascular compromise and infarction of portions of the brain, disruption of white matter pathways, and direct pressure on structures such as cranial nerve III.

Subfalcal Herniation

Occurs in patients with a frontal lobe mass as the cingulate gyrus herniates beneath the falx. Symptoms are often related to the mass or increased ICP.

Lateral Mass Herniation

Occurs in patients with an expanding lateral mass. Symptoms include contralateral hemiparesis, diminished consciousness, and an ipsilateral cranial nerve III palsy. Compression of pupillary fibers also causes a dilation of the pupil and as lateral displacement of the midbrain continues there is ipsilateral hemiplegia. Late in the process, the uncus and hippocampus may herniate transtentorially.

Cerebellar Tonsillar Herniation

Posterior fossa masses cause symptoms by compression of the brainstem and obstructing the flow of CSF (hydrocephalus). As pressure increases, the cerebellar tonsils may be pushed into or through the foramen magnum. As the medulla is compressed, apnea results from dysfunction of the medullary respiratory center.

Upward Transtentorial Herniation

Posterior fossa masses may cause obstructive hydrocephalus. If these patients undergo ventriculostomy, there is a

possibility of upward herniation of posterior fossa contents into the region of the thalamus and hypothalamus.

DIAGNOSTIC EVALUATION OF ALTERED CONSCIOUSNESS

The diagnosis of an altered state of consciousness is provided by general physical examination, neuroradiological imaging, drug screens, and certain laboratory studies.

► Neurological Examination

The neurologic exam includes assessment of level of consciousness, brainstem reflexes, and motor activity. Rapid, standardized assessment of the level of consciousness is useful for clinical decision-making and communication. The level of alertness reflects the severity of the underlying condition; severely affected patients are comatose. Commonly, the Glasgow Coma Scale (GCS) (Table 36–2) is used to assess level of consciousness in patients with head injury, but is also widely used as assessment of level consciousness regardless of etiology. A patient with a GCS score 8 or less is generally considered to be comatose. The cardinal feature of confusion and delirium is impaired attention. Simple bedside tasks such as serial subtraction or naming the months of the year in reverse can test attention. Marked fluctuations in mental status over time are characteristic. Other common findings include a disturbed sleep-wake cycle, decreased alertness, hypervigilance, hallucinations, sensory misperceptions, impaired memory,

Table 36–2. Glasgow coma scale.

and disorientation. The thought process is often disorganized, manifested by confused or rambling conversation.

The cranial nerves and their corresponding brainstem reflexes, including pupillary response to light, corneal reflexes, oculocephalic reflex (doll's eyes), vestibulo-ocular reflex (cold calorics), breathing patterns, cough, and gag reflexes are further used to describe accurately the neurologic status and localize the level of brainstem dysfunction. Generally, the brainstem reflexes are only affected in severe TME. Abnormal patterns of respiration, particularly Cheyne–Stokes respiration, may also occur with significant brainstem dysfunction.

Motor responses may be delineated as spontaneous or induced by noxious stimuli, purposeful or nonpurposeful, unilateral or bilateral, and upper or lower extremity. The patient may display withdrawal from a stimulus, abnormal flexion (decorticate posturing), abnormal extension (decerebrate posturing), or absence of motor activity. A variety of motor abnormalities are also associated with TME: tremor, asterixis, multifocal myoclonus (sudden, nonrhythmic gross muscle twitching), paratonia (increased tone with variable resistance), diffuse brisk deep tendon reflexes, or bilateral extensor plantar responses.

► Laboratory Studies

The laboratory investigation of decreased level of consciousness includes a complete blood count, coagulation studies, electrolyte panel, and examination of calcium, magnesium, phosphate, glucose, blood urea nitrogen, creatinine, bilirubin, liver enzymes, ammonia, serum osmolality, and arterial blood gases. Toxicology screening should be performed for suspected intoxications. Blood and CSF cultures should be obtained if infection appears present. Further analysis of CSF with cell counts, protein, glucose, and organism-specific studies such as herpes simplex virus PCR and fungal serology can reveal meningitis, neoplastic cells, or subarachnoid hemorrhage. Thyroid function tests and vitamin B₁₂ and serum cortisol concentrations should be assessed if endocrinopathy is considered.

► Neuroradiological Studies

Emergent computed tomography (CT) imaging to assess for structural lesions (intracerebral hemorrhage, large territory ischemic stroke, hydrocephalus, neoplasm, and diffuse cerebral edema) is strongly recommended for patients presenting with focal neurological deficits or severe decline in the level of consciousness. Acute ischemic stroke within the first 3–4 hours may be clinically occult on CT imaging. Magnetic resonance imaging (MRI) of the head is generally reserved to further assess for acute ischemic stroke as well as further characterization of neoplastic lesions. MRI should be not relied upon for an emergent diagnosis given the duration of the study.

► Electroencephalography

The electroencephalogram (EEG) can both confirm global cerebral dysfunction and exclude subclinical status epilepticus with greater sensitivity than clinical examination alone. After structural lesions have been excluded, EEG should be performed in most patients with altered consciousness at some point during the course of their care. The degree of diffuse slowing of the normal background plus abnormal mixed rhythms in the EEG correlates with the severity of TME. Slowing can be categorized as follows: mild, with a reduction in the normal alpha frequencies (8–13 Hz); moderate, with theta frequencies (4–8 Hz); severe, delta frequencies (less than 4 Hz).

► ICP Monitoring

Quantification of ICP is critical for management of patients with large intracerebral lesions resulting in mass effect and shift of midline structures, diffuse cerebral edema, or hydrocephalus. ICP cannot accurately be estimated based on clinical findings or imaging. There are several methods of direct ICP measurement, but the two most commonly employed in clinical practice are ventricular catheters and intraparenchymal microtransducer systems. Other methods such as subarachnoid and epidural devices have much lower accuracy.

The gold standard of ICP monitoring is via an intraventricular catheter connected to a standard pressure transducer. These catheters are usually placed into the lateral ventricle by a small frontal burr hole. The advantages of intraventricular catheters are that they measure global ICP, allow for therapeutic drainage of CSF, and are amenable to external calibration. Disadvantages are risk for infection, hematoma, or difficult insertion.

Microtransducer-tipped ICP monitors are placed in the brain parenchyma or subdural space either through a skull bolt, a burr hole or intraoperatively. They are almost as accurate as intraventricular catheters and have the advantages of lower infection and complication rates. The major disadvantages are an inability to drain CSF, no in vivo calibration and a small zero drift over time.

MANAGEMENT OF ALTERED CONSCIOUSNESS

The initial treatment of a patient with an alteration in consciousness must employ management of the ABCs: airway, breathing, and circulation. Patients who are not responsive enough to protect their own airway require intubation to reduce the risk of aspiration of gastric contents. During intubation, hypoxia and hypotension should be avoided in brain-injured patients and a high suspicion of cervical spine injury should be maintained. A patient presenting with a GCS score 8 or less should be intubated. Mechanical ventilation should be used if necessary to provide adequate oxygenation and ventilation as guided by

arterial blood gases. Patients presenting with hypotension and shock must be aggressively treated with fluids and vasopressors to maintain adequate perfusion. Sources of shock (septic, cardiogenic, hypovolemic) should be investigated and treated appropriately.

Regardless of the cause of acute decline of mental status, a number of general measures should be instituted. There should be a discontinuation of all drugs with potential toxicity to the central nervous system, if possible. Antipsychotic medications such as haloperidol or quetiapine can be used for management of severe agitation. Thiamine should be administered to patients with a history of alcoholism, malnutrition, cancer, hyperemesis gravidarum, or renal failure on hemodialysis in order to prevent the development of Wernicke encephalopathy.

In the event that a patient presents with history or examination findings suggestive of elevated ICP, immediate life-saving measures may be required prior to a more detailed workup with neuroradiological imaging or ICP monitoring. These situations generally rely upon clinical judgment and expert consultation with a neurosurgeon or neurologist is strongly recommended. An examination consistent with a critically elevated ICP (coma with GCS score < 8, unilateral or bilaterally fixed and dilated pupil(s), decorticate or decerebrate posturing and Cushing triad of bradycardia, hypertension, and respiratory depression) warrants immediate intervention while delaying additional diagnostic studies. In addition to standard resuscitation measures, elevation of the head above the heart (usually 30 degrees) to increase intracranial venous outflow, temporary hyperventilation to a goal P_{aCO_2} of 26-30 and administration of intravenous hyperosmolar therapy (either mannitol 1-1.5 g/kg or hypertonic saline infusion). Immediately following these measures, rapid evaluation of the underlying diagnosis by the patient history, detailed neurological examination and neuroradiological imaging should be pursued. Neurosurgical consultation should be considered for potential placement of a ventriculostomy as a means to assess ICP and potentially treat with CSF drainage.

If elevated ICP is present, therapy should be directed to maintain ICP less than 20 mm Hg. Interventions should be utilized only when ICP is elevated more than 20 mm Hg for more than 5 minutes. Transient physiologic elevations in ICP may be observed in the setting of coughing, movement, suctioning, or ventilator asynchrony that should not be targeted by therapy. During periods of elevated ICP, it is important to maintain adequate mean arterial pressure to ensure adequate cerebral perfusion pressure (which is mean arterial pressure - ICP).

GENERAL MANAGEMENT OF ELEVATED ICP

1. Blood pressure control—Therapy with vasopressors should be targeted to maintain an adequate cerebral

perfusion pressure ($CPP = MAP - ICP$), typically more than 60 mm Hg. Hypertension should generally only be treated when CPP more than 120 mm Hg. CPP more than 50 mm Hg is associated with cerebral ischemia.

2. Position—Patients with elevated ICP should be positioned with the head elevated 30 degrees above the heart while maintaining the neck in neutral position without excessive flexion or rotation to maximize intracranial venous outflow.

3. Removal of CSF—When hydrocephalus (either obstructive or communicating) is discovered, a ventriculostomy may be utilized to reduce intracranial CSF volume and secondarily ICP. Controlled drainage of CSF at a rate of approximately 1-2 mL/min, at intervals of a few minutes until the goal ICP is reached ($ICP < 20$ mm Hg) or until CSF is no longer easily obtained is recommended. CSF drainage via an intrathecal lumbar drain is generally contraindicated in the setting of elevated ICP due to the risk of transtentorial herniation.

4. Hyperventilation—The use of mechanical ventilation to lower P_{aCO_2} to a goal of 26-30 mm Hg will induce cerebral vasoconstriction, decrease the cerebral blood volume, and rapidly reduce ICP. The effect of hyperventilation on ICP typically lasts for a period of hours prior to metabolic compensation. Therapeutic hyperventilation should be utilized only as an emergent intervention to temporarily control ICP and be replaced by other therapy modalities.

HYPEROSMOTIC THERAPY

1. Mannitol—Osmotic diuretics reduce brain volume by creating an osmotic gradient from the brain parenchyma to the intravascular space, thus drawing free water from the parenchyma. Mannitol, prepared in a 20% solution, can be given as a bolus of 1-1.5 g/kg. Mannitol can be used in serial doses at intervals of every 6-8 hours at a reduced dosage on 0.25-0.5 g/kg as needed for continued elevated ICP. The onset of action is within minutes and the duration of effect varies widely from 4 to 24 hours. Serial measurements of serum sodium, serum osmolality, and renal function are necessary to prevent overdose. Contraindications to the use of mannitol include serum sodium more than 150 mEq, serum osmolality more than 320 mOsm, or evidence of evolving acute tubular necrosis. In addition, mannitol frequently can induce hypotension and subsequently cerebral perfusion. Mannitol should not be used in patients with acute or chronic renal disease.

2. Hypertonic saline—Bolus dosing of hypertonic saline (tonicity ranging 1.8-23.4 percent) can acutely lower ICP. The typical volume of hypertonic saline varies widely depending on tonicity, ranging from 30 mL of 23.4% to 1 L of 1.8%. Continuous infusion of hypertonic saline (1.8%-3%)

to maintain hyponatremia may also be effective in controlling ICP. A meta-analysis of multiple clinical trials comparing the efficacy of mannitol to hypertonic saline for management of elevated ICP from a variety of causes (traumatic brain injury, stroke, tumors) found that hypertonic saline appeared to have greater efficacy in reducing elevated ICP, but clinical outcomes were not examined. Hypertonic saline should generally not be administered through a peripheral intravenous catheter.

3. Fluid management—Typically, patients with elevated ICP should be kept euvolemic and normo- to hyperosmolar. Administration of free water and hypotonic solutions should be strictly avoided and instead isotonic fluids should be used in all maintenance fluids and infusions. Serum sodium levels should be closely monitored and hyponatremia should be appropriately corrected.

4. Sedation—Maintenance of adequate sedation can decrease ICP by reducing cerebral metabolic demand, ventilator asynchrony, and the sympathetic responses of hypertension and tachycardia. Adequate sedation typically requires the establishment of a secure airway. Infusion of propofol is often the drug of choice for sedation because it can be rapidly titrated, thus allowing for frequent neurologic assessments.

5. Fever—Fever increases brain metabolism, which increases cerebral blood flow and thus elevates ICP. Additionally, fever has been demonstrated to worsen brain injury in animal models. Therefore, aggressive treatment of fever, including acetaminophen and cooling, is recommended in patients with increased ICP.

6. Antiepileptic therapy—Seizures, either convulsive or nonconvulsive, increase cerebral metabolism and result in ICP elevation. Aggressive treatment of seizures with antiepileptic therapy or infusion of anesthetics as well as continuous EEG monitoring is warranted. There is no clear evidence that prophylactic antiepileptic therapy is of any clinical benefit; however, consideration of prophylactic antiepileptic therapy is reasonable when high-risk mass lesions, such as those within supratentorial cortical locations, or lesions adjacent to the cortex, such as subdural hematomas or subarachnoid hemorrhage are present.

7. Glucocorticoids—Glucocorticoids, typically dexamethasone, are reserved for the management of elevated ICP secondary to vasogenic edema secondary to intracranial neoplasm and infection. Typically, dexamethasone is dosed every 6-12 hours at a wide range of dosages. The use of glucocorticoids has been associated with a worse outcome in a large randomized clinical trial in traumatic brain injury and is no longer recommended. Glucocorticoids are not considered to be useful in the management of cerebral infarction or intracranial hemorrhage.

8. Barbiturates—The use of barbiturates to control ICP is based on the drug's ability to dramatically reduce brain metabolism and secondarily cerebral blood flow. Pentobarbital is most commonly used, with a loading dose of 5-20 mg/kg as a bolus, followed by 1-4 mg/kg/h. The barbiturate infusion is titrated based on assessment of ICP, CPP, and the tolerance of side effects. Continuous EEG monitoring is generally used, with titration to an EEG burst suppression pattern indicating appropriate suppression of cerebral metabolism. Barbiturate therapy is complicated and fraught with complications, particularly hypotension, adynamic ileus, reduced mucociliary clearance of the airway, and high risk of infections. In general, the use of barbiturates is reserved for elevated ICP refractory to all other treatment modalities.

9. Therapeutic hypothermia—The use of hypothermia to treat elevated ICP has been controversial for decades, and its use is not recommended as a standard treatment for increased ICP. Hypothermia decreases cerebral metabolism and secondarily reduces cerebral blood volume and ICP. When used, hypothermia is achieved by whole body cooling using surface or intravascular cooling devices to a goal of 32-34°C. Studies have demonstrated significant side effects, including cardiac arrhythmias and severe coagulopathy. Given the multiple uncertainties of the appropriate use of therapeutic hypothermia in patients with elevated ICP, this treatment should be limited to patients with intracranial hypertension refractory to other therapies.

10. Decompressive craniectomy—Decompressive craniectomy is the surgical removal a large portion of the cranial vault to allow for the edematous intracranial contents to expand and subsequently reduce ICP. At the time of the procedure any mass lesion (neoplasm or hematoma) is also removed. Decompressive craniectomy has been considered a last resort; some evidence suggests that it does improve outcomes.

IMAGING OF THE CENTRAL NERVOUS SYSTEM

Douglas J. Quint Shawn L.A. Hervey-Jumper

INTRODUCTION

Imaging has become central to medical care in the past 25 years and is one of the fastest growing components of medical care expenditures in this country. In no field of medicine has imaging made more of an impact than in the neurosciences. Our ability to demonstrate anatomy and pathology noninvasively and to treat many pathologic central nervous system (CNS) processes utilizing minimally invasive techniques has grown immensely with improvements in imaging technology in the last few years.

Forty years ago, the only way to image the CNS was to replace cerebrospinal fluid (CSF) with contrast material (dye) or air via a lumbar puncture and take x-rays—a painful technique called pneumoencephalography—normal and abnormal CNS structures could be crudely outlined in this manner. Pneumoencephalography was abandoned in the late 1970s with the development of computed tomography (CT). Injecting dye directly into major blood vessels of the neck (cerebral angiography) has been available for three quarters of a century and allows exquisite delineation of intrinsic vascular pathology, but still does little to directly visualize the brain or spinal cord. While angiography is still performed today for both diagnostic and therapeutic purposes, the catheter is now placed via femoral arterial cannulation instead of directly into a neck blood vessel.

With the advent of CT scanning in the early 1970s, direct visualization of the brain was finally possible though resolving different normal brain structures and some pathologic processes remained difficult. Magnetic resonance imaging (MRI) first became available for clinical use in the early 1980s and has been the standard for evaluation of most CNS processes since the mid-1980s.

CT and MRI have continued to mature through the 1990s and into the 21st century. In addition to the introduction of lower radiation dose scanner capabilities on the most recent generation CT scanners, rapid scanning techniques on such scanners (“multislice” or “multidetector” CT scanners) now allow for collection of data reflecting cerebral blood perfusion, which can be collected during a 5-minute study. Similarly, such state-of-the-art scanners can be used to generate models of the major blood vessels of the brain (CT angiograms) lessening the need for more invasive intravascular catheterization in some patients.

MRI advances have been even more dramatic particularly with the release of higher field strength MR scanners (3.0 T) for clinical use in 2005. For example, the sensitivity of some of the newer MRI scanning techniques enables identification of physiologic changes in the brain minutes after ischemia occurs, a time frame that can potentially permit pharmacologic interventions that can affect clinical

outcomes (eg, stroke). Functional MRI can assess eloquent areas of the brain near pathologic lesions (eg, tumors) that ideally should be avoided during surgery. MR spectroscopy (MRS) can identify lesion metabolites that can help discriminate among pathologic processes (eg, tumors vs. necrosis vs. ischemia vs. inflammation vs. infections). MRS can also identify metabolites accumulating in the brain in patients with congenital metabolic disorders. MRI can also be used to generate angiographic (MR angiography, MRA) images to evaluate blood vessels without injection of dye or the use of ionizing radiation.

Catheter (endovascular) angiography has been available in various forms for over 80 years, and has also continued to evolve over the last decade. Endovascular surgery—treating blood vessel abnormalities such as aneurysms or arteriovenous malformations (AVMs) through a catheter instead of with open surgery—is now commonly performed and has become the treatment of choice for the management of many lesions. More than half of aneurysms treated in the United States are currently managed endovascularly avoiding the need for craniotomy in the majority of those patients. Similarly, in the setting of an acute stroke due to an obstructing thromboembolus, in an attempt to reopen the involved vessel, a catheter can be placed in the region of the obstructing lesion and a clot mechanically removed through the catheter, or clot-dissolving (eg, thrombolytic) agents injected.

BASIC CENTRAL NERVOUS SYSTEM IMAGING TECHNIQUES

1. Plain radiographs (“x-rays”) are relatively inexpensive, universally available and can demonstrate osseous abnormalities such as fractures or gross destructive lesions (Figure 36–2). The main disadvantage of plain x-rays is that essentially all normal soft tissues (eg, all intracranial and spinal canal structures) and pathologic processes (eg, hemorrhage, infarctions, tumors, abscesses, herniated disks, etc) cannot be detected. Even many intrinsic osseous lesions are difficult to delineate. In fact, until 30%-50% of bone marrow trabeculae is replaced by a pathologic process (eg, tumor, infection), no osseous abnormality is seen on a plain radiograph.
 - a. Another limitation of plain radiographs is that all structures are superimposed on a single image as the x-ray beam passes through the entire head or spine (as opposed to the “slices” generated on CT and MR scans).
 - b. There is little role for plain radiographs for the evaluation of CNS disease as the interior of the head or spinal canal is not imaged. One exception is in patients with suspected child abuse. In these patients, in addition to other cross-sectional imaging (such as CT/MR which are performed to assess for intracranial injuries), plain radiographs should

▲ **Figure 36–2.** Lateral plain radiograph (x-ray) of the skull (ionizing radiation). Note the excellent delineation of the osseous structures, but poor delineation of soft tissues; specifically, no portion of the brain is imaged. Also, this study is not tomographic (ie, is not a slice) and therefore both the left and right sides of the head are superimposed.

also be obtained as they may show subtle nondisplaced fractures not readily identified on other imaging tests.

- c. Other roles for plain radiographs include assessing spinal motion (ie, lateral flexion/extension radiographs of the cervical or lumbosacral spine to assess spinal stability), localization of foreign bodies, and assessing intracranial or spinal structures where internal fixation hardware and/or other radiodense/ferromagnetic foreign material is present (which can limit the use of CT or MRI scanning).
2. Ultrasound of the CNS, beyond the neonatal period, is predominantly used in the intraoperative setting to evaluate ventricular morphology and underlying parenchymal pathology. Intraoperative ultrasound can be used to help position ventricular catheters during placement of shunts. It can also be used to guide intracranial and intraspinal tumor resections.
 - a. Outside of the operative setting, ultrasound has growing applications because it is noninvasive, portable, and does not involve radiation. However, an “acoustic window” is necessary for viewing the intracranial/intraspinal tissues meaning that overlying osseous structures usually must be removed before scanning can be performed (ie, portions of the skull or posterior spinal elements must be removed before the desired regions of the brain or spinal cord, respectively, can be evaluated).
 - b. Ultrasound has multiple applications in infants (usually such infants still have open fontanelles so no additional “acoustic window” to the brain needs to be created). It has become the imaging study of choice for the evaluation of premature infants to assess for intraventricular hemorrhage and/or hydrocephalus. In adults, intracranial Doppler examinations can be performed by scanning through sutures. For example, scanning through the temporal suture allows access to the circle of Willis. These examinations can be performed at the bedside for assessment of arterial vasospasm (eg, in the setting of subacute subarachnoid hemorrhage). Ultrasound can also be used in younger children to identify the conus medullaris.
 3. CT scanning without or with intravenous administration of iodinated contrast material is performed utilizing a thin fan-like band of x-rays (ionizing radiation) that are generated by an x-ray tube that literally moves around the patient in approximately 1 second. The resultant image, which represents a “slice” of tissue, can be obtained with imaging thickness as thin as 1 mm. “Reformatted” submillimeter images can also be generated by the CT computer from the primary axially obtained CT scan data in any plane (sagittal, coronal, off-axis, etc). Three-dimensional images can also be created in this manner.
 - a. CT demonstrates most osseous abnormalities better than any other imaging test with the possible exception of nondisplaced, nondistracted fractures which are still often better seen on plain x-rays (Figure 36–3). Soft tissue lesions can also be detected with much better sensitivity than plain x-rays. However, resolving some similar, but not identical, normal soft tissues from one another, delineating normal from pathologic soft tissue, and evaluating certain areas of the brain which are limited by scanning artifacts can still be difficult with CT scanning which is why CT remains inferior to MRI for evaluation of most brain and spinal canal abnormalities.
 - b. When discussing CT images, the terms “density” and “attenuation” refer to the same process, namely, absorption of the x-ray beam. Areas of increased “density” have greater “attenuation” of the x-ray beam and result in more whitish areas on the CT scan image (eg, bones, iodine-based contrast material, acute blood, areas of calcification, and some foreign bodies). Areas of lower density have lower “attenuation” as they absorb less of the x-ray beam as it passes through the patient resulting in darker

▲ **Figure 36–3.** CT scan (ionizing radiation). This image represents a single section (“slice”) through the head (ie, it is a tomographic image; the left and right sides of the head can be separately delineated). The brain is directly imaged though resolving differences in intracranial structures can be difficult (eg, resolving gray and matter structures).

areas on the CT scan image (eg, fluid in the ventricles, gas, and fat).

- c. CT image contrast can be adjusted at a workstation after scans have been obtained to highlight differences in the densities of different tissues.
 - d. Finally, the recent development of new methods of reconstructing CT data has resulted in significant reduction in patient radiation dosage exposure during many CT scans.
4. Myelography involves performing a lumbar subarachnoid puncture (or a lateral C1-2 subarachnoid puncture) and instilling less than an ounce of iodinated contrast material to opacify the spinal canal subarachnoid space which results in outlining cauda equina nerve roots and the spinal cord, and any process that impinges upon (or is within) the subarachnoid space. Such processes include extrathecal tumors, infections, herniated disk material, degenerative spinal changes,

and also processes that directly involve the intrathecal structures (spinal cord tumors, vascular malformations, metastases, etc).

- a. Myelography is no longer a primary imaging technique for evaluating the spinal canal having been replaced by MRI. It is currently reserved for “problem-solving” such as when the results of an MRI scan are not clear or when MR imaging is not possible (contraindications to MR scanning, internal fixation hardware limits evaluation by MRI, etc).
 - b. Myelography is essentially always followed immediately (within hours) by CT scanning to better delineate relationships of pathologic processes to the subarachnoid space.
5. MRI is an imaging technique that does not use ionizing radiation.
 - a. The physics of creating an MR scan are quite complex. Briefly, a patient is placed in a strong magnetic field ($30,000 \times$ that of the earth’s magnetic field). Radiofrequency pulses are transiently (milliseconds) applied to the patient to briefly perturb the patient’s water molecules by raising them to a slightly higher energy level (quantum mechanical model). After turning off the radiofrequency pulse, these water molecules rapidly return to their respective baseline states by giving off their recently absorbed energy. The rate at which these perturbed water molecules return to their respective baseline states can be measured by using extremely sensitive receiver coils in the MR scanner. As the rates at which these molecules return to their respective baseline states varies by local magnetic environment (eg, the local magnetic environment is different in the ventricular system as opposed to the lentiform nucleus, white matter, the eyeball, muscles, tumors, etc), these detectable differences among tissues can be localized in 3-dimensional space and used to create an image.
 - b. MR images are obtained which highlight different kinds of magnetic field differences between tissues. In general, most MR studies include “T1-weighted” and “T2-weighted” scans as part of the overall evaluation of the patient. MR scans take longer to perform than CT scans in part because T1-weighted (T1w) and T2-weighted (T2w) scans and often additional scans must be obtained separately. T1w images are distinguishable by the black appearance (“absence of MR signal”) of the CSF over the surface of the brain and in the ventricles. In contrast, on a T2w scan, the CSF over the surface of the brain and in the ventricles is white (Figure 36–4).

▲ **Figure 36-4.** MR scan (no ionizing radiation). Similar to CT, this image represents a single section (“slice”) through the head. The white matter and gray matter structures are more easily resolved than on a CT scan, and even some gray matter structures can be resolved (eg, putamina and globus pallidus).

- c. In general, T1w scans are best for delineating anatomy and areas of contrast enhancement. T2w scans are exquisitely sensitive to subtle changes in water concentrations (in both normal and pathologic tissues). These changes are seen in most pathologic processes (eg, strokes, tumors, infections). These subtle changes are manifest as increased signal (more whiteness) on T2w scans.
- d. In the past 10 years, most MR studies include “FLAIR” (FLuid Attenuated Inversion Recovery) scans. In general, FLAIR scans can be considered super T2w scans on which normal fluid (eg, in the ventricles and subarachnoid spaces) has no signal (ie, black), and therefore, subtle pathologic process (which still appear white on the FLAIR scans similar to that seen on standard T2w scans) are easier to identify.
- e. A gadolinium-based contrast agent can be injected intravenously to enhance the appearance of some

pathologic processes such as those outside the blood-brain-barrier (BBB) or are intraaxial but do not have a functioning BBB.

- f. MRI best delineates soft tissues both intrinsic and immediately extrinsic to the brain, can be performed in any plane (including nonorthogonal planes), and has no known side effects at the field strengths used for clinical studies. In addition to better demonstrating tissues than CT, MRI is not limited by many of the artifacts that limit evaluation by CT, particularly in the posterior fossa and spinal canal regions where CT can be severely limited. While not ideal for directly visualizing dense osseous structures (where many fractures, cortical erosions, and degenerative changes occur), MR is superb for detecting intrinsic (eg, bone marrow) osseous abnormalities (eg, metastatic disease, discitis/osteomyelitis, etc).
6. Cerebral angiography is performed by directly placing a catheter into the femoral artery, passing it cephalad in a retrograde manner up the aorta to the level of the aortic arch, manipulating it into either a vertebral or carotid artery and then further cephalad into the neck and even intracranially (Figure 36-5). The catheter is moved utilizing intermittent fluoroscopic guidance with small amounts of dye injected at selected intervals to confirm the location of the catheter. When in position, larger amounts of dye are injected and serial plain digital x-rays are rapidly exposed as the dye passes through the intracranial vessels in the distribution of the injected blood vessel. Over 100 images might be obtained during a single 8-second injection of contrast material. This procedure is associated with a 0.1%-0.5% chance of causing a stroke.
 - a. This technique best delineates intrinsic blood vessel pathology such as atherosclerosis, aneurysms, AVMs, fistulas, vasculitis, blocked vessels, and other intrinsic vascular disorders. It can be used to inject medications into specific blood vessel territories for diagnostic or therapeutic purposes. Catheters can be placed directly into aneurysms, vascular malformations, and recently occluded vessels for definitive therapy.
 - b. Endovascular (catheter) angiography is risky, expensive, requires complex equipment, and is performed by highly trained personnel. There are currently several alternatives to catheter angiography to evaluate for vascular lesions such as atherosclerotic vascular narrowing and aneurysms. Ultrasound (in the neck), CT angiography, and MR angiography are each useful alternatives in many situations (Figure 36-6).
 7. Radionuclide Imaging (Scintigraphy) includes positron emission tomography (PET) and SPECT (single

▲ **Figure 36-5.** Angiogram (ionizing radiation). A catheter was placed in the right carotid artery in the neck and dye injected while imaging was performed in a front-to-back projection of the right side of the head. The bones are then digitally “subtracted” from the image. The exquisite delineation of the blood vessels of the right carotid territory are demonstrated, but no intra-axial (ie, brain soft tissues) structures.

photon emission CT) scans which are molecular imaging techniques. Unlike other imaging techniques, these imaging modalities provide information beyond the structural appearance of normal and pathologic tissues. These techniques can provide physiologic information reflecting the functional state of tissues.

- a. Low doses of radiotracers (positron emitters for PET scanning and single photon emitting isotopes for SPECT scanning) are used to label molecules or pharmacologic agents to image molecular interactions of biological processes in vivo. The nanomolar concentration of the radiotracer allows in vivo assessment of biologic processes without interfering with the process itself.

▲ **Figure 36-6.** Aneurysm demonstrated by multiple imaging techniques. **A.** Catheter angiogram (ionizing radiation). **B.** CT angiogram (ionizing radiation). **C.** MR angiogram (no ionizing radiation). Note that the catheter angiogram (A), an imaging modality that is associated with a risk of causing a stroke, best defines this anterior communicating artery region aneurysm (arrow). However, the aneurysm is still well-seen on the CT angiogram (B), an imaging technique that is not associated with any risk of causing a stroke, and is also well-seen on the MR angiogram (C), an imaging technique that is not associated with any risk of causing a stroke and does not employ ionizing radiation.

- b. PET and SPECT cameras are able to detect, localize, and quantify regional distribution of radioactivity within the brain. Reconstruction techniques similar to those used in CT (eg, “filtered backprojection” and “iterative reconstruction”) yield 2-dimensional and 3-dimensional images of the brain.
- c. The main advantage of a PET imaging over SPECT imaging is that PET utilizes “coincidence” detection, which is the ability to detect the simultaneous emission of 2 gamma rays that are generated when positrons annihilate when encountering negative electrons. Practically, this results in the greater spatial resolution of PET compared to SPECT. Both techniques can be used to study the same biologic processes.
- d. The biological significance of measured radioactivity on PET and SPECT scans depends on the biological function of the molecule that is attached to the radioisotope. For example, radioligands are available to measure cerebral blood flow, blood brain barrier permeability, neurotransmitter synthesis, enzyme activity, receptor density, glucose metabolic rates, and gene expression, among other physiologic processes. Analysis of regional brain functions can be more specific by performing imaging both before and after specific pharmacological interventions, specialized motor or mental tasks (so-called “activation” studies), or therapeutic interventions, such as stem cell or gene therapy.
- e. PET or SPECT imaging can also be used in the clinical arena for localization of epileptogenic foci, diagnosing dementing disorders, distinguishing between tumor recurrence and radionecrosis, and providing a chronologic record of disease progression (or response to therapy).
- f. Finally, the same SPECT radioligands that are used for cerebral blood flow imaging (such as Tc-99m HMPAO) can also be used for bedside brain death studies using a standard planar gamma camera. Radioligands such as In-111 DTPA can be used intrathecally for radioisotope cisternograms for the clinical evaluation of patients with hydrocephalus or suspected CSF leaks. Radioisotope studies can also be performed to evaluate patency of CSF shunts.

ADVANCED CENTRAL NERVOUS SYSTEM APPLICATIONS OF MRI, CT, AND ANGIOGRAPHY

► Magnetic Resonance Imaging

A. MRA

MR data can be collected using software that images only moving tissues (ie, extravascular stationary soft tissue does not generate any MR signal on these studies while moving

blood or CSF will generate signal). Using these techniques, images of blood vessels can be created with a sufficient level of detail that, in many cases, formal endovascular catheter angiography can be avoided (eg, demonstration of significant atherosclerotic disease in the region of the carotid artery bifurcation, surveillance imaging of a known aneurysm, etc). CSF flow evaluation can also be performed (eg, at the craniovertebral junction in Chiari patients).

B. Diffusion MRI and Perfusion MRI

Using rapidly applied magnetic field gradients, random molecular motion of water molecules can be converted to images and can be presented as “Diffusion” MR images. Rapidly applied gradients can also be used without or with contrast agent administration to assess cerebral blood perfusion.

Diffusion MR imaging is sensitive to early changes of cerebral ischemia, often on the order of minutes. In the setting of acute cerebral ischemia, MR diffusion imaging changes (which usually reflect acute irreversible ischemic change) and MR perfusion imaging changes (which reflect cerebral blood flow) can be performed. The MR perfusion and diffusion images can then be compared. As diffusion images usually represent permanent injury (infarction) and perfusion (blood flow) deficits are potentially reversible, if an MR perfusion deficit is more extensive than an associated MR diffusion deficit, it is possible that an area of perfusion abnormality without diffusion abnormality represents viable brain that is at risk to go on to permanent injury, but is not yet irreversibly injured (the so-called “ischemic penumbra”) and might benefit from aggressive therapy. Alternatively, if a diffusion deficit (representing a region of irreversible brain injury) is similar in extent to a perfusion deficit, then maybe the ischemic changes are permanent and there is no remaining “at risk” penumbra brain, and therefore no aggressive therapy is warranted.

C. MRS

Using standard MR hardware, MRS can be performed to evaluate brain metabolites. Normal brain tissue includes many metabolites the most important of which are *N*-acetyl-aspartate [NAA] (which is found in normally functioning neurons and decreases with neuronal injury), Choline [Cho] (a component of cell membranes which increases in any process that increases cellular turnover such as tumors, acute infections, etc) and Creatine [Cr] (a marker of cellular energy). Lactic acid can also be seen in ischemic cells (as a byproduct of anaerobic glycolysis), but is not present in detectable amounts on MRS in normal brain tissue.

► Computed Tomography

A. Biopsy

CT can be used for guidance to percutaneously biopsy many lesions that previously required an open surgical procedure.

B. Perfusion CT

While rapidly infusing contrast material through a peripheral vein, using a high-speed multidetector CT scanner, data can be collected that reflects how well different portions of the brain are being perfused. In some patients, there are areas of underperfused brain which may manifest clinically with transient symptoms (eg, transient ischemic attacks); these regions might benefit from revascularization before the patient suffers irreversible injury (ie, a stroke). Evaluations similar to diffusion/perfusion brain MRI to assess for penumbra brain (see above) can also be performed.

C. CT Angiography (CTA)

While rapidly infusing contrast material through a peripheral vein, using a high-speed multidetector CT scanner, data can be collected that can be “reconstructed” with background data removed such that images similar to catheter angiograms can be created without risk of stroke. While intrinsic vascular detail is not as good as endovascular catheter angiography, in many patients, it is adequate to address the relevant clinical issue.

► Angiography

A. Endovascular Coiling of Aneurysms

Small wires can be passed through an endovascular (ie, within a blood vessel) catheter and directly deposited into a saccular aneurysm where they form coils after release from the catheter; an aneurysm can be filled with these wire coils resulting in the complete obliteration of the patency of the aneurysm lumen eliminating the chance that such an aneurysm might rupture in the future and obviating the need for a craniotomy for placement of an aneurysm clip.

B. Stenting

Instead of open surgery to address a narrowed atherosclerotic or dissected blood vessel, affected blood vessels can be treated via an intravascular catheter which first uses a balloon to dilate the narrowed portion of the blood vessel and then release a mesh stent to maintain the patency of the newly dilated vessel. Stents can also be placed at the base of wide-necked aneurysms allowing for the endovascular coiling of aneurysms that otherwise would not be technically possible.

C. Treating Intraluminal Thrombus

An acute (within 6-8 hours of onset of symptoms) intraluminal occluding thrombus (clot) or thromboembolus can often be treated with intraarterial catheter placement within the blood clot with off-label (as of 2013) injection of a clot lysing agent (eg, tissue plasminogen activator [t-PA]) to reestablish blood flow to an affected vascular territory

before permanent brain damage occurs. Alternatively, some intravascular clots can be captured and removed from the vascular system using specialized catheters [10].

CRANIOCEREBRAL TRAUMA

Hugh J. L. Garton, MD, MHSC Emily Lehmann, MD

OVERVIEW & EPIDEMIOLOGY

Head injury (traumatic brain injury [TBI]) is a leading cause of morbidity and mortality. The incidence of hospitalization for TBI is 75-200/100,000 population. TBI occurs among all ages, peaking in 15- to 24-year-old males. Head injury is very frequent in poly trauma patients managed by trauma surgeons or emergency physicians. Thorough familiarity of the basics of care is therefore highly desirable.

Motor vehicle accidents are the most frequent cause of TBI in the developed world, accounting for 30%-50% of all serious head injuries. Falls and recreational injuries account for about 10%-15% of TBI. Inflicted injury (assault) accounts for about 10%-20% of injuries in adult patients. Age and mechanism of injury are related, as assaults occur mostly to very young infants (child abuse) and to young adults ages 18-24. Falls are the most common source of head injury in patients over 80 years of age. Response to injury also appears to be age dependent. Young people, particularly young men, are more likely to suffer a brain injury, but the chances of dying from that injury are much higher in the elderly. Head injury is the leading cause of death among all patients suffering traumatic injury.

Head injury can be divided on clinical grounds into mild, moderate, and severe forms. About 80% of injuries are mild, including most concussions. Many patients with these

injuries do not require hospitalization. Moderate and severe injuries account for about 10% each of the total injury burden and all of these patients are hospitalized. The death rate from head injury is estimated as 20-30/100,000.

Because recovery from moderate and severe injury is often incomplete, survivors of head injury and their care providers often must manage life-long disability.

PATHOPHYSIOLOGY

► Classifications/Definitions

Brain injury literature groups injury in several different and unrelated ways which may cause confusion. First, injury can be divided into primary versus secondary types. Primary injury occurs at the time of the brain injury or immediately thereafter. It includes the immediate deformative or concussive forces applied to the brain. Clinically, *primary* injuries include skull fractures, lacerations of the brain, and hemorrhage in and around the brain (which may take some time to fully accumulate). In contrast to *primary* brain injury, *secondary* brain injury denotes the brain's response to injury, including, for example, loss of regulation of cerebral blood flow, cellular ischemic injury, and brain edema. Most of head injury research involves identification and interruption of these secondary injury pathways. Primary injuries can be induced by either *focal* or *diffuse* force application and by either *linear* or *angular* changes in momentum. The brain is much more sensitive to a diffuse, angular application of force than a focal, linear one. Experimentally, concussions occur at much lower total acceleration when an angular force is applied compared to a linear one.

Penetrating injury to the brain results in trauma both from the direct disruption of the brain cause by the projectile, as well as compression/decompression injury due to the passage of the bullet or other device. The energy that a projectile imparts to the head is directly proportional to the projectile mass and to the square of the velocity. Velocity therefore is usually the stronger determinant of the extent of projectile injury and the distinction between low- and high-velocity injuries is important.

Secondary brain injury describes the processes that occur in the brain in response to the primary brain injury. These occur from the sub-cellular to the macroscopic level. Calcium-dependent mechanisms, oxidative stresses from free radicals, and apoptotic mechanisms are all likely involved. Tissue ischemia clearly occurs after severe TBI, and in most cases cerebral blood flow (a marker for tissue perfusion) drops considerably in the early phases after severe TBI. The consequence of the microscopic injury cascade at a more macroscopic level is an increase in brain water content: cerebral edema. This occurs both through cytotoxic (cell injury and cell swelling) and vasogenic (incompetent vasculature) mechanisms, although likely the former mechanism is the

more important. Brain edema acts as additional mass within the cranial vault that must be accommodated in managing intracranial pressure. The skull forms a rigid, protective covering for the brain. Any increase in the amount of material within the skull, such as a hematoma or edema, must be accommodated within the fixed volume of the skull, and will generally increase the intracranial pressure (ICP) (Figure 36-1). The intracranial compartment is subdivided into compartments by folds in the dura. The tentorium divides the cranial vault into a supra and infratentorial compartment while the falx cerebri divides the supratentorial compartment into right and left halves. This compartmentalization is of benefit after trauma by helping restrict the consequences of injury from impacting the other compartments. However, the compartmentalization and the protections that occur because of it are incomplete and in severe injuries, brain material will herniated out from its compartment of origin often producing specific clinical herniation syndromes.

► Clinical Assessment

The basics of management for patients with brain injury can be divided into initial resuscitation, primary neurologic survey, a search for lesions requiring immediate surgical management, and finally, identification and management of cerebral edema and increased ICP. These steps are often applied recursively as the patient condition may change frequently during injury course. The processes required to resuscitate, triage, and manage a concussion are less involved than for a severe brain injury, but the basic steps are similar.

Initial resuscitation for patients suffering brain injury is similar to that for all trauma victims. Management of the airway, breathing, and circulation (the ABCs) is paramount. While patients sustaining isolated mild TBI will usually maintain these functions, patients with multiple injuries, or patients with severe brain injuries often cannot maintain these critical functions without assistance. For example, hypoxia occurs in 30% of patients presenting with severe TBI, who often, because of their injury, cannot protect their airway. In addition to its obvious primary deleterious effects on the brain, hypoxia is also a strong stimulus to increase cerebral blood flow through vasodilatation of the cerebral vasculature. The additional volume of blood in the cerebral vasculature then adds measurably to the ICP after injury. Early endotracheal intubation to secure an airway and provide adequate ventilation is essential. All patients with severe brain injuries and many patients with more serious moderate brain injuries may require intubation, purely on the basis of a reduced ability to protect the airway and maintain ventilation. Intubation of a brain-injured patient should be performed with short acting pharmacologic agents. It is best to avoid the use of long-acting sedating medications and even the reflexive repetitive use of shorter acting agents

Table 36–3. Common brainstem reflexes evaluated in patients with traumatic brain injury.

Reflex	Afferent	Brainstem Level	Efferent	How Tested
Pupillary	CN II	Midbrain	CN III	Light shined in the eye, observed for pupillary constriction
Corneal	CN V	Pontine	CN VII	Saline dropped into the eye, observed for blink
Gag	CN IX	Medulla	CN XI	Pharynx stimulated with ET tube or probe, observed for swallow/cough or aversion

in the prehospital and trauma bay settings. The loss of the neurological exam that results can impair or delay critical management decisions. Adequate analgesia and sedation are necessary for many trauma patients at intubation and during early resuscitation but the goal should be use the minimum necessary with repeated doses based on reassessment of patient status.

Restoring and maintaining an adequate blood pressure is also of critical importance. This should be accomplished by using intravenous fluids and blood as needed to restore a normal circulating blood volume, and by control of active hemorrhage. The use of pressor agents to support blood pressure may also be appropriate if hypotension persists despite an adequate circulating blood volume. Brain injury, unless it has progressed past a herniation event, is rarely the cause of hypotension, so that a standard search for the source of hemorrhage should accompany resuscitation as for any traumatic injury. Scalp injuries, which often accompany TBI, can be significant source of blood loss especially in children. Database research demonstrates that a single episode of hypotension following a brain injury doubles the risk of dying compared to patients who never have such an episode.

► The Glasgow Coma Scale

Once the ABCs have been addressed, the goal of the primary neurologic survey is a rapid, accurate categorization of the severity of the brain injury and a search for clinical evidence of large intracerebral hematomas that could require immediate evacuation. The Glasgow Coma Scale is a three component scoring system that is the main tool of the primary neurological survey (Table 36–1). To apply the scale, a patient is asked to give their name or description of what happened and to follow a simple command. Patients who are unresponsive to verbal requests should receive a brief, firm, noxious stimuli. An effective approach is to apply digital pressure to the trapezius muscle and observe for the response. Additional stimuli may be needed elsewhere to confirm the motor response. A patient can localize when their actions are purposeful and they attend specifically to a noxious stimuli, in an attempt to remove it. A patient is withdrawing when they do not attend to stimuli, but do act to move away from noxious stimuli in a nonstereotypic fashion. Decorticate and decerebrate posturing are stereotypic

movements. The possible scores range from 3 to 15. Patients receive the better score when the left and right sides are different. Intubated patients may be given a score of “T” or their verbal score may be estimated from other communicative efforts that they make. The power of this grading scheme is that it is quick and accurate in terms of long term prognosis, assuming the examination is not clouded by sedatives or other confounding factors. Patients who score between 3 and 8 have severe TBI, 9–12 are categorized as moderate and 13–15 as mild closed head injury.

In addition to the determination of the GCS scale, the primary neurological survey includes an assessment of the pupils and gross motor function to assess for the presence of lateralizing signs of a large intracranial hemorrhage. These exams can also alert to the potential presence of a concomitant spinal cord injury. The mass of hematoma, depending on size and location, may produce uncal herniation with unilateral pupillary dilation and contralateral hemiparesis. These findings may indicate that a life threatening intracranial hemorrhage is present, which can be amenable to urgent evacuation. Depending on the situation it may be appropriate to assess other brainstem responses during the primary survey, but more often these are deferred until after an initial head CT scan is obtained. These brainstem reflexes can help to localization injuries (Table 36–3). Two additional brainstem reflexes, the Oculocephalic (doll’s eyes) and Oculovestibular (caloric testing) are not usually tested initial in traumatic settings because of potential exacerbation of cervical spine injuries (doll’s eyes) or basilar skull fractures (caloric testing).

► Diagnostic Imaging

Once the patient’s airway, breathing, and circulation are safe, the severity of the head injury is determined and the primary neurological survey is completed, all patients with moderate and severe brain injuries should have a CT scan of the head. Rapid use of the head CT is also appropriate in many cases of mild closed head injury, especially when other risk factors, such as the use of anticoagulants, are present. Though the presence of a skull fracture significantly increases the chances of finding a lesion on a head CT, plain skull x-rays are not advised as a substitute to the head CT. MRI may at some point replace CT as the primary imaging tool for

▲ **Figure 36-7.** **A.** Normal head CT demonstrating normal basal cisterns (white arrows). **B.** A head CT demonstrating effacement of basal cisterns (black arrow) and global edema after head trauma.

TBI, but this has not yet occurred. CT is quicker, safer for management of uncooperative patients, and safer for the environmental issues of loose ferromagnetic materials near, on or in the patient. MRI may be useful in assessing cervical and intracranial vasculature, and it may be helpful in more accurate prognostication of injury outcome.

The head CT is reviewed for the presence of surgically significant intracranial hemorrhage. In addition, there are specific radiographic markers that predict increased ICP (Figure 36-7). These include effacement of the basal and convexity subarachnoid spaces (so-called “cisternal effacement”), mass effect (compression/deformation of adjacent brain structures), and shifting of the brain contents from one side to the other causing “midline shift.” Patients with certain facial, skull base, and cervical fractures are at risk for cervical intracranial vascular injury and dedicated vascular imaging may be indicated. Conventional angiography, CT, and MRI-based angiography are all potential considerations in these situations. Conventional angiography is the gold standard for injury detection and offers the option of endovascular treatment; however, it is also time intensive and may separate the patient from the optimal critical care environment for a protracted period. CT angiography is convenient and rapid, but may miss some injuries. MRI angiography may be more sensitive but has the same downsides as MRI in other trauma settings. No highly regarded predictive tool exists, but risk factors that should prompt consideration of a vascular injury and subsequent vascular imaging include an

unexplained neurological deficit, massive facial bleeding, or epistaxis, fracture involving the foramen lacerum of the skull base or foramen transversarium of the cervical vertebrae.

At the conclusion of the of the head CT scan, the clinical and radiographic information should be synthesized to formulate a plan either to operate to evacuate an intracranial lesion, to evaluate for intracranial hypertension with monitoring technology and clinical examination, or to observe clinically for worsening of neurological status with clinical examinations alone. Radiographic assessments, similar to clinical assessments, are often iterative with repeat imaging used regularly to assess for an alteration in status and optimal management plan.

CLINICAL INJURY PATTERNS/ HERNIATION SYNDROMES

There are several important clinical syndromes that herald herniation events within the brain. Each has both an imaging and clinical correlate. Immediate recognition and treatment of these is essential for patient survival. Herniation is the decompensated response to an increasingly large intracranial mass or unchecked cerebral edema. When the ICP or regional compartment pressure reaches a sufficiently high level, the brain tissue is displaced out of the compartment into the adjacent one. If all the intracranial compartments are under equally high pressure, the brain seeks to exit the calvarium through the foramen magnum. **Subfalcine**

herniation occurs when part of the cerebrum is forced from one side to the other under the falx cerebri. This is evident radiographically by the degree of *midline shift* present on head CT or MRI. Usually the falx itself is shifted to some extent with the brain. In trauma, there is a general correlation between the degree of midline shift, the depression in the level of consciousness, and the severity of the injury. Rarely, the anterior cerebral artery can be pinched by the falx when there is subfalcine herniation. **Uncal herniation** occurs when the uncus (latin for “hook”) of the temporal lobe is shifted medially by a mass or swelling in the ipsilateral hemisphere. This is most likely to happen with temporal lobe masses because of the close proximity of the mass or swelling to the uncus. Anatomically, the uncus compresses the adjacent subarachnoid space, wherein lies cranial nerve III (oculomotor), resulting in loss of its parasympathetic fiber function to the ipsilateral eye and pupillary dilatation from unopposed sympathetic tone. With more severe or prolonged compression the extraocular muscle function of CN III is lost also, leading to a eye that is deviated inferiorly and laterally (unopposed lateral rectus and superior oblique function). If the uncus is forced further medially, it compresses the cerebral peduncle producing contralateral hemiparesis. The clinical syndrome associated with these events therefore is an initial restlessness, then somnolence followed by a dilated ipsilateral pupil, and then contralateral hemiparesis. A somewhat confusing variation is the *Kernohan’s notch phenomenon*, wherein the entire brainstem is shifted by the uncus and the contralateral peduncle comes into contact with the opposite tentorial edge, leading to weakness that appears clinically on the same side as the pupillary dilatation. This is relevant clinically, because if faced with the clinical contradiction of left pupillary dilatation and left hemiparesis, the left pupillary dilatation is a stronger predictor of the ipsilateral nature of the cranial problem, than the left hemiparesis which would otherwise predict a right sided problem. Uncal herniation can have the secondary complication of compression of the posterior cerebral artery which runs near CN III. Patients are at risk for a PCA distribution stroke. **Tonsillar herniation** occurs when the intracranial contents, particular the contents of the posterior fossa, are forced out of the foramen magnum at the base of the skull. The tonsils of the cerebellum are pushed downward and compress the medulla oblongata, leading to respiratory depression and death. Radiographically, this is identified by the loss of CSF spaces around the brainstem and foramen magnum, as brain tissue is pushed into these spaces.

Cushing triad is the constellation of bradycardia, hypertension, and respiratory irregularity that often occupies a herniation event clinically. It is likely due to brainstem compression. The hypertension can be conceptualized as an attempt to protect the brain’s perfusion pressure from the high ICP. Intubation and mechanical ventilation often

obscure the respiratory part of the triad, but the other two are observed regularly.

SPECIFIC INJURIES AND SURGICAL MANAGEMENT

Skull fractures are the usually the result of focal application of force to the head. These are usually categorized as open or closed, depressed or nondepressed, and basilar or convexity varieties. Depressed fractures can tear the dura or lacerate the cortex of the brain. Depressed fractures greater than the width of the bone are usually considered for operative repair, particularly if there is an associated laceration of the skin. Skull fractures that are not depressed usually do not usually require repair. *Basilar skull fractures* (those fractures involving the bones at the base of the brain (parts of the sphenoid, temporal, occipital bones, and clivus) can damage the vasculature and cranial nerves, and can lead to a CSF leak and meningitis. Clinically, one may suspect a basilar skull fracture in the presence of Battles sign, which is retroauricular ecchymosis, or “raccoon eyes,” which is bilateral periorbital ecchymosis. Basilar and nondepressed calvarial vault fractures are usually managed conservatively, although their presence should prompt consideration of vascular and cranial nerve injury. Controversy exists as to the best management of fractures involving the inner table of the frontal sinus, or extending from the skull base into the ethmoid or other skull base sinus. There is the potential for the spread of infection through sinus communication with the epidural space. However, many such fractures heal spontaneously without complications, and management must be individualized.

An **Epidural Hematoma (EDH)** can occur with a skull fracture that lacerates an artery in the dura (Figure 36–8). The classic example is laceration of the middle meningeal artery by the temporal bone. The bleeding occurs on the outside of the dura and collects in and expands the potential epidural space between bone and dura. Because the source of bleeding is an artery, the hematoma can compress the adjacent brain to the point of serious injury or death. Not all epidural hematomas are caused by an arterial injury in the dura. Bleeding from a skull fracture or dural venous sinus can sometimes collect in the epidural space. These “venous epidural hematomas” are much less likely to produce life-threatening compression of the brain. Distinguishing between the two types is largely a matter of location (temporal vs. nontemporal), size (small vs. large), and rate of change (slow vs. fast). Because the primary injury in an isolated epidural hematoma does not involve the brain, the neurological outcome is excellent if the diagnosis and treatment are prompt. The classic presentation of a temporal epidural hematoma is a patient suffering a blow to the temple, and a brief loss of consciousness. This is followed by a lucid interval during which the patient

▲ **Figure 36–8.** Acute epidural hematoma after head trauma in a 5-year-old patient.

appears to be neurologically well, as there has been little primary brain injury. During this time, the epidural hematoma either expands slowly enough for the compensatory mechanisms of the brain to maintain consciousness, or the hemorrhage stops temporarily. Subsequently, either due to rebleeding or exhaustion of the compensatory mechanisms, a rapid decline in level of consciousness follows from the mass of hematoma associated with the other elements of uncal herniation, including an ipsilateral CN III Palsy and contralateral hemiparesis. However, this classic sequence is only present in about 25% of patients with EDH. Many patients have no loss of consciousness with injury while conversely, about 20% decline after injury without the lucid interval. Epidural hematomas are usually diagnosed from CT imaging and have a lens-shaped (lenticiform) appearance, as the dura is attached firmly to the skull at nearby sutures, tapering each end of the hematoma. CT images are also helpful to judge the impact on the hematoma on the brain, such as the degree of shift of the midline, or compression of adjacent structures. Management of an EDH is determined by lesion size, location, and time from injury to diagnosis. Generally, an EDH more than 1 cm in depth is considered for surgical removal, as are lesions in the temporal fossa where there is less room for further expansion before brain injury occurs. In some cases, an EDH is diagnosed two or more days after the injury that caused it. Since the bulk of hematoma expansion occurs within the first 24–36 hours,

it is considered safe to observe patients with EDH of modest size (about 1-cm deep) when the diagnosis is made in a delayed fashion. The hematomas in many of these cases will reabsorb spontaneously. In contrast, a 1-cm-thick temporal epidural hematoma in a patient only 30 minutes out from injury should be strongly considered for emergent surgical removal of the hematoma prior to care of other injuries not immediately threatening to the airway, breathing, or circulation. The operative approach involves positioning the patient to gain access to the site of the hematoma. For a temporal epidural hematoma, a skin incision is made from the root of the zygoma extending into the ipsilateral frontal region in a reverse question mark fashion. As circumstances dictate, a burr hole can be placed in the temporal region, after incising the temporalis muscle before the skin incision is completed to allow blood to escape from the epidural space. However, in most instances, the blood is clotted and rapid completion of craniotomy must follow. The temporalis muscle is elevated and retracted anteriorly. Additional burr holes are placed as needed and a bone flap is elevated. The hematoma is removed. Lacerated dural vessels can be controlled with bipolar cautery or suture depending on size. The dural surface is inspected for an associated subdural hematoma, and intraoperative ultrasound may be useful as needed. The dura is then sutured to the bony margins of the craniotomy to prevent reaccumulation. When a hematoma has collected in the vicinity of a major dural venous sinus, such as the transverse or sigmoid, the sinus itself may be torn and the resulting hemorrhage that is very difficult to control. The outcome for a patient suffering even from a large EDH can be quite good if managed promptly.

Acute Subdural Hematomas (ASDH) are the result of trauma to the brain causing rupture of veins over the surface of the brain that transit from the cortical surface to the inner surface of the dura to reach the dural sinuses. When these vessels are injured, the blood collects between the dura mater and the arachnoid membrane, in the potential subdural space. The force required to shear vessels in this fashion can occur with a focal blow to the head, but is likely more common with diffuse, rotational force applications to the brain, as often occur in motor vehicle accidents. Except in the elderly, ASDH generally occurs in conjunction with fairly severe associated brain injury. Focal bruising of the brain is often present beneath the subdural hematoma. Most patients present with a significantly depressed level of consciousness and may have other findings related to the compressive mass of the hematoma. A subdural hematoma has more of a crescent shape to it on imaging studies, because there is no barrier to it spreading over the hemispheric surface of the brain. Associated intracerebral hemorrhage and edema is often evident beneath the ASDH (Figure 36–9).

Management of the acute subdural hematoma involves emergent operative removal by craniotomy for lesions more than 1-cm thick. A large craniotomy is generally required,

▲ **Figure 36-9.** Acute subdural hematoma with an associated intraparenchymal hemorrhage after head trauma in a 25-year-old patient.

and acute brain swelling during the surgical procedure must be expected. Unlike the situation in an EDH, the bleeding source in an ASDH is often difficult to discern. Diffuse hemorrhage arising from under the margins of the bone flap adjacent to dural venous sinuses, is often best managed with gentle packing of hemostatic materials rather than aggressive exploration. Medical management of elevated ICP and the underlying brain injury (see below) is an essential part of the patient's care. Outcomes are often poor, with a mortality of 50%-90%. Survivors often have significant disabilities. Outcomes can be predicted by the admission Glasgow Coma Scale score and in certain cases medical care is likely to be futile and offered only with reservations.

In the elderly, the atrophy of the brain places the transiting veins under stretch and injury can occur with much less force. Subdural hematomas can present more chronically in such elderly patients, even several months after injury, with a several centimeter thick collection. Such **chronic subdural hematomas** should be thought of as a different injury from the ASDH (Figure 36-10).

In cases of chronic subdural hematoma, drainage of the hematoma either through a burr hole in the skull or

▲ **Figure 36-10.** Chronic subdural hematoma with acute blood layering in fluid in a 55-year-old patient.

via a craniotomy is indicated. Outcomes are much better than for ASDH, although recurrence and reoperation are common.

Coagulopathy, whether from anticoagulant medications, or as a complication of severe trauma, presents a special risk to TBI patients who are prone to sudden deterioration from hematoma expansion. Immediate, aggressive correction of coagulopathy is indicated for such patients.

Intraparenchymal contusions are common after trauma. These are hemorrhage mixed with brain and usually occur either at the site of a direct blow to the head, or at a point opposite the point of impact. This latter phenomena is called a *contra-coup* injury and is the result of the pressure wave of force moving through the brain and impacting and rebounding from the skull opposite the impact site. Contusions often occur in anterior temporal lobes after frontal impact as the temporal lobes impact into the sphenoid wing anteriorly. The base of the frontal and temporal lobes is also a common site for contusions caused by the brain moving roughly over the irregular bony surfaces of the frontal and middle fossas. Posteriorly, this does not occur as the brain is moving over the smoother tentorium. The clinical presentation of such contusions is specific to their location in the brain, but they can also produce more widespread symptoms through their

mass effect as discussed below in secondary brain injury. Intraparenchymal contusions should be distinguished from smaller hemorrhages associated with **diffuse axonal injury (DIA)** discussed below. There is certainly overlap in terms of size and location, but the typical intraparenchymal hemorrhages are more than 0.5 cm in diameter, and relate to either bony anatomy or force vector as described above. Management for these lesions is generally as conservative as the situation will allow because the hematoma is often intimately mixed with brain, some of which may still be functional. Lesions more than 25 cc are often considered for resection, but the relative eloquence of brain and the response to attempted medical management are often important considerations.

Penetrating brain injury usually produces a focal injury pattern specific to the site of penetration. High-velocity injuries such as those from a gunshot produce, in addition to the focal injury, a large area of cavitation, and hemorrhagic injury from the blast effect. Gunshot wounds that pass through the ventricular system, as a marker for the “middle” of the brain, are most often fatal. Management of less-severe penetrating injury revolves around managing the potential infectious complications of injury and repairing the breach to the skull.

DIFFUSE BRAIN INJURY DIAGNOSES NOT TYPICALLY REQUIRING IMMEDIATE SURGICAL MANAGEMENT

Concussion is an immediate and transient loss of consciousness or normal mentation after head trauma, often associated with a period of amnesia. It is a very common injury. Sport injuries are a common source of concussions and young patients appear to be at highest risk. Concussion is most easily induced by sudden rotation of the head. The presumption is that the cerebral cortex is rotating around the more fixed midbrain and diencephalon, producing disruption of input and outflow from the reticular activating system. Presentation after concussion can be surprisingly varied, with some patients displaying no loss of consciousness, but rather confusion and amnesia. The severity of concussion appears to be proportional to the duration of amnesia, particularly the anterograde (since injury) amnesia. Relying on consensus/expert opinion, several different criteria for diagnosis and grading systems for severity have been proposed. These systems use the duration of the confusion or amnesia and the presence or absence of a loss of consciousness to form a three-tiered scale of severity and are primarily designed to assist with return-to-play decisions for athletes. To the surgeon, the more typical concern is to decide whether a patient presenting with a concussion needs a CT scan of the head. Validated clinical decision rules stress that all patients with a Glasgow Coma Score of less than 15, those that are vomiting and those that are older than 60-65 years

are at high enough risk to warrant a CT scan. Other factors warranting a CT for presenting concussed patients are severe headache, intoxication, persistent anterograde amnesia, a seizure with the injury, evidence of trauma to bone or soft tissue above the clavicle, and severe mechanism of injury such as autopedestrian or ejection injury.

Management for isolated concussions presenting for emergency room evaluation usually includes a period of observation for at least 2 hours, assuming the individual is neurologically normal. Dependent on any other injuries, the patient may be discharged to a responsible adult with written instructions to return for specific symptoms as listed for obtaining a head CT. Patient with abnormal CT scans are usually admitted for care. Long-term outcome is generally good with the majority of patients experiencing no long-term sequelae. However, up to 25% of patients report an increased incidence of headaches and memory difficulties even several months later. **Postconcussive syndrome** is a more severe version of this phenomenon that includes these and other symptoms such as depression, anxiety, emotional lability, insomnia, and fatigue. Treatment is largely one of reassurance and management of individual symptoms. Because athletes are often concussed, questions arise around when it is reasonable to return to play.

Traumatic Subarachnoid Hemorrhage is a relatively common finding in patients suffering severe TBI. Following injury, a relatively small amount of blood may collect in the subarachnoid space, often over the convexities of the brain, but also in the basal cisternal arachnoid spaces. Trauma is the most common cause of subarachnoid hemorrhage, not rupture of an aneurysm, so the report of subarachnoid hemorrhage after trauma should not automatically prompt a search for a ruptured aneurysm. A history of a neurological collapse before the trauma or more dense blood collecting in the basal cisterns or around the larger intracranial vasculature should prompt more concern for a cerebral aneurysm.

Diffuse Axonal Injury occurs when axons become sheared off at the boundary between gray and white matter during rapid brain acceleration or deceleration. The substance of the cerebral cortex is organized in to a series of alternating layers of gray and white matter (gray cortical mantle, subcortical white matter, deep gray matter nuclei of the basal ganglia, and white matter of the internal capsule). These layers have different tissue densities and when subjected to force in trauma, behave differently. The border between these two tissues is often a site of injury as these two layers accelerate or decelerate at rates according to their tissue properties. DIA is a common finding in severe injury, occurring in up to 50% of pts. Clinically, DIA can occur in varying degrees of severity. In minimal cases, a prolonged mildly concussive state of confusion and memory loss might occur. In more severe cases, the presentation is a depressed level of consciousness. Focal findings can occur if there are DIA hemorrhages in specific locations such as the internal

capsule or brainstem. The appearance on head CT is one of multiple small (< 1 cm) hemorrhages, scattered throughout the brain at the junction of gray and white matter. Grading schemes that relate the severity of the CT findings to the eventual neurological outcome exist. Effacement of the basal cisterns and midline shift are examples of radiographic prognosticators of poor outcome after DIA. Management for patients suffering from DIA is primarily medical and focuses on prevention and management of secondary brain injury discussed below.

MEDICAL MANAGEMENT AFTER TBI

The medical management is largely directed at detecting and preventing secondary brain injury from seizures, systemic phenomena such as hypotension and hypoxia and intracranial hypertension.

► Seizure Management

The incidence of seizures following TBI is estimated at between 5% and 15%. The majority of these events occur within the first 7 days after trauma. A seizure has the possibility of increasing brain demand for oxygen and nutrients, at a point when the injury may limit the ability of the brain to respond in this fashion. Prophylactic anticonvulsants, usually phenytoin (dilantin), or more recently levetiracetam (Keppra), are reasonably used to prevent seizures after a moderate and severe TBI, when there is evidence of non-trivial brain injury on CT scans. However, experimental evidence only supports their use for the first 7 days after a TBI, and there does not appear to be benefit to continuing the prophylaxis beyond 7 days. Patients experiencing seizures outside of the immediate point of impact are candidates for therapeutic anticonvulsant use extending beyond the 7 day time frame, usually for several months or more, depending on whether the seizures recur.

► Homeostasis

Just as in the initial resuscitation, ongoing care of acute brain injury requires careful protection against hypoxia, hypotension, and hyperthermia. Each of these has the potential to increase ICP or further deprive the brain of adequate glucose or oxygen, or both.

► Physiology of Increased Intracranial Pressure

Other than its impact on the neurological examination, secondary brain injury manifests itself clinically as cerebral edema and an increase in ICP. **The Monroe-Kelly Doctrine** states that given a fixed intracranial volume, consisting of brain, cerebrospinal fluid, and arterial and venous blood, any additional material must be accommodated by a decline in the amounts of the others, or a rise in pressure due to

the increase in total intracranial material (Figure 36-1). When a mass is introduced into the cranial vault, CSF and later venous blood are displaced to make room for the mass while initially allowing relatively normal ICPs. However, these mechanisms are overcome and eventually the rise in pressure with increasing volume becomes exponential. The compensatory phase is very important clinically, as a patient may harbor a clinically important lesion while showing only modest symptoms of increased pressure in the brain. This model works well in trauma but is overly simplistic and does not explain clinical phenomena that occur over a longer time frame, such as might occur with chronic hydrocephalus or a brain tumor. In such cases, the compressibility of the brain, usually described as its compliance (change in volume for a given change in pressure) matters a great deal and brain pressures may be normal even in the face of a mass that, if it occurred acutely, would overwhelm the compensatory mechanisms mentioned above. Despite these limitations, the compartment model is very useful for managing cerebral edema and increased ICP. Left unchecked, these consequences of secondary injury lead to increased cerebral edema, increased ICP, compression and finally injury of adjacent brain and its vasculature, producing additional brain ischemia and tissue injury, cyclically generating more brain edema and further increased ICP. ICP is both a surrogate measure of the presence of cerebral edema and also a primary actor in ongoing secondary brain injury. Increased ICP, like hypoxia and hypotension, is a strong predictor of mortality and morbidity after head injury.

The concept of **cerebral perfusion pressure (CPP)** highlights the ability of elevations in ICP to reduce tissue perfusion:

$$CPP = MAP - ICP,$$

where MAP is mean arterial pressure.

In adult patients, CPP of less than 70 mm HG is associated with worsened outcome. The equation also illustrates the importance of maintaining an adequate blood pressure in TBI management. Hypotension is among the strongest predictors of poor neurological outcome after TBI.

Detection of cerebral edema and intracranial hypertension is based on suspicion, radiographic features, and direct measurement of ICP. In severe head injury, as measured by the GCS score, the incidence of increased ICP is 50%-60%. Radiographic findings of concern include the presence of mass effect, midline shift, the loss of the evident pattern of sulci and gyri from displacement of CSF, the loss of distinction of the gray/white matter junction, and the effacement of the basal CSF cisterns. Increased ICP can occur in the absence of any of these findings, so in severely head injured patients, direct measurement of the ICP can still be indicated without concerning radiographic features. At present, it is unproven whether treatment directed by ICP is preferable to one based on CT and clinical examination. Nevertheless

current guidelines from the Brain Trauma Foundation recommend ICP monitoring for:

1. All patients with GCS 3-8 and abnormal head CT;
2. GCS 3-8 with normal head CT but with hypotension or age more than 40;
3. Patients in whom the neurological exam cannot be assessed because of sedation or need for general anesthesia, if the suspicion of increased ICP is high.

ICP is measured in trauma by either introduction of a transducer into the brain parenchyma or placement of a catheter into the ventricles of the brain to measure the pressure of the cerebrospinal fluid in a minor surgical procedure. Complication rates of intracranial hemorrhage (2% vs. < 1%) and infection (10% vs. 2%) are higher for catheter-based measurement systems over parenchymal transducers, but only a catheter based system can drain CSF, a distinct treatment advantage. Parenchymal monitors are subject to drift in accuracy and may be inaccurate by 3-4 mm HG after 4-5 days. Catheter-based systems may occlude or be unreliable in the face of very compressed ventricles. In trauma, ICP is not measured by lumbar puncture as there is a risk of brain herniation from higher cranial versus lumbar pressures. Normal ICPs range between about 5 and 15 mm Hg at rest and vary with position and activity. Treatment thresholds after brain injury are typically more than 20 mm HG in adult patients, while children and infants likely require treatment at a lower ICP, although the precise numbers are not yet established. Measurement of the ICP allows calculation of the CPP. Managing brain injury patients based on CPP rather than ICP holds interest as a sufficiently high blood pressure should be able to perfuse the brain despite the ICP. However, clinical research suggests that while CPPs less than 70 mm HG in adult patients are associated with poor outcome, artificially raising blood pressure to supraphysiologic levels in an effort to overcome an increase in ICP, worsens, rather than improves outcomes. CPP measurements currently focus care on avoiding relative hypotension during management.

Treatment options for intracranial hypertension and cerebral edema are most easily understood with reference to the four compartment model of the brain noted above (brain, venous, arterial blood, and CSF). When patients present with elevated ICP, treatments available manipulate the volume of one of these compartments. At present, the selection and style of intracranial hypertension management is as much art as science. Few well-designed studies exist to directly compare different management strategies. Each treatment has risks associated with its use. General strategies include employment of less-risky strategies first and escalation as needed, and to apply methods directed at each of the compartments before applying multiple methods to the same compartment, although many therapies work on

multiple parts of the model. The following section covers the treatment options in general but not rigid order of preference. A therapy from the end of the list would very rarely be used before one at the beginning, but that adjacent items in the list might be interchanged.

A. Improve Venous Drainage

If blood is restricted from exiting the central nervous system, ICP increases as the venous compartment size is larger. In trauma patients, tight fitting cervical collars, a supine body position, and fighting against the ventilator all increase venous pressures. Loosening collars, elevating the head of the bed 30 degrees and minimizing ventilator pressures all improve venous drainage and lower ICPs. These measures have very little risk and can be employed widely.

B. CSF Drainage

Reducing the size of the CSF space can make more room for brain edema and lower ICP. This is done by draining CSF from the same ventricular catheter used to measure ICP. The risks of this therapy are infection and hemorrhage, and a capable surgeon must be available to place the catheter.

Sedation/Paralysis

Besides caring for the patient's comfort after an injury, sedation and/or chemical paralysis are important in reducing excessive brain metabolism that accompanies agitation from brain injury. This metabolism can be directly toxic in an injured brain, and obligates increased arterial and venous blood volume to supply the tissue with nutrients. In addition, sedatives/paralytic agents reduce fighting against the ventilator, reducing venous congestion. However, these agents reduce the ability to follow the neurological exam and have the side effect of hypotension when given in excess. Typically, agents such as morphine and ativan are used for analgesia and sedation, while muscular paralytics such as vecuronium are used to facilitate ventilation, but there is little evidence supporting the use of specific regimens with the exception of propofol, which should not be used in children. In general, shorter acting agents are preferable to long acting ones because of the desire to periodically examine the patient without their influence.

Osmotic Agents and Diuretics

In theory, excessive brain water can be removed directly in some cases by establishing a favorable osmotic gradient for diffusion of fluid back into the blood stream. Mannitol, a sugar, and concentrated saline solutions (3% NaCl), do not cross the blood brain barrier and therefore provide such a gradient. Their effect appears to require an intact blood brain barrier. Experimentally, they draw water from less injured areas of the brain, rather than from the more injured areas.

This reduces the overall brain volume, and can decrease the ICP, in the four-compartment model. In addition, experimental evidence suggests that a significant part of the ICP reducing effect of osmotic agents comes from reducing the viscosity of blood by altering RBC morphology. This allows delivery of more blood through smaller channels, permitting safe reduction in vessel caliber and, therefore, total intracranial blood volume. The adverse effects of these therapies include dehydration (and hypotension) in the case of mannitol, and nephrotoxicity from increased osmolality for all agents. In addition, some of the osmolar particles do make it across the blood brain barrier, and can pull water back into the brain if the therapy is withdrawn too quickly. Dosing regimens for these agents are variable but mannitol is usually used at 0.5-1 gm/kg per dose as often as every 2-3 hours. Dose of 1 gm/kg are given for impending herniation. NaCl 3% may be dosed either continuously at 1-3 cc/kg/h or as bolus doses of similar amounts. Serum sodium and osmolality measurements should be assessed frequently. For mannitol, a serum osmolality more than 320 mOsm/L appears to threaten toxicity and limit efficacy, while for hypertonic saline, serum osmolalities of 360 mOsm/dL or more have been reported without renal injury. In this area, the medical literature is limited.

Hyperventilation

The autoregulatory mechanisms of the brain rely in part on CO₂ (or perhaps pH) concentrations in the blood. A high metabolic rate leads to increased CO₂ production and acidosis. The natural response to this is vasodilatation, to remove waste products and increase the supply of metabolites. Clinically, artificially increasing the respiratory rate (and dropping the CO₂) significantly decreases the intracranial blood volume by vasoconstriction. The downside risk is that if done to excess, the vasoconstriction produces ischemia. While hyperventilation was once widely practiced, it is now reserved for situations in which the brain injury has produced an excessive, as opposed to reduced degree of blood flow. This is relatively rare. However, it is important to manage ventilator settings to avoiding elevated CO₂ levels (and reduced O₂ levels). This avoids unnecessary vasodilatation and the increased ICP that results. Arterial CO₂ levels of 35 mm HG and O₂ levels of 100 mm HG are the common therapy targets.

Barbiturates

High doses of barbiturates reduce cerebral metabolism and experimentally protect against brain injury from the regional ischemia common in secondary brain injury ("the induced coma"). This reduced demand for metabolites decreases the blood flow requirements for adequate cell nutrition, and thus can decrease ICP. However, no clinical experiment has clearly shown that barbiturates improve outcome. The risk is that these agents can profoundly lower blood pressure. They must be used very carefully if at all.

Hypothermia

In experimental settings, hypothermia appears to slow the destructive secondary injury pathways at a cellular level. This reduces the edema that comes from cell death. However, randomized trials in adult head injury have not shown benefit while pediatric trials are ongoing. In the published trial protocols, cooling is typically begun early in the hospital course, if not immediately, with target temperatures of 32-33°C maintained for several days after the initial injury. Complications associated with the therapy in the adult clinical trials have been an increase in infection rate, and serious electrolyte disturbances, particularly hyperkalemia.

Surgical Decompression

Surgical management of cerebral edema involves enlarging the space available for swelling by removing a portion of the calvarium. The surgical technique is to remove a large portion of the skull over the more effected side (hemicraniectomy) or removal of large portions of both frontal bones (bifrontal craniectomy). The dura is generally opened and patched with either allograft or native periosteum. Clinical studies suggest that surgical decompression is effective in lowering ICP, but data regarding neurological outcomes are varied.

OUTCOMES AFTER TRAUMATIC BRAIN INJURY

While many patients with mild traumatic brain injury return to their preinjury level of function, a significant number develop chronic symptoms of fatigue, memory impairment, headaches, and difficulty with concentration. In one study of prospectively followed injury victims, Thornhill, Teasdale, and colleagues reported that over 50% had some identifiable disability one year after injury, including both physical and mental impairments. These were severe enough to impact activities of daily living in one-third to one-fourth of patients. Predictors for poor outcome included age less than 40, and preinjury disability. The medical literature is mixed with regard to the longer term outcome. In a separate study by the Whitnall and coauthors, the overall rates of disability were similar at 1 year and 5 years from injury, but about 25% of patients had exchanged categories from good to disabled and vice-versa. Changes in depression, anxiety, and reported stress appeared to correlate strongly with category change, and only 7% reported the use of rehabilitation services by the 5 year postinjury point. Patients with moderate closed head injuries have more varied outcomes. Most recover to maintain their activities of daily living and even return to work or school. Detailed neurocognitive testing, however, often reveals deficits in executive function and memory. There are more consistent reports of chronic fatigue and headaches. Severe TBI is often a life altering event for both patient and family event. The prognostic implications of injury are often vitally important for family members making decisions

about what degree of aggressive care to provide. As an average, perhaps 15%-20% of all patients with severe injury will make a good recovery, while more than 50% will either die or be severely disabled. Sadly, for some patients, the degree of injury and the poor likelihood of meaningful recovery make the provision of aggressive care an exercise in futility. Elderly patients, those more than 80 years old, with severe head injuries have a very poor prognosis. For patients with the worst prognostic features, such as older age, very low GCS or 3-5 without improvement with resuscitation, lack of pupillary response to light and associated chest or abdominal injuries with hypotension, the prognosis for meaningful recovery is very poor. Once the diagnosis and injury severity are confirmed by examination and imaging studies and the condition is unchanged despite resuscitation and withdrawal of all pharmacologic agents likely to be affecting the examination, a gentle but frank discussion of the situation is necessary and appropriate. However, generally, the younger the patient is, and the higher the presenting GCS score, particularly the motor GCS scores, even within the severe injury group, the better the chances of some degree of recovery. The physician would do well to remember that prognostic information represents a probability of an outcome not a certainty of it. While some families may appreciate knowing these details, others will more appreciate whatever kernels of hope can be provided under the circumstances.

37.6 years. The main causes in order of incidence are: motor vehicle collision, fall, violence, and sports injuries. Despite maximal medical and surgical therapy, the prognosis for significant recovery of a complete lesion is poor. Recent research into stem cell technology and other new modalities of therapy have not yet been effective in human clinical trials.

The cost to the healthcare system and to society is significant. A 25 years old with a high cervical cord injury (C1-4) is estimated to incur \$741,425 in medical costs in the first year following SCI, and \$132,807 for each year survived thereafter. In addition, the loss of wages and productivity for SCI patients averages \$57,000 annually. With 12,000-14,000 Americans suffering SCI per year, the social and economic costs are significant.

The demographics of SCI have changed in the last 30 years. The median age of 37.6 years has increased from 28.7 years in the 1970s. This is a largely due to an increase in the incidence of falls causing SCI in patients more than 60 years of age. Though the relative incidence of both sports injuries and violent injuries has declined over the last 30 years, the larger decrease in sports injuries has placed it below violent injuries as a cause of SCI.

Treatment for SCI consists of acute and chronic management. Acutely, the ABCs (airway, breathing, circulation) must be secured, and the spine immobilized to prevent extension of injuries. Compressive lesions must be identified and the need for urgent surgical management determined. Methylprednisolone is currently a treatment option used widely in the initial phases of SCI, though it is associated with side-effects which may sometimes outweigh the potential benefits of its use. Other acute nonsurgical treatment options aimed primarily at minimizing secondary injury are modest induced hypothermia and hyperbaric therapy. The first would be based on the neuroprotective properties of hypothermia in brain injury but has not yet shown to have proven beneficial effects in humans with traumatic SCI. The second has shown to increase speed of neurological recovery but not an overall improvement in final outcome. Chronic management includes physical, and occupational therapy designed to maximize functionality. Specific therapy and improvement depends on the level and completeness of the injury.

► Clinical Findings

Clinical findings in SCI depend on the level, mechanism, and severity of injury. Injuries can be classified as either complete or incomplete. A complete SCI refers to the lack of motor or sensory function below the level of the lesion. Incomplete lesions spare some degree of sensory and/or motor function below the level of the lesion. Incomplete lesions often result in recognized SCI syndromes based on the region of the spinal cord affected. The American Spinal Injury Association publishes a scale to further classify the severity of SCI (Table 36-4).

SPINAL CORD INJURY

John Ziewacz, Frank La Marca

► General Considerations

Traumatic spinal cord injury (SCI) is devastating. It primarily affects young people, and often results in significant disability or death. The median age at diagnosis of SCI is

Table 36–4. The ASIA classification of spinal cord injury.¹

A	= Complete: No sensory or motor function preserved in the lowest sacral segments (S4/5).
B	= Sensory incomplete: Sensory but no motor function preserved below the neurologic level including the sacral segments S4/5.
C	= Motor incomplete: Motor function is preserved below the neurologic level, and more than half of the key muscles below the neurologic level have a muscle grade less than 3. There must be some sparing of sensory and/or motor function in the segments S4/5.
D	= Motor incomplete: Motor function is preserved below the neurologic level, and more than half the key muscles below the neurologic level have a muscle grade greater than or equal to 3. There must be some sparing of sensory and/or motor function in the segments S4/5.
E	= Normal: Sensory and motor functions are normal. Patient may have abnormalities on reflex examination.

¹Adapted from: American Spinal Injury Association. Standards for neurological classification of spinal cord injury (revised 2000). Chicago: ASIA; 2002.

Initial clinical findings include motor deficit, sensory deficit, and hyporeflexia. Initially, all reflexes below the lesion are lost including the bulbocavernosus, cremasteric, and abdominal cutaneous reflex. Over time, these reflexes may return, and the deep tendon reflexes become hyper-reflexive due to the loss of descending tonic inhibition of the reflex arc. Initially, paralysis is flaccid, but eventually upper motor neuron signs develop, and a spastic paralysis results. If the lesion is in the high cervical region (C1-5), respiratory effort may be compromised due to the loss of innervation to the phrenic nerve. Loss of bowel or bladder function often occurs, and loss of rectal tone and sensation, as well as priapism may result. The loss of bladder control manifests as urinary retention, and developing urinary incontinence is typically overflow incontinence. Loss of anal sphincter tone and sensation results in leakage of stool and lack of awareness of bowel movements.

An important early finding that can occur in SCI is “spinal shock.” This refers to a drop in the systolic blood pressure with accompanying bradycardia, often to a level of 80 mm Hg systolic following SCI. This is due to the loss of sympathetic tone to the regions below the lesion and causes venous pooling and decreased venous return to the heart.

Chronic clinical findings in SCI are related to the long-term need for ventilatory support, immobilization, and need for catheterization. Pneumonia, urinary tract infections, and decubitus ulcers are common findings, and are often the cause of death in spinal cord injured patients.

Incomplete SCIs may demonstrate a variable pattern of sensory or motor preservation, though they can often be categorized into recognizable clinical syndromes, depending on the mechanism of injury and the portion of the cord affected.

A. Central Cord Syndrome

Central cord syndrome (CCS) refers to a pattern of injury that affects the motor strength in the upper extremities more severely than the lower extremities. Sensory function is variable below the level of the lesion, and sphincter control is often affected. This usually occurs in older patients with spinal stenosis following a hyperextension injury. The central cervical cord is a watershed vascular territory that is thought to be disrupted in this syndrome. The spinal cord is somatotopically organized such that cervical fibers are more medial compared to fibers traveling to the lower extremities, resulting in the more severely affected upper extremities.

B. Anterior Cord Syndrome

Anterior cord syndrome (ACS) results from the compression of the anterior portion of the cord by a herniated disk, bone fragment, or from occlusion of the anterior spinal artery. The corticospinal tracts and spinothalamic tracts are preferentially affected due to their more anterior location. The posterior columns are relatively spared. This results in loss of motor function and loss of pain and temperature sensation below the level of the lesion, with preserved proprioception, vibration, and pressure sensation. It is important to distinguish surgical from nonsurgical (ie, anterior spinal artery occlusion) etiologies in this condition.

C. Brown–Séguard Syndrome

Brown–Séguard syndrome occurs after spinal cord hemisection. It is usually the result of penetrating trauma occurring in 2%-4% of spinal cord injuries. Motor function and posterior column function (proprioception, vibration sense) is disrupted on the side of the lesion. Pain and temperature sensation is diminished on the contralateral side due to the crossing of the spino-thalamic tract in the spinal cord at or one or two levels above the entrance of the fibers into the cord.

D. Conus Medullaris Syndrome

Conus medullaris syndrome (CMS) results from injury to the sacral spinal cord. Symptoms include saddle anesthesia, loss of bowel/bladder function, and lower extremity weakness. It includes a combination of both upper and motor neuron signs.

E. Cauda–Equina Syndrome

Cauda–Equina syndrome refers to compression and dysfunction of the lumbo-sacral nerve roots. It is not a true SCI as it only affects the nerve roots and not the cord itself. The clinical syndrome is similar to CMS with saddle anesthesia, loss of bowel/bladder function, and lower extremity weakness, but findings are all lower motor neuron.

► Physical Examination

Initial physical examination in SCI focuses on the ABCs (airway, breathing, circulation). The spine should be immobilized to prevent further injury. Special attention must be focused on the airway in high cervical injuries as patients may require endotracheal intubation given injury to the nervous supply to the diaphragm. Blood pressure must be closely monitored given the possibility of spinal shock. This manifests as a drop in the systolic blood pressure and must be addressed immediately in order to prevent further cord ischemia.

In the awake patient after the ABCs have been attended to, a history focusing on mechanism of injury and detailed neurologic examination is undertaken in order to determine the level and completeness of the injury. Motor strength should be tested in all muscle groups and sensation should be tested with pinprick, and proprioception. Rectal tone and sensation should be tested with digital examination. Reflexes should be examined including the bulbocavernosus, cremasteric, and abdominal cutaneous reflexes. Careful palpation of the spine is important to evaluate for obvious step-offs or tenderness to palpation at all levels. The examination must be carefully documented and a neurologic level and evaluation of completeness of the lesion determined.

In the comatose patient, a complete neurologic examination is often difficult. In this situation, observation of spontaneous movements or movements to painful stimuli is important. Deep tendon reflexes should be examined and palpation of the spine should be undertaken to observe for obvious step-offs. Radiologic imaging is often required to adequately determine a level of injury and its etiology.

► Differential Diagnosis

After a complete history and physical examination is performed, with the addition of radiographic imaging, the diagnosis of SCI is usually apparent. Radiographic imaging can help determine the mechanism of the injury, which is usually due to a fracture or subluxation of the bony spinal elements.

Some peripheral nerve lesions may resemble SCI, but these can usually be distinguished after careful examination and knowledge of the anatomy of the spinal cord and the peripheral nervous system. Peripheral injuries are typically unilateral and affect only lower motor neurons. Sometimes malingering and conversion disorders may mimic SCI. Serial examinations and inconsistencies in examination, in the setting of unremarkable imaging usually permits differentiation.

► Radiologic Examination

In the asymptomatic patient with no spinal tenderness, no distracting injury (eg, long-bone fracture), and no evidence of disturbed consciousness or intoxication, no radiographic imaging is necessary. Patients with spine tenderness, numbness, tingling, or obvious signs of SCI (eg, weakness, loss

of bowel/bladder control) require radiographic imaging. The hallmark of radiographic imaging has been three-view cervical spine x-rays with AP/Lateral films of the thoracic and lumbar spine. Current recommendations of the American Association of Neurological Surgeons/Congress of Neurological Surgeons (AANS/CNS) recommend three-view cervical spine x-rays in conjunction with CT scanning of the cervical spine in patients with suspected SCI. With the advent of CT scanning with detailed coronal and sagittal reconstructions, CT scanning alone has replaced x-ray examination as the initial diagnostic study of choice in many centers (Figure 36–11). This obviates the need for multiple

▲ **Figure 36–11.** Sagittal reconstruction of a cervical computed tomography (CT) scan demonstrating a C6-7 traumatic fracture.

x-rays and diagnostic/treatment delay in the case of inadequate plain films. MRI is listed as an option in the diagnosis of SCI by the AANS/CNS as it can better detect ligamentous/soft tissue injury, though it often “overcalls” injuries that do not cause instability and may lead to prolonged and unnecessary immobilization. MRI is often reserved for patients for whom SCI signs and symptoms are present and no clear evidence is found on x-ray imaging or CT, or a herniated disk or other soft-tissue abnormality is suspected. MRI (particularly T2-weighted sequences) also clearly demonstrates compression of and/or signal change within the spinal cord (Figure 36–12).

▲ **Figure 36–12.** Sagittal T2-weighted magnetic resonance image of a C6–7 traumatic fracture demonstrating spinal cord compression and signal change within the spinal cord (arrow).

In awake patients, clearance of the cervical spine consists of normal x-rays (or CT w/reconstructions), CT scan, and flexion/extension views or MRI obtained within 48 hours of injury. At this point, cervical immobilization may be discontinued.

Under current recommendations in obtunded patients, cervical spine clearance may be obtained following normal x-rays, CT, and dynamic flexion/extension films performed under fluoroscopic guidance, normal MRI obtained within 48 hours of injury, or at the discretion of the treating physician. However, with the advent of CT with sagittal and coronal reconstruction providing greater sensitivity for the detection of injury, and the propensity of MRI to “overcall” injuries, some centers clear the cervical spine in obtunded patient with normal x-rays and CT scans. Clearance of the cervical spine in this population is still cause for debate and recommendations are in flux. Further studies will elucidate the necessary and sufficient studies to definitively clear the cervical spine in this population.

In the patient with SCI the combination of x-rays with CT scanning has high sensitivity and identifies the vast majority of lesions causing SCI.

► Treatment

Initial treatment of SCI consists of securing the ABCs and immobilizing the spinal column. In the case of high cervical spine injury, the need for endotracheal intubation must be identified and if it is not immediately necessary serial arterial blood gas assessments should be monitored to evaluate for hypocapnia and progressive ventilatory failure. Spinal shock and the resultant decrease in blood pressure must be treated aggressively if it occurs. Volume expansion should be initiated promptly and decreased systolic blood pressure refractory to volume expansion should be treated with pressor therapy. The choice of pressors has not been conclusively defined, but typically a beta-agonist is followed by an alpha-agonist given the possibility of bradycardia in spinal shock.

Patients should be placed in a hard cervical collar and cervical immobilization should be ensured until clearance of the cervical spine, or definitive treatment has occurred. Patients should be placed on a board for transfers and log-rolled for movement until the thoracic and lumbar spine is cleared.

Other initial management considerations include placement of an arterial line to monitor blood pressure on a constant basis, and placement of a Foley catheter to decompress the bladder.

Methylprednisolone has been used in the acute phase of SCI based on studies that demonstrated motor improvement in patient groups that received methylprednisolone in the early period after SCI. However, due to the lack of demonstrated clinical significance of any improvement, and studies demonstrating side-effects of high-dose methylprednisolone,

it is offered as an option by the AANS/CNS current guidelines with the knowledge that “evidence suggesting harmful side-effects is more consistent than any suggestion of clinical benefit.”

Following initial stabilization and imaging studies, the need for surgical intervention is assessed. Surgery has two main goals: decompression and stabilization. Surgery is employed on an emergent basis for incomplete lesions in the hopes of preserving or improving neurologic function, and on a nonemergent basis for complete lesions, as there is no demonstrated improvement in neurologic function for emergent surgery for complete lesions. Goals of surgery in this setting are to prevent cranial extension of injury, and to prevent progressive deformity. Choice of surgical approach for SCI is not standardized and is dependent on the location of the pathology. Current stabilization procedures typically involve instrumented fusion techniques, and may be approached via an anterior, posterior, or combined approach.

Cervical traction may be employed either alone, or as an adjunct to surgical therapy to attempt realignment of the spinal column. This is accomplished by fixing a halo ring, or specialized devices (ie, Gardner–Wells tongs) to the head, connecting this to a rope and pulley system, and adding weight to adjust the spine in the desired vector.

Chronic treatment of SCI focuses on rehabilitation and adaptation to permanent injury. Rehabilitation can often result in improved neurologic function in incomplete lesions and can help those with complete injuries become as functional as possible. Patients may require ventilatory support, tracheostomy, intermittent catheterization, frequent turning (to prevent decubitus ulcers), and functional accommodations such as wheelchairs and other devices aimed at improving functionality. Attention to long-term care issues can prolong the life and productivity of SCI patients.

► Prognosis/Outcome

Despite exciting research into novel treatments, SCI remains a devastating injury. Death in the acute trauma setting from SCI is 20%. Complete lesions that remain so at 72 hours are unlikely to improve beyond one level above the lesion in the long term. Patients with quadriplegia who have initial ventilator dependency have 5-year survival rates of approximately 33%. Incomplete lesions have a more favorable outcome. Among recognized SCI syndromes, CCS and BSS have the most favorable outcomes, with up to 90% of BSS and CCS patients being able to ambulate independently at 1 year. ACS patients have a worse prognosis, with 10%-20% recovering functional motor control. Causes of death in long-term SCI patients are usually due to cardiac, respiratory, or infectious causes—often related to the sequelae of SCI.

Current multidisciplinary approaches to SCI, including emergency department, medical, surgical, and rehabilitation staff provide the best therapy for patients with SCI. Despite

this, SCI remains a devastating injury with high rates of mortality and permanent disability. Novel research and innovations will hopefully provide better outcomes for SCI in the future.

PERIPHERAL NERVE LESIONS

Cheerag Upadhyaya, MD Linda Yang, MD John McGillicuddy, MD

► General Considerations

Familiarity with the pertinent aspects of peripheral nerve anatomy and physiology combined with focused history and physical examination aids in the management of peripheral nerve lesions. The history and physical examination may then be complimented by electrodiagnostic and radiographic studies.

► Microscopic Anatomy

Peripheral nerves are composed of varying combinations of sensory and motor axons. An axon is a long projection from a nerve cell body that is bounded by a cell membrane as well as a basement membrane. Some axons are surrounded by sheaths of myelin, a fatty substance secreted by Schwann cells. Myelin insulates the axon, thereby increasing the velocity of neurotransmission. The axon is, in turn, surrounded by a layer of connective tissue called endoneurium. Axons travel together in bundles called fascicles, each of which is covered by another layer of connective tissue called perineurium. Fascicles are grouped together to form a peripheral nerve, which is surrounded by a final layer of connective tissue called epineurium.

► Gross Anatomy

A peripheral nerve is comprised of fibers from more than one spinal nerve root and each spinal nerve root contributes fibers to more than one peripheral nerve. Spinal nerve

lesions manifest as radiculopathies with blurred sensory disturbances, while peripheral nerve lesions demonstrate sharply demarcated sensory disturbances. Spinal nerve lesions result in mild to moderate weakness in muscles supplied by one spinal nerve, but by more than one peripheral nerve. Peripheral nerve lesions manifest more severe muscle atrophy and weakness in muscles supplied solely by the peripheral nerve.

ACUTE PERIPHERAL NERVE INJURIES

► General Considerations

Common etiologies of acute peripheral nerve injury include penetrating trauma, blunt trauma, traction, fractured bones, or compression from hematomas. Minor peripheral nerve injuries arise from blunt trauma that temporarily compresses or stretches a nerve, but leaves its axons intact (neurapraxia). In such cases, axonal transport may be temporarily impaired, but Wallerian degeneration, or the death of axons distal to the point of injury, does not occur. These injuries generally recover spontaneously over the course of days to weeks. Slightly more severe injuries may interrupt axons and their myelin sheaths while leaving endoneurium intact (axonotmesis). In these cases, Wallerian degeneration inevitably follows. Axonal regeneration may occur spontaneously, however, guided to areas of previous innervation by intact endoneurial tubes. With this type of injury, there is a good prognosis for spontaneous functional recovery, with axonal regeneration occurring at a rate of about 1 mm/d or 1 inch/mo.

Peripheral nerves may be severed cleanly (neurotmesis), as in the case of iatrogenic scalpel injuries during surgery. If the divided ends of the nerve remain in proximity, regeneration can occur via axonal sprouting from the proximal stump. These axonal sprouts may bridge the gap to the distal stump, propagating through preserved endoneurial tubes at a rate of 1 mm/d. Severe crush injuries may create internal damage to a peripheral nerve without completely transecting it. Such injuries disrupt axons and their endoneurium and disturb the organization of fascicles within the nerve. In these cases, fibrous scar tissue may form within the macerated nerve which can block the regeneration of axonal sprouts. A tangle of axonal sprouts contained in fibrous scar tissue is called a neuroma. Neuroma formation acts as a barrier to spontaneous peripheral nerve regeneration.

► Clinical Findings

A careful clinical history and a meticulous neurological examination are paramount in determining which peripheral nerves have been injured and the type of injury present. The type of trauma will generally suggest whether or not the nerve is in continuity. A penetrating injury with a sharp object, such as a knife, suggests a clean transection that is

amenable to immediate surgical repair. Nonpenetrating trauma or a stretch injury is more suggestive of nerve continuity.

Determine the timing of motor and sensory deficits may also aid in the assessment of the nerve injury. For example, in the setting of a penetrating sharp injury, an immediate deficit at the time of the injury would suggest direct involvement of the peripheral. However, a delayed deficit would suggest an enlarging adjacent lesion such as a hematoma or pseudoaneurysm.

The physical examination includes inspection, observation, evaluation of the relevant vasculature, range of motion assessment, and neurological examination. A laceration, fracture, or bruising/abrasions may suggest the site of an underlying nerve injury. A Horner's sign (ptosis, meiosis, anhydrosis) is suggestive of a proximal T1/lower trunk brachial plexus lesion. An impaired range of motion can make assessment of strength difficult to evaluate accurately. An elevated hemidiaphragm is suggestive of a phrenic nerve injury.

The sensory and motor findings associated with acute peripheral nerve injury vary widely, depending on which particular nerve is injured. Pain may also be a symptom, but it usually develops in a delayed fashion. Pain can occur as a result of neuroma formation, where it is often associated with a tender lump in the area of injury. Neurogenic pain may also develop because of a disturbance in the processing of pain signals. This type of pain, when associated with autonomic hyperfunction, is referred to as complex region pain syndrome (formally known as causalgia or reflex sympathetic dystrophy); it is notoriously difficult to treat. When neurogenic pain is associated with nerve root avulsion it is known as deafferentation pain. Deafferentation pain often responds well to surgical intervention via dorsal root entry zone ablation.

In the diagnosis of acute peripheral nerve injury, EMG and nerve conduction studies are generally not useful until at least three weeks after injury. Nevertheless, it is important to obtain baseline electrodiagnostic studies as they are important for monitoring recovery. In the case of brachial plexus injury, it is useful to obtain an MRI scan or CT myelogram to look for pseudomeningoceles in the vicinity of the nerve roots, which would indicate nerve root avulsion.

Certain peripheral nerve injuries are associated with traumatic fractures of specific bones. For example, the radial nerve is particularly vulnerable to injury from fractures of the humerus. Traumatic injuries of the radial nerve classically occur with fractures of the shaft of the humerus, at the level of the spiral groove. Such injuries result in weakness of wrist extension, finger extension, and thumb extension, as well as numbness over the radial aspect of the dorsal surface of the hand. In this type of injury, elbow extension is not affected, since muscular branches to the triceps are given off proximal to the spiral groove.

Trauma to the brachial plexus can cause a wide array of neurological signs and symptoms. Clinical manifestations are determined by the location of the lesion within the brachial plexus as well as the severity of the injury. Erb-Duchenne palsy is a well-described condition involving injury primarily to the upper trunk of the brachial plexus (derived from C5 and C6 nerve roots). It typically results from a stretch injury such as traction on the arm at the time of birth, or a fall that forcefully separates the head from the shoulder. The resulting deficits to the deltoid, biceps, rhomboids, brachioradialis, supraspinatus, and infraspinatus, leave the arm hanging to the side, internally rotated and extended at the elbow. This posture is often called the “waiter’s tip position.”

► Differential Diagnosis

In acute trauma, when unilateral limb findings are present, it is important to differentiate acute radiculopathy from peripheral nerve injury. A thorough neurological exam is critical. Several general principles should be considered. Radiculopathy is often accompanied by neck or back pain, which tends to radiate down an arm or a leg. Also, the sensory findings of radiculopathy tend to be blurred, reflecting the overlapping nature of dermatomes, while sensory findings in peripheral nerve injuries are sharply demarcated. Weakness from radiculopathy occurs in muscles innervated by one spinal nerve, but by more than one peripheral nerve. Thus, it is often only partial weakness, since nearly all muscles are innervated by more than one spinal nerve.

One crucial task in diagnosing acute peripheral nerve trauma is to rule out ongoing neural compression. Acute trauma to a peripheral nerve usually results in maximal deficits at the time of injury. A peripheral nerve deficit that progresses should raise a red flag and initiate further workup. Immediate surgical exploration should be considered in order to address compressive lesions such as expanding hematomas or growing traumatic pseudoaneurysms. Sources of ongoing neurologic compression should be removed as soon as possible.

► Treatment and Prognosis

Sharp nerve transections with clean ends (knife wounds, for example) should be repaired within three days. The repair should be performed in an end-to-end fashion, with no tension across the repair site. Transections from penetrating trauma that do not have clean edges or where significant tissue loss is present, should be repaired in a delayed fashion. During exploration of the wound, transected nerve stumps should be identified and tagged. The tagged nerve ends should be attached to fascia to reduce the possibility of retraction. After three weeks, the lesion should be reexplored and the injured nerve repaired. At that time, areas of axonal damage and neuroma formation are easier to visualize.

Better visualization of damaged axons reduces the possibility of subsequent neuroma formation at the site of repair.

In the case of nonpenetrating injury, where stretch or temporary compression is the likely etiology of the problem, recovery often occurs spontaneously, without the need for surgery. In these cases, nonoperative management with serial neurological examinations, including electrophysiologic testing, should be the initial treatment modality. If, after three months, there is no sign of clinical recovery, the injured nerve should be explored. Intraoperative electrophysiologic nerve mapping should be performed to determine if there is conduction across the site of injury. If there is no conduction of evoked potentials, the neuroma should be resected. The stubs should be trimmed and brought together primarily if it can be done without creating tension. If primary anastomoses of the two nerve ends would result in tension across the repair, then a nerve graft should be employed (usually the sural nerve). If intraoperative stimulation reveals conduction across an area of injury, then the nerve should be left intact and allowed to regenerate on its own. A well-known mnemonic for remembering the appropriate timing of operative repair for traumatic nerve injuries is “the rule of threes”: three days for a sharp transection, three weeks for an open ragged transection, and three months for a closed stretch injury.

Peripheral nerve repair is generally performed under the microscope using 8-0 or 9-0 suture for coaptation. Many surgeons now use tissue glue, rather than suture, to coapt the nerve endings. In the case of nerve root avulsions, which cannot be repaired directly, nerve-transfer procedures may be employed, such as coapting a fascicle from an intact ulnar nerve to a nonfunctioning musculocutaneous nerve in order to restore elbow flexion.

Prognosis for recovery depends on the type of injury as well as the treatment. Axonal regeneration occurs at a rate of one inch per month, proximally to distally. Thus, clinical recovery may proceed slowly. Maximal recovery occurs over the course of approximately one to two years. Rehabilitation and physical therapy is important for avoiding the development of muscle contractures that may limit mobility when nerve function has returned. Tendon transfers may be of assistance if neural function does not completely recover.

PERIPHERAL ENTRAPMENT NEUROPATHIES

► General Considerations

Peripheral nerves are subjected to chronic mechanical forces, such as compression, stretching, and friction. These forces, when applied over time, may lead to peripheral nerve entrapment syndromes, such as carpal tunnel syndrome, or ulnar nerve entrapment. Both static and dynamic factors may contribute to chronic peripheral nerve injury. Static factors include musculotendinous anomalies or inflexible

anatomic tunnels that compress peripheral nerves. Dynamic factors include mobile joints, muscular contraction, or nerve mobility that leads to stretching of a peripheral nerve or increased friction along its course during movement. Peripheral entrapment neuropathies occur more frequently in upper rather than lower limbs, probably because of the greater mobility of the arms.

► Clinical Findings

Entrapment neuropathies are characterized by weakened muscles as well as sensory disturbances in the distribution of a single peripheral nerve. In general, any given individual muscle is supplied by one peripheral nerve. Thus, entrapment of a peripheral nerve can lead to severe motor findings in a muscle it innervates. Muscle atrophy and fasciculations are not uncommon in peripheral nerve entrapment. Marked atrophy on clinical examination should raise the surgeon's suspicion that a peripheral nerve lesion is present. Sensory complaints associated with entrapment neuropathy generally include paresthesias, rather than pain, in the distribution of the involved nerve. Percussion over the nerve may result in an electric sensation radiating along the nerve and its territory. In the clinical setting, this is known as Tinel's sign. Electrodiagnostic testing is also useful in the diagnosis of peripheral nerve entrapment. The finding of a nerve conduction delay at the site of compression on nerve conduction studies is common to all compression neuropathies.

The most common peripheral nerve entrapment syndrome is median nerve entrapment at the wrist. This condition generally arises from compression of the median nerve by the transverse carpal ligament, and is therefore referred to as carpal tunnel syndrome. Carpal tunnel syndrome occurs with higher frequency in patients with conditions leading to connective tissue thickening: rheumatoid arthritis, acromegaly, hypothyroidism, pregnancy, and may be related to repetitive hand or wrist movements. Common presenting symptoms include dysesthetic pain in the hands that is worse at night, often awaking the patient from sleep. This occurs because many people sleep with flexed wrists, a position which exacerbates median nerve compression at the wrist. The pain sometimes radiates upward, into the forearm. Patients also complain of numbness on the palmar side of the hand as well as the first three to three and a half digits, including the thumb. When the ring finger is involved, the sensory disturbance "splits" the finger, involving the radial side of the digit only. The intrinsic hand muscles innervated by the median nerve in the hand are sometimes referred to as the "LOAF" muscles, stemming from a commonly used mnemonic device: Lumbricals (first and second only), Opponens pollicis, Abductor pollicis brevis, and Flexor pollicis brevis. Patients with carpal tunnel syndrome may complain of decreased grip strength, or difficulty grasping small objects. Atrophy of the abductor pollicis brevis, at

the lateral base of the thumb may be present. There is often a positive Tinel's sign at the wrist. Phalen's test is a clinical maneuver that is sometimes used in the diagnosis of carpal tunnel syndrome. The patient's wrists are held in forced flexion for at least thirty seconds. The test is considered positive if this maneuver produces symptoms of median neuropathy in the hand.

Ulnar nerve entrapment is the second most common peripheral nerve entrapment syndrome, behind carpal tunnel syndrome. The most common site of ulnar nerve entrapment is at the elbow. Patients typically present with upper extremity pain that localizes to the medial aspect of the elbow. Paresthesias and numbness of the small finger and the ulnar half of the ring finger are also common. A Tinel's sign is often present at the medial aspect of the elbow: tapping the patient over this area sends electric sensations into the fourth and fifth digits. The ulnar nerve innervates most of the intrinsic hand muscles, including the adductor pollicis, the first dorsal interosseous, and the hypothenar muscles. Patients complain of hand weakness, leading to reduced grip strength and pinch strength. They complain of dropping things, or of trouble opening jars. Atrophy of hand intrinsic muscles may be marked, particularly the first dorsal interosseous and the muscles of the hypothenar eminence. When nerve dysfunction is severe, the hand may take on a "claw hand" appearance. The patient may also exhibit a Froment sign: when asked to hold a piece of paper between the thumb and index finger, the distal interphalangeal joint will flex because the patient fires the flexor pollicis longus muscle, innervated by the median nerve, to compensate for lack of abductor pollicis function.

► Differential Diagnosis

The differential diagnosis for peripheral nerve dysfunction includes neuropathies of infectious origin (both bacterial and viral), hereditary conditions (such as Charcot-Marie-Tooth disease), neuropathy associated with nutritional deficiency (such as vitamin B₁₂ deficiency), metabolic or endocrinologic conditions (such as diabetes), inflammatory or immune-mediated conditions (such as polyarteritis nodosa), and toxic conditions (such as lead poisoning.) When more than one peripheral nerve is involved, the surgeon should be wary of the diagnosis of generalized neuropathy, which is typically symmetrical and bilateral. Decreased amplitude on electrodiagnostic studies (which suggests axonal loss) is characteristic of neuropathy of hereditary or metabolic origin. Peripheral nerve entrapment, on the other hand, causes damage to the myelin surrounding an axon, thereby slowing conduction velocity but not affecting amplitude.

Chronic cervical or lumbar radiculopathy must also be ruled out. Several features that separate radiculopathy from peripheral nerve dysfunction were outlined in the section on acute peripheral nerve injuries. It is important to recognize

that sensory changes that “split” the ring finger suggest ulnar nerve dysfunction, rather than C8 radiculopathy.

► Treatment and Prognosis

Surgical management of peripheral nerve entrapment generally involves decompressing the involved nerve. In the case of carpal tunnel syndrome, the transverse carpal ligament is divided, thus relieving compression on the median nerve as it passes from the wrist into the hand. In the case of ulnar neuropathy, simply freeing the nerve from surrounding scar tissue or hypertrophied connective tissue (external neurolysis) is usually sufficient.

Surgical management of peripheral nerve entrapment should be strongly considered when patients present with significant motor weakness or muscle atrophy. Surgical intervention should also be considered when patients fail to improve with medical treatments. Nonoperative management strategies include avoidance of repetitive activities that precipitate symptoms, or the use of immobilization braces that hold joints in positions that avoid compression.

Carpal tunnel release results in excellent relief of symptoms in 80% of patients and partial relief in another 10%. Similar results are observed for surgical management of ulnar neuropathy.

PERIPHERAL NERVE TUMORS

► General Considerations

Peripheral nerve tumors can be divided into non-neoplastic masses, benign masses, and malignant masses. The non-neoplastic masses include traumatic neuromas, Morton neuromas, and nerve sheath ganglion cysts. Benign masses include neurofibromas, schwannomas (also known as neurilemmoma), perineuriomas, lipofibromatous hamartoma (also known as neural fibrolipoma), nerve sheath myxoma, and finally granular cell tumors. Malignant masses include the malignant peripheral nerve sheath tumor (MPNST).

Neurofibromas can be subdivided into solitary, diffuse, and plexiform varieties. The solitary neurofibroma is the most common benign peripheral nerve tumor. Axons are incorporated within the neurofibroma along with Schwann cells, collagen matrix, perineurial cells, and fibroblasts. Because the axons are intermixed within the tumor, the tumor cannot be excised without resecting a portion of the involved nerve. Diffuse neurofibromas and plexiform neurofibromas are less common than the solitary variety. The diffuse neurofibroma typically involves the skin and subcutaneous tissues. Plexiform neurofibromas are large, irregular expansions of nerves ranging from small cutaneous nerves to large trunks. Neurofibromas are commonly found in patients with neurofibromatosis Type 1 (NF1/von Recklinghausen’s disease).

Schwannomas are slowly growing lesions made up of Schwann cells in a collagen matrix. Differentiating schwannomas from neurofibromas is that the nerve fascicles run alongside the tumor, rather than through the tumor as in neurofibromas. Schwannomas are the second most common peripheral nerve tumor. Generally, only mild neurologic deficits occur, and operative resection can be considered in the setting of pain, paresthesias, or weakness in the distribution of the nerve.

MPNST is the most common malignant peripheral nerve tumor. Nearly two-thirds arise from neurofibromas in the setting of NF1. The remainder arise either *de novo* or in patients with history of prior external beam radiation.

► Clinical Findings

The symptoms of peripheral nerve tumors are generally related to the nerve involved and include weakness, numbness, paresthesias, and pain. MRI with gadolinium contrast can be useful in imaging the tumors.

► Differential Diagnosis

The differential diagnosis of peripheral nerve tumors include entrapment neuropathies, non-neoplastic masses, radiculopathies, and neuropathies associated with infection, malnutrition, metabolic, endocrinologic, inflammatory, immune-mediated, and toxic conditions. Generally, a symptomatic peripheral nerve tumor will be palpable. Further, the peripheral nerve tumor can occur anywhere along the course of the nerve, whereas entrapment neuropathies typically occur in defined locations and the various other neuropathies listed are often diffuse processes. Finally, a radiculopathy will be symptomatic in the distribution of the nerve root, likely involving several peripheral nerves.

► Treatment & Prognosis

Schwannomas can generally be resected without any neurologic deficit since the nerve fascicles run alongside the tumor. The fascicles can generally be dissected free. Operative resection is curative. Neurofibromas generally cannot be resected without neurologic deficit since the axons run within the substance of the tumor. Indications for surgical resection of solitary neurofibromas are large tumor mass, accelerated growth, neurologic deficit, and pain. Plexiform neurofibromas (excluding superficial ones) can rarely be totally resected and should generally be followed.

Generally, the prognosis for benign peripheral nerve sheath tumors is very good with improvement in pain, weakness, and paresthesias noted after resection of solitary lesions. MPNST require aggressive surgical treatment. The expected 5 year survival is 15%-20% in patients with NF-1 and 56% in patients with *de novo* disease.

BRAIN TUMORS

Daniel Orringer, MD Shawn Hervey-Jumper, MD

Clinical Presentation

Whenever possible, the evaluation of a brain tumor patient begins with a detailed history focusing on the most common symptoms observed in patients bearing intracranial mass lesions. Headaches are the most common symptom in brain tumor patients, occurring in at least 50% of patients at some point. Classically, brain tumor patients present with headaches that are worse upon waking in the morning and may often be severe enough to wake a patient from sleep. This type of headache is thought to occur as a result of temporary increases in intracranial pressure caused by physiologic elevations in PCO_2 common during sleep. Normally, transient increases in PCO_2 that occur during sleep do not result in headache. However, in the brain tumor patient, during sleep, the combination of elevated intracranial pressure due to mass effect from the presence of the tumor and cerebral vasodilation due to increased PCO_2 , causes an additive increase in intracranial pressure, ultimately resulting in headache. Headaches related to elevated intracranial pressure can also occur throughout the day as a result of maneuvers that raise intracranial pressure, such as straining, coughing, or bending over.

More commonly, headaches seen in brain tumor patients are not related to elevations in intracranial pressure. Headaches typically caused by brain tumors occur as the neoplastic process involves intracranial structures containing pain fibers. Unlike the brain parenchyma, the dura is richly innervated with pain fibers and is likely the most common source of headaches in brain tumor patients. Dural irritation is also involved in the pathogenesis of other types of headaches. This pathophysiologic overlap may explain the clinical observation that brain tumor-associated headaches may lack any distinguishing characteristics. Brain tumor patients often describe their headaches as deep and aching but these features are highly variable. These may have been previously misdiagnosed as sinus, tension, or migraine headaches. Headaches in brain tumor patients may also be due to visual difficulties in the setting of direct or indirect (through elevated intracranial pressure) tumor effects on the optic pathways and oculomotor nerves.

A number of attributes of the headaches associated with brain tumors can provide useful diagnostic information.

First, brain tumors in patients who present with headaches are more likely to be found in noneloquent or functionally silent areas of the central nervous system. Second, headaches occur more frequently in patients with rapidly growing brain tumors. Rapidly growing brain tumors commonly cause severe headaches from meningeal irritation, hemorrhage within the tumor, and/or obstructive hydrocephalus. Obstructive hydrocephalus is a neurosurgical emergency that must be considered in any brain tumor patient presenting with the acute onset of severe headache. In addition, the location of headaches in brain tumor patients commonly provides localizing information. Brain tumors are usually located ipsilateral to the most severe pain.

Seizures are another common presenting finding in patients with brain tumors. Interestingly, seizures are more common with low-grade gliomas than high-grade gliomas. The incidence of seizures in patients with low-grade glioma is estimated as high as 85%. Seizures are the initial presenting symptom in 9% of patients with metastatic brain tumors and 18% of patients with high-grade glioma. Moreover, 25%-50% of all patients with brain tumors experience seizures at some point in their disease course. While seizures associated with brain tumors can be disabling, they can also lead to early diagnosis, and, therefore early treatment.

The nature of seizure activity may hold diagnostic significance. Subcortical and cortical tumors are more likely to cause seizures than those of deeper structures. Focal seizures with primarily motor phenomena, such as tonic-clonic seizures, often occur as a result of involvement of tumor with the primary motor cortex within the frontal lobe. Temporal tumors resulting in temporal lobe seizures typically have variable manifestations that may make localization difficult. Focal seizures due to parietal lesions may present with language disturbance, somatosensory abnormalities, or vestibular symptoms. Focal seizures caused by brain tumors may be secondarily generalized and may ultimately affect multiple cortical regions, causing variable symptomatology. Status epilepticus also can occur as a presentation of brain tumors.

Syncope, another common presentation of brain tumor, must be distinguished from seizure. There are multiple pathophysiologic mechanisms underlying syncope in brain tumor patients. In patients with tumor burden resulting in chronically elevated intracranial pressure and decreased brain compliance, a sudden additional rise in intracranial pressure may compromise cerebral blood flow, resulting in syncope. Transient increases in intracranial pressure that may result from sneezing, coughing, vomiting, or straining are tolerated in patients with normal physiology but may cause syncope in brain tumor patients. Syncope caused by transient increases in intracranial pressure may represent impending herniation and requires urgent neurosurgical attention.

In addition, there are a number of symptoms that commonly present in association with headache, seizure, or

syncope. Nausea and vomiting are present at the initial encounter with at least 40% of patients with brain tumors. Nausea and vomiting may be caused by elevations in intracranial pressure and/or direct tumor involvement of the area postrema in the dorsal surface of the fourth ventricle.

Cognitive decline is common especially in the elderly patient and is often misdiagnosed as Alzheimer's disease. Cognitive decline may easily be confused with depression and is thought to result from generalized fatigue, loss of appetite, and interest in everyday activities. Frontal tumors frontal masses are commonly associated with cognitive decline. Frontal masses, especially those affecting both frontal lobes may also result in apraxia and urinary retention.

A key component of the interview of the brain tumor patient the past medical and family history. The incidence of central nervous system metastases is increasing due to improved survival in patients with the most common types of solid organ cancers. A family history of brain tumors may suggest a familial cancer syndrome. Among the most common familial syndromes predisposing to brain tumor occurrence include von Hippel–Lindau syndrome, tuberous sclerosis, neurofibromatosis 1 and 2, Turcot syndrome (familial adenomatous polyposis), and Lynch syndrome (hereditary nonpolyposis colorectal cancer).

► Physical Findings

Physical findings are highly variable depending on tumor location and extent of disease. Nonspecific physical findings can occur with elevated intracranial pressure including papilledema (edema of the head of the optic nerve associated with engorgement of retinal veins) and oculomotor palsy (due to uncal herniation). However, the most helpful physical findings are those that assist in localizing the lesion (Table 36–5). Focal neurologic signs such as muscle weakness are common and when caused by peritumoral edema may be rapidly reversible with the administration of steroids.

Aphasia suggests involvement with cortical language centers located in the dominant frontal or parietal lobe. Aphasic patients may be misdiagnosed with dementia or psychiatric disorders. The diagnosis of brain tumor should be considered in, patients without psychiatric history who develop a psychiatric disorder.

► Imaging

Radiographic imaging is performed to confirm the clinical diagnosis of brain tumor. Imaging provides information regarding localization, tumor type and the effect of a lesion on surrounding structures. Due to its wide availability, speed, and affordability, noncontrast CT is commonly the initial screening test for patients with brain tumors. CT is also the test of choice for evaluating the extent of tumor invasion into adjacent bony structures. CT angiography can

be helpful in evaluating blood supply to tumors or in evaluating the relationship of blood vessels to the tumor.

Whenever possible MRI of the brain with and without gadolinium-based contrast is performed in the brain tumor patient. Traditional morphologic MRI is performed to assess tumor location, size, cellularity, associated cystic components, associated edema or hemorrhage, necrosis, margins, and invasion into surrounding structures, vascularity, and enhancement. Morphologic data can be used to estimate the WHO grade and suggest the tissue diagnosis of a lesion. However, the gold standard for brain tumor diagnosis remains tissue histology. High-quality contrast MRI images are vital for defining the relationship of tumor tissue to eloquent cortical areas and, consequently an operative plan. In addition, MRI images can be reconstructed to create three-dimensional models that can be used during surgery.

Metabolic MRI or magnetic resonance spectroscopy (MRS) can be used to supplement information obtained from traditional morphologic MRI. MRS is used to compare the small molecule content of tumor tissue and normal surrounding brain tissue. MRS improves the accuracy of brain tumor diagnosis by differentiating brain tumors from lesions that appear similar on routine MRI such as abscesses. In addition MRS detects subtle changes in small molecule content that correlate with tumor grade. In treated brain tumors, MRS enables differentiation between radiation necrosis and residual tumor.

A number of alternative magnetic resonance techniques have clinical application in the imaging of brain tumors. These can enable clinicians to make more accurate preoperative diagnoses and provide information about interaction of tumor tissue with adjacent functional cortical structures. Diffusion MRI characterizes brain tumors based on measurement of molecular mobility and is useful in differentiating tumors from similar-appearing lesions, estimating cellularity, and measuring response to treatment. Perfusion MRI is useful for evaluating tumor angiogenesis, endothelial permeability, and response to treatment. Functional MRI maps functional cortical areas and can be used to create an operative corridor or plan for resection that minimizes risk to eloquent surrounding structures. Similarly diffusion tensor imaging defines the integrity of white matter tracts surrounding a tumor and is commonly used in the planning of both surgical and radiation therapy.

Traditional catheter-based cerebral angiography has both historical and contemporary significance in brain tumor imaging. Cerebral angiography was once used to infer tumor location and morphology by measuring displacement of blood vessels by a tumor. Currently, angiography is used in the context of highly vascular lesions, including some meningiomas and hemangiomas, for preoperative embolization. Embolization of vascular tumors diminishes operative risk and difficulty.

► Tumor Types

A. Gliomas

Fifty percent of newly diagnosed brain tumors are primary tumors of glial origin (astrocytes and oligodendrocytes). Glial tumors are stratified in a scale of increasing aggressiveness. Grades one and two are classified as low-grade gliomas whereas, grades three and four are high grade. High-grade gliomas are faster growing and consequently carry a worse prognosis than low-grade gliomas.

Low-Grade Gliomas: Astrocytes, Oligodendrogliomas, and Mixed Gliomas—Approximately 26% of newly diagnosed glial tumors are astrocytomas and 2% are oligodendrogliomas. Between 1500 and 1800 new low-grade gliomas are diagnosed in the United States each year. WHO grade 1 gliomas are reserved for pilocytic tumors. Pilocytic astrocytomas represent 5.2% of all primary intracranial tumors in adults and 20% of all brain tumors in children younger than 15 years. WHO grade 2 lesions are diagnosed based on their infiltration and tendency to progress to higher grade lesions over time. The most common subtypes of low-grade gliomas include juvenile astrocytomas, diffuse astrocytomas, oligodendrogliomas (representing 6.5%), and mixed gliomas.

The etiology of low-grade gliomas is unknown. Genetic studies suggest that mutation or deletion of the tumor suppressor gene *TP53* plays a role in the tumorigenesis of low-grade gliomas. Known oncogenic signaling pathways have consequences on tumor metabolism promoting a cellular switch to aerobic glycolysis. Isocitrate dehydrogenase 1 and 2 (IDH 1 and 2) catalyze the decarboxylation of isocitrate into alpha ketoglutarate. IDH1 and IDH2 mutations are found in 40% glioma (70% of low grade, 50% of grade III, and 5%-10% of primary glioblastoma). The impact of these mutations on low-grade diffuse gliomas remains unclear; however, they offer a robust and independent survival benefit in all tumor grades.

Low-grade astrocytomas occur with peak incidence in the young adult population (most commonly in 20-40s). They originate in white matter regions within the CNS, grow slowly and distort surrounding brain structures. Histologically, there is a modest increase in cellularity, disruption of the normal orderly pattern of glial cells, and elongated nuclei. There is no endothelial proliferation or tissue necrosis. Three histologic subtypes of low-grade astrocytomas include fibrillary, gemistocytic, and protoplasmic.

Oligodendrogliomas occur predominantly within the gray matter of the cerebral hemispheres, are well-circumscribed, calcified, and have a slight predominance for the frontal lobes. Like astrocytomas, they occur predominantly in younger patients with most frequent diagnosis in the third decade of life. Histologically, oligodendrogliomas are characterized by uniform cell density and round nuclei with

▲ **Figure 36-13.** Magnetic resonance imaging of a deep right temporal mass proven to be a high-grade glioma. (A) FLAIR imaging demonstrating a mass with significant surrounding white matter edema. (B) T1-weighted contrast enhanced image demonstrating smaller enhancing portion of the mass.

perinuclear halos appearing as a classic “fried egg” appearance. Oligodendrogliomas rarely show a mutation in *TP53*. In 1994 a codeletion in the long arm of chromosome 1p36 and the short arm of chromosome 19q13 was shown to predict chemosensitivity and better prognosis.

Radiographically, low-grade gliomas are iso- or hypodense to brain on CT scan and do not enhance with contrast. Calcification is common in oligodendrogliomas. On MRI, low-grade glioma are iso- to hypointense on T1-weighted imaging (T1WI) and typically hyperintense on T2-weighted imaging (T2WI) and are not contrast-enhancing.

High-Grade Gliomas—The term malignant glioma includes anaplastic astrocytoma (AA), glioblastoma multiforme (GBM), gliosarcoma, and malignant oligodendroglioma (Figure 36-13). There is wide difference in the prognosis, aggressiveness, and response to therapy between the different tumors in this group.

Malignant astrocytoma, the most common type of adult brain tumor, makes up 15% of all intracranial tumors and 50%-60% of primary brain tumors. While relatively rare, malignant astrocytoma is the fourth most common cause of cancer-related deaths. The incidence of AAs and GBM increases with increasing age. There is little difference in incidence from nation to nation, however, in the United States these tumors are less common among Africans and African Americans.

The majority of malignant gliomas occur sporadically. However, patients with the autosomal recessively inherited, Turcot syndrome have a high rate of malignant glioma (usually medulloblastomas and astrocytomas) in combination with familial adenomatous polyposis. Similarly, patients with tuberous sclerosis and neurofibromatosis type 1 and 2 often develop brain tumors including gliomas.

The most significantly mutated genes in glioblastoma include *TP53* (seen in 42% of patients), *PTEN* (seen in 33%), neurofibromatosis 1 (*NF1*) (21%), *EGFR* (18%), *PIK3R1* (10%), and *PIK3CA* (7%). Mutations of *TP53* have been identified in the autosomally dominantly inherited Li-Fraumeni syndrome, which results in malignant gliomas in addition to tumors involving breast, blood, bone, and the adrenal cortex. It has recently been suggested that a subpopulation of cells with stem-like properties (cancer stem cells) are present in glioblastoma offering resistance to chemotherapy and radiation.

A hallmark of malignant gliomas is the propensity to invade and migrate along white matter tracts. Invasion increases with increased grade and growth factors such as epidermal growth factor increase this invasion. Autopsy studies show that malignant glioma cells spread through the CSF and extend into and beyond areas on MRI with T2 signal change. Histologically, grade 3 gliomas show mitotic activity and nuclear atypia but no necrosis, while grade 4 tumors have nuclear atypia, mitoses, endothelial prolifera-

tion, and areas of necrosis. The radiologic hallmarks of GBM are ring enhancement and areas of central necrosis detected on CT and MRI.

Gangliogliomas—Gangliogliomas are rare tumors found most commonly in patients between the ages of 15 and 20 with a history of seizures. They represent 1% of CNS neoplasms in adults, 7.6% in children. They can be found in any region of the central nervous system, but seem to occur predominantly in the temporal lobes. Gangliogliomas are distinguished histologically from pure gliomas by their mixture of neuronal and glial elements. Calcification is common. Macroscopically, they may appear solid or cystic. They are generally well-circumscribed, cystic tumors that may display a mural nodule projecting into the cyst cavity. Imaging characteristics vary in their enhancement and signal qualities on MRI. Lesions can exhibit cystic or solid components or a combination of both. Tumor calcification is a common imaging feature. Gangliogliomas are typically benign WHO I or II tumors with indolent behavior offering a 93%-98% 5-year survival. Five percent of gangliogliomas, however, are aggressive anaplastic or malignant gangliogliomas WHO grade III-IV based on the presence of increased cellularity, microvascular proliferation, and areas of necrosis.

Brainstem Gliomas—Brainstem gliomas represent 10%-20% of all CNS tumors in children. Brainstem gliomas are a heterogeneous group with diverse clinical presentations, prognoses, and patterns of growth. They are described as focal, diffuse, cervicomedullary, and dorsally exophytic. Focal tumors are less than 2 cm in size with a well-circumscribed appearance on MRI and no surrounding edema. They are most prevalent in the midbrain and medulla, but can occur at any level in the brainstem. These children typically present with focal cranial nerve deficits and contralateral hemiparesis. Diffuse tumors (diffuse intrinsic pontine gliomas) account for the majority of brainstem gliomas (80%) and commonly arise in the pons. These patients typically present with bilateral cranial nerve deficits, ataxia, and long tract signs. Cervicomedullary brainstem gliomas take their origin from the upper cervical cord and extend rostrally into the cervicomedullary junction and often present with lower cranial nerve deficits and long tract signs. Dorsal exophytic tumors account for 20% of brainstem gliomas and arise from the floor of the fourth ventricle. They are typically sharply delineated from surrounding structures. These patients present with cranial nerve deficits, elevated intracranial pressure, and failure to thrive.

MRI scan has allowed for the recognition of the four classes of brainstem glioma. Even though MRI contrast signal poorly correlates with histologic grade, MRI provides adequate anatomic visualization. Focal tumors are classically well circumscribed and small without infiltration or a significant amount of surrounding edema. Dorsal exophytic tumors arise in the floor of the fourth ventricle and are

typically hypointense on T1-weighted imaging, hyperintense on T2-weighted imaging, and homogeneously enhance with gadolinium contrast. Diffuse brainstem tumors are hypointense on T1-weighted images and hyperintense on T2 sequences. Because MRI characteristics for diffuse tumors are highly specific an accurate diagnosis can be made in the majority of cases. Recent literature has shown that the mortality associated with biopsy of brainstem tumors may have been modestly exaggerated. Biopsy is therefore considered in cases of abnormal clinical presentation or imaging.

B. Primitive Neuroectodermal Tumors

Primitive neuroectodermal tumors (PNET) are thought to originate in cells from primitive neural crest. PNET includes medulloblastomas, pinealoblastomas, ependymoblastomas, esthesioneuroblastomas, and neuroblastomas. PNET are more common in children than adults. Medulloblastomas are PNETs within the posterior fossa and account for 20% of childhood brain tumors and 1% of all adult tumors. Medulloblastomas are the most common primary central nervous system tumor in children younger than 18 years old.

Several syndromes result in an increased incidence of medulloblastomas, including tuberous sclerosis, neurofibromatosis, Gorlin syndrome, and Turcot syndrome. Loss of portions of chromosome 17 either through deletions or unbalanced translocation is associated with over 50% of medulloblastomas. Over the past decade, transcriptional profiling of medulloblastomas revealed the existence of 4 distinct subgroups; WNT, SHH, Group 3, and Group 4. WNT medulloblastomas have a classic histology, WNT gene expression signature, and the best prognosis with more than 95% in 5 years. These patients tend to be the least common (10% of cases) and are rarely metastatic. SHH-driven medulloblastomas exhibit a desmoplastic histology (although occasionally large cell or anaplastic are seen). Patients SHH tumors represent an intermediate prognosis with survival ranging from 60% to 80%. Group 3 medulloblastoma have the worst prognosis with 50% metastatic at the time of diagnosis. These tumors exhibit aberrant MYC expression with focal high-level amplifications. Group 4 medulloblastomas account for 40% of cases with an intermediate prognosis similar to the SHH subgroup. Group 4 tumors are driven by the oncogenes MYCN and CDK6 (cyclin-dependent kinase 6). Unlike other subgroups group 4 medulloblastoma predominately affect men and metastases are seen in 30% of cases. These subgroups have reestablished what was previously considered a single tumor entity but are now requiring different therapeutic approaches.

Grossly, medulloblastomas typically occur within the cerebellar vermis and are poorly demarcated, purplish, soft, and friable. Histologically, these tumors are highly cellular, composed of homogenous fields of small, round, blue-cell tumors with hyperchromatic nuclei, minimal cytoplasm, and occasional calcification. Other histologic characteristics of

these tumors include varying degrees of neuronal and glial differentiation, Homer Wright rosettes (nuclei surround a clear central area of cell processes indicative of neuroblastic differentiation) are often present and mitotic figures are numerous.

Medulloblastomas are PNET within the posterior fossa. Histologically similar tumors within the pineal gland are pinealoblastomas, and within the supratentorial space are neuroblastomas. Retinoblastomas are histologically similar tumors within the eye, PNET originating from olfactory epithelium are termed *esthesioneuroblastomas*, and intraventricular PNET are ependymoblastomas.

On CT, medulloblastomas are typically hyperdense, homogeneously enhancing, and occasionally cystic. Small areas of calcification can be appreciated on CT. Scattered areas of hemorrhage, necrosis, and calcification can occur. On MRI, medulloblastomas are isointense or hypointense to brain on T1WI, hyperintense to brain on T2WI and intensely contrast enhancing. If medulloblastoma is suspected, MRI of the spine is obtained to rule out metastases. Lumbar puncture should be performed with extreme caution because the majority of children have associated obstructive hydrocephalus.

C. Pineal Tumors

The pineal gland is bounded ventrally by the quadrigeminal plate and midbrain tectum, dorsally by the splenium of corpus callosum, rostrally by the posterior aspect of the third ventricle, and caudally by the cerebellar vermis. Tumors in this region are usually found incidentally on MRI and are most common in children, making up 3%-8% of pediatric brain tumors. The pineal region has several diverse cell types including glial cells, arachnoid cells, pineal glandular tissue, ependymal lining, sympathetic nerves, germ cells, and remnants of ectoderm. Tumors within this area can therefore be grouped into 4 categories: germ cell tumors, pineal parenchymal cell tumors, glial cell tumors, and other miscellaneous tumors and cysts. In the pediatric population germinomas and astrocytomas are the most common tumor type. Germ cell tumors and pineal cell tumors occur primarily during childhood. In the adult population, pineal tumors are more commonly gliomas and meningiomas.

Germ cell tumors, ependymomas, and pineal cell tumors can metastasize through the CSF causing myelopathic or radiculopathic symptoms. Pineal tumors typically present with symptoms of increased intracranial pressure from obstructive hydrocephalus, direct brainstem and cerebellar compression and endocrine dysfunction. In addition, Parinaud syndrome (upgaze paralysis, convergence-retraction nystagmus, pseudo-Argyll Robertson pupils, eyelid retraction, and conjugate downgaze in the primary position) is associated with pineal tumors.

MRI is the primary diagnostic imaging modality for pineal tumors, but it does not reliably predict tumor histology. In contrast, tumor markers may be useful in the

diagnostic process, to determine response to treatment, or as an indicator of early recurrence. Elevation of serum or CSF alpha-fetoprotein (AFP) or human chorionic gonadotropin (HCG) suggests a germ cell tumor. Mildly elevated AFP suggests the presence of a fetal yolk sac tumor. Marked elevation of AFP suggests endodermal sinus tumors while smaller elevations are suggestive of embryonal cell carcinoma or immature teratoma. HCG is often markedly elevated with choriocarcinomas.

D. Ependymoma

Ependymomas were previously thought to arise from the ependymal cells lining the ventricles and central canal of the spinal cord; however, they have recently been shown that radial glial cells are the cells of origin. They occur in both children and adults and 65% occur within the posterior fossa (most commonly in children). Ependymomas are quite rare representing only 6% of all gliomas in adults. However, they are the third most common brain tumor in children (behind pilocytic astrocytomas and medulloblastomas). Three cases per 100,000 children younger than 15 are diagnosed each year with this tumor type.

The etiology of posterior fossa ependymomas is unknown however significant advancements have been made over the past decade on their biological profile allowing the identification of different molecular subgroups. Group A patients have laterally located tumors and younger patients with more than 50% recurrence rate (independent of extent of surgical resection). Group B patients have a slightly more favorable prognosis and older age at diagnosis. Familial cases have also been identified. As with several other primary CNS tumors, these tumors often have loss of heterozygosity of chromosome 22q, which contains the neurofibromatosis 2 (*NF2*) gene. Patients with neurofibromatosis have an increased incidence of gliomas including ependymomas.

A histologic grading system that correlates with tumor aggressiveness is used to classify ependymomas. Histologically, ependymomas are often characterized by epithelium-like cells in a rosette pattern, formed by a ring of polygonal cells surrounding a central cavity. Tumors may also exhibit perivascular pseudorosettes, intranuclear inclusions, calcifications, and papillary clusters.

The imaging characteristics of ependymomas are variable, but they are typically isodense to cerebral cortex on noncontrast head CT. Calcifications and cystic components within the tumor are frequent. On MRI the solid portion is typically isointense to gray matter on T1WI and isointense to hyperintense on T2WI.

E. Cerebral Lymphoma

Cerebral lymphoma involving the brain, spinal cord, or ocular structures can occur either primarily or as a metastasis. The source of premalignant lymphocytes is

controversial because the CNS lacks lymphoid tissue. CNS lymphoma occurs most commonly in severely immunocompromised patients where it is commonly associated with Epstein–Barr virus infections. CNS lymphoma represents 1% of intracranial tumors with a steady increase in prevalence over the past 20 years. The increase in CNS lymphoma is likely secondary to the increased number and longer lifespan of patients with acquired immunodeficiency syndrome (AIDS) and immunosuppression after organ transplantation. Interestingly, the incidence of CNS lymphoma has steadily increased in immunocompetent patients with an increase from 2.5 to 30 cases per 10 million. Deletions of *DKN2A* are frequently reported in CNS lymphoma.

Macroscopically, primary CNS lymphomas occur within the parenchyma, subependyma, or meninges and can be either circumscribed or irregular. Microscopically, they exhibit diffuse perivascular distribution and infiltrate the walls of blood vessels (perivascular cuffing). The tumor cells are similar in histology to systemic non-Hodgkins lymphoma cells. Primary CNS lymphomas are monoclonal B-cell lymphomas of diffuse large cell or large cell immunoblastic variant. Anti-CD45 antibody staining differentiates CNS lymphoma from other tumor types.

On CT, CNS lymphomas are typically hyper- or isodense to brain with strong contrast enhancement. On MRI, these tumors are usually isointense or hypointense on T1WI, hyperintense on T2WI and display varying degrees of gadolinium enhancement. Low-volume lumbar puncture performed during the workup of CNS lymphoma may reveal high protein, low glucose pleocytosis. While CSF cytology may be diagnostic, stereotactic brain biopsy is often needed for definitive diagnosis.

F. Choroid Plexus Tumors

The most common tumors of the choroid plexus include choroid plexus papillomas. Choroid plexus carcinomas are rare. Choroid plexus papillomas are most prevalent in patients less than 2 years old and account for less than 1% of all intracranial tumors. Presenting symptoms result from elevated intracranial pressure due to hydrocephalus, and mass effect from tumor growth.

G. Meningiomas

Meningiomas are typically benign, slow growing extra-axial tumors arising from the arachnoid cap cells of the meninges (Figure 36–14). They can originate wherever arachnoid is present. They are characterized by either their location, or histopathology, and are commonly located along the falx, cortical convexity, and sphenoid bone.

Meningiomas account for 15%–19% of primary brain tumors and as many as 3% of the population older than 60 years have an intracranial meningioma on autopsy.

▲ **Figure 36–14.** Sagittal MRI image demonstrating a contrast enhancing dural-based lesion (arrow) proven to be a meningioma at time of resection.

Their incidence increases with age and peaks by 45 years of age. There is a female-to-male ratio of 2:1.

Inactivation of the *NF2* gene found on the long arm of chromosome 22 (22q12.3) is the main genetic event associated with the development of meningiomas. Loss of one copy, truncated, or mutations toward the 5' end of the *NF2* gene occurs in up to 80% of sporadic meningiomas and all patients with neurofibromatosis type 2. Consequently, *NF2* patients are more likely to develop intracranial meningioma of varying types. Chromosome 22q contains the *NF2* tumor suppressor gene, Merlin.

There are multiple histologic subtypes of meningioma, but they are typically characterized by the presence of densely packed sheets of cells (similar to appearance of normal arachnoid cells), psammoma bodies (whorls of calcium and collagen), intranuclear cytoplasmic pseudoinclusions, and Orphan Annie nuclei (nuclei with central clearing from peripheral migration of chromatin). Radiographically, meningiomas are hyperdense to brain and a broad dural attachment can often be identified. On T2-weighted MRI, most meningiomas are hyperintense and are typically contrast enhancing on both CT and MRI.

H. Nerve Sheath Tumors and Acoustic Neuromas

Nerve sheath tumors are benign tumors of Schwann cell origin that involve predominantly the fifth, seventh, eighth, and tenth cranial nerves. The most common, vestibular schwannomas (aka acoustic neuromas, AN) originate in the internal auditory canal from the inferior or superior portion of the vestibular nerve at the junction of the central

and peripheral myelin. The three most common presenting symptoms include insidious hearing loss, high-pitched tinnitus, and disequilibrium.

AN account for 8%-10% of all intracranial tumors in adults. Most ANs are unilateral, however, patient with neurofibromatosis type 2 commonly have bilateral AN. AN is believed to result from the loss of a tumor suppressor gene located on the long arm of chromosome of 22.

Macroscopically, ANs are lobular, encapsulated, and solid with grayish colored material. Surrounding cranial nerves are often stretched over the capsule of the tumor. Microscopically, these tumors are identical to peripheral schwannomas. They are comprised of Antoni A and Antoni B fibers. Antoni A fibers are dense, narrow, elongated bipolar cells with numerous nuclei and firm cytoplasm. Antoni B fibers are a loose reticulated semi-palisading arrangement of Schwann cells.

CT is useful for distinguishing tumor extension into the bony internal auditory canal. On MRI, ANs are isointense on T1WI without contrast. With gadolinium enhancement they are often homogeneously enhancing. The lack of a dural tail, differentiates AN from cerebellopontine angle meningiomas.

I. Pituitary Tumors

Pituitary adenomas are benign tumors originating from the anterior pituitary gland and represent 10% of intracranial tumors diagnosed. They are most commonly diagnosed between 40 and 50 years of age. They are classified according to their endocrine function or histological staining. Secreting tumors release supraphysiologic levels of hormones that result in distinct clinical syndromes. Hypersecretion of prolactin causes amenorrhea-galactorrhea syndrome in women and impotence in men. Hypersecretion of adrenocorticotropic hormone (ACTH) causes Cushing's disease. Hypersecretion of growth hormone causes acromegaly in adults and gigantism in children. Pituitary adenomas can hypersecrete thyrotropin (producing hyperthyroidism) or gonadotropins (leutinizing hormone and follicle stimulating hormone).

Pituitary tumors may exert mass effect on adjacent structures. Optic chiasm compression results in bitemporal hemianopsia. Compression of the pituitary gland itself results in varying degrees of hypopituitarism. Compression upon the cavernous sinus causes ptosis, facial pain, and diplopia from pressure upon cranial nerves III, IV, V1, V2, and VI. Occlusion of the cavernous sinus may cause proptosis and chemosis.

J. Metastatic Brain Tumors

Metastatic brain tumors originate in from malignancies outside of the CNS that have spread to the brain or spinal cord (Figure 36-15). They are most common brain tumor

▲ **Figure 36-15.** Sagittal MRI image demonstrating multiple contrast enhancing lesions (arrows) in the infra- and supratentorial spaces. Biopsy demonstrated metastatic adenocarcinoma.

with a yearly incidence of 100,000-200,000 cases per year in the United States. Autopsy studies show that 20%-25% of patients with cancer have brain metastasis. Metastases occur more frequently in adults in their fifth to seventh decades of life. The most common primary tumors in adults giving rise to CNS metastases are lung, breast, skin, renal, and colon cancers. In children, leukemia and lymphoma, osteogenic sarcoma, and rhabdomyosarcoma are the most common primary tumors that spread to the CNS.

Histopathology of metastases mirrors that of the primary tumor. MRI is more sensitive than CT in detecting metastases. Metastases are typically seen at the gray-white junction and show varying degrees of contrast enhancement.

► Differential Diagnosis

The differential diagnosis of intracranial masses is narrowed through a detailed history and physical exam. Important considerations include patient demographics, chronology of symptoms, past medical history, and specific neurologic deficits. Once imaging is obtained, the list of possible diagnoses can be further refined, as the location of a lesion can suggest its nature. For example, the three most common posterior fossa tumors of childhood include astrocytoma, medulloblastoma, and ependymoma. The most common tumors of the cerebellopontine angle include meningioma, acoustic neuroma, and epidermoid cyst. In addition the pattern of contrast enhancement and whether the lesion appears to arise from within the brain parenchyma or meninges are important considerations in generating an accurate differential diagnosis.

► Treatment

A. Preoperative Medical Management

With few exceptions, surgery is the backbone of the current treatment of brain tumors. The success of surgical intervention depends on adequate preoperative medical management and surgical planning. Steroids are commonly used preoperatively to reduce the symptoms of mass effect and edema caused by the tumor. The timing and dose of steroids varies based on surgeon preference. A common regimen for adults is dexamethasone 6 mg IV or PO every six hours. If mass effect is profound, doses as high as 20 mg every four hours may be considered. Some surgeons believe that it is easier to resect a tumor when peritumoral edema is minimized by preoperative dexamethasone administration.

The use of anticonvulsants in brain tumor patients at presentation, preoperatively, and postoperatively is somewhat controversial. Without question, patients presenting with seizures attributed to a brain tumor should be initiated on an anticonvulsant. However, with few exceptions, there is no data to suggest prophylactic use of anticonvulsants reduces the risk of new onset seizures in brain tumor patients. Among the exceptions are: (1) tumor involvement in highly epileptogenic areas such as the motor cortex, (2) low-grade gliomas, which carry a high risk of seizures, (3) patients with metastatic lesions that commonly invade the cortex, and (4) patients with both metastases and leptomeningeal spread.

Because of a favorable toxicity profile and cost, phenytoin is the first line antiepileptic agent. Phenytoin may cause GI upset and should be administered with a H₂ blocker or proton-pump inhibitor. Phenytoin levels must be monitored to ensure a therapeutic serum drug concentration. Levetiracetam is an alternative used for patients if there is potential for drug interactions related to induction of the P450 system by phenytoin. In contrast to phenytoin, levels of levetiracetam need not be monitored.

B. Surgical Considerations

The surgeon must decide whether the goal of intervention is obtaining biopsy only, subtotal resection, or attempting gross total resection. With few exceptions, gross total resection offers the best chance of survival and is the preferred treatment. Tumor resection requires careful consideration of a number of key factors including: (1) tumor size, (2) location, (3) gross, radiographic, and pathologic characteristics, (4) sensitivity to radiation, and importantly, (5) the medical and neurologic status of the patient.

The timing of surgery is important in preoperative planning. Patients who present with rapid deterioration due to elevated intracranial pressure typically require prompt intervention. Tumor growth can be brisk in patients with large, high-grade tumors and small increases in tumor volume can

cause a profound increase in intracranial pressure. Rapid intervention may also be necessary in the setting of obstructive hydrocephalus. Cerebrospinal fluid diversion (typically via ventriculostomy) is an alternative to urgent tumor resection in patients with obstructive hydrocephalus secondary to tumor growth. In cases where tumor burden is not causing profound neurologic deficit or elevated intracranial pressure, resection can be arranged as a semi-elective procedure.

Once in the operating room for brain tumor resection, a number of important principles of positioning are vital to a successful resection. Most tumor resections require immobilization of patient's head in a Mayfield head holder. The position should be selected create the most direct access to the lesion while avoiding risk to other bodily structures. Positioning should promote venous drainage from the lesion and the cranial compartment by ensuring the jugular veins are not compressed and that the head is elevated. In most cases, surgeons prefer to position the patient with the operative corridor perpendicular to the floor. This approach generally minimizes brain retraction and is the most ergonomic for the surgeon. Pressure points of the remainder of the patient should be padded especially thoroughly given the lengthy nature of some tumor resections.

The shape of the skin incision and bone flap is dependent on the desired approach, size of the lesion, and surgeon preference. Small tumors can be adequately exposed and resected via linear or curvilinear incisions with a small bone flap. Resection of deep lesions, especially those involving the skull base, often require creation of a sizable scalp flap and removal of a large window of bone. Whenever possible, incisions should be planned behind the hairline, minimizing the amount of hair removal in deference to cosmetic concerns. The placement of the incision is largely determined by the location of the lesion. Frameless stereotaxy, a technology that relies on a three-dimensional rendering of the patient's preoperative MRI, can enable accurate tumor localization based on preoperative imaging and can be helpful in minimizing the size of the incision. Standard approaches to intracranial lesions minimize the morbidity of exposure by limiting the risk to key neural and vascular structures.

The central goal of brain tumor surgery is maximizing the removal of neoplastic tissue while minimizing collateral damage to surrounding normal brain and vascular structures. Standards for achieving this goal vary based on tumor type. For example, the goal of the resection of a high-grade glioma is to remove all enhancing portions of the tumor, in contrast to the goal for the resection of a low-grade glioma to remove the tissue that appears abnormal on T2-weighted MRI. Several large retrospective studies published in the last decade suggest that duration of survival is directly related to extent of resection or the proportion of tumor removed at the time of surgery. The goal for resection of meningioma is to remove both the tumor and its dural origin. Metastatic

tumors are typically well demarcated and often encapsulated and the goal is to remove the entire tumor.

One of the central challenges in brain tumor surgery is that neoplastic tissue that is easily detected on MRI is often virtually indistinguishable from normal brain. Several studies evaluating the extent of brain tumor resection highlight the fact that in many cases, especially in diffusely invasive brain tumors, a significant amount of residual tumor remains even after gross total resection. Moreover, surgeons have a limited ability to predict when all resectable tumor has indeed been removed. Consequently, a variety of technologies have been developed to improve surgical outcomes. Stereotactic navigation is utilized to improve extent of resection but there is little evidence that it can improve extent of resection. Retrospective analyses suggest that intraoperative MRI, an approach in which brain tumor resection is performed in a highly specialized surgical suite containing an MRI machine, improves extent of resection. Fluorescent and visible dyes have been proposed as a means of identifying tumor margins intraoperatively for more than 60 years. Recently a phase III clinical trial has demonstrated that the fluorescent dye 5-ALA may improve the extent of resection and six-month progression-free survival in glioblastoma patients. A number of efforts are underway to use dye-based and label-free intraoperative microscopy to improve the surgeon's ability to distinguish tumor-infiltrated brain from noninfiltrated tissue.

Intraoperative electrophysiologic monitoring of brain activity is often used in tumors within eloquent cortex to determine a safe route for exposure of tumor and the safe limits for extent of resection. Electrophysiologic motor mapping can be performed with the patient under general anesthesia or awake. In asleep motor mapping, specific regions of the motor cortex or corticospinal tract are stimulated with electrical current while the electromyographic response in target muscles is recorded. In awake motor mapping direct electrical stimulation of motor cortex or corticospinal tracts is performed while a patient is asked to perform specific tasks. An arrest of motor activity with direct electrical stimulation suggests that the portion of brain being stimulated is involved in motor function. Similarly, in awake language mapping specific regions of the brain, commonly the dominant frontal and temporal lobes are stimulated to look for speech arrest. Awake language mapping of brain tumor patients has broadened our understanding of the organization of the human language cortex and circuits.

Following resection, meticulous attention is paid to achieving hemostasis in the operative corridor to minimize the risk of postoperative hemorrhage. Whenever possible, to diminish the risk of cerebrospinal fluid leak, a watertight dural closure is performed. The bone flap is replaced and the galea is reapproximated. Scalp closure that omits closure of the galea provides little strength and raises the risk of dehiscence.

C. Postoperative Management

Following resection patients are observed closely in an ICU setting, typically for overnight, where serial neurological examinations are carried out. Depending on the extent of resection, steroids may be tapered over the days following surgery. Anticonvulsants are continued in patients who have a history of seizures and, when there has been extensive brain dissection, they may be continued for 1-4 weeks following surgery. Given the prognostic significance of extent of resection for glioma patients and the difficulty in detecting residual tumor during surgery, it is becoming standard practice for surgeons to obtain postoperative MRI imaging with contrast to evaluate for residual tumor within 24 hours of resection. When there is a low suspicion of residual tumor or when further surgery is not possible, postoperative imaging may be deferred.

D. Adjuvant Therapies

Surgical resection is cornerstone of brain tumor therapy but it is rarely capable of eradicating all tumor cells. Furthermore, resection may not be favored when eloquent structures are likely to be damaged. Adjuvant radiation and chemotherapy regimens have been developed to address the inability of current surgical techniques to reliably eradicate residual or unresectable tumor.

1. Radiation—Radiation kills tumor cells by directly damaging cellular structures, inducing lethal mutations in cellular DNA and by activating pathways for programmed cell death. Radiation can be delivered to brain tumors in a fractionated manner, which allows normal tissue repair between treatments and increases the toxicity of the radiation to tumor tissue.

Regimens for radiation therapy of brain tumors vary with tumor type. The optimal dose and timing of adjuvant radiation therapy for low-grade glioma is controversial. Typically, radiation is reserved in low-grade glioma until there is evidence of tumor progression or neurologic deterioration. Early radiation therapy is suggested in elderly patients, for tumors that have crossed the midline and in the setting of intractable seizures. Because of the cognitive consequences of radiation therapy, it may be delayed in younger patients until there is suspicion of recurrence.

For high-grade glioma, the findings of a study conducted by the Brain Tumor Cooperative Group (BTCG) demonstrated an increase in survival in HGG patient undergoing radiation therapy plus surgery compared to surgery alone from 14 to 31 weeks. A landmark study on the use of radiation in conjunction with temozolomide has defined the current standard for radiation therapy in glioblastoma patients: 2 Gy given 5 days per week for 6 weeks, totaling 60Gy.

Two important clinical trials have established the standard therapy for metastatic lesions. Currently, acceptable

care of patients with brain metastases consists of resection followed by whole brain radiation therapy, or stereotactic radiosurgery (SRS), in which a high dose of radiation is administered to the tumor bed, in addition to whole brain radiation therapy. The use of radiation therapy has been extensively investigated. Currently, radiation therapy is indicated as an adjunct to surgery in the setting of recurrent meningioma or subtotal resection. Occasionally in a poor surgical candidate or if a meningioma is in a location carrying high surgical risk, radiation therapy may be used in isolation.

2. Chemotherapy—Clinical trials of chemotherapy for low-grade glioma have been limited and the use of chemotherapy for this remains experimental. The one exception is low-grade gliomas, typically those with 1p deletion and oligodendroglial lineage, which are particularly sensitive to PCV (procarbazine, carmustine, and vincristine) or temozolomide. In contrast, a recent clinical trial in patients with proven GBM comparing radiation alone to radiation in combination with the oral alkylating agent temozolomide demonstrated a modest but significant increase in survival from 12.1 to 14.6 months. The current standard of care for patients with GBM combines radiation therapy with oral temozolomide. Chemotherapy has not shown any benefit in the treatment of brain metastases and meningiomas. Future efforts in the development of novel chemotherapeutic agents are focused on developing novel inhibitors of signaling pathways that are active only in brain tumor cells. Developing novel methods for the delivery of traditional chemotherapeutic agents is also an area of active research.

► Complications

Patients with primary and metastatic brain tumors are at risk of developing postoperative medical as well as surgical complications. Sawaya proposed the most common classification scheme for complications associated with brain tumor surgery in 1998. In a case series of 400 craniotomies for treatment of brain tumors, complications were classified as neurological, regional, and systemic. Neurologic complications are outcomes that produce visual field, motor, sensory, or language deficits. Neurologic complications are the result of injury to normal brain structures, cerebral edema, hematoma, or vascular injury. In most series, the risk of a new neurologic deficit after craniotomy for resection of an intrinsic brain tumor ranges from 10% to 25%. The risk factors for adverse neurologic outcomes include older age (greater than 60 years), deep tumor location, tumor proximity to eloquent regions, and low functional performance score (Karnofsky score less than 60%). Neurologic complications can be minimized by individualizing the surgical approach for each patient, cortical mapping techniques, minimizing excessive brain retraction, meticulous hemostasis, and early identification of major venous structures.

Regional complications are those related to the surgical wound or brain parenchyma, without neurologic deficit. They occur in 1%-5% of patients undergoing craniotomy for resection of an intrinsic brain tumor. Regional complications include wound infections, pneumocephalus, Cerebrospinal fluid fistula, hydrocephalus, seizure, brain abscess/cerebritis, meningitis, and pseudomeningocele. These complications occur more readily in the elderly. Posterior fossa location and reoperations are associated with a higher rate of pseudomeningocele, CSF fistula, hydrocephalus, and wound infections. Postoperative wound infections and cellulitis occur in 1%-2% of patients after supratentorial craniotomy. They typically result from skin bacterial contamination (*Staphylococcus aureus* and *Staphylococcus epidermidis*). The risk of postoperative seizures following supratentorial craniotomy is 0.5%-5%. Prophylactic antiepileptic drugs can be routinely used in the postoperative period; however, their dose and duration is an area of controversy.

Systemic complications include all generalized adverse events, including deep vein thrombosis (DVT), pulmonary embolus, pneumonia, urinary tract infections, myocardial infarction, and sepsis. These medical complications occur in 5%-10% of patients undergoing craniotomy for removal of an intrinsic brain tumor and are more prevalent in older patients (greater than 60 years) and neurologically impaired patients (Karnofsky score less than 60%). DVT is the most common complication occurring in 1%-10% of patients within the first month after a craniotomy. Patients with systemic cancer, glioblastoma multiforme, meningiomas, lower extremity paralysis, bed rest, and prolonged surgery are at particularly increased risk of developing a DVT or pulmonary embolus. Early postoperative mobilization, intermittent compression devices, and postoperative anticoagulation with low-molecular-weight heparin have decreased the incidence of postoperative DVT.

Craniotomy for resection of brain tumor can be performed safely and most complications can be prevented with careful preoperative planning, meticulous surgical technique, and attentive postoperative care.

► Prognosis

The prognosis of brain tumor patients varies based on a number of factors, including, but not limited to, general functional status at the time of diagnosis, tumor type, location, and age.

A. Glioma

The prognosis of glioma patients is determined by tumor grade, age, extent of resection, Karnofsky performance status, and treatment response. Improvement in survival when radiographically complete resection is achieved is greatest for those with low-grade lesions. While more modest, high-grade glioma patients with radiographically complete resection also

have survival improvement compared to incomplete resection. Achieving gross total resection improves survival by lowering the risk of recurrence and reducing tumor cell burden to levels that can be eradicated or controlled with adjuvant therapy.

B. Meningioma

In general, the prognosis of meningioma patients is more favorable than that of glioma patients. The prognosis of meningioma patients is determined by the extent of resection and tumor grade. The Simpson classification system stratifies meningioma patients into outcome groups based on extent of resection. Patient age, extent of surrounding structure invasion, male gender, genetic factors, and tumor grade are among the factors that are linked to prognosis. Recurrence has been estimated to occur in approximately 20% of patients with benign meningiomas but is much more common in higher grade lesions.

► Metastases

The survival of patients with untreated brain metastasis is quite poor (1-2 months), but survival can be prolonged by 4 or more months with optimal surgical and radiation therapies. Extent of extracranial disease is a key prognostic factor in patients with brain metastases. Age and Karnofsky performance status have an important bearing on overall survival.

TUMORS OF THE SPINE AND SPINAL CORD

Anthony C. Wang, MD Khoi D. Than, MD Paul Park, MD

INTRODUCTION

Neoplastic pathology affecting the spinal cord is uncommon in the general population but it is an important consideration in the evaluation of patients presenting with neck and/or back pain with or without associated radicular symptoms, sensorimotor deficits, and bowel or bladder dysfunction. An estimated 15% of primary CNS tumors are intraspinal, and most of these are benign. Since the first resection of a spinal cord tumor was reported in 1888, surgery has remained a mainstay of treatment in the majority of spinal tumors, though radiotherapy and chemotherapy have demonstrated benefit in a growing number of instances.

Spinal tumors are differentiated based upon their locations relative to three anatomic compartments. Extradural tumors are located outside of the thecal sac, and arise either from the osseous spine or epidural space. Intradural-extramedullary tumors occur within the thecal sac but are outside of the neural tissues of the spinal cord. These tumors most commonly develop from the leptomeninges or nerve roots. Intramedullary tumors are found within the spinal cord and originate from either the spinal cord parenchyma or pia mater.

In addition to gender and age of presentation, localization of the lesion to the cervical, thoracic, lumbar, or sacrococcygeal spine aids in refining the differential diagnosis as certain tumors demonstrate a predilection for particular regions of the spinal column.

► Clinical Presentation

Symptoms experienced by patients presenting with spinal tumors are more commonly produced by compression than direct invasion of the spinal cord or nerve roots. Classically, the pain associated with neoplasms is unremitting, worse in the supine position, and more noticeable at rest or in bed. Hence, the patient may wake up at night due to pain. Although the progression of symptoms can be insidious, radicular pain, motor weakness, paresthesias, or anesthesia can frequently occur as a result of nerve compression. Long tract myelopathic findings such as ataxia, hyperreflexia, spasticity, fasciculations, sensorimotor loss, or sphincter dysfunction can be caused by spinal cord compression. Recognized unusual findings include muscle wasting or hyporeflexia, referred pain, autonomic changes such as in Horner's syndrome, and Brown-Séquard hemiparalysis syndrome. Fracture and deformity causing axial pain often occur as well, and may be the presenting complaint.

Extradural tumors frequently involve the osseous spine, and so most typically present with axial pain, often increased by motion or Valsalva maneuver. Signs and symptoms of neural compression occur secondarily. Intradural-extramedullary tumors present most commonly with motor deficits and other long tract disturbances. Intramedullary tumors can demonstrate an insidious succession of symptoms including neuralgic pain that can progress to myelopathy.

► Diagnosis

A. Radiographic Evaluation

MRI is currently the primary mode of assessment of spinal tumors (Figure 36-16). Contrast-enhanced T1-weighted sequences are the standard initial imaging modality for the evaluation of suspected extradural, intradural-extramedullary, and intramedullary lesions. Nearly all intramedullary lesions demonstrate contrast uptake, and the resolution

▲ **Figure 36–16.** Sagittal T1-weighted image with contrast of the upper thoracic spinal cord demonstrating an intradural, intramedullary lesion found on biopsy to be a high-grade glioma.

that MRI provides is typically sufficient for determination of margins and infiltration. The addition of angiography is indicated for the suspicion of a vascular pathology.

If MRI is not obtainable, then more invasive methods are used. Myelography, which was once the modality of choice for imaging the spinal canal, provides excellent structural detail. Fusiform cord widening, a dumbbell-shaped deformity, or complete blockage are classic findings suggesting the presence of a mass lesion. Plain, contrast-enhanced, and postmyelography CT imaging can aid in the assessment of bony spine anatomy. Nuclear scintigraphy is used primarily in the identification of skeletal metastases. Catheter angiography can be employed in the evaluation of suspected vascular lesions. Plain x-rays of the spine have limited utility in the initial assessment of spinal tumors. Findings such as enlarged intervertebral foramina and interpedicular spaces, or bone erosion with scalloped edges suggest the presence of an enlarging mass.

B. Laboratory Analysis

Lumbar puncture can provide additional clues to the presence of a spinal cord tumor. Elevated CSF protein is present in approximately 95% of cases, though CSF glucose is

normal. Xanthochromia and the presence of fibrinogen causing clotting can also occur. Specific CSF and serum immunocytochemical tests can aid the diagnosis of specific neoplasms.

C. Differential Diagnosis

Among all spinal tumors, extradural lesions are discovered with the greatest frequency, comprising an estimated 55%–60%. A vast majority of these are metastatic lesions via hematogenous dissemination along Batson's venous plexus. The most common primary sources of vertebral metastases are lung, breast, and prostate.

Benign spine tumors of the osseous spine are very rare, and may be incidental findings, or cause pain, radiculopathy, myelopathy, spinal instability, or deformity. Biopsy is utilized at times, and appropriate management may be observational, as is common in the case of eosinophilic granuloma, ablative, as can be performed for osteoid osteoma, or surgical. Primary benign spine tumors can be classified using the Enneking system.

Approximately 5% of bone malignancies involve the spine, the four most common being osteosarcoma, chondrosarcoma, Ewing's sarcoma, and chordoma. Survival varies significantly by pathology. The high rates of recurrence, limited survival duration, and functional morbidity associated with these tumors support the aggressive multimodal strategies typically employed in treatment of these tumors. In some cases, complete resection with negative margins, or even en bloc resection, is possible. In other cases, surgical resection may serve to decrease tumor burden, thereby improving the efficacy of adjuvant treatments such as chemotherapy and radiotherapy. At times, surgical intervention is necessary for functional indications, either for neural decompression or spinal stabilization.

Only 0.5% of tumors involving the spinal column are primary neoplasms. Of the intradural tumors, an estimated 70% are extramedullary. Schwannoma, neurofibroma, and meningioma comprise the bulk of these cases. The nerve sheath tumors, schwannoma and neurofibroma, are usually benign, and can demonstrate a typical dumbbell-shaped appearance, caused by the neuroforamina through which they sometimes pass. They are an important consideration when deviation of the pleural reflection on x-ray suggests a posterior mediastinal mass. Schwannomas are well-differentiated and typically grossly resectable; however, neurofibromas cannot be resected completely from its parent nerve. In the setting of type-1 neurofibromatosis, suspicion of multiple neurofibromas, meningioma, and ependymoma should be heightened. Schwannoma, neurofibroma, and meningioma multiplicity is associated with type-2 neurofibromatosis. Meningiomas are seen most often in the thoracic spines of middle-aged women, and arise from persistent arachnoid cap cells.

Intramedullary tumors comprise only approximately 10% of all spinal tumors, and arise most commonly in the cervical segment of the spinal cord. Glial tumors are the most common of these, with ependymomas occurring twice as frequently as astrocytomas in adults. In children, the relationship is reversed, with astrocytomas being twice as common as ependymomas. Myxopapillary ependymomas form at the conus medullaris and filum terminale, and are a very common tumor to be found at this location.

► Treatment

Treatment options are tailored to the patient. Some patients present with axial pain absent of radiculopathy while others present with mild or stable evidence of spinal cord compression causing myelopathy. Still others present with rapidly progressive course of neurologic deterioration.

Generally, primary tumors of the spinal column are best treated by complete resection, if possible. In the vertebral column, en bloc resection is frequently the goal of surgery, whereas with any involvement of the spinal cord, gross total resection is the desired treatment. Symptomatic deformity or spinal instability warrants consideration for surgical fixation, as functional deterioration profoundly affects survival.

Extradural metastases are the most frequently seen tumors of the spinal column, and their treatment is complicated by many factors. Decompression of the spinal cord is the initial surgical consideration. Resection followed by adjuvant radiation has shown promising oncologic results. Spine stability must then be addressed depending on the patient's overall prognosis.

In 2007, the WHO updated a comprehensive classification of neoplasms affecting the CNS based upon the specific cell type from which each tumor arises, which guides therapy and prognosis in cases of most intramedullary tumors. Overall, functional outcome depends heavily on the severity and duration of neurologic symptoms at the time of presentation, while survival outcome depends largely on the pathology in question, and less so, on the ability to gain adequate surgical resection.

Intradural-extramedullary tumors are generally best treated by surgical resection; outcomes appear to depend heavily upon extent of resection, though preservation of preexisting neurologic function remains the primary objective in surgery. Determination of a dissection plane between tumor and spinal cord is the initial aim of any resection procedure. Overall, prognosis is excellent in nearly all cases of spinal intradural-extramedullary neoplasms, unless paraplegia is the presenting condition. In contrast, recurrence of infiltrative neoplasms is very common, and progression to paralysis is common. Progressive neurologic deterioration demands particular focus on facilitating appropriate surgical therapy.

PITUITARY TUMORS

Wajd N, Al-Holou, John E, Ziewacz, Ariel Barkan, William F. Chandler, Stephen E. Sullivan

► Clinical Considerations

The pituitary gland, involved in the regulation of the major hormonal axes of the body, is located in the sella turcica ("Turkish Saddle") of the sphenoid bone and is comprised of the anterior pituitary (adenohypophysis), posterior pituitary (neurohypophysis), and functionally insignificant pars intermedia separating the two lobes. The anterior pituitary secretes Prolactin, ACTH, TSH, LH, FSH, and GH. The posterior lobe is a repository of the hypothalamic hormones Oxytocin and Anti-Diuretic hormone (ADH, vasopressin).

Pituitary tumors are typically benign adenomas that arise from the anterior lobe of the pituitary gland. They comprise approximately 10% of CNS tumors. With the increasing use of brain MRI, there has been an increase in the diagnosis of incidentally discovered pituitary adenomas, known as incidentalomas, with nearly a 23% imaging prevalence. Pituitary adenomas are classified by both their secretory status (secreting vs. nonsecreting), and their size. Microadenomas have diameters up to 1 cm, while tumors greater than 1 cm are termed macroadenomas (Figure 36-17). Secreting (endocrine-active) tumors are further classified by which hormone is being hypersecreted and the resulting clinical syndrome.

► Clinical Findings

Clinical findings in patients with pituitary adenomas are caused by compression of surrounding structures, decrease in pituitary function, hypersecretion of pituitary hormones, and rarely, acute pituitary failure (apoplexy). Pituitary tumors can also be asymptomatic, and discovered incidentally.

▲ **Figure 36-17.** Magnetic resonance imaging **A.** sagittal plain and **B.** coronal plain of a pituitary macroadenoma.

A. Compression

Compression caused by slowly expanding adenomas causes a variety of findings which include headache, bitemporal hemianopsia (decreased perception of the lateral visual fields), diplopia, and hypopituitarism (decreased secretion of pituitary hormone).

Bitemporal hemianopsia results from the upward extension of the tumor with associated compression of the decussating nasal fibers of the optic chiasm, which lie directly above the pituitary gland. This can be detected on examination as red color desaturation in the temporal visual fields. Without treatment, visual findings can progress to loss of visual acuity and eventual blindness.

Hypopituitarism results from compression and injury of the normal pituitary cells by the expanding mass. Diminished secretion of GH, LH, and FSH occurs early, while diminished secretion of TSH and ACTH occurs later.

Symptoms related to decreased production of LH and FSH manifest as hypogonadism: loss of libido and erections in men and amenorrhea in women. In men, this is often overlooked and only recognized in retrospect. The decreased production of LH and FSH can be due to either direct compression of the gland, or to compression of the stalk, which releases the tonic inhibition of prolactin secretion by dopamine from the hypothalamus. This results in a mild increase in prolactin (usually less than 150 ng/mL) which inhibits *gonadotropin* release. This can cause galactorrhea as well, and is the mechanism of the amenorrhea/galactorrhea syndrome.

Decreased production of TSH causes classic findings of hypothyroidism, including cold intolerance, weight gain, fatigue, coarse hair, and myxedema. Decreased production of ACTH causes hypocortisolism resulting in fatigue, slow return to health after minor illness and orthostatic hypotension. As the body's intrinsic stress response is diminished

with the loss of ACTH production, in rare circumstances, this can result in cardiovascular collapse when the individual is under extreme stress.

B. Hypersecretion

Functional adenomas produce symptoms related to hypersecretion of a specific hormone. They can also produce findings related to compression, but this is less common than in nonfunctional tumors, given that they are often discovered at an earlier stage because of the clinical findings caused by hypersecretion.

Prolactinomas are the most common functional pituitary tumor, accounting for nearly 30%-40% of pituitary tumors. Prolactinomas cause hypersecretion of prolactin. Interruption of the pituitary stalk can cause hyperprolactinemia as well, but levels are typically more modest (150 ng/mL or less). Levels greater than 300 ng/mL are virtually always associated with prolactin secreting tumors. Symptoms of hyperprolactinemia are gender-dependent and may include galactorrhea, amenorrhea (via suppression of gonadotropins), diminished libido, and infertility.

Growth hormone-secreting tumors are the next most common endocrine active tumors. They cause gigantism in children and acromegaly in adults. Acromegaly is characterized by classic physical changes such as soft tissue and skeletal overgrowth, prognathism, widely spaced teeth, macroglossia, as well as nerve entrapment syndromes and arthropathy. It also results in conditions associated with increased morbidity and mortality including cardiomyopathy, sleep apnea, and glucose intolerance. Acromegaly is insidious in onset and is often not noticed by the patient's friends or family. Patients often note a change in shoe size as an adult, an inability to wear a wedding ring, or recognize a striking physical change when comparing a recent to a past photograph.

Tumors that secrete ACTH are the cause of Cushing disease, which refers specifically to hypercortisolism caused by a functional, ACTH-producing, pituitary tumor. The resultant signs and symptoms of hypercortisolism from any etiology are termed Cushing syndrome. Characteristic findings include weight gain (with centripetal fat distribution), "buffalo hump," that is, redistribution of fat to the posterior neck, purple abdominal striae, thin skin with easy bruising, round "moon" face, glucose intolerance, hypertension, osteoporosis, poor wound healing, psychiatric disturbance (depression, mood lability), amenorrhea, impotence, and hyperpigmentation (only with elevated ACTH). These patients have a significant increase in morbidity and mortality if left untreated, with reports of a fourfold to fivefold increase in mortality in some studies. Gonadotropin producing tumors are rare and result in the hypersecretion of LH and FSH. They are often clinically silent, and usually behave like nonfunctioning tumors. In women, they can produce amenorrhea and infertility.

TSH-producing tumors are very rare, accounting for less than 1% of secretory tumors. Clinical findings are those of classic hyperthyroidism including weight loss, tachycardia, heat intolerance, anxiety, and tremor. As opposed to classical thyrotoxicosis (multinodular goiter, Graves' disease, and iatrogenic causes) in which plasma TSH concentrations are undetectably low, in patients with thyrotropinomas TSH levels are "normal" or frankly elevated despite high free T4 and T3 concentrations.

C. Acute Pituitary Failure (Apoplexy)

Acute pituitary failure is usually the result of hemorrhage and/or necrosis in a preexisting adenoma. Symptoms are abrupt and may result in severe headache, visual disturbance, ophthalmoplegia, and change in mental status. Pituitary apoplexy is often considered a neurosurgical emergency, especially in the setting of visual loss. Urgent decompression is warranted for acute or continuing neurologic decline, in order to prevent untoward neurologic consequences, especially blindness. Pituitary hormonal failure almost always accompanies an apoplectic event, and rapid administration of corticosteroids is necessary to avoid cardiovascular collapse.

D. Stalk Compression

Symptoms related to stalk compression are rare in the setting of pituitary adenomas and consist of prolactin elevation and loss of antidiuretic hormone (ADH). Diabetes insipidus results from impairment of hypothalamic input and the resultant diminished release of ADH. This causes an inability to concentrate the urine and resulting dehydration and hypernatremia. Symptoms include frequent high-volume urination and excessive thirst. This can be very dangerous in the setting of a patient with an impaired thirst mechanism. Stalk compression is more common with tumors directly involving the stalk such as craniopharyngioma and Langerhans cell histiocytosis.

Mild prolactin elevation results from blocking hypothalamic dopamine from accessing the pituitary prolactin-producing cells. This release of tonic inhibition results in a modest elevation of prolactin (usually less than 150 ng/mL). This is called the "stalk effect" and may result in amenorrhea and galactorrhea.

► Differential Diagnosis

The differential diagnosis for sellar and parasellar masses is broad. The hallmarks of distinguishing among the multiple possibilities are a detailed history and physical examination, MRI scan, and pituitary hormone testing. The history and physical examination should be aimed at symptoms related to pituitary hyper- or hyposecretion, and compression of surrounding structures. A detailed visual field

examination should be included in the evaluation of any potential pituitary mass. Often, formal visual field testing by an Ophthalmologist is warranted. MRI should be obtained with and without contrast, with thin cuts through the sellar region in coronal and sagittal planes. This will identify the size, configuration, and extent of invasion of a pituitary tumor. Laboratory testing should include evaluation of anterior pituitary hormones, directly or indirectly, in order to establish a hyper- or hyposecretory state. These include prolactin, 8:00 AM cortisol, free T4, TSH, IGF-1, GH, LH, FSH, and testosterone (in men). If symptoms of diabetes insipidus are present, serum sodium and osmolality, and urine osmolality should be obtained to confirm the diagnosis. An overnight water deprivation test may be warranted to evaluate if the patient is able to concentrate urine appropriately.

If a hypersecretory state is not detected on detailed laboratory testing, the lesion is likely a nonfunctional pituitary adenoma or other entity. Other possibilities include craniopharyngioma, Rathke's cleft cyst, or meningioma. A number of other less common lesions are in the differential including metastasis, epidermoid, dermoid, germinoma, abscess, Langerhans histiocytosis, choristoma, chondrosarcoma and chordoma. Rarely, a giant aneurysm can mimic a pituitary tumor.

If a hypersecretory state is discovered, the diagnosis depends on the hormone that is being hypersecreted. It is important to distinguish a primary pituitary lesion causing hypersecretion from a lesion in another location, such as an ACTH-secreting carcinoid lung tumor.

Prolactin levels greater than 200 ng/mL indicate the presence of a prolactinoma. Modest elevations in prolactin, less than 150 ng/mL, can be caused by compression of the pituitary stalk, antidopaminergic drugs, estrogen excess (usually from oral contraceptives), chest wall lesions, primary hypothyroidism, and hypothalamic damage. In evaluating prolactin in patients with giant adenomas (> 3.5 cm), it is important to include serial dilutions up to 1:1000 in addition to the undiluted serum value. The purpose of this is to obviate a false negative value in cases of extremely elevated prolactin levels caused by the so-called "hook effect." This results from excess prolactin binding to both antibodies of the laboratory assay, causing a lack of formation of the complexes identified in the current assays. If the diluted level is still elevated, one can conclude there is a truly elevated prolactin level.

If there is concern for hypercortisolism, a 24-hour urinary free cortisol should be obtained to diagnose hypercortisolism. This should always be repeated for confirmation of the abnormal elevation. If this value is clearly elevated then hypercortisolism is definite and search is initiated to find the etiology of the hypercortisolism. If the level is equivocal and suspicion of hypercortisolism is still strong, then a low- and high-dose dexamethasone suppression test may be employed.

Once hypercortisolism is confirmed, the location of the pathology must be identified. Identification of an adenoma

on MRI will obviate the need for further endocrinological studies. Endogenous hypercortisolism is either ACTH-dependent, most commonly from a pituitary adenoma or ectopic ACTH from a pulmonary malignancy, or ACTH-independent, resulting from an adrenal source (adrenal adenoma or carcinoma). Tests useful in confirming an ACTH-dependent tumor include a 4 pM serum ACTH. If ACTH level is elevated, then the source needs to be identified. The low- and high-dose dexamethasone suppression test (Liddle test) can also help to confirm a pituitary etiology. In Cushing disease serum cortisol is not suppressed with the low dose of 0.5-mg dexamethasone q 6 hours for 2 days, but does suppress with the higher dose of 2.0 mg q 6 hours for 2 days. In patients with ectopic sources of ACTH production, cortisol level is not suppressed even with the high-dose dexamethasone suppression test. In cases of proven ACTH-dependent hypercortisolism in which a pituitary tumor is not seen on MRI, inferior petrosal sinus sampling (IPSS) is required to confirm a pituitary etiology, as well as to help localize the side of the tumor. IPSS can identify a pituitary source of hypercortisolism in 98%, but it is not very effective in identification of laterality, being correct in no more than 69% of cases.

Laboratory diagnosis of GH secreting tumors is often indirect. This is because the secretion of GH is pulsatile and levels in patients without a hypersecreting tumor can often be elevated at certain times during the day. Patients with active acromegaly may have completely normal random GH levels. IGF-1 (somatomedin-C) is the gold standard for diagnosing GH secreting tumors. IGF-1 is produced in the liver and other organs and is dependent on GH for its production. Serum levels of IGF-1 are relatively stable and provide a better confirmatory test than the more volatile GH.

LH and FSH secreting tumors are diagnosed by serum elevated levels in the setting of a pituitary mass diagnosed on MRI.

TSH secreting tumors are rare and must be distinguished from other pathologic entities on the hypothalamic-pituitary-thyroid axis. Secondary hyperthyroidism (that produced by a pituitary tumor) is diagnosed by an elevated TSH level as well as an elevated free T4 level. In primary hyperthyroidism, free T4 would be elevated and TSH would be suppressed via a negative feedback mechanism.

► Treatment

Treatment of pituitary tumors depends on their size, hormonal characteristics, and level of invasiveness. Micro- or macroadenomas that are nonsecreting and are not causing symptoms of compression may be treated conservatively, and followed with serial imaging. The natural history of nonsecreting microadenomas is often benign.

Nonsecreting macroadenomas that cause signs of compression are currently treated surgically. The typical surgical

approach is a transsphenoidal route. This is generally performed transnasally, using the operating microscope and/or the endoscope. Recent advances in frameless stereotactic guidance and endoscopic techniques have allowed a greater ability to localize lesions intraoperatively and provide a more minimally invasive approach to treatment of pituitary adenomas. The use of endonasal endoscopic approaches has increased in recent years and provides wider intraoperative visualization, but may be associated with increased intranasal morbidity. Nonetheless, both endoscopic and microscopic endonasal approaches are effective surgical treatment modalities, and the choice of technique is often surgeon-dependent.

Occasionally, if an adenoma has an unusual amount of suprasellar extension, or lateral extension a craniotomy may be necessary. In some cases, lesions that invade the cavernous sinus or have a significant amount of extrasellar extension are not surgically accessible by any approach and radiation therapy is often necessary to provide tumor control.

Patients with hypopituitarism due to compression who do not experience return of pituitary function postoperatively require hormone replacement on a chronic basis. If chronic steroid replacement is necessary, it is important that patients be provided with a medic-alert bracelet for the possibility of trauma or illness. These patients have a loss of intrinsic cortisol production, and can suffer from cardiovascular collapse if their cortisol deficiency is not recognized and supplemented with stress-dose steroids.

Treatment for hypersecreting tumors depends on the hormone being secreted. It is very important to establish the hormonal profile of a tumor prior to treatment for this reason. Currently, prolactinomas are treated first with a dopamine agonist. The most common medications used to treat prolactinomas are cabergoline and bromocriptine. Cabergoline is a selective D-2 dopamine receptor agonist that is widely considered first-line therapy for prolactinomas. It is favored over bromocriptine because of its selectivity, twice weekly dosing, better tumor control, effective lowering of prolactin levels, greater return of gonadal function/menstrual cycles, and possibility of obviating the need for life-long therapy. Two randomized trials showed better prolactin normalization with cabergoline as compared to bromocriptine. Recently, association of cabergoline with cardiac valvular disease has prompted a reexamination of the initial treatment of prolactinoma, but currently medical treatment as first line is still favored. Cardiac complications are generally seen with much higher doses than required to treat a prolactinoma. Most prolactinomas respond well to medical treatment, but 10%-20% of patients do not. If medical therapy fails to reduce the tumor size or its mass effect, or sufficiently control prolactin levels, surgery via transsphenoidal approach may be offered. Surgical management occasionally may be indicated in patients with rapidly worsening visual loss, and can be considered in patients

attempting pregnancy, although cabergoline is still the first-line intervention in these patients.

Other hypersecreting tumors are treated via transsphenoidal approach, as with nonsecreting adenomas. Postoperative laboratory testing confirms the efficacy of therapy. As with nonsecreting tumors, craniotomy and/or radiation are sometimes necessary, depending on the extent and location of tumor growth. Pituitary replacement may be necessary postoperatively as well.

In the case of pituitary apoplexy, treatment often consists of urgent transsphenoidal decompression to prevent further visual deficit, and prompt initiation of stress dose steroid replacement in order to avoid a pituitary crisis.

► Summary

Pituitary adenomas are largely benign tumors that are either secreting or nonsecreting. Diagnosis is established with history, physical examination, MRI, and hormonal testing. Treatment consists of conservative therapy for nonsecreting micro/macroadenomas without symptoms of compression, medical therapy for prolactinomas, and transsphenoidal surgery for symptomatic macroadenomas and other hypersecreting tumors. Occasionally, craniotomy and/or radiation may be necessary for further tumor control. Depending on hormonal status, chronic pituitary replacement may be necessary postoperatively. Successful treatment of pituitary tumors can often be achieved with the combined effort of a medical endocrinologist and pituitary neurosurgeon.

PEDIATRIC NEUROSURGERY

Debbie K Song, MD Cormac O. Maher, MD Karin M. Muraszko, MD

CONGENITAL MALFORMATIONS

► Craniospinal Dysraphism

Craniospinal dysraphism results from improper formation and closure of the neural tube during development. These may be classified based on whether they are open or closed neural tube defects, the location of the lesion, or the embryological basis for the malformation. Open neural tube defects are those in which neural elements are exposed or covered by a dysplastic membrane, while closed neural tube defects are skin covered.

Myelomeningocele, the most common type of spinal dysraphism compatible with life, occurs with an incidence of 1 in every 1200-1400 live births. It is due to a local failure of neural tube closure during primary neurulation. Fusion of the lateral cutaneous ectoderm and the process of disjunction also fail to occur in myelomeningocele, resulting in a midline cutaneous defect over exposed neural tissue called the neural placode. Therefore, myelomeningoceles are considered open neural tube defects. Myelomeningoceles occur most commonly in the lumbar spine, and the anatomic level of the spinal cord lesion approximates the patient's neurologic deficits. The diagnosis of a neural tube defect can be suspected prenatally with an elevated maternal serum alpha-fetoprotein and confirmed by in utero imaging such as a maternal-fetal MRI or ultrasound. Pregnant mothers who have inadequate folate intake or who have other children with neural tube defects are at increased risk for giving birth to a child with a myelomeningocele. A Chiari II malformation is found in most patients with myelomeningocele. Eighty percent of patients with myelomeningocele have associated hydrocephalus. Other CNS abnormalities that can be found with increased incidence among patients with myelomeningocele include lipomas, syringomyelia, and diastematomyelia. Patients with myelomeningocele commonly have orthopedic problems that include scoliosis, hip dislocation, knee, and foot deformities. Besides a neurogenic bladder, patients with myelomeningocele are at increased risk of genitourinary abnormalities, as well as intestinal, cardiac, esophageal, and renal abnormalities. Workup for the newborn child with myelomeningocele includes a cranial and spinal ultrasound, and orthopedic and urology consults. The neonate should be placed in the prone position, with pressure off of the myelomeningocele. The myelomeningocele should

be covered in moist. Surgical closure of the myelomeningocele is performed soon after birth. The Management of Myelomeningocele Study is an ongoing trial examining the utility of in utero myelomeningocele repair.

Closed neural tube defects, also referred to as occult spinal dysraphisms, can arise from problems with disjunction, secondary neurulation, or postneurulation events. Types of closed neural tube defects include dermal sinus tracts, spinal lipomas, neurenteric cysts, sacral dysgenesis, and diastematomyelia. Spina bifida occulta, which is characterized by a defect in the posterior elements of the spine, is often a harbinger of an underlying closed neural tube defect. These malformations can tether the spinal cord in an abnormally low position and produce excessive tension on the neural elements. Neuronal dysfunction may ensue with symptoms of a clinical tethered cord syndrome such as back or leg pain, worsening lower extremity motor and sensory function, decline in bladder and bowel function, worsening lower extremity orthopedic deformities, and progressive scoliosis. Early surgical repair of occult spinal dysraphisms is often recommended at the time of diagnosis in order to prevent the onset or halt the progression of neurological symptoms.

Dermal sinus tracts are epithelial-lined tracts that originate in the midline skin, usually in the caudal lumbosacral region above the S2 level. The sinus tract extends from a pinhole opening in the skin, through bifid spinous processes, and extends into the dura to communicate with the spinal cord. The lining of the dermal sinus tract contains normal skin appendages which can shed and communicate with the intradural space, and recurrent episodes of meningitis and arachnoiditis may ensue. They appear as dimples above the gluteal crease and must be differentiated from pilonidal cysts, which are closer to the anus. Both entities may drain from the skin. The skin around the ostium of a dermal sinus tract may be discolored or have a hairy tuft. Dermal sinuses can be associated with lipomas, dermoid tumors, or epidermoid cysts at any point along the tract or within the spinal canal. Examination of the child with a suspected dermal sinus tract should include assessment of sphincter function, lower extremity reflexes, and motor and sensory function. Treatment should be performed in an expeditious fashion after diagnosis in order to reduce the risk of CNS infection and prevent the development of neurological deficit. Less commonly, dermal sinus tracts can occur in the cranial region. The most common cranial locations are in the occipital or nasal region. Children may present with a midline dimple at the tip of the nose or in the occipital region and a history of recurrent meningitis. Cranial dermal sinus tracts can be associated with intracranial dermoid cysts.

Spinal lipomas are the most common closed neural tube defects and include three separate entities: intradural lipomas, lipomyelomeningoceles, and lipomas derived from the caudal cell mass including fibrolipomas of the filum terminale. A lipomyelomeningocele consists of an

intradural lipoma that is attached to the spinal cord and extends through defects in the dura, bony spine, and fascia to become continuous with the subcutaneous fat. Seventy percent of lipomyelomeningoceles are associated with subcutaneous fatty masses. Lipomyelomeningoceles present as skin-covered lumbosacral masses above the gluteal crease. The overlying skin may be discolored from a port-wine stain or hemangioma, have a hairy tuft, or contain an ostium of a dermal sinus tract. The caudal end of the spinal cord is usually tethered in a low-lying position in cases of lipomyelomeningocele, with the conus medullaris positioned below the normal L1-2 level. Filum terminale fibrolipomas and distal conus lipomas, in contrast to lipomyelomeningoceles, are malformations of secondary neurulation. Intradural lipomas, lipomyelomeningoceles, and filum terminale lipomas can all tether the spinal cord. The neurological examination in such children may be normal, or patients may present with symptoms of a clinical tethered cord syndrome. Symptoms may become more prominent and neurological deficits can worsen during growth spurts. As a child gains weight, intraspinal lipomas will also undergo fat deposition which can compress or tether neural elements. Treatment of lipomyelomeningoceles includes cord untethering with resection or debulking of the intraspinal lipoma.

Diastematomyelia, also known as a split cord malformation, occurs when the spinal cord is split into 2 hemicords. The hemicords may be contained within separate dural sleeves separated by a bony septum, or both hemicords may be contained within a single dural sac and separated by a fibrous septum. The 2 hemicords reunite below the level of the lesion. Diastematomyelia is most commonly found in the lumbar spine and has a gender predilection for women. Children with diastematomyelia often have cutaneous stigmata such as a nevus or a hairy tuft (hypertrichosis) at the level of the malformation. Bony anomalies, including spina bifida occulta, hemivertebrae, butterfly vertebrae, bony spurs at the level of the lesion, scoliosis, and orthopedic foot deformities are associated with split cord malformations. Clinically, diastematomyelia presents with symptoms of a tethered cord. Surgical treatment involves resection of any bony spurs and/or septum, untethering of the spinal cord, and reconstitution of a single dural sac.

Encephaloceles occur when there is a herniation of brain tissue and meninges through defects in the cranial vault. The tissue contained within an encephalocele consists of dysplastic and nonfunctional neural tissue with variable amounts of blood vessels, choroid plexus, dura, and ventricular tissue. The prognosis in children with encephaloceles is dependent on the amount of neural tissue contained within the encephalocele. Encephaloceles can be categorized as either posterior or anterior cranial fossa malformations depending on their location, and they are further classified according to the bone through which the herniation of tissue occurs. Posterior encephaloceles are associated with other midline

congenital anomalies, including myelomeningocele, Dandy-Walker malformation, Klippel-Feil anomaly, dorsal interhemispheric cysts, abnormalities of the corpus callosum, and neuronal migration disorders. For occipital and parietal encephaloceles, it is important to delineate the relationship of the lesion with adjacent venous sinuses. The goals of operative repair include removal of the encephalocele sac, preservation of any possible functional neural tissues, and closure of the dura in a water-tight fashion and of the wound with nondysplastic skin. Up to 50% of infants will develop hydrocephalus within 1 month of encephalocele repair; thus, surveillance with serial cranial ultrasounds is warranted in this group.

► Arachnoid Cysts

Arachnoid cysts are developmental anomalies that form between separated layers of the arachnoid membrane. The walls of an arachnoid cyst may thicken with collagen deposition over time or hemorrhage. These cysts most commonly occur in the middle cranial fossa and retrocerebellar region. The brain may be shifted by the arachnoid cyst, but the overall brain volume is usually close to normal. Arachnoid cysts are asymptomatic, incidental findings in the vast majority of cases. Occasionally, they may present with symptoms specific to the location of the lesion. The natural history of an arachnoid cyst is usually benign. Most cysts do not change over time, although some may enlarge, shrink, or even disappear completely. Treatment is rarely indicated, and only if the arachnoid cyst is clearly symptomatic. There are various surgical treatment options available including endoscopic or open fenestration of the cyst as well as cystoperitoneal shunting.

► Chiari Malformations

Chiari malformations consist of 4 types of congenital hindbrain abnormalities. Only Chiari Malformation Types I and II are commonly seen. Chiari I malformations are defined on imaging when the cerebellar tonsils extend at least 5 mm below the foramen magnum (Figure 36–18). The tonsils may assume a pointed, peg-shape instead of the normal rounded shape, causing crowding at the foramen magnum which limits CSF flow through the craniovertebral junction. Other CNS abnormalities associated with Chiari I malformation include syringomyelia (cavitation within the spinal cord), basilar invagination, platybasia, and Klippel-Feil anomaly. Children with Chiari I malformations are often asymptomatic but may also present with occipital headaches that are exacerbated by straining or coughing. Other symptoms include weakness, numbness, progressive scoliosis, long tract signs, central sleep apnea, or hydrocephalus. The work-up should include imaging of the brain and spine to assess for the presence of a syrinx and CSF flow studies to evaluate flow at the foramen magnum. For symptomatic children with a Chiari I malformation and syrinx, surgical treatment

▲ **Figure 36–18.** Sagittal T2-weighted MRI scan of a Chiari showing typical peg-like appearance of cerebellar tonsils and associated syringomyelia.

is recommended. Surgery is never indicated for asymptomatic children with no syrinx. The decision to proceed with surgical intervention in a child with a diagnosis of type I Chiari malformation on imaging, headaches, but no syrinx must be made carefully given the common occurrence of headaches as well as incidental Chiari I in the neurologically normal population. Surgical treatment entails some combination of a suboccipital craniectomy, C1 laminectomy, and duraplasty. Syringomyelia associated with Chiari I malformation usually resolves or improves significantly after posterior fossa decompression.

Chiari II malformations are found in patients with myelomeningocele. On imaging, these patients exhibit a low position of the cerebellar vermis and tonsils below the foramen magnum; elongation, kinking, and displacement of the medulla below the foramen magnum and around the cervical spinal cord; abnormal lamination of the cerebral cortex; and often an upward displacement of the rostral cerebellum through a low-lying tentorium. Additional associated MR imaging characteristics of Chiari II malformations include hydrocephalus, fusion of the inferior colliculi of the brainstem, a large thalamic massa intermedia, a high-riding third ventricle, an elongated fourth ventricle, and a disproportionately small posterior fossa with asymmetric and flattened cerebellar folia. Symptomatic patients may present with apnea and other respiratory abnormalities secondary to compression of the medullary respiratory control center. Long tract signs, headache, ataxia, and gait instability may

also be evident. In addition to myelomeningocele, other CNS abnormalities associated with Chiari II malformations include basilar impression, corpus callosum abnormalities, and cortical malformations. For symptomatic patients, surgical treatment consists of a posterior fossa decompression. Chiari III and IV malformations are very rare. Chiari III malformations include features of Chiari II malformation as well as an occipital encephalocele. Chiari IV malformations are characterized by severe cerebellar hypoplasia without an encephalocele.

► Craniosynostosis

Craniosynostosis refers to the premature fusion of one or more cranial sutures. When this occurs, bone growth is restricted in a direction perpendicular to the fused suture, and there is compensatory growth at other sites. The result is a misshapen head which may take one of several forms depending on which of the cranial sutures is involved. One or multiple sutures may be affected. The incidence of craniosynostosis is approximately 5 per 10,000 live births, and men are affected more than women.

Sagittal synostosis, the most common type of single suture synostosis, results in an elongated, boat-shaped skull referred to as scaphocephaly. In scaphocephaly, the biparietal diameter is reduced, while the anterior-posterior (AP) diameter is increased. Frontal bossing is common in this condition. Patients with sagittal synostosis have a palpable keel-like prominence over the fused sagittal suture.

Coronal synostosis may be either unilateral or bilateral. Unilateral coronal synostosis produces an asymmetric head shape known as plagiocephaly. The forehead on the affected side is flattened, while the forehead on the unaffected side appears to bulge abnormally. Bilateral coronal synostosis results in brachycephaly, characterized by a broad, flattened forehead. The AP diameter is reduced, while the bitemporal and biparietal diameters are increased. When bilateral coronal synostosis occurs in combination with sagittal synostosis, turricephaly results. Turricephaly is characterized by a high, tower-like head shape with a vertical forehead.

Metopic synostosis is associated with trigonocephaly, a head shape that is characterized by a triangular-shaped forehead and hypotelorism. The bitemporal diameter is narrowed, and there is often a bony ridge in the midline of the forehead, over the fused metopic suture.

True unilateral lambdoid craniosynostosis is rare with an incidence of 1 in 300,000 live births, and it must be differentiated from positional posterior plagiocephaly, an increasingly common diagnosis. In unilateral lambdoid synostosis, there may be slight prominence of the forehead on the unaffected side. The ear on the affected side will be posteriorly and inferiorly displaced relative to the contralateral ear of the unaffected side. The head shape is trapezoidal when viewed from above.

While most cases of craniosynostosis are sporadic and involve a single suture, multiple-suture craniosynostosis occurs in certain genetic syndromes. Crouzon's syndrome is an autosomal dominant disorder characterized by the premature fusion of the bilateral coronal, frontosphenoid, and frontoethmoid sutures. Clinically, the condition is characterized by brachycephaly, maxillary hypoplasia, shallow orbits, proptosis, and a beaked nose. Apert's syndrome is an autosomal dominant condition which is characterized by pansynostosis. Clinically, patients have hypertelorism, midface hypoplasia, and shallow orbits in addition to their craniosynostosis. Symmetric syndactyly and short thumbs are also characteristic of Apert's syndrome. Hydrocephalus is common in this condition.

Operative repair of craniosynostosis is often improving cosmesis. Operative approaches vary from endoscopic strip craniectomies of the involved suture to more extensive cranial vault reconstruction.

HYDROCEPHALUS

Disturbances in cerebrospinal fluid (CSF) circulation or absorption result in hydrocephalus. Hydrocephalus can be classified into 2 types: obstructive or communicating. In obstructive hydrocephalus, CSF circulation is blocked within the ventricular system and there is enlargement in the ventricles proximal to the obstruction. In communicating hydrocephalus, CSF absorption is blocked at the level of the arachnoid granulations. Rarely, hydrocephalus may be due to the overproduction of CSF, as is the case in certain choroid plexus tumors.

The incidence of congenital hydrocephalus ranges from 0.9 to 1.8 per 1000 births. Neonatal hemorrhages of the germinal matrix and choroid plexus, as well as infections can cause adhesions to form in the cerebral aqueduct or at the foramen of Magendie and Luschka, interfering with CSF absorption.

Hydrocephalus can cause elevations in intracranial pressure which may manifest in different ways depending on the age of the child. In neonates and infants whose anterior fontanelle is still open, untreated hydrocephalus will present with a tense or bulging fontanelle, apneic and bradycardic episodes, engorgement of the scalp veins, upward gaze palsy, gaps between the cranial sutures, rapid increases in head circumference, irritability, poor head control, and poor oral intake. In children with a closed cranial vault whose fontanelle has closed, untreated hydrocephalus will present with symptoms of intracranial hypertension including lethargy or excessive sleepiness, papilledema, headache, nausea, vomiting, gait disturbance, increased fussiness, or upgaze or lateral gaze palsy.

Several surgical options can be considered in the treatment of hydrocephalus. The most common CSF diversionary procedure is ventriculoperitoneal shunting, creating a

shunt between the cerebral ventricles and the peritoneal cavity. Other types of shunts may drain into other locations including the right atrium (ventriculoatrial shunt) or pleural cavity (ventriculopleural shunt). In children with certain types of obstructive hydrocephalus, an endoscopic third ventriculostomy may be considered, which involves fenestration of the floor of the third ventricle, thereby creating an alternative CSF pathway.

Shunt failure or infection may manifest with signs and symptoms of acute intracranial hypertension. Ventricular enlargement may or may not be present in shunt failure. Prompt treatment of acute hydrocephalus and/or shunt failure is indicated to prevent irreversible neurologic injury including herniation, blindness, or death.

PEDIATRIC CENTRAL NERVOUS SYSTEM TUMORS

Brain tumors are the most common solid tumors of childhood. The locations and types of tumors in the pediatric population differ from those in adults. Approximately two-thirds of brain tumors in children between 2 and 12 years of age occur in the infratentorial space. Brain tumors present in varying manners among different age groups. In neonates and infants, brain tumors may manifest with nonspecific findings, and mass effect from a tumor may not be clinically evident initially due to a compliant skull and an open fontanelle. In young children, a primary brain tumor may present with symptoms related to intracranial hypertension such as headache, nausea, and vomiting. Papilledema may be evident on fundoscopic examination. Older children more often present with focal neurological signs and symptoms. The most common pediatric posterior fossa brain tumors are medulloblastoma, juvenile pilocytic astrocytoma, and ependymoma. When a posterior fossa brain tumor is diagnosed, preoperative imaging of the entire neuraxis should be performed whenever possible to evaluate for drop metastases in the spinal canal.

► Medulloblastoma

Medulloblastomas comprise approximately 20% of all pediatric brain tumors and 30% of all posterior fossa tumors in children. They appear as hyperdense lesions in the region of the fourth ventricle on CT imaging and enhance following contrast administration (Figure 36–19). Complete or near-complete surgical resection is the goal, as the extent of residual tumor is related to prognosis. Patients with medulloblastoma are stratified into either a standard or high-risk group. Those children who are younger than three years, have greater than 1.5 cm² residual tumor on postoperative imaging, or have dissemination of tumor away from the primary site as deemed by either imaging studies or positive CSF cytology have a worse prognosis and are classified as high risk. Postoperative craniospinal radiation with a boost

▲ **Figure 36–19.** Head CT demonstrating large mass (medulloblastoma) within the fourth ventricle causing ventricular dilation.

to the posterior fossa is indicated in children older than 3 years. Those patients who are classified as high risk are typically treated with chemotherapy as well. Because of the increased morbidity of radiation in children less than 3 years of age, chemotherapy is used to delay the radiation dose in such young patients. Recurrences, if they occur, typically occur within 3 years. The 5-year survival in standard risk patients is 70%, while that in high-risk patients is approximately 40%. Up to 25% of patients with a posterior fossa medulloblastoma may require a CSF diversionary procedure due to persistent postoperative hydrocephalus.

► Cerebellar Astrocytoma

Cerebellar astrocytomas account for approximately 20% of all pediatric brain tumors. The peak age of presentation is 10 years. The characteristic appearance on imaging studies is an enhancing mural nodule with a surrounding cyst. The goal of treatment is complete surgical resection, as patients with a gross total resection have a 90% long-term survival rate without any additional adjuvant therapies.

► Ependymoma

Ependymomas can arise anywhere along the neuraxis in relation to an ependymal surface. In the pediatric population, 90% of ependymomas are intracranial, and of these, two-thirds are located in the posterior fossa. Ependymomas commonly arise from the floor of the fourth ventricle in

close proximity to the brainstem. When located in the fourth ventricle, ependymomas may extend out the foramina of Luschka and Magendie into the surrounding CSF subarachnoid cisterns. Dissemination of ependymoma tumor cells in the CSF can occur in up to 10% of cases, underscoring the importance of full neuraxis imaging to properly stage the disease. Treatment usually consists of tumor resection and postoperative focal radiation.

► Brainstem Glioma

Brainstem gliomas are a heterogeneous group of tumors of varying histology, biological behavior, and prognosis. Brainstem gliomas are typically subdivided into four groups based on imaging characteristics: diffuse brainstem gliomas, focal brainstem gliomas, dorsally exophytic brainstem gliomas, and cervicomedullary gliomas. Diffuse brainstem gliomas represent up to 80% of all brainstem gliomas and carry the worst prognosis. They most commonly occur in the pons and can extend into the medulla or midbrain. The majority of children who are affected are between 6 and 10 years of age, and they present with a relatively short clinical history of unilateral or bilateral cranial neuropathies, progressive ataxia, gait abnormality, and long tract signs. On MR imaging studies, diffuse brainstem gliomas appear as non-enhancing, hypointense masses that expand the pons (Figure 36–20). They appear hyperintense on T2-weighted sequences, and with disease progression the tumor may completely encase the basilar artery. Histologically, they are

▲ **Figure 36–20.** Magnetic resonance imaging appearance of a diffuse pontine glioma.

malignant (WHO grade III or IV) astrocytomas. Diagnosis of a diffuse brainstem tumor can be made on the basis of imaging alone, and biopsy is usually not recommended. Radiation therapy and steroids may improve symptoms but have not been shown to prolong survival. These tumors are universally fatal, with a median survival of 8–10 months.

Other types of brainstem gliomas are associated with a better prognosis. Dorsally exophytic brainstem tumors grow from the subependymal surface into the fourth ventricle, away from the brainstem. They are characterized by slow growth with gradual onset of symptoms. Eventually they may obstruct CSF outflow from the fourth ventricle and result in hydrocephalus. Surgical excision should be performed when the predicted morbidity is not prohibitive. Histologically, focal intrinsic and dorsally exophytic brainstem gliomas are usually lower grade (WHO grade I or II) lesions. Cervicomedullary brainstem gliomas have similar behavior and histology as intramedullary spinal cord gliomas. These tumors may cause symptoms including weakness and lower cranial neuropathies. They should be resected.

► Tumors of Infancy

Brain tumors are present in 1.1 newborns per 100,000 births. Infantile tumors include medulloblastoma, central neuroblastoma, supratentorial primitive neuroectodermal tumor (PNET), pineoblastoma, and atypical teratoid/rhabdoid tumor (AT/RT). These are all high-grade tumors with a propensity to spread throughout the CSF. Medulloblastoma, central neuroblastoma, supratentorial PNET, and pineoblastomas are all considered PNETs with similar histologies. The combination of bilateral retinoblastomas and a midline pineoblastoma is referred to as “trilateral neuroblastoma” and carries a dismal prognosis. Atypical teratoid/rhabdoid tumors are usually found in the posterior fossa and are associated with deletions on chromosome 22 in over 90% of cases. AT/RTs have a poor prognosis, and most children die within 1 year of diagnosis.

► Pineal Region Tumors

Tumors arising in the region of the pineal gland comprise 3%–8% of pediatric brain tumors. Histologically, pineal region tumors are most often germ cell tumors such as germinomas, teratomas (mature and immature), embryonal cell carcinomas, choriocarcinomas, and endodermal sinus tumors. Germinomas are the most common pineal region tumors and demonstrate a gender predilection for men. Pineal parenchymal tumors such as pineocytoma or pineoblastomas occur less frequently. Pineal tumors can compress the cerebral aqueduct and cause hydrocephalus. Patients may present with a Parinaud’s syndrome consisting of impaired upgaze, convergence-retraction nystagmus, lid retraction, convergence paralysis, pupillary dilatation, and light-near dissociation. Complete neuraxis imaging should

be performed as drop metastases can occur via CSF pathways. Serum and CSF should be tested for tumor markers that may be secreted by germ cell tumors including placental alkaline phosphatase, alpha-fetoprotein, and beta-human chorionic gonadotropin (beta-HCG). Radiation therapy with or without chemotherapy is the mainstay of treatment for germ cells tumors.

► DNET

Dysembryoplastic neuroepithelial tumor (DNET) is a low-grade cortical based tumor with a median age of presentation of 7 years. They appear as superficial cystic tumors in the temporal or frontal lobes. On MR imaging, they are hypointense on T1-weighted sequences, hyperintense on T2-weighted sequences, and do not enhance. The affected cortical gyrus often has a bubbly appearance. There is no edema or mass effect associated with DNETs. Patients with these tumors typically present with a long history of intractable complex partial seizures and have a normal neurological exam. Gross total resection of the tumor is curative and usually eliminates seizures.

► Sellar Tumors

Tumors that arise in the region of the sella turcica and pituitary gland in children include pituitary adenomas and craniopharyngiomas. Pituitary adenomas are relatively rare among children. Craniopharyngiomas, however, represent 6%-9% of all pediatric brain tumors and are the most common nonglial intracranial masses in children. On imaging, craniopharyngiomas appear as cystic tumors which originate from a suprasellar location. Calcification within these tumors is common. Craniopharyngiomas are hyperintense on T1- and T2-weighted sequences due to fat, cholesterol, and proteinaceous contents within the cystic tumor. Craniopharyngiomas may cause symptoms attributable to intracranial hypertension and hydrocephalus or they may present with visual disturbances. Also, craniopharyngiomas may cause endocrine disturbances such as growth failure, diabetes insipidus, hypothyroidism, or menstrual dysfunction. A thorough endocrine workup is warranted in patients with suspected craniopharyngioma. The surgical approach depends on the location and extent of the craniopharyngioma. Potential surgical complications include diabetes insipidus or hypothalamic insufficiency.

► Hypothalamic Optic Gliomas

Gliomas of the optic pathway are more common in the pediatric population. Included in this category are optic nerve gliomas and chiasmatic/hypothalamic astrocytomas. Histologically, these tumors are most often pilocytic astrocytomas. Optic nerve gliomas are associated with neurofibromatosis 1 (NF-1). Gliomas of the optic chiasm and

hypothalamus are cystic, globular tumors that enhance and rarely calcify. They may cause hydrocephalus due to compression at the foramen of Monro. Infants with hypothalamic/chiasmatic gliomas present with visual loss, macrocephaly, and a diencephalic syndrome consisting of failure to thrive, cachexia, motor hyperactivity, and hyperalertness. Children 2-5 years of age may present with visual loss and endocrine dysfunction including short stature or precocious puberty. Symptoms in older children include visual loss and hypopituitarism. The goals of surgical treatment for chiasmatic/hypothalamic tumors are to obtain a tissue diagnosis and reestablish patent CSF pathways. Radiation has a clear benefit in extending progression-free survival. The 10-year relapse-free rate is approximately 55% with radiation versus 14% with biopsy alone. Chemotherapy is reserved for younger patients less than 5 years of age in order to delay radiation. The 10-year survival following surgical biopsy and radiation for chiasmatic/hypothalamic gliomas ranges from 48% to 55%; however, these tumors and their treatments are associated with significant morbidity, including visual impairment, endocrine dysfunction, obesity, and neurocognitive decline.

► Choroid Plexus Tumors

Choroid plexus tumors include choroid plexus papillomas and choroid plexus carcinomas. They represent 2%-4% of all pediatric brain tumors. Choroid plexus papillomas occur in the atrium of the lateral ventricle in children and are attached to normal choroid plexus. These tumors avidly enhance and may calcify. If a gross total resection of the tumor is achieved, no adjuvant therapy is required. Choroid plexus papillomas are WHO grade I or II tumors and have a good prognosis. Choroid plexus carcinomas are malignant tumors for which the average age of diagnosis is 2 years. Like choroid plexus papillomas, these tumors are usually located in the lateral ventricles. Forty-five percent of choroid plexus carcinomas demonstrate dissemination at diagnosis. These tumors contain necrosis and can hemorrhage. Treatment consists of surgical resection, radiation therapy, and possibly chemotherapy. For children younger than 3 years of age, multiagent chemotherapy is used to delay the onset of radiation therapy. The prognosis is poor.

► Spinal Cord Tumors

Spinal cord tumors in children account for 15% of all pediatric CNS tumors. Spinal cord tumors typically present with progressive back and leg pain, neurologic deficit, gait instability, torticollis, or bowel and bladder dysfunction. The most common intradural-intramedullary spinal cord tumors are low-grade glial tumors including astrocytomas. Treatment consists of early surgery, as postoperative morbidity is worse if preoperative neurologic deficits exist. Near-total resections of low-grade spinal cord gliomas in

children can confer long-term progression-free survival. High-grade gliomas are treated with surgical debulking followed by adjuvant therapies. Intradural-extramedullary tumors in children include dermoid cysts, teratomas, and neurofibromas. Extradural primary spinal tumors that occur in childhood can present with myelopathy and spinal cord compression; such tumors include aneurysmal bone cysts, osteoid osteomas, osteoblastomas, eosinophilic granulomas, and rarely, metastatic disease.

▶ Phakomatoses

Phakomatoses are neurocutaneous syndromes that manifest with skin lesions and central nervous system tumors. Most of the phakomatoses are inherited conditions. NF-1 is an autosomal dominant inherited condition caused by a mutation on chromosome 17. Optic nerve gliomas are associated with NF-1 and, in affected children, usually occur before 6 years of age. Neurofibromatosis 2 (NF-2) is an autosomal dominant syndrome that results from a mutation on chromosome 22. Typical CNS tumors associated with NF-2 include bilateral acoustic neuromas, meningiomas, schwannomas, and intramedullary spinal cord ependymomas.

Tuberous sclerosis (TS) is an autosomal dominant syndrome that arises from mutations in chromosomes 9, 11, or 16. Children with TS can get periventricular hamartomas known as subependymal nodules near the foramen of Monro and adjacent to the caudate nucleus. In 15% of patients with TS, subependymal nodules can transform into a subependymal giant cell astrocytoma, a WHO grade I lesion. These are benign, enhancing tumors that arise at the foramen of Monro and cause obstructive hydrocephalus. These tumors typically occur prior to the end of the second decade of life. They can enlarge with time, and gross total resection of the subependymal giant cell astrocytoma is considered curative. The CNS lesions in TS frequently cause seizures.

Von Hippel-Lindau (VHL) disease is an autosomal dominant disease due to a mutation on chromosome 3. Patients with VHL can get hemangioblastomas, most commonly in the posterior fossa and spinal cord. Although hemangioblastomas are considered benign tumors, they may recur in multiple locations in patients with VHL.

CEREBROVASCULAR DISEASE IN CHILDREN

▶ Aneurysms & Vascular Malformations

Children may present with a variety of intracranial vascular malformations such as arteriovenous malformations (AVMs), venous angiomas, capillary telangiectasias, and cavernous malformations. AVMs may present with seizures or focal deficits from a hemorrhage. Without treatment, patients are at risk for recurrent hemorrhages. AVMs are usually treated with surgery in the pediatric age group but

may occasionally be treated with stereotactic radiation or embolization techniques. In patients with an autosomal dominant inherited cavernous malformation syndrome, the cavernous malformations may be multiple and hemorrhage at an earlier age. Cavernous malformations are treated with surgical resection. Intracranial saccular aneurysm rupture is rare in the pediatric population. Depending on the size and configuration of the aneurysm, these lesions may be treated by surgical clipping, endovascular coiling, or managed conservatively.

▶ Vein of Galen Malformations

Vein of Galen malformations are congenital vascular malformations characterized by extensive arterial feeders draining into an enlarged vein of Galen. Although these malformations are also known as Vein of Galen aneurysms, they represent arteriovenous fistulae. Newborns can present with high-output cardiac failure due to the arteriovenous shunting. Hydrocephalus is common from compression of the cerebral aqueduct by the malformation. Seizures are also associated with these lesions. The extensive arteriovenous shunting can produce a steal effect and result in cerebral ischemia and infarction. The prognosis may be poor for patients diagnosed in early infancy with heart failure. The prognosis is better for those diagnosed later in life. Treatment usually involves endovascular embolization of feeding arteries.

▶ Moyamoya Disease

Moyamoya disease is an idiopathic vasculopathy that leads to progressive occlusion of one or both internal carotid arteries with secondary formation of a collateral capillary network at the base of the brain. The disease can also involve the proximal middle and anterior cerebral arteries. On angiography, the collateral vessels have a characteristic “puff-of-smoke” appearance. Children with Moyamoya disease present with ischemic events that may be provoked by straining or hyperventilation. Refractory headaches, seizures, and alternating hemiplegia are also associated with Moyamoya disease. Moyamoya is treated with surgical revascularization to improve blood flow via direct or indirect bypass procedures.

SPASTICITY

Spasticity in children is most often due to cerebral palsy, and several surgical options are available for treatment. In determining whether a child with hypertonia will benefit from surgical intervention, it is important to assess if dystonia is present as well and its contribution to the hypertonia, the ambulatory potential of the child, and to what extent the underlying spasticity is useful for the child in terms of providing strength and allowing them to support their own weight.

In addition to medication, orthopedic procedures, and periodic injections that are used to treat spasticity, the neurosurgical treatments for spasticity include placement of an intrathecal baclofen pump and selective dorsal rhizotomy (SDR). An intrathecal baclofen pump entails inserting a catheter into the intrathecal space and connecting it to a subcutaneous pump so that the antispasticity drug baclofen may be continuously delivered. Depending on at what spinal level the catheter tip is placed, upper and lower extremity spasticity may be treated. Intrathecal baclofen pumps are useful if the upper extremities are affected by severe hypertonia, if the tone conferred by spasticity is required for standing or walking, or if the lower extremity spasticity in nonambulatory patients is disabling and hinders care of the patients. Those patients who are ambulatory and whose spasticity primarily affects their lower extremities may be candidates for an SDR. It is thought that inputs entering the spinal cord through the dorsal roots have a net excitatory effect on the anterior roots, thus contributing to spasticity. The premise of an SDR is to intraoperatively stimulate lumbosacral dorsal nerve rootlets and record responses from the anterior nerve roots and muscles. This allows for the identification of those nerve rootlets that are relatively more involved into maintaining hypertonia, and such nerve rootlets are sectioned. SDR has been shown to improve ambulation, but the procedure does not confer previously nonambulatory patients the ability to walk.

PEDIATRIC TRAUMA AND BIRTH INJURIES

► General Principles

Head injury and its management are discussed elsewhere, and treatment principles used in the management of adult trauma also apply to the pediatric patient. Certain aspects of trauma that are unique to the pediatric population are highlighted. Head injuries are 30 times more common in children than spinal cord injuries, and they represent the most common cause of mortality and morbidity in children. In infants and young children, the brain and head are disproportionately large compared to the trunk and torso, and the neck and paraspinal musculature are incompletely developed. In children younger than 4 years, the skull is soft, unilaminar, and without diploë; as a result, it provides less protection to the brain for absorbing a traumatic impact and is more prone to fracture. Skull fractures in children can be linear, depressed, or ping-pong ball fractures. Ping-pong ball fractures occur in newborns and appear as a focal area of caved in skull that resembles a crushed ping-pong ball. No surgical intervention is required for ping-pong ball fractures in the temporoparietal region, as the growing skull will correct the deformity. Surgical elevation of a frontal ping-pong ball fracture may be considered for cosmetic purposes.

► Nonaccidental Trauma

Nonaccidental head trauma is the leading cause of death and morbidity in children less than 2 years of age. In shaken baby syndrome, there may be few signs of external trauma with significant neurological injury. Alternatively, the child may present with lethargy, irritability, poor feeding, apneic episodes, or seizures. Multiple skull fractures that are associated with underlying brain injury, bilateral chronic subdural hematomas or subdural hematomas of varying ages, subarachnoid hemorrhage, and retinal hemorrhages should raise the index of suspicion for child abuse. Subdural hemorrhages commonly occur along the bilateral convexities or in the posterior interhemispheric fissure. MR imaging is best at evaluating subdural hematomas of varying ages, as well as the extent of DIA that occurs with the acceleration-deceleration and rotational forces in shaken baby syndrome. A workup should include imaging of the brain and possibly spine, a skeletal survey to assess for long-bone or rib fractures, a funduscopic examination to check for retinal hemorrhages, and a thorough external exam to assess for bruising. Death from nonaccidental trauma is most often due to refractory intracranial hypertension.

► Spine Trauma

Spinal cord injury is relatively rare in the pediatric population and accounts for 5% of all spinal cord injury. The pediatric spine continues to develop throughout the first 2 decades of life. Ligamentous injury is more common than bony injury, owing to ligamentous laxity, immature supporting musculature, and the developing bony joints of the spine. The cervical spine is most commonly injured in children, and in children less than 9 years of age, two-thirds of cervical spine injuries occur between the C1 and C3 levels.

INTRACRANIAL ANEURYSMS AND ARTERIOVENOUS MALFORMATIONS

Aditya S. Pandey, MD Tristram Horton, MD John A Cowan, Jr, MD Neeraj Chaudhary, MD Joseph G. Gemmete, MD B. Gregory Thompson, MD

INTRACRANIAL ANEURYSMS

► General Considerations

Intracranial aneurysms (IAs) represent an abnormal dilation or expansion of an artery within the cranial vault. Autopsy studies suggest that IAs are present within 1%-5% of the population. Most epidemiologic studies suggest that CAAs are more common in women (3:2) and results in the clinical presentation of approximately 30,000-35,000 people annually in the United States. Aneurysms are categorized as saccular, fusiform, or mycotic, and can be ruptured, expanding, or unruptured. Aneurysms can be located anywhere within the cerebral artery tree but are most commonly located in the Circle of Willis. The specific type, status, and location of an IA can drastically affect a patient's clinical presentation, treatment options, and outcome. Intracranial aneurysms can be detected with a variety of imaging modalities, including cerebral angiography (Figure 36–21), computed tomography angiography (CTA), or magnetic resonance angiography (MRA). Patients with intracranial aneurysms should be referred to a neurosurgeon who specializes in the treatment of neurovascular diseases.

▲ **Figure 36–21.** An anterior view of left carotid artery cerebral angiogram demonstrating a large cerebral artery aneurysm (arrow) at the middle cerebral artery bifurcation.

Table 36–6. Hunt–Hess scale.¹

Grade	Findings
I	Mild headache or nuchal rigidity
II	Severe headache, nuchal rigidity, possible cranial nerve deficit
III	Lethargic, confused, mild focal deficit
IV	Stuporous, moderate to severe hemiparesis, early decerebrate posturing
V	Deep coma, decerebrate posturing, moribund

¹Adapted from: Hunt WE, Hess RM: Surgical repair as related to time of intervention in the repair of intracranial aneurysms. *J Neurosurg* 1968;28:14.

► Clinical Findings

A ruptured intracranial aneurysm typically presents as a sudden, severe headache associated with nuchal rigidity and lethargy. Patients often describe the headache as the “worst headache of my life,” however, sentinel (or smaller) bleeds may not present with such severity. Other features at presentation can include vomiting, seizure, focal neurologic deficit (eg hemiparesis, oculomotor palsy, etc), or coma. The Hunt–Hess grading scale is commonly used to convey the severity of symptoms and is often used to risk-stratify patients (Table 36–6). The Fisher and World Federation of Neurological Surgeons are other grading scales commonly employed for patients presenting with spontaneous subarachnoid hemorrhage (SAH), based radiographically and clinically, respectively. Approximately 10%-20% of patients die prior to reaching a hospital and the overall mortality rate approaches 30%-50%. The peak age of rupture is between 45 and 55 years. The rebleed rate of a ruptured intracranial aneurysm is approximately 25% at two weeks and 50% by 6 months. The mortality of a rebleed approaches 80%.

Since the cerebral arteries course within the subarachnoid space, aneurysm rupture results in SAHs. Subarachnoid hemorrhages have a classic appearance on computed tomography (CT) scans, where the blood fills the normal cerebrospinal fluid (CSF) spaces surround the cortex, brainstem, and cerebellum (Figure 36–22). The differential diagnosis of SAH includes aneurysm rupture, trauma, coagulopathy, pretruncal (or perimesencephalic) venous bleed, cranial/spinal AVM, or dural venous sinus thrombosis. Intracranial aneurysm rupture may cause intracerebral hemorrhage, subdural hemorrhage, and intraventricular hemorrhage.

Expanding IAs may or may present with symptoms of SAH. Patients with an expanding IA may exhibit neurologic symptoms consistent with focal compression. Though often not as dramatic a presentation as with rupture,

▲ **Figure 36–22.** Classic appearance of a large subarachnoid hemorrhage. Notice the hemorrhage pattern fills the cerebrospinal fluid spaces at the base of the brain and around the brainstem.

expanding CAAs should be treated as emergencies. The specific deficit at presentation is dependent on the location of the aneurysm. Aneurysms along the posterior communicating (PComm) artery, classically present with a third nerve palsy (pupil dilation, eye abducted, and downward in position). Aneurysms along the posterior cerebral artery, although rarer, can have such a presentation. Aneurysms on the anterior communicating (AComm) artery can present with signs of optic apparatus compression. Cavernous internal carotid artery aneurysms can produce oculomotor palsies with retro-orbital pain. Ophthalmic artery aneurysms can lead to unilateral vision loss. Giant aneurysms (> 2.5 cm) can lead to more pronounced symptoms, including hemiparesis, obstructed hydrocephalus, hypothalamic dysfunction, seizures, and brainstem compression due to mass effect.

With the increasing availability and resolution of neuroimaging modalities, the detection of unruptured (and often asymptomatic) aneurysms is increasing. Although controversial, the estimated rupture rate of an unruptured intracranial aneurysms is 0.1%-2% per year. The rupture risk is dependent upon a number of factors, including aneurysm size, shape, and location. Other factors, including the hypertension and smoking history, as well as genetic predisposition (female sex, family history of SAH, certain arteriopathies), also play an important role in estimating the risk of aneurysm growth and rupture. Given the potentially

devastating consequences of IA rupture, however, treatment of an unruptured IA should be considered in most cases.

► Treatment

A. Initial Management

A rapid history and physical examination of the patient including determination of the patient's airway, breathing, and circulation ("ABCs") should be performed in patients with a suspected ruptured intracranial aneurysm. Patients with unstable or unprotected airways or poor respiratory effort should be intubated and placed on mechanical ventilation. Maintenance of P_{CO_2} values between 28 and 32 mm Hg can help acutely lower intracranial pressure and this range promotes adequate cerebral perfusion. Blood pressure should be controlled with a ceiling level of 160/90 mm Hg, maintained as needed with intravenous medications. Prophylactic anticonvulsant and gastrointestinal (H_2 blocker or proton pump inhibitor) should be given as well. An arterial line and central venous line should be placed to further assist in management. Basic laboratory values needed include blood gas, complete blood count, coagulation function, sodium level, blood urea nitrogen, and creatinine. An electrocardiogram and chest x-ray should also be performed. Occasionally, patients presenting with SAH can exhibit signs and symptoms of pulmonary edema and/or heart failure requiring further intervention. Determination of the type and status of the CAA, via cerebral imaging, is paramount in dictating the remainder of the treatment algorithm. Demonstration of SAH on the initial head CT in patients with suspected CAA should be immediately followed by an assessment of the cerebral vascular tree (conventional angiography, CTA, etc). If the head CT does not demonstrate SAH and suspicion is high, a lumbar puncture can be performed. Typically, in the setting of CT-negative SAH, a lumbar puncture will reveal xanthochromia or high red blood cell counts that do not decrease (or "clear") across serial CSF samples. Cerebrospinal fluid diversion, typically through ventriculostomy, can be performed if the patient presents with hydrocephalus or has concerns for elevated intracranial pressure.

B. Surgical Management

Currently, two (three) main modalities exist for treating CAAs: surgical clip occlusion and endovascular coiling, and more recently, endovascular flow diversion. Surgical clip occlusion requires an open craniotomy and microsurgical dissection to the base of a CAA in order to apply a surgical clip around the neck of the aneurysm. In some cases, the aneurysm may require trapping and bypass (either surgical or endovascular) for treatment. Endovascular coiling utilizes a similar approach as conventional angiography and is thus less invasive. The endovascular surgeon navigates a microcatheter

to the aneurismal defect and inserts detachable coils into the aneurysm dome. These coils promote thrombus formation and thus exclude the aneurysm from the native circulation.

The decision between clipping or coiling a CAA is complex and beyond the scope of this text. Factors considered in this decision include a patient's age, overall medical condition, and preference as well as the aneurysm's size, location, and morphology and the ruptured versus unruptured status of the aneurysm. To date, one trial has attempted to compare the two approaches for a very select group of ruptured CAAs. The study concluded that endovascular coiling resulted in slightly less morbidity and mortality at one year follow-up. The three randomized prospective trials comparing clipping and coiling have all found coiling to have lower risk of unfavorable outcome compared to clipping in the treatment of ruptured intracranial aneurysms. One study found clipping to be superior to coiling, with a significantly higher increased risk of death or readmission secondary to rebleeding in patients treated endovascularly. However, this study was limited by its retrospective cohort design. Case series with long-term follow-up have demonstrated some increase in rebleeding and/or the need for further treatment with endovascular coiling as compare to clip occlusion. More recent studies have shown a decrease in the recurrence and rebleeding rate after endovascular treatment of intracranial aneurysms. One study found that rebleeding rate was a function of degree of aneurysm occlusion on initial treatment, rather than the treatment modality itself.

C. Medical Management

The medical management of patients who undergo either surgical clip occlusion or endovascular coiling for a ruptured CAA is particularly challenging. Patients require recovery in an intensive care setting that has particular expertise in neurological conditions. Once an aneurysm has been secured the blood pressure parameters are loosened and "permissive" hypertension is allowed (typically do not treat unless SBP > 200 mm Hg). Early tracheostomy and enteral feeding tubes are placed in patients who have neurologic deficits affecting respiratory or swallowing function. Patients are typically placed on Nimodipine, which has been demonstrated to slightly decrease postoperative vasospasm. Magnesium sulfate infusions are used in some centers for prevention of vasospasm although the data for this, while promising, is emerging.

Vasospasm is an idiopathic response of cerebral blood vessels to subarachnoid blood whereby the vessel constricts thus limiting distal blood flow. The peak time for vasospasm occurs between 4 and 14 days postbleed. Approximately 20%-40% of patients with have symptomatic vasospasm with 30% of those suffering a permanent neurologic deficit. Vasospasm can occur anywhere along a vessel and in vessels distant from the treated aneurysm. Patients can exhibit significant neurologic

sequelae from vasospasm such as hemiparesis, aphasia, visual disturbance, etc depending on the particular vessel affected. Subtle findings including elevation in temperature and mental status changes can be harbingers of vasospasm. Vasospasm is typically treated using a regimen referred to as "triple H" therapy. This therapy involves hypertension (using vasopressors if needed to achieve SBP > 180), hemodilution (achieve hematocrit ~30%), and hypervolemia (using albumin or hypertonic solutions to achieve CVP 8-14 mm Hg). Cerebral angioplasty is an effective means for treating proximal constriction and is a first line treatment for symptomatic patients. Distal or diffuse spasm can respond to injection of calcium-channel blockers (eg, verapamil and nicardipine) papaverine, or milrinone (a phosphodiesterase-3 inhibitor) through a super-selective microcatheter.

► Outcomes/Prognosis

For elective surgical clip occlusion or endovascular coiling, mortality rates (1%-2%) and morbidity rates (5%-10%) are relatively low. Risk factors for poor outcome would include aneurysm location, size, and presence of intraoperative rupture as well as other comorbid conditions (eg, coronary artery disease, diabetes, age, etc). In patients presenting with SAH, patient age, comorbid conditions, and Hunt-Hess grade are the strongest predictors of outcome. Overall, for patients stable enough for surgical intervention, mortality rates range from 10% to 20% with morbidity rates of 20%-40%.

▶ Arteriovenous Malformations

Key concepts:

1. Congenital, abnormal connections of arteries and veins without intervening capillaries
2. Annual rupture risk of brain AVM's is 2%-4% per year
3. Treatment may be surgical, endovascular, or with radiosurgery and is performed to prevent intracranial hemorrhage
4. In some instances, observant management may be appropriate

▶ General Considerations

AVMs are tangles of congenital abnormal connections between artery and vein with no normal intervening capillary bed. Ninety percent of AVMs are found in the supratentorial space with the remainder found in the brainstem and spine. AVMs can present at any time but are more common in younger patients. Vascular malformations are commonly seen in neurosurgical practice and with modern imaging techniques are increasingly diagnosed in asymptomatic patients being evaluated for headaches or after minor head trauma. Because of this, as well as their risk of rupture and the high morbidity associated with intracranial hemorrhage, it is important that all acute care physicians be aware of their presentation, initial management, and treatment of these lesions.

▶ Epidemiology and Presentation

As many AVMs are asymptomatic, it is difficult to absolutely determine their prevalence. Autopsy data estimate that AVMs occur in less than 1%-4% of the population. A limited number of population-based studies have been conducted to study the natural history and bleeding risks in patients with AVMs. In counseling patients, the following formula has been used to estimate lifetime of intracranial hemorrhage due to AVM rupture:

Lifetime risk (%) = 105 – patient age in years

Hemorrhage is the most common presentation, occurring in over 50% of patients. Because of this, many patients with AVMs are initially evaluated in the emergency department. Seizures and headaches are also frequent, especially with larger lesions. Spinal AVMs may cause back or radicular pain, lower extremity weakness, gait disturbance, or incontinence. Large AVMs with high-volume venous drainage can cause steal phenomena; focal neurologic deficits may result from decreased tissue perfusion of surrounding brain. Increasingly, patients are referred after AVM's are found incidentally by computed tomography (CT) or magnetic resonance imaging (MRI).

▶ Initial Evaluation & Care

The initial evaluation of AVMs depends upon the patient's presentation. Many patients who present with rupture are stable, neurologically and medically. The majority of intracranial bleeding from AVM rupture is intraparenchymal. Although there may be an aspect of subarachnoid hemorrhage, it is rare to see isolated subarachnoid hemorrhage in the setting of AVM rupture. In contrast to aneurysmal subarachnoid hemorrhage, where the presence of clot in the subarachnoid space is often immediately devastating, AVM bleeds are less likely to cause death. Also in contrast to aneurysmal subarachnoid hemorrhage, vasospasm is a relatively rare event with AVM associated hemorrhage. This is not to suggest a ruptured AVM is a minor problem—mortality associated with a single hemorrhage is estimated at 10% and morbidity 30%. However, the heterogeneous nature of presenting complaints in patients with AVMs helps explain why the initial approach to patients with AVM's varies from those with aneurysms, especially in the acute setting.

In ruptured patients, after ensuring the fundamentals of emergency care—airway, breathing, and circulation—are addressed, a complete neurological evaluation should be performed. Neurosurgical consultation is appropriate. Blood pressure should be maintained in the normal range. In any patient with suspected intracranial hemorrhage, a noncontrast head CT should be obtained as soon as possible. Depending upon physician and institutional preferences, CT angiography (CTA) or conventional diagnostic angiography (Figure 36–23) may then be performed to further evaluate the angiographic architecture of the AVM and to guide treatment. MR angiography (MRA) takes longer to obtain than CTA and the angiographic image quality, in our opinion, is suboptimal when compared to CTA; it is not routinely used in the acute setting.

With an initial CT scan that appears consistent with AVM rupture, a standard approach includes conventional angiography. This provides the neuroendovascular team the potential to proceed with AVM embolization during the same procedure as the diagnostic angiogram. Alternatively, for small or deep AVMs, CTA may be appropriate, as these types of lesions are often treated with radiosurgery and the risks of diagnostic angiography may be avoided. In some instances, CTA may not provide a sufficiently clear picture of the AVM and conventional angiography will need to be performed. In this case, it is important to closely monitor renal function due to the multiple contrast dye loads. Adequate hydration with intravenous fluids is important, and in patients with renal insufficiency, bicarbonate infusion and Mucomyst are useful for renal protection. Any patient with intracranial hemorrhage, even those who are neurologically intact, should initially be admitted to the neurosurgical intensive care unit for close monitoring with hourly neurologic examinations.

▲ **Figure 36–23.** Cerebral angiogram demonstrating a frontal arteriovenous malformation filling from the left anterior cerebral artery.

In patients presenting with seizures or those with large bleeds and mass effect, treatment with antiepileptic medication is appropriate. Phenytoin or Keppra are effective in the acute setting for seizure prophylaxis.

An important concept when discussing brain AVM treatment options and prognosis with patients and the multiple physicians who may care for patients with these lesions is AVM grade. Grading is most often performed using the Spetzler–Martin scale (Table 36–7). Points are assigned based upon size (< 3 cm, 1 point; 3–6 cm, 2 points; or > 6 cm, 3 points), venous drainage (superficial, 0 points; or deep, 1 point), and eloquence (absent, 0 points; present, 1 point) of the surrounding brain, yielding Grades of I–V. The size and venous drainage categories are straightforward; eloquent areas are defined as the sensorimotor, language, and visual cortex; the thalamus and hypothalamus; the internal capsule; the brainstem; the cerebellar peduncles; and the deep cerebellar nuclei. AVM grade correlates with surgical results.

► Treatment

Four options currently exist for the treatment of AVMs. They are endovascular embolization, microsurgical resection, SRS, and observant management. Treatment often employs a combination of these approaches. AVMs should be treated in referral centers with significant experience. There is no treatment algorithm for these complex lesions.

Table 36–7 Spetzler–Martin AVM grading scale.

Graded Feature	Points Assigned
Size of AVM	
< 3 cm	1
3–6 cm	2
> 6 cm	3
Eloquence¹ of adjacent brain	
Noneloquent	0
Eloquent	1
Venous drainage	
Superficial	0
Deep	1

¹Eloquent areas include: visual, language, and sensorimotor cortex; the thalamus and hypothalamus; the internal capsule; the brainstem; the cerebellar peduncles; and the deep cerebellar nuclei.

Multiple variables intrinsic to the AVM or the patient have been implicated as making certain lesions higher risk for bleeding; most of these are controversial. It is important to evaluate each patient individually, preferably with a multidisciplinary team of vascular neurosurgery, interventional neuroradiology, and radiation oncology. Multiple factors must be considered prior to recommending treatment, including AVM grade and location (for surgical safety), angiographic architecture and presence of reachable arterial pedicles (for endovascular safety), and the ability of the patient to safely tolerate an invasive procedure. Patient preference is also important, especially when considering radiosurgery. Treatment is primarily performed because of intracranial hemorrhage—to prevent an initial or recurrent hemorrhage, or to evacuate the intracranial clot that occurs after AVM rupture. Secondary treatment goals include the relief of mass effect causing headache or seizures.

A. Endovascular Embolization

The goal of endovascular embolization for AVMs is usually to reduce the size of the nidus and risk of bleeding during microsurgical resection or to reduce the size of the AVM prior to radiosurgery. However, in some cases (10%–20%) complete cure can be achieved with embolization alone. It is important to appropriately counsel patients prior to AVM embolization that if complete occlusion of the AVM cannot be achieved, further treatment with surgery or radiosurgery is necessary as incompletely embolized AVMs may have a higher risk of bleeding.

B. Microsurgical Resection

As complete obliteration is the only way to cure an AVM, microsurgical resection for small, superficial lesions is the

gold standard by which all other treatment modalities are measured. Most neurosurgeons agree that Spetzler–Martin Grade I–III AVMs on the cerebral convexity should be surgically resected. Complication rates associated with these lesions are low, when they are operated on by neurosurgeons with significant experience. Spetzler and Martin retrospectively reported the risk of minor and major neurologic deficit and death in a series of 100 patients with Grade I–V AVMs. For Grade I patients, risk of minor and major deficit was 0%; Grade II AVMs carried a 5% risk of minor deficit and 0% risk of major deficit; Grade III lesions had a 12% risk of minor deficit and 4% risk of major deficit. There were no deaths. Complication rates are higher for Grade IV and V AVMs. Grade IV AVMs carried a 20% risk of minor deficit and 7% risk of major deficit. With Grade V lesions, risks of minor and major deficit were 19% and 12%, respectively. The prospective application of the Spetzler–Martin scale in 120 patients revealed permanent, major neurological deficits in 0% of Grade I–III patients, 21.9% of Grade IV patients, and 16.7% of Grade V patients. The relatively high risk of neurological deficit in Grade IV and V patients make recommending surgery for these lesions a difficult decision. As endovascular technology has improved, however, some of these lesions may be approached endovascularly first, with the goal of attempting to reduce the size of the AVM prior to surgical resection.

C. Stereotactic Radiosurgery

Radiosurgery is an excellent treatment modality for many AVMs, especially those located in deep locations of the cortex or lesions of the basal ganglia, thalamus, or brainstem that are not easily approachable from a microsurgical or endovascular standpoint. SRS is also indicated for patients with significant medical comorbidities and can be used if an AVM is subtotally resected. In general, SRS works best for AVMs less than 3 cm in size. In patients with AVMs larger than 3 cm, preradiosurgical embolization may be used to reduce the size of the nidus. The complete obliteration rate after SRS is 90% with small AVMs. The primary disadvantage of SRS is the 2–3 years it takes for the AVM to involute. During that period, the patient remains at baseline risk of hemorrhage (~4%) from AVM rupture.

D. Observant Management

Although this is not the opinion of the vast majority of neurosurgeons and neurointerventionalists, there are occasions when conservative management is indicated. Older patients with comorbid conditions may not benefit from aggressive management. Because of the risk of complications during open or endovascular operations with Grade IV and V AVMs, and because of the reduced rate of complete obliteration after radiosurgery for large lesions, some surgeons advocate conservative treatment for these AVMs.

► Postoperative Care

Patients who have undergone endovascular or open operations should be observed postoperatively in an ICU until it is certain they are neurologically stable. Typically, patients are sent to the ward on postoperative day one from microsurgical resection. Postembolization patients are usually discharged home after an overnight stay. Complications after microsurgical resection include the usual postcraniotomy difficulties such as bleeding and seizures. Hydrocephalus can also occur, especially in patients who present with ventricular blood as part of an initial intracranial hemorrhage. Complications to keep in mind after embolization include stroke, renal insufficiency, and groin hematoma. Creatinine and hematocrit should be monitored. Any patient with unstable vital signs or decreasing hematocrit after embolization should be assumed to have a retroperitoneal hematoma, should undergo abdominal CT scanning and be treated aggressively.

After AVM resection, a phenomenon known as normal perfusion pressure breakthrough can occur. As the pathological shunting of blood through the AVM nidus is removed, relative increases in blood flow to the surrounding blood vessels and brain occurs. As these blood vessels are often chronically dysregulated by the relative lack of blood flow caused by the AVM, hemorrhage can result when blood flow returns to normal. One similarly dangerous potential complication after partial embolization is AVM rupture. In general, endovascular neurosurgeons and interventionalists do not embolize more than 1/3 of an AVM at a time. This is because with larger embolizations, dramatic changes in blood flow to the AVM can occur, effectively overwhelming the pathologic vessels remaining, causing hemorrhage. For these reasons, in both instances, patients must be carefully observed postoperatively. Also, it is critical that blood pressure remain in the normotensive range for at least 24 hours posttreatment.

► Spinal Arteriovenous Malformations

Spinal AVMs are divided into 4 types: (1) dural arteriovenous fistulas; (2) glomus AVMs; (3) juvenile intradural AVMs; and (4) intradural, extramedullary arteriovenous fistulas. Types 1 and 4 have high blood flow but low pressure; types 2 and 3 have high blood flow, high pressure and are more likely to hemorrhage. Dural arteriovenous fistulas (type 1) are the most common spinal vascular malformation seen. They typically occur near the thoracolumbar junction and consist of a single transdural arterial feeding vessel that directly connects to an intradural arterialized vein. Embolization of the feeding artery, or clip placement across the artery, is curative. Symptoms from spinal AVMs may be due to hemorrhage or venous congestion. Acute or subacute lower extremity neurological deficit, gait difficulties, myelopathy, or loss of bladder or bowel control may result. Initial diagnostic evaluation should include spinal MRI/

MRA. Patients with spinal vascular malformations should also undergo cranial imaging to ensure vascular abnormalities of the brain are not present. In patients with negative imaging, spinal angiography is performed.

► Summary

Arteriovenous malformations within the central nervous system are rare. However, with advances in imaging, an increasing number of these lesions are being diagnosed. Arteriovenous malformations are congenital tangles of direct arterial-venous connections that place patients at risk of hemorrhage of approximately 2%-4% per year. The morbidity and mortality associated with intracranial hemorrhage is high and the most patients with AVMs are young. Because of this, treatment is often recommended to prevent intracranial hemorrhage, or to relieve mass effect causing seizures, headaches, or other neurologic deficits. Treatment options include endovascular embolization, surgical resection, SRS, or a combination of these. With an experienced team of neurosurgeons, interventionalists, and radiation oncologists, treatment can be accomplished with minimal risk. In a minority of cases, observant management may be appropriate.

SURGICAL MANAGEMENT OF MEDICALLY INTRACTABLE REFRACTORY EPILEPSY

J. Nicole Bentley Oren Sagher

KEY CONCEPTS

- Understand the prevalence, varied etiologies, and broad classification of epilepsy
- Describe the various diagnostic modalities for epilepsy
- Recognize that focal and lateralizing epilepsy is more amenable to surgery
- Recognize that mesial temporal sclerosis is highly epileptogenic with very favorable outcomes following surgical resection
- Appreciate palliative and curative surgical treatments for epilepsy

INTRODUCTION

Epilepsy is a disease affecting 1% of the world's population, and is characterized by a wide range of phenotypes and physical manifestations. The underlying pathology giving

rise to epilepsy is equally varied, resulting in a disease that is challenging both to classify and to treat.

Epilepsy is a syndrome of recurrent seizures, the onset of which is due to abnormal neuronal synchronization. The locus of misfiring characterizes a seizure's semiology, or external signs, and may propagate to surrounding areas. Medical management involves pharmacotherapies and occasionally, alternative therapies, such as dietary restrictions, to reduce seizure frequency. However, one-third of patients are refractory to these therapies. Many studies have demonstrated the efficacy of surgery in cases of failed medical management, and have repeatedly shown that early surgery in appropriate candidates provides the greatest benefit. This chapter will focus on the workup and surgical options in these patients.

CLASSIFICATION

Seizures are classified by their association with alteration in consciousness; "simple" seizures are defined as those that occur in the setting of retained awareness, and "complex" seizures result in loss of awareness. Further classification relies on the locus of seizure onset. If focal, the seizure is considered "partial," and may be characterized by a stereotypical movement, such as lip smacking or eye deviation. Primary generalized seizures, on the other hand, are considered to affect the entire brain *at their onset*. Primary generalized epilepsy is usually secondary to a genetic derangement in cell membrane function. A localized group of misfiring neurons may also give rise to *auras*, or sensory forewarnings, heralding an oncoming seizure. Examples of auras include a taste or light perception, or paresthesias. A partial seizure may spread within the brain—a process known as secondary generalization.

DIAGNOSIS

Several modalities are employed in the diagnosis of epilepsy. These include clinical examination, neurophysiology, imaging, and neuropsychologic assessments.

► Clinical Examination & Laboratory Assessment

The clinical symptomatology associated with the epilepsy is a critical component of the diagnosis of epilepsy, and is called its semiology. Symptoms during the time of seizure may provide localizing clues to the region of onset. For example, seizures starting with motor twitching of the upper extremity are likely to be caused by a lesion in the vicinity of the primary motor cortex. Past medical history of febrile seizures or encephalitis are associated with risk of epilepsy. In addition, family history of epilepsy appears to be a strong risk factor in the development of epilepsy. Finally serum metabolic studies should be undertaken in order to rule out potentially reversible entities. Such studies include fast-

ing blood glucose, serum electrolyte panel, complete blood count, and erythrocyte sedimentation rate, renal and hepatic functional assays. In patients where historical data and the clinical examination point to an intoxicating entity, applicable urine and serum toxicology assays should be obtained.

► Electrophysiology

The standard modality for recording brain activity is the scalp electro-encephalogram (EEG). EEG recordings are usually obtained both between and during seizures. In some instances, patients undergo long-term monitoring with video EEG where seizure semiology can be assessed together with EEG pattern. Generally, the presence of lateralized or localized seizures is suggestive of a focus that may be amenable to surgical resection. In patients whose seizure localization cannot be demonstrated convincingly by scalp EEG, intracranial EEG electrodes may be placed. These electrodes can either be placed on the surface of the brain (subdural electrodes) or within the substance of the brain (depth electrodes). Subdural electrodes register surface cortical activity, while depth electrodes can provide information related to deep structures such as the hippocampus.

► Imaging Studies

MRI is the usual imaging study of choice for evaluating patients with epilepsy. Structural lesions such as tumors, vascular malformations, or dysplastic cortex can be easily identified on MRI. Highly epileptogenic entities such as mesial temporal sclerosis with hippocampal atrophy can also be detected with high resolution MRI scans, as demonstrated in Figure 36–24.

Nuclear medicine studies such as positron emission tomography (PET) and single photon emission computed tomography (SPECT) scans can serve as complementary diagnostic tests. These tests are especially useful when the MRI and EEG do not correlate. PET studies demonstrate metabolic activity within the brain, while SPECT studies reflect regional blood flow patterns at the time of tracer injection. SPECT studies performed at the beginning of a seizure often demonstrate increased flow to areas involved in seizure onset. Alternatively, PET studies performed between seizures are more likely to demonstrate hypometabolism within epileptogenic foci. Both studies are useful for patients with focal epilepsy who have normal MRIs, or in whom the site of seizure origin is uncertain.

Magnetoencephalography (MEG) is a functional imaging technique that can accurately provide information on synchronized electrical activity in the brain. MEG detects the magnetic dipole equivalents of electrical current. In addition, it has the advantage of providing a three-dimensional localization of neuronal activity. Finally, there is accumulating data to suggest a high correlation between MEG and intracranial seizure localization.

▲ **Figure 36–24.** Coronal MRI of the brain demonstrating right mesial temporal sclerosis with associated atrophy of the right hippocampus and prominence of the temporal horn of the right lateral ventricle.

► Neuropsychological Examination

Neuropsychological evaluation is an important component of the epilepsy workup. Patients should undergo a battery of standardized neuropsychological tests assessing verbal and nonverbal intelligence, memory, executive functions, and behavioral functions. These tests often point to subtle deficiencies that accompany the presence of a seizure focus. In addition to these tests, patients may undergo more invasive neuropsychological tests such as the **Wada test**. The Wada test involves selective injection of a fast-acting barbiturate such as amobarbital into each hemisphere via the carotid artery while memory and language functions are tested. The goal of the Wada test is to assess language and memory dominance. If the Wada test suggests that a significant amount of language function is subserved by the diseased hemisphere, then surgical resection may result in significant deficits.

SURGICAL SELECTION

In general, patients with structural lesions such as tumors and vascular malformations should be managed primarily with surgical resection. Additionally, patients for whom medical therapies have failed to produce an adequate response should be considered for surgery. A consensus definition of medical failure has recently been published, and is defined as failure of two or more antiepileptic drugs

to reduce seizures to a clinically meaningful level, assuming that appropriate doses and regimens have been used. The likelihood of attaining seizure-freedom with pharmacotherapies once two drugs have failed has been shown to be consistently low, less than 5%.

Evidence suggests that early surgical intervention improves outcomes. Delays in surgery may result in encephalopathy, psychosocial abnormalities, learning disabilities, and risk of seizure-related injuries. Additionally, a condition known as SUDEP, or sudden unexpected death in epilepsy, affects a significant number of patients suffering from epilepsy, presumably occurring secondary to cardiorespiratory compromise. With surgical success, patients can be gradually weaned off anticonvulsants, thereby sparing them of the deleterious long-term effects of these medications. However, in patients with epileptogenic foci within the eloquent cortex, the risk of postsurgical deficits must be considered against the probability of rendering the patients seizure-free. Ultimately, the decision to recommend surgery is made by a multidisciplinary team consisting of epileptologists, neurosurgeons, radiologists, neuropsychologists, and social workers.

GOALS OF SURGERY

Surgical procedures can be viewed as either curative or palliative. Curative procedures are designed for patients with seizures convincingly localized to a specific cortical region which is safe to remove. The goal in curative surgery therefore is complete resection of the affected cortex, and procedures include anterior temporal lobectomy, selective amygdalohippocampectomy, neocortical resections, and hemispherectomy. Palliative surgery is employed in situations where a seizure focus is either not identified or cannot be safely removed. For example, patients with congenital syndromic epilepsies such as Lennox-Gastaut syndrome experience life-threatening generalized seizures for which there is no identifiable focus. The goal of palliative surgery therefore is reduction in seizure frequency and severity. Common palliative procedures include placement of a vagus nerve stimulator and corpus callosotomy.

SURGICAL TECHNIQUES

► Temporal Lobectomy

The most common cause of drug-resistant epilepsy is mesial temporal sclerosis. Among its several radiographic features, this entity is characterized by hippocampal atrophy on MRI, however, the relationship between the presence and timing of MRI abnormalities and pathophysiology remains poorly understood. While abnormalities on MRI are not an absolute necessity for successful temporal lobectomy, rates of seizure-freedom are lower. Consensus guidelines have recommended that patients who are medically refractory

to drug therapy, having failed two or more appropriately prescribed anticonvulsants, should be evaluated by a multidisciplinary epilepsy surgery center.

The surgical technique involves a temporal craniotomy with en bloc resection of 3.5 cm (dominant) or 4 cm (non-dominant) of the lateral temporal lobe. En bloc resection of the amygdala, parahippocampal gyrus, and hippocampus is also performed. The long-term seizure-free outcomes are around 60%-80%, with strong trends toward improved quality of life in surgical groups. Though studies have been limited by small sample sizes, there are several well-designed trials that continue to support surgery for appropriate candidates, with a safety profile similar to medically treated groups.

Potential complications include minor visual field deficits and deficits with short-term memory.

► Selective Amygdalohippocampectomy

As mentioned earlier, the extent of surgical resection is limited in mesial temporal sclerosis of the language-dominant hemisphere. However, minimally invasive techniques have been developed that spare more of the overlying temporal cortex, minimizing damage to the language pathways. This “selective” procedure involves resection of the amygdala and hippocampus via a temporal craniotomy. The approach to these structures is variable, either through a slit in the temporal lobe cortex or through the sylvian fissure. A comparison of the standard anterior temporal lobectomy to selective amygdalohippocampectomy found that seizure freedom was comparable in the two groups, with 85.2% and 93.1% of patients experiencing seizure-freedom at 3-years, respectively. Potential complications are similar to nonselective lobectomies.

► Extratemporal Resections

These procedures are performed in patients with focal epilepsy arising outside the temporal lobe. The frontal lobe is the most common location for such resections. In light of the potential overlap with functional areas, resection is often limited and seizure-free outcome is not as favorable as that seen in temporal lobe epilepsy, averaging approximately 50%. Surgery entails a craniotomy with resection of cortex, at times guided by intraoperative EEG recordings. Complications are contingent upon associated eloquent areas involved.

► Hemispherectomy

The hemispherectomy or functional hemispherotomy involves surgical resection or disconnection of one hemisphere from the other. The procedure is used in patients with diffuse unilateral hemispheric seizures that typically result in a neurologically devastated or nonfunctional hemisphere. Hemispherectomy

can control seizures in about 70%-90% of patients, with the best outcomes being reported in Sturge-Weber syndrome, Rasmussen's Encephalitis, and porencephaly. In properly selected cases, function is preserved with associated improvements in cognitive, behavioral, and motor domains.

As originally described, hemispherectomy entailed complete removal of half of the brain. This was fraught with progressive postoperative neurological deficits secondary to deposition of iron over the brain (superficial cerebral hemosiderosis). In light of these problems, a modified functional hemispherectomy has replaced the anatomic hemispherectomy. This procedure involves disconnecting the corpus callosum and the various interhemispheric commissures. The major risks include hemorrhage, damage to functioning cortex, persistent seizures, disseminated intravascular coagulation, and transient decrease in contralateral muscle tone.

► Corpus Callosotomy

This procedure is palliative and is utilized in situations where patients have diffuse epileptogenic foci involving both hemispheres. Sectioning the corpus callosum prevents interhemispheric propagation of seizures and is used in both pediatric and adults, with varying extent of sectioning based on patient age and EEG. The procedure typically involves resection of the anterior two-thirds of the corpus callosum, with the option of further resections if seizures persist. Efficacy of the procedure is greatest in drop attacks that cause sudden atonic attacks, with a reported response of 88%. Less responsive seizure types include generalized tonic-clonic, absence, complex partial, and simple partial, with success ranging from 14% to 40%.

► Multiple Subpial Transections

This procedure is indicated for patients with seizure foci within functionally important cortex, such as primary motor cortex. The procedure is palliative, with reported efficacy ranging from 33% to 46%. Shallow vertical transections are created across cortical gyri, disrupting the horizontal connections believed to propagate seizures between vertical columns of cells. The procedure is often performed with cortical resections, which has limited the ability to conclusively define outcomes in many studies.

► Vagus Nerve Stimulation

The vagus nerve stimulation (VNS) is a relatively low-risk surgical procedure that decreases seizure frequency in patients whose disease is not safely amenable to resection. The exact mechanism by which this technique curbs epilepsy is unknown, but may be due to innervation of the nucleus solitarius which sends fibers to hemispheric regions involved in seizure onset. The stimulator electrode is placed along the vagus nerve in the neck, which is then

connected to a generator implanted on the anterior chest wall. In multi-institutional double-blinded, randomized controlled trials, a reduction of seizure frequency of 24%-31% has been reported. A greater response was seen in the pediatric population, with a seizure reduction rate of 50%-90%. Although not considered a curative, intervention, 2% of patients become seizure-free. The main risks of the procedure include injury to the vagus nerve, carotid artery, and jugular vein; however, this remains a low-risk intervention in comparison to other surgical modalities.

► Stereotactic Radiosurgery

The application of highly focused irradiation to specific brain regions, known as radiosurgery, has been used to treat a wide variety of brain lesions such as tumors and vascular lesions. The role of radiosurgery in seizure control has been fairly limited. However, it has been proposed as a potential treatment of deep-seated seizure foci, such as hypothalamic hamartomas, which are benign malformations in the hypothalamus associated with gelastic epilepsy. Surgical resection in this location is fraught with risk, and it appears that radiosurgery may be used more safely in this subset of patients.

FUTURE DIRECTIONS

Many avenues of surgical treatment for refractory epilepsy are being developed in response to advancements in technology. One example is a closed-loop system implanted into the brain that detects seizure onset and automatically responds by delivering pulsed stimulation to the focus. Preliminary trials have reported seizure reductions of 50%-75%. Stimulation of the anterior nucleus of the thalamus has also been shown to result in seizure reduction, though the mechanism is poorly understood. Stem-cell therapies, gene therapies, and advances in neuronal visualization are also providing tools that increase the understanding and successful treatment of refractory epilepsy.

SURGICAL MANAGEMENT OF PAIN

Arnold Etame Parag G. Patil

The subjective, emotional, and physical components of pain make its management complex. Hence, pain management is an interdisciplinary endeavor encompassing medical, surgical, and psychological treatment modalities. Surgery for pain should be reserved for patients who have been unresponsive to therapies directed toward the inciting processes and to oral pain medications.

Pain may be classified as *nociceptive or neuropathic*. Nociceptive pain results from tissue injury. Common characteristics include constant aching or throbbing and responsiveness to opiate medications. Neuropathic pain is initiated or caused by a primary lesion or dysfunction in the nervous system. Common characteristics include burning, allodynia, and paresthesias. Neuropathic pain responds poorly to opiate medications. Pain surgeons should be familiar with these concepts to assess medical intractability.

The aim of surgery is to interrupt pain signaling pathways. Ablative surgical techniques involve physical interruption through the destruction of neural tissue. Nonablative procedures involve functional interruption through the modulation of pain transduction mechanisms.

ABLATIVE PROCEDURES TO INTERRUPT AFFERENT PAIN PATHWAYS

Neurosurgical procedures to physically interrupt pain signaling have been directed toward the nerves (neurectomy), spinal roots (rhizotomy), dorsal root ganglia (ganglionectomy), dorsal root entry zone (DREZ lesioning), spinal cord (cordotomy, myelotomy), and cerebral cortex (cingulotomy). Ablative surgery for pain is most often utilized in the treatment of cancer-related, nociceptive pain, as long-term analgesia is less commonly observed for these procedures.

► Neurectomy

Neurectomy involves cutting an injured nerve or the nerve to a painful region. Target nerves are identified on the basis of local anesthetic blockade. Denervation of joints, distal sensory nerves, and neuroma surgery are examples of peripheral neurectomy. Neurectomy is not typically utilized for cancer-related pain because of the changing pain distribution with tumor growth. Reported success rates for pain control with neurectomy vary widely between 40% and 90%.

► Rhizotomy & Ganglionectomy

Rhizotomy and ganglionectomy target the dorsal sensory rootlets or ganglia, respectively. Spinal cord segments are identified through paraspinous local anesthetic blockade, with placebo controls. The procedures are utilized most commonly for cancer-related regional pain or occipital neuralgia. These procedures are rarely utilized in the treatment of extremity pain because of functional impairment resulting from the loss of proprioception. Successful longer term pain control has been reported in 40% to 70% of patients.

► Dorsal Root Entry Zone Lesioning

Dorsal root entry zone surgery targets the superficial dorsal horn region, where sensory fibers enter the spinal cord. Levels including and flanking the region of interest, as defined by imaging studies or pain distribution, are typically ablated. A knife or radiofrequency heating is used to make the lesion. Dorsal root entry zone surgery is most effective in the treatment of neuropathic pain following nerve root avulsion and at-level spinal cord injury pain. Risks of surgery include injury to descending motor pathways and decreased sensory function in the territory of the ablated region. In carefully selected patients, rates of successful pain control range from 70% to 90%.

► Cordotomy & Myelotomy

Cordotomy is a spinal procedure to interrupt pain transmission along the lateral spinothalamic tract. Cordotomy is most commonly performed in patients with intractable, unilateral, nociceptive cancer pain at the level of the chest or below. The procedure may be performed either with a knife or with radiofrequency heating. Risks of surgery include lower extremity weakness, ataxia, and respiratory or urinary dysfunction. These risks are significantly increased when cordotomy is performed bilaterally.

Midline myelotomy involves destruction of the mesial dorsal columns at a single spinal level to treat midline, bilateral, or visceral pain. The procedure typically preserves dorsal column and spinothalamic signal transmission. Risks include transient lower extremity paresthesias and weakness.

Rates of successful pain control with cordotomy and myelotomy are initially high (> 80%) but decline over time (40% at 2 years).

► Cingulotomy

Unlike procedures directed along pathways of pain neurotransmission, cingulotomy is directed toward alteration of the experience of pain. Because the cingulate gyrus is part of the limbic system, radiofrequency ablation of the anterior cingulate gyrus reduces the affective, unpleasant aspects of pain, particularly in patients with obsessive and affective components to their pain. Cingulotomy is performed in relatively few centers and only in carefully selected patients. Following cingulotomy for intractable, cancer-related pain, over 50% of patients have been reported to have moderate to complete pain relief.

PROCEDURES TO MODULATE AFFERENT PAIN PATHWAYS

► Intrathecal Analgesic Delivery Pumps

When compared to oral narcotics, intrathecal administration of morphine provides more potent analgesia with reduced side effects, such as nausea, constipation, and sedation. To benefit from intrathecal delivery, patients should have significant reduction in pain level with oral opiates, limited by intolerable side effects.

Analgesics such as morphine are delivered through a catheter placed into the cerebrospinal fluid of the spinal canal. The catheter tubing is then connected to an external or surgically implanted pump. External pumps are utilized in patients with cancer-related pain and expected survival of less than 3 months. Principal complications of intrathecal drug delivery include the side-effects of the medication, mechanical failure of the system, and infection.

Intrathecal drug delivery may be effective in either nociceptive or neuropathic pain syndromes. However, as with oral opiate administration, long-term tolerance to medications can develop. Hence, these devices are most beneficial for patients with cancer-related pain syndromes and limited life expectancy.

► Peripheral Nerve & Spinal Cord Stimulation

Peripheral nerve and spinal cord stimulators deliver pulses of electricity to injured nerves or the dorsal columns of the spinal cord, respectively. According to the gate theory of pain, such stimulation blocks the flow of pain signals from the periphery to the brain.

Peripheral nerve stimulation is most effective in neuropathic peripheral nerve syndromes such as occipital neuralgia and complex regional pain syndrome. More recently, peripheral stimulation has been used to treat headaches and

fibromyalgia. Spinal cord stimulation is most effective in patients with lumbosacral radiculopathy due to scar tissue formation following back surgery as well as in patients with complex regional pain syndrome.

Patient candidates typically undergo an initial trial with a temporary electrode applied to the spinal cord or nerve. After the 1-week trial, permanent placement is performed if benefit is demonstrated. Benefit is measured as a reduction in pain as well as an increase in daily activities. Complications of the therapy are most commonly stimulating lead migration, breakage, and infection.

► Deep Brain Stimulation

Deep brain stimulation involves the precise surgical placement of electrodes into the deep nuclei of the brain. Common targets of deep brain stimulation for pain include the thalamus, which is the sensory relay of the brain, and the periaqueductal gray region, which results in the upregulation of endogenous opiates. Once electrodes are implanted, trial stimulation is performed for 1-2 weeks. A successful trial is characterized by the experience of pain-relieving and tolerable paresthesias in the treated region during thalamic stimulation, a sense of warmth and ocular movement during periaqueductal stimulation, a poststimulatory pain-relieving effect, and the absence of an analgesic effect during sham stimulation. Following the trial, a pulse generator is connected to the wires and implanted in the chest. Long-term results in patients with a successful trial are variable, ranging from 19% to 79%.

► Motor Cortex Stimulation

Electrical stimulation of the region of the motor cortex results in analgesia in neuropathic pain syndromes such as hemibody poststroke pain and trigeminal deafferentation pain. The mechanism of motor cortex stimulation is unknown.

The surgical procedure involves placement of a stimulating electrode under the skull in the region of the motor cortex. Patients undergo a trial of stimulation. Stimulus intensity is typically set to 80% of the level needed to produce motor cortical responses. Following a successful trial, the electrodes are connected to an implantable pulse generator in the chest. Motor cortex stimulation has a success rate of 70% in facial pain syndromes and of 50% in central neuropathic pain.

SURGICAL MANAGEMENT OF MOVEMENT DISORDERS

Arnold Etame Parag G. Patil

Neurosurgical procedures for movement disorders have evolved considerably in recent years. Formerly popular stereotactic tissue-destructive procedures, such as pallidotomy

and thalamotomy, have been superseded by nonlesional deep-brain stimulation (DBS). Careful, prospective and well-controlled studies have demonstrated significant benefits of DBS in the treatment of Parkinson disease, essential tremor (ET), and dystonia.

PARKINSON DISEASE

► Clinical Considerations & Pathophysiology

James Parkinson was the first to describe the “shaking palsy” in 1817. The clinical signs of Parkinson disease (PD) are tremor, bradykinesia (slowness of movement), rigidity (increased muscle tone), and postural instability. The tremor of PD occurs at rest, has a “pill-rolling” character, and typically decreases with voluntary movement. The rigidity of PD has a “cogwheel” ratchet-like quality during passive movement. Postural instability results from a loss of reflexes, leading to impaired balance. Other signs of PD include a shuffling gait, decreased voice volume, slowed reaction time, and dementia. A popular scale for the measurement of Parkinsonism is the Unified Parkinson Disease Rating Scale (UPDRS).

PD is accompanied by a loss of dopaminergic neurons in the substantia nigra pars compacta. According to a well-accepted model of basal-ganglia function, the loss of dopamine results in activation of the subthalamic nucleus and the globus pallidus pars interna (GPi). The GPi inhibits motor regions of the thalamus, resulting in decreased cortical excitation and the symptoms of PD. The central role of the GPi and subthalamic nucleus in this scheme provides the impetus for the surgical therapies for PD.

Idiopathic PD must be distinguished from other Parkinsonian syndromes that have similar signs and symptoms. These syndromes include multiple system atrophy, progressive supranuclear palsy, corticobasal degeneration, and dementia with Lewy bodies. There are no laboratory or blood tests that help in the diagnosis of PD. CT and MRI studies of patients with PD are typically normal. For each patient, the diagnosis is based entirely on the history and physical examination as well as responsiveness to medication. As a result, only 75% of patients with a clinical diagnosis of PD are confirmed at autopsy.

► Medical Management

Medical management strategies for the treatment of PD center upon manipulation of the dopaminergic system. l-dopa, which was introduced in 1967, crosses the blood-brain barrier and is converted by dopaminergic neurons into dopamine. l-dopa is often compounded with carbidopa, an inhibitor of dopamine metabolism in the bloodstream, to increase the efficiency of l-dopa delivery to the brain. Other medications that are useful in the treatment of PD include inhibitors of the COMT and MAO-B enzymes, which metabolize dopamine, as well as direct agonists of

dopamine receptors in the brain. Patients with non-PD, atypical Parkinsonian syndromes do not respond well to l-dopa therapy.

Over 5-10 years, PD patients develop several troublesome side effects of l-dopa. Dyskinesias are involuntary writhing movements of the face and extremities that occur at peak dopamine levels. In addition, after chronic therapy, patients may develop on-off fluctuations in which their Parkinsonian symptoms oscillate in an unpredictable manner. Finally, patients may develop involuntary freezing during movement. The presence of such side effects of l-dopa should prompt surgical evaluation.

► Surgical Management

Lesional stereotactic surgery for PD has been performed since the 1950s. Principal targets for ablation include the thalamus (thalamotomy) and the GPi (pallidotomy). With the introduction of l-dopa, these lesional surgical therapies declined. However, with the appearance of l-dopa side effects in the 1980s and with the development of DBS techniques in the 1990s, surgery for PD has increased significantly. At present, DBS of the subthalamic nucleus or GPi is favored over lesional surgery because of its heightened safety and reversibility. Since FDA approval in 1997, over 10,000 patients with PD have been treated with DBS.

Surgical indications for the treatment of PD are well established. Guidelines defined by the Core Assessment Program for Surgical Interventional Therapies in PD (CAPSIT-PD) include the following:

- A diagnosis of idiopathic PD for a period of 5 years
- Exclusion by history and MRI of atypical Parkinsonism
- Dopaminergic responsiveness (33% reduction in UPDRS motor score with l-dopa)
- No significant cognitive deterioration or depression

The goal of surgery for PD is an improvement in motor symptoms. DBS results in significant improvements in tremor, rigidity, bradykinesia, postural stability, freezing, and gait, compared to the *off*-l-dopa state. DBS is not expected to provide improvement to patients with PD beyond their best *on*-l-dopa state. However, as doses of l-dopa are typically lowered after DBS surgery, DBS provides relief from the dyskinesias and on-off fluctuations associated with chronic l-dopa therapy.

A recent study has determined that DBS results in a significant improvement in quality of life for patients with PD. Compared to medication alone, DBS provides increased ability to perform activities of daily living, improved emotional well-being, decreased stigma of disease, and reduced bodily discomfort. Benefits are likely to be reduced, however, in patients over 70 or with significant cognitive deficits in whom motor improvements alone are unlikely to alter quality of life significantly.

ESSENTIAL TREMOR

► Clinical Considerations & Pathophysiology

ET is the most common movement disorder, affecting an estimated 2% to 4% of the population. ET can be present in adolescence but most often appears in middle age or later life and is slowly progressive. There is a strong genetic component, with 25% to 60% of patients reporting a family history of tremor, typically with an autosomal dominant pattern of inheritance.

The tremor of ET occurs during maintenance of posture against gravity and with action. ET can occur in any part of the body but is most commonly observed in the hand (90%-100%), head (40%-60%), and voice (25%-35%). The tremor of ET is distinguished from rest tremors, which occur when a limb is fully supported against gravity, and from intention tremors, which occur during visually guided movement as the limb approaches the target. However, in severe cases, patients with ET may experience either rest or intention tremor in addition to action tremor.

The pathophysiology of ET is not well understood, though cerebellar function appears to be involved. In addition to tremor, patients with ET may have mildly ataxic or dysmetric gait, oculomotor deficits, and disordered eye-hand movements, reminiscent of cerebellar dysfunction. In addition, PET studies have demonstrated increased cerebellar activity in patients with ET. It is thought that disruption to olivocerebellar rhythmicity may be central to the development of ET.

ET must be differentiated from other tremor disorders. Disease processes resulting in action tremor may include PD, enhanced physiological tremor, dystonia, and Wilson disease. Other tremor disorders may include cerebellar (intention) tremors, Holmes (rubral) tremor, toxic/metabolic disorders, and psychogenic disorders.

► Medical Management

In many cases, ET begins late in life, progresses slowly, and is neither physically disabling nor psychologically burdensome. Some patients may experience reduced tremor by restricting or eliminating caffeine from the diet or by wearing small weights about their wrists. Some patients may experience reduced tremor with moderate alcohol consumption. However, alcohol is not typically recommended as a treatment because of risks of resulting chemical dependence in susceptible individuals.

For patients with disabling tremor, first-line therapies include beta-blockers, such as propranolol, and the anti-epileptic primidone. Approximately 50%-70% of patients obtain benefit from beta-blockade. Primidone is a medication related to phenobarbital, with similar efficacy to beta-blockade in the treatment of ET. In some patients, the two therapies may be combined for an additive effect. Additional

pharmacological agents for ET include gabapentin, topiramate, and long-acting benzodiazepines, such as clonazepam. Finally, a subset of patients with ET may be treated by local botulinum toxin injection.

► Surgical Management

As in the treatment of PD, lesional surgery for ET has been largely superseded by DBS. The targets of ablation and DBS are the same, the ventralis intermedius nucleus of the thalamus. The ventralis intermedius nucleus receives inputs from the deep cerebellar nuclei, including the dentate nucleus, which may account for its importance in the treatment of ET. A unilateral procedure is favored for patients with disabling unilateral extremity tremor, while a bilateral procedure may be required to control bilateral or axial tremors.

Thalamotomy of the ventralis intermedius nucleus is highly effective in the treatment of ET, with over 80% of patients experiencing effective long-term tremor suppression. Complications of thalamotomy occur in some 25% of patients and primarily include hemorrhage, weakness, dysarthria, and ataxia.

Ventralis intermedius nucleus DBS has largely replaced thalamotomy in the surgical treatment of ET. In a prospective, randomized study comparing DBS to thalamotomy, both therapies achieve similar tremor control. However, DBS results in fewer adverse effects. DBS may have more favorable effects on patient functional status, including activities of daily living. Complications of thalamotomy and DBS are more pronounced in patients following a bilateral procedure.

PRIMARY DYSTONIA

► Clinical Considerations & Pathophysiology

Dystonia is the sustained cocontraction of opposing muscle groups. Patients with dystonia exhibit abnormal and awkward postures, engage in repetitive movements, and often experience significant pain. Dystonia may affect muscles throughout the body (eg, generalized dystonia) or muscles in a region (eg, torticollis), or it may have a specific focus (eg, blepharospasm). Like tremor, dystonia may be an isolated finding or a manifestation of a more generalized neurological condition.

The pathophysiology of dystonia is not known. Some cases of dystonia have been shown to result from dopamine deficiency or disordered function of dopamine receptors in the basal ganglia. One model suggests that decreased or dysregulated activity in GPi results in disinhibition of motor cortical areas.

Dystonia often occurs as an idiopathic condition, without a clear etiology. Alternatively, dystonia may occur as a secondary condition, resulting from birth injury, stroke, drug toxicity, or a hereditary degenerative neurological condition.

Recently, over a dozen hereditary forms of previously idiopathic dystonia have been identified, including mutations of the *DYT1* gene on chromosome 9. The distinction between primary and secondary dystonia is important, as secondary dystonias respond less well to surgical interventions.

► Medical Management

Primary dystonia may be treated with anticholinergic drugs such as trihexyphenidyl, benzodiazepine muscle relaxants such as valium, or the injection of botulinum toxin into affected muscle groups. In addition, some dopamine-blocking medications have been utilized in the treatment of dystonia, although use of such medications also may worsen some forms of dystonia. Physical therapy is also an important component of dystonia treatment to prevent the formation of fixed muscle contractures.

► Surgical Management

Patients who fail to respond to oral medications and who fail to achieve adequate relief with botulinum toxin injections should be referred for surgical management. Dystonia has been treated with either ablation or stimulation of the GPi. Pallidotomy improves dystonia by 60% to 70% when measured by standard rating scales. Bilateral pallidal DBS is also highly effective in the treatment of primary dystonia. By comparison to sham stimulation, DBS significantly improved motor symptoms, pain, and quality of life. The most common side effect of pallidal DBS is dysarthria.

TECHNIQUES OF STEREOTACTIC NEUROSURGERY

Stereotactic neurosurgery involves the ablation of tissue or the placement of electrodes deep into the brain. Both the clinical efficacy and risks of surgery depend on submillimeter accuracy, requiring specialized techniques. Patients are typically placed in a stereotactic frame. This frame is affixed to the skull, under local anesthetic. The patient then undergoes an MRI or CT scan. Performance of a scan while in the frame allows a precise coordinate system to be defined within the brain.

In the operating room, a small hole is drilled into the skull, allowing the introduction of microelectrodes along a trajectory leading to the target. The microelectrodes record extracellular neuronal activity. Each region of the brain has a specific electrophysiological signature. Depending on the surgery, the patient may be examined for motor or sensory responsiveness of cellular activity.

Once electrophysiology has confirmed the target for surgery, DBS electrodes are placed into the same location along the same trajectory. With the electrode in position, stimulation is applied and the patient is examined for undesirable clinical effects. Once a desirable effect is confirmed,

the electrodes are secured. As a second stage, the electrodes are tunneled under the skin to an implantable stimulation generator placed under the skin, just below the clavicle. This generator may be precisely tuned to the requirements of each patient.

In lesional surgery, a radiofrequency or cryoprobe is placed into the location following microelectrode recording, and a temporary lesion is created. When the absence of undesired effects is confirmed, a permanent lesion is created.

INTERVERTEBRAL DISK DISEASE

D. Andrew Wilkinson Khoi Than Paul Park

► General Considerations

The spinal column is composed of 33 longitudinally stacked bone segments called vertebrae: 7 cervical, 12 thoracic, 5 lumbar, 5 sacral (fused), and 2-4 coccygeal (fused). A typical vertebra is composed of a rounded body anteriorly and a protective bony arch posteriorly, which together form a canal through which the spinal cord passes. Vertebral bodies articulate anteriorly via intervertebral discs and posteriorly via synovial joints formed by the articular facets of adjoining vertebrae. They are also connected by several ligaments: the anterior and posterior longitudinal ligaments which traverse the vertebral bodies from top to bottom, the supraspinous and interspinous ligaments which run between the posterior projecting spinous processes of each vertebra, and the ligamentum flavum which connects the lamina (part of the posterior arch) at each vertebral level.

In a normal adult, the spinal cord extends from the cranio-cervical junction to the lumbar level, where it tapers and typically ends at L1-2 as the conus medullaris. Eight sets of nerve roots exit the spine in the cervical region, though there are only seven cervical vertebrae. The C1 nerve root exits above the C1 vertebra, while the C2 nerve root exits between the C1 and C2 vertebrae. The C8 nerve root exits between the C7 and T1 vertebral bodies, and the T1 nerve root exits between the T1 and T2 vertebral bodies. This relationship continues downward to the level of the sacrum. Thus, the nerve root that emerges at the L5-S1 level is the L5 nerve root. In the case of lumbar disk herniation, the affected nerve root is typically the root that is passing by to exit at the next level. As an example, a disk herniation at the L4-5 level would typically compress the L5 nerve root. Conversely, in the cervical spine the nerve that is affected is at the level of the disk herniation. A C5-6 disk herniation would therefore impact the C6 nerve root.

Intervertebral disks act as pads separating the vertebral bodies of the spine. They also function as shock absorbers, helping to cushion and distribute downward forces on the spine. Additionally, intervertebral disks allow a limited amount of movement to occur between different spinal

levels so that the spine may bend and rotate. The intervertebral disk is composed of a gel-like, elastic fibrocartilaginous central nucleus (the nucleus pulposus) surrounded by a fibrous outer ring (the annulus fibrosus) composed of 15-25 concentric layers of parallel fibers. Vertebral body end-plates less than 1 mm thick and composed of hyaline cartilage form an interface between the bone of the vertebral bodies and the disk, sandwiching the nucleus pulposus superiorly and inferiorly.

Intervertebral disks degenerate over time. Coupled with degeneration of the facets, this process is termed spondylosis. At birth, the nucleus pulposus contains 80% water. As people age, however, disks gradually lose their water and elasticity, becoming less gel-like. The process of disk degeneration is common and may even be “normal” as people age. About 20% of teenagers have signs of mild disk degeneration, whereas by age 70, approximately 60% of disks are severely degenerated. Degenerated disks do not distribute load in the same way as healthy, well-hydrated disks. They do not maintain their height under load-bearing conditions and, as a consequence, more load is placed on vertebral bodies and adjacent facet joints. This promotes the formation of osteophytes. If osteophytes form in the spinal canal, within the neural foramina, or in the lateral recess, neurologic compression may develop over time. With loss of disk height, the tensional forces on the ligamentum flavum are reduced, causing the ligamentum to remodel, thicken, and bulge into the canal (ligamentous hypertrophy). Degeneration can also lead to spondylolisthesis or subluxation of one vertebral body over another. Degenerative disk disease occurs at all levels of the spine; however, because the lumbar spine and cervical spine have greater mobility, pathology is more common in these regions.

CERVICAL SPINE

► General Considerations

Degeneration of the cervical spine is a process leading to bulging of intervertebral disks, hypertrophy of facet joints, and osteophyte formation. Chronic degeneration initially manifests as neck pain. As osteophytes enlarge and ligamentous hypertrophy progresses, neurologic symptoms may develop. Compression of nerve roots leads to radiculopathy, while compression of the spinal cord itself leads to myelopathy. Alternatively, disk degeneration may occur acutely when the nucleus pulposus of a disk is extruded through a tear in the annulus. If an acute disk herniation occurs centrally, the spinal cord may become compressed, causing severe neurologic injury. This may result in paraplegia or quadriplegia, depending on the level and severity of the herniation. More commonly, however, disk rupture results in compression of a nerve root by the extruded disk fragment as well as local inflammatory changes, causing radiculopathy. This is

typically manifest as pain radiating down the arm, sensory disturbance and, sometimes, weakness in the distribution of the involved nerve root.

► Clinical Findings

A. Symptoms & Signs

Degenerative disease of the cervical spine often presents with a history of neck pain which may either be abrupt, in the case of disk rupture, or slowly progressive. There is often a loss of cervical lordosis (the normal, backward, C-shaped curvature of the neck), which may be related to muscle spasm or to deformity from chronic degeneration. In addition to neck pain, which often abates over time, compression of a single nerve root by an osteophyte or disk fragment (radiculopathy) often causes an aching pain along the medial border of the scapula on the side of the lesion. This scapular pain tends to be longer lasting than the neck pain. The characteristic finding in radiculopathy is a sharp, burning pain that radiates down the arm, following the distribution of the involved spinal nerve. This pain may be exacerbated when the patient tilts the head toward the side of the pain, crowding the neural foramina on the affected side (Spurling maneuver). Indeed, the patient may habitually tilt the head to the opposite side to reduce the pain. Hyperextension of the neck (with or without compression of the head) may worsen the pain. Sensory disturbances (parasthesias, numbness, or decreased sensation) tend to occur in the terminal distribution of the involved dermatome, that is, in the fingers rather than the proximal arm. Hypersensitivity of the skin in the distal distribution of the dermatome is also common. A decrease or loss of deep tendon reflexes is a frequent and early finding in radiculopathy from a herniated disk or a compressive cervical osteophyte. Weakness from radiculopathy occurs in muscles innervated by one spinal nerve (but by more than one peripheral nerve); that is, it is myotome-based. Thus, weakness from radiculopathy is often partial or incomplete, since nearly all muscles are innervated by more than one spinal nerve. Profound weakness, atrophy, and muscle fasciculations are rare in radiculopathy, except in very long-standing cases. The presence of these findings should generate suspicion of a peripheral nerve lesion.

C5 radiculopathy (typically resulting from pathology at the C4-5 level) involves pain radiating into the shoulder, with sensory disturbances crossing over the top of the shoulder and extending to the mid-portion of the upper arm (following the distribution of the C5 dermatome). Patients may exhibit weakness of shoulder abduction (deltoids) and forearm flexion. The biceps reflex may be attenuated. C6 radiculopathy (as from a C5-6 herniated disk) typically involves pain radiating from the neck into the lateral aspect of the arm, with sensory disturbance in the dorsum of the hand and, in particular, the thumb. Patients may present

with weakness of forearm flexion (biceps). The biceps reflex as well as the brachioradialis reflex may be attenuated. C7 nerve root compression (from C6-7 pathology) often involves pain radiating from the neck into the back of the shoulder, the triceps and the dorsolateral surface of the forearm. Sensory disturbance typically involves the index and middle fingers. Weakness of forearm extension (triceps) is generally noticed in a delayed fashion, perhaps because day-to-day extension of the forearm occurs with the assistance of gravity. The triceps reflex is often attenuated.

In advanced cases of degenerative disk disease of the cervical spine, signs of myelopathy may develop, including hyperreflexia, spasticity leading to gait disturbance, and sensory disturbance in the upper and lower extremities. Patients with myelopathy from cervical stenosis often complain of difficulty manipulating objects with their hands (eg, problems buttoning their shirt).

B. Diagnostic Studies

Plain films are useful in determining the degree of degenerative change present in the cervical spine. In cases of cervical deformity, plain films are used for evaluating the alignment of the cervical spine. Flexion-extension plain films are important when there is a question of instability of the cervical spine (eg, when a patient is having positional symptoms). Likewise, computed tomography (CT) scans may offer detailed views of the bony anatomy and are often useful for preoperative planning, especially in cases of severe deformity. CT also offers good resolution of bony anatomy when bone spurs are suspected as the cause of neural compression. The major disadvantage of CT scanning is the lack of resolution of soft tissue structures; it is difficult to detect compression from a herniated disk on a normal CT scan. CT myelography solves the problem of visualizing soft tissue compressive lesions. However, its main disadvantage is its invasiveness: Puncture of the thecal sac (required for dye injection) carries a small risk of neurologic injury. In the era of magnetic resonance imaging (MRI), CT myelography is often reserved for cases where the spine has been previously instrumented, which may cause significant artifact on MR imaging, or if the patient has other metallic devices that preclude magnetic scanning (eg, a cardiac pacemaker).

MR imaging allows the resolution of neural structures in a noninvasive manner and has become the most common imaging method for evaluating potentially compressive pathology of the cervical spine. MRI can detect soft tissue disk herniation and nerve root compression. It is also useful in detecting chronic or acute changes in the spinal cord that may be associated with myelopathy. Findings on MRI should be carefully correlated with clinical findings, as false positives are frequently generated. MR imaging reveals degenerative disk disease of the cervical spine in 25% of asymptomatic people less than 40 years of age and in 60% of people over 40 (Figure 36–25).

▲ **Figure 36–25.** Sagittal T2-weighted MRI of cervical spine showing multilevel disk protrusions causing central canal stenosis and cord signal change.

Electrodiagnostic studies, particularly EMG, may be useful in diagnosing radiculopathy. Nerve conduction studies alone are of little value in identifying radiculopathy and are generally normal, even with severe compression of a nerve root. EMG, on the other hand, is more sensitive. Classic EMG findings in radiculopathy are fibrillations at rest in muscles supplied by a single nerve root (ie, a myotome) along with denervation in the corresponding paraspinal muscles. Unfortunately, EMG will not reliably detect fibrillations in muscles until at least 3-4 weeks following the onset of radiculopathy. This may lead to false negative studies if the test is performed too soon. Even when performed after an appropriate waiting period, EMG findings may be normal in upward of 50% of cases of spinal nerve compression in patients with radicular symptoms, but no signs of weakness, numbness, or decreased reflexes.

▶ Differential Diagnosis

Neck pain associated with a history of malignancy, unexplained weight loss, pain unrelieved by bed rest, or age more than 50 with cancer risk factors should raise suspicion of a metastatic tumor invading the cervical spine. Similarly,

infectious etiologies such as diskitis, osteomyelitis, or abscess should be considered when there is a history of fever, immunosuppression, or recent infection. Peripheral nerve entrapment syndromes such as carpal tunnel syndrome or ulnar nerve compression may mimic cervical radiculopathy. In general, severe weakness and muscle atrophy is suggestive of a peripheral nerve lesion, while early loss of a reflex (biceps, triceps) suggests radiculopathy. Other conditions that may mimic cervical degenerative disk disease include myocardial infarction, idiopathic brachial plexitis (Parsonage Turner syndrome), or inflammatory conditions such as ankylosing spondylitis or sarcoidosis. Local conditions affecting the shoulder (rotator cuff tears, acromial bursitis, etc) must also be ruled out.

► Treatment & Prognosis

Most conditions that cause pain in the cervical spine (such as exacerbations of degenerative arthritis, muscle spasm, or minor trauma) are self-limiting and ultimately do not require operation. Acute neck pain may be treated with gentle exercise or a mobilization program, moist heat, or a soft collar to help muscle relaxation. Anti-inflammatory medications are also useful in this regard. For persistent neck pain, intermittent traction is sometimes helpful, either through physical therapy or with a home traction kit. Roughly 80%-90% of patients improve with medical management alone, though many continue to have mild symptoms they ultimately learn to manage.

Neck pain itself responds poorly to operative management. Even in cases of radiculopathy where imaging reveals a clear-cut disk herniation compressing a nerve root, surgical management is most likely to improve only arm pain rather than neck pain. Surgical management of cervical degenerative disk disease should be reserved for cases failing medical management and where there is neurologic compression (leading to either myelopathy or radiculopathy). Operative management of the cervical spine involves decompression of the spinal cord or nerve roots, with or without fusion. The cervical spine may be approached either anteriorly or posteriorly. The choice depends on many factors, including the age of the patient, the number of levels involved, whether the compressive lesion is predominantly anterior or posterior, and any concurrent deformity of the cervical spine. Both anterior and posterior approaches may be used to decompress nerve roots and/or the spinal cord. For complicated cases involving extensive degenerative change, particularly with severe deformity, a combined anterior/posterior approach may be employed.

Disk herniations and osteophytes may be addressed anteriorly, either by removing just the disk (anterior cervical discectomy, with or without fusion) or by drilling away the vertebral body (a procedure known as corpectomy). Posterior cervical laminectomy is useful for decompression of multiple levels, as in the case of multilevel cervical stenosis

secondary to ligamentous hypertrophy. Because there is a risk of subsequent deformity (progressive kyphosis related to loss of the posterior tension band following operation), some patients who are approached posteriorly may need to be fused. The decision to fuse should be made on a case-by-case basis. Artificial disk replacement (arthroplasty) in lieu of fusion has been shown to maintain segmental mobility and appears to be a viable alternative to fusion, though long-term results are not yet available. Posterior keyhole foraminotomy is ideally suited for soft disk herniations that occur laterally (it cannot be used for central disk bulges) and may be done in a minimally invasive fashion using tubular retractors.

In the case of cervical radiculopathy, symptoms improve in approximately 80% of patients following operative management. Where surgical decompression is performed for myelopathy, neurologic improvement occurs in approximately 70% of cases.

THORACIC DISK DISEASE

Thoracic disk herniations are rare, with an incidence between 0.25% and 0.75% of all disk herniations. The majority of thoracic disk herniations occur below the level of the mid-thoracic spine. Often there is a delay in diagnosis because of poorly defined symptoms and the lack of objective findings on physical exam. If the disk herniation is secondary to trauma and results in severe cord compression, paralysis may be the result. If the disk herniation is secondary to degenerative changes, the cord compression occurs more slowly and is associated with a variety of presentations.

Patients may present with symptoms of axial pain, radiculopathy, myelopathy, or some combination of the three. The axial pain may be described as dull, aching, burning, stabbing, or cramping. Load bearing, activity, or Valsalva will often exacerbate the pain. Radicular symptoms generally present in the appropriate dermatomal band. Myelopathy can present as paraparesis, but more often presents with a vague history of lower extremity weakness, heaviness, stiffness, or numbness. Bowel and bladder complaints can occur.

Treatment is surgical and is directed at alleviating pain or preventing progression of a neurologic deficit. There are a variety of surgical options including laminectomy for stenosis as well as a variety of approaches (thoracotomy, costotransversectomy, lateral extracavitary, transpedicular) for pathology that occurs in the anterior spine, such as a disk herniation. In cases of a thoracic disk herniation, a strictly dorsal midline approach (laminectomy) offers poor exposure of the disk and has a high risk of neurologic injury.

LUMBAR SPINE

► General Considerations

One must understand the anatomy of the lumbosacral roots to appreciate the clinical syndromes associated with a displaced lumbar intervertebral disk. An extruded lumbar

Intervertebral disk can lead to loss of reflexes (ankle jerk, patellar reflex), motor loss, sensory loss, and pain in a dermatomal distribution. A central disk herniation can lead to a variety of presentations up to paraplegia below the level of the lesion along with urinary symptoms. A typical disk herniation will usually spare the exiting nerve root, but impinge upon the traversing nerve root of the level below. A rarer far lateral disk herniation, however, will impinge upon the exiting nerve root.

With age, the disk will degenerate. Autopsy specimens have noted disk degeneration starting as early as the second decade of life, and nearly all individuals have some degree of degeneration by the sixth decade. Osteophytes may then form around the disk space and cause stenosis of the spinal canal and neuroforamina.

Ninety-five percent of lumbar disk herniations occur at the L5/S1 and L4/L5 levels. Only 4% of lumbar disk herniations occur at the L3/L4 levels and are infrequent at the upper lumbar levels.

► Clinical Findings

A. Symptoms & Signs

The symptoms and signs of lumbar disk herniation are variable. A large central disk herniation can present with cauda equina syndrome. In these cases, patients may present with saddle anesthesia, urinary dysfunction, diminished rectal tone, and leg weakness. Generally, however, patients complain of symptoms of radiating leg pain with a variable component of back pain. Valsalva maneuvers (coughing, sneezing, etc) or movement will generally exacerbate the pain. Alternatively, rest will often improve the pain. The pain itself can be described as a constant burning, aching type pain with an intermittent sharp, shooting pain that radiates down into the legs. Straight leg raise and crossed straight leg raise may support the diagnosis of lumbar disk herniation. The straight leg raise is positive if raising the straightened leg to an angle of 30 degrees causes sciatica in the ipsilateral leg. This test is 80% sensitive but only 40% specific. The crossed straight leg raise is positive if raising the leg to 30 degrees causes sciatica in the contralateral leg, and though this test is only 25% sensitive, it is 90% specific. It should be noted that patients with a high lumbar disk herniation or a far lateral disk herniation may not have these signs. Examination of the paravertebral musculature may reveal tenderness and/or muscle spasm.

Motor findings may be helpful in predicting the involved lumbar level. Compression of the L4 nerve root (L3/4 herniation) may cause weakness of knee extension (quadriceps). Compression of the L5 nerve root (L4/5 herniation) may precipitate weakness of the extensor hallucis longus and ankle dorsiflexion (tibialis anterior). Finally, compression of the S1 nerve root (L5/S1 herniation) may lead to weakness

of ankle plantarflexion (gastrocnemius). Reflexes may also be diminished. The ankle jerk (Achilles) reflex is diminished with S1 nerve root compression and the patellar reflex is diminished with L4 nerve root compression.

Sensory examination is often variable and the least helpful in predicting the involved lumbar level. L4 nerve root compression can be associated with anterior thigh to medial ankle sensory findings. L5 nerve root compression can present with findings along the dorsum of the foot and the first web space. Finally, S1 nerve root compression may present with sensory findings along the lateral and plantar regions of the foot.

B. Imaging Studies

If symptoms are limited to pain and the patient does not have risk factors for other diseases, it is reasonable to delay imaging workup for 4 weeks since improvement in pain over time is not uncommon. Persistent symptoms, however, are an indication for imaging. Plain radiographs have limited utility in the diagnosis of disk herniation. However, they are useful in evaluating trauma, infection, or neoplastic process. Myelography may identify extradural filling defects and can be particularly helpful when combined with CT scanning. Indeed, CT myelography remains useful in the setting when an MRI scan is not possible.

MRI has become the gold standard for the diagnosis of herniated disks (Figure 36–26). MRI is noninvasive and does not involve radiation exposure. MRI provides detailed images of the disk spaces, surrounding soft tissue, and thecal sac. MRI can help exclude tumors, cysts, and post-operative scarring as etiologies of the patient's symptoms. It is important to correlate the patient's symptoms and the imaging findings precisely since MRI imaging can generate a significant number of false positives. For example, nearly 20% of normal individuals under the age of 40 and over 50% of individuals over the age of 40 were noted to have lumbosacral imaging abnormalities.

C. Special Examinations

EMG can be useful diagnosing radiculopathy, but its utility is rather limited. EMG classically has findings of fibrillations at rest in the muscles supplied by a single nerve root and denervation of corresponding paraspinal muscles. Unfortunately, fibrillations require at least 3–4 weeks from the onset of the radiculopathy to be evident on EMG examination. Nerve conduction studies (NCS) are of minimal utility in diagnosing radiculopathy.

► Differential Diagnosis

It is important to obtain a complete history and physical, as the differential diagnosis for patients with back pain and radicular

▲ **Figure 36–26.** Sagittal T2-weighted MRI of lumbar spine showing multilevel disk bulges, ligamentum flavum hypertrophy, and retrolisthesis at L2-L3.

symptoms is broad. A history of trauma can point to fractures, especially in the setting of osteoporosis and/or steroid use. Tumors which often metastasize to the spine include prostate, breast, kidney, thyroid, and lung cancer. Patients with metastatic disease often have nocturnal pain and pain that persists even with rest and a supine position. Inflammatory disorders, infections, bony abnormalities (spondylolithesis), peripheral neuropathies, degenerative spinal cord lesions, peripheral vascular occlusive disease, and peripheral nerve lesions should all be considered in the differential diagnosis.

► Treatment

A. Medical Measures

The natural history of the radicular pain associated with lumbar disk disease is that of improvement over time.

Therefore, conservative measures are recommended for patients who present with a new radiculopathy without neurologic impairment. Conservative measures are directed toward initially limiting physical activity, including a brief period of bed rest followed by a gradual exercise program. It is also important for patients to modify their types of movement, for example to limit heavy lifting, twisting, or bending. Physical therapy can be useful after the acute period for instruction in abdominal and back musculature strengthening exercises.

The core of medical treatment is nonsteroidal anti-inflammatory drugs (NSAIDs). Oral steroids (ie, solumedrol dose pack) also may be useful in the acute setting, and epidural steroid injections and narcotics may be helpful in alleviating pain.

B. Surgical Treatment

Patients who present with acute neurologic motor deterioration warrant immediate surgical attention. Surgery is also indicated in patients who fail the conservative measures outlined above and continue to suffer from debilitating pain.

The microdiscectomy is the “gold standard” surgical intervention for patients with a herniated lumbar disk. A microdiscectomy involves a laminotomy to gain access to the disk space. The nerve root and the thecal sac are protected while the disk fragment is identified and removed. A fusion can sometimes be recommended in the setting of recurrent disk herniations at the same level or pain associated with joint instability.

► Prognosis

Overall, patients who have symptoms of radicular pain without neurologic deterioration have an excellent prognosis with improvement in symptoms over time. However, if loss of motor strength has already occurred, it is less likely to return even after surgical correction.

CSF DIVERSION FOR HYDROCEPHALUS

Hugh J. L. Garton, Jason Sack

OVERVIEW, EPIDEMIOLOGY, & PATHOPHYSIOLOGY

Hydrocephalus is a common diagnosis in both adult and pediatric patients. Most often this disease is chronically treated with an implanted catheter system to divert CSF from the brain to an alternative absorptive space such as the pleural or peritoneal space. Children and adults with CSF shunts can require surgical treatment for other associated conditions. The presence of the shunt may thus complicate the surgical management of various intra-abdominal processes. For example, a child with the distal portion of his shunt within the peritoneal may develop appendicitis. What management steps should be taken with regard to the management of the potentially contaminated CSF shunt catheter? In addition, CSF shunt failure is common, occurring in up to 30%-35% of individual within 1 year of initial shunt placement. About 1% of all shunt failures are fatal. Familiarity with the diagnosis and treatment of shunt failure is therefore desirable for providers caring for patients in whom a CSF shunt is present.

In pediatric patients, hydrocephalus is commonly seen in patients with a history of premature birth, intraventricular hemorrhage, after meningitis, in patients with myelomeningocele or other congenital cranial malformations and in patients with brain tumors. In adults, patients suffering from subarachnoid hemorrhage, brain tumor, or head injury may develop hydrocephalus. In older adults, "normal pressure" hydrocephalus is a potentially treatable cause of dementia. CSF shunt management is also used in the management of idiopathic intracranial hypertension (IIH) (also known as pseudotumor cerebri).

Among children, the prevalence of hydrocephalus is estimated at about 1-2 per 1000 children. Among adult patients, the incidence of IIH, and the shunt treatment for it appear to be increasing in accordance with increasing obesity rates.

Pathophysiologically, hydrocephalus results from an interruption in CSF circulation. The choroid plexus of the brain's ventricular system generates about 80% of the total adult CSF production of about 20 cc/h, by an active ion pump dependent process. The remainder is thought to be generated by more general metabolic processes of the brain and arachnoid. Importantly, the production of CSF is independent of the intracranial pressure over a wide range of physiologic values. Thus, the increase in intracranial pressure that typically results from the increasing CSF volumes within the nervous system does not act to check the further production of spinal fluid. Once produced, spinal fluid moves in an oscillatory fashion out of the ventricular system and into the subarachnoid space around the brain. From there, it is reabsorbed by passive, pressure dependent mechanisms into the

cerebral venous sinuses and possibly into lymphatic systems adjacent to the dura. The vast majority of hydrocephalus results from interruption of the egress of CSF. Traditionally, hydrocephalus has been classified as either **obstructive**, if the blockage to CSF outflow prevents egress from the ventricular system, or **communicating** if reabsorption is interrupted beyond the ventricular system, at the dural venous and/or lymphatic absorption sites. The determination of the site of obstruction is usually radiographic and may require invasive studies. To the non-neurosurgeon, this distinction is mostly important in determining the safety of lumbar puncture. If a patient has obstructive hydrocephalus, a lumbar puncture (LP) may be unsafe because of the potential for differential pressures between the cranial and spinal spaces after the LP. Radiographically, hydrocephalus is sometimes assumed to be communicating when all four ventricles are dilated, as opposed to only ventricles I-III. However, blockage at the outflow of the fourth ventricle to the subarachnoid space could produce the same CT or MRI picture despite obstructive physiology. Consultation with a neurosurgeon or neurologist may be helpful if the situation is unclear.

CLINICAL PRESENTATION/ASSESSMENT

The relative difference between the volume of CSF produced and reabsorbed, along with the relative compressibility of the brain determine the severity and type of clinical symptoms and signs at presentation. Slower buildup of CSF or a brain more compliant to compression, such as might occur at the extremes of age, produce a more protracted course of symptoms compared to rapid CSF accumulation in a poorly compressible brain. Whether presenting initially or after treatment failure, the symptoms of hydrocephalus can be grouped in to three broad categories: those related to acute increased intracranial pressure, usually seen with a more rapid accumulation of CSF or a poorly compliant brain, those related to more chronic deformation of the nervous system by more slowly accumulating CSF, and those symptoms that are specific to treatment complications, including CSF shunt infection.

Acute, rapidly progressive hydrocephalus presents with headaches, nausea, and vomiting and as it progresses, a deterioration in level of consciousness. The headaches associated with hydrocephalus and/or CSF shunt failure may have morning predominance, or worsen with a valsalva maneuver. Patient may be lethargic, or difficult to arouse or awaken with ordinary stimuli. Some patients may present with a loss of upgaze or Parinaud's syndrome, others with cranial nerve VI palsy from increased intracranial pressure. In young children with an open fontanelle, this area may be tense and raised. Hydrocephalus of a more slowly progressive nature may present with more subtle signs of cognitive impairment. In the elderly, so called **Normal Pressure Hydrocephalus** presents with the triad of dementia, gait

disturbance and incontinence. Other signs include papilledema, and in young children, an inappropriately expanding head size. If the patient has already undergone treatment for hydrocephalus with a CSF shunt, then additional symptoms and signs to consider include those of device infection, including a stiff neck, fever, and redness around the device. If the device has broken or malfunctioned then CSF may accumulate around the shunt. If the distal cavity into which a shunt is placed fails to absorb spinal fluid, there may be symptoms related to this such as abdominal pain with a large intraperitoneal fluid collection (so-called pseudocyst). Some CSF shunt devices possess diagnostic chambers that can be manually compressed and observed for response. However, the utility of such tests is questionable and best left to a neurosurgeon.

Patients presenting with clinical features described above, especially with a history of a CSF shunt in place for prior treatment of hydrocephalus must be promptly evaluated with imaging studies, usually a CT or MRI scan of the brain. In the setting of a possible shunt failure, it is critical to have previous images available for comparison. Patients with working shunts may have ventricles that are smaller than normal; “normal ventricular size” or “no evidence of shunt failure” in a radiology report has been demonstrated to correlate poorly with final diagnosis. Additional studies that can be useful include plain radiographs of the shunt and imaging of the cavity into which the CSF shunt is draining, such as by ultrasound of the abdomen. Other invasive diagnostic studies may be necessary, usually as directed by a neurosurgical consultant. These can include a CSF shunt tap, in which a portion of the shunt that sits under the scalp is accessed percutaneously similar to a vascular access port. It is helpful to know that a high percentage of shunt failures occur within the first 2 years after shunt failure, with a reduction in failure rates following this. In children, young age at presentation also appears to be a risk factor for repeated shunt failure. Similarly, most shunt infections occur within 1 year from shunt placement. However, despite these epidemiologic data, a perfectly predictive clinical decision algorithm remains elusive and a low threshold for obtaining imaging studies and appropriate expert consultations is warranted.

► MANAGEMENT

Progressive hydrocephalus must be dealt with in a timely manner to minimize neurologic deterioration. As noted above, the rate of pathologic CSF accumulation may vary and produce different clinical symptoms. However, because of the potential for acute and fatal deterioration from hydrocephalus, the initial presumption should be that rapid intervention is needed, subject to reconsideration after all the data are available.

Medical management of hydrocephalus may be appropriate in the management of IIH (pseudotumor cerebri),

and in some patients after subarachnoid hemorrhage. It is also used in the initial management of hydrocephalus in neonates after an intraventricular hemorrhage. The diuretics acetazolamide and furosemide are used in this context. Both decrease CSF production by inhibiting carbonic anhydrase, albeit by slightly different mechanisms—thus producing an additive effect when used in combination. However, randomized control trials of diuretic therapy in newborns demonstrated no reduction in the need for subsequent shunt placement for patients on diuretic regimens. If diuretics are utilized, patients must be closely monitored for electrolyte imbalances and acetazolamide toxicity (acute gastritis, paresthesias, drowsiness.). It should be noted that with the exception of IIH, protracted use of diuretics to manage hydrocephalus is rarely successful and in most cases, surgical therapy is indicated without a trial of diuretics.

Intraventricular administration of fibrinolytic agents (eg, streptokinase) has also been investigated as a treatment for newborns with posthemorrhagic hydrocephalus. However, a systematic review of randomized trials failed to show any benefit, in terms of reducing shunt requirement or death. Furthermore, secondary intraventricular hemorrhage is a potential complication of this treatment.

Temporary drainage includes serial LPs, ventricular taps, placement of an external ventriculostomy catheter, or implanted reservoir in communication with the ventricular system for periodic aspiration. These techniques are used when natural history suggests possible resolution of the hydrocephalus, as may occur in IVH in the newborn and in SAH. In addition, temporary diversion is appropriate when the patient's condition precludes definitive treatment.

Endoscopic third ventriculostomy (ETV) is an alternative to CSF shunt placement for the treatment of some forms of hydrocephalus. During the endoscopic procedure a perforation is made in the floor of the third ventricle communicating it to the subarachnoid space. ETV is currently used as the initial treatment of choice in cases of obstructive hydrocephalus and is curative in 80% of properly selected patients, avoiding the need for shunt placement. ETV patients may suffer recurrent hydrocephalus if the fenestration closes. The vast majority of such failures have occurred within the first year after the procedure, and failures beyond 5 years are exceedingly rare.

CSF shunt treatment is indicated in most cases of progressive hydrocephalus, when conservative management and ETV are not indicated, or have previously failed. This procedure involves placement of a mechanical shunt as a means to divert excess CSF from the ventricles into other body cavities. CSF shunts have a ventricular catheter, a valve that regulates unidirectional flow, and distal tubing to distribute the CSF to its absorption site. Many shunts also have reservoirs that can be percutaneously tapped for diagnostic purposes, or as a temporizing measure in shunts in which the distal tubing or valve becomes blocked. Most often,

the proximal catheter of the shunt system is placed into one of the lateral ventricles, either in the frontal horn via a frontal approach or via the atrium of the lateral ventricle via a parietal approach. Shunt systems are used to treat a variety of other conditions such as intracranial cysts, or chronic subdural hematomas/hygromas. The proximal catheter placement in such cases is dictated by the location of the pathology to be treated. Shunt valve mechanics regulate the amount of drainage. Most are differential pressure systems that respond to increasing fluid pressure by allowing more CSF through the valve. Various shunts are designed to open in different pressure ranges (eg, low: 4-7 cm H₂O; medium: 8-12 cm H₂O; high: 13-15 cm H₂O), and some valves can be externally adjusted to different performance levels using a magnet. These adjustable (“programmable”) valves may be inadvertently reprogrammed by other external magnets and while all systems approved for sale in the United States as of this writing are MRI compatible to 1.5 Telsa, the patient must have the valve setting checked and reset as necessary following an MRI. Alternative systems are designed to produce a constant flow through the valve over a range of physiological intracranial pressures. Valve systems may incorporate devices that prevent excessive drainage from the siphoning effect of a long run of distal tubing running inferiorly when patients assume an upright posture. The distal end of the system is comprised of a catheter that terminates in a body cavity, wherein the fluid can be adequately absorbed. A ventriculoperitoneal (VP) shunt, in which the catheter terminates into the abdominal cavity and fluid is absorbed by the peritoneum, is the most commonly used shunt at present. Other common distal sites include the pleural space (V-Pleural shunt) and the cardiac atria (VA shunt). These two sites are chosen when extensive scarring or adhesions, recent abdominal infection, peritonitis, or morbid obesity preclude peritoneal catheter placement. Other less common options for distal placement of a ventricular shunt include gall bladder, and ureter/bladder. Immediate complications from shunt placement are fortunately rare but include misplacement of the ventricular catheter with inadequate shunt function. Much more rarely a patient may suffer intracranial hemorrhage or perforated abdominal viscus.

Complications that are not encountered intraoperatively, but may nonetheless present in the early postoperative period include: inguinal hernia and/or hydrocele; ascites; pseudocyst formation; septicemia, pulmonary thromboembolism, and cardiac tamponade with VA placement; subcutaneous CSF collections and fistulas; hemorrhage; shunt obstruction/occlusion; and infection (shunt and/or incisional).

CSF SHUNT FAILURE

While the surgical procedure of CSF shunt placement is generally an uncomplicated process, the long-term management of shunted hydrocephalus is more problematic. Multiple

clinical studies in both adult and pediatric patients attest to the high rate of device failure, from tubing obstruction, catheter fracture, infection, excessive drainage, and compartmentalization of the ventricular system (with a catheter draining part of the ventricular system, but with another part expanding because of noncommunication). In young children undergoing first shunt placement, roughly 1/3 of shunts will require reoperation in the first year following surgery. Shunt infection rates in these children are as high as 10%-12%. Adult patients fair somewhat better but 20% will still require reoperation within the first year after shunt failure. Analysis of the “shunt survival” curves shows that failure rates for devices drops considerably after the first year or two from surgery, but the threat of failure remains present to some degree as long as the device remains in place.

In evaluating a patient for potential CSF shunt failure, the epidemiological data above provide a baseline estimate of the probability of the diagnosis. Other risk factors for shunt failure include young age at shunt placement and recent previous shunt surgery. A history and physical exam along with images compared to previous findings, as described above, should allow for a reasonably accurate diagnosis. However, several pitfalls deserve mention. First, as has been noted, not all patients with CSF shunt failure will show significant expansion of the ventricular system. Some patients, particularly those with a long history of shunted hydrocephalus may present with the so-called “slit-ventricle” syndrome. The radiographic finding of “slit-ventricles” is relatively common for patients with a functioning shunt. The clinical “slit-ventricle” syndrome presents with episodic severe headaches that appear to be due to intermittent occlusion of the shunt in a small ventricular system that does not dilate despite an increase in CSF pressures because change in ventricular size is too small to be noted on standard radiographs. The diagnosis is often confirmed by direct intracranial pressure measurements obtained from a separately placed ICP monitor.

A second group that deserves special attention is children and adults with myelomeningocele. Given a frequent need for both urological and plastic surgical care, these patients are frequently encountered on surgical services. About 70% of patients with this spinal dysraphism will require treatment for hydrocephalus, most with a CSF shunt. Myelomeningocele is associated with a number of abnormalities of the brain stem and foramen magnum. These abnormalities allow CSF shunt failure to produce a much wider array of clinical symptoms than would otherwise be the case. As intracranial CSF and pressure build because of CSF shunt failure, downward pressure on the brainstem can produce lower cranial nerve palsies, including swallowing and breathing irregularities. The death rate from shunt failure may be higher in this population, and more precipitous, related to the susceptibility of the hindbrain to herniation. In addition, CSF shunt failure may precipitate or exacerbate

a preexisting syrinx in these patients, producing symptoms related to spinal cord dysfunction.

Shunt contamination may occur during unrelated intra-abdominal procedures, in the case of a VP shunt, or from repeated bacteremia in ventriculoatrial shunts. Infections of this sort can obviously occur at any time, and are not temporally restricted to the year or so following the most recent shunt surgery. Clinically, the presentation of infection may lack an overt inflammatory response with fever and redness around the shunt. Rather, the presentation may be more insidious, with failure of the CSF to absorb and development of a pseudocyst. The presence of a large intra-abdominal fluid collection in a patient with a VP shunt should raise suspicion of shunt infection, although sterile fluid collections are not uncommon.

Abdominal surgical procedures in patients with VP shunts raise the issue of the best management of an intraperitoneal distal shunt catheter during and after the procedure. While no validated guideline exists, the literature and the author's experience suggest that the infection risk is low during clean and clean contaminated cases. If an enterotomy or open bladder procedure is to be performed, it is reasonable to relocate the shunt away from this area once the tubing is identified intraperitoneally, and/or protect it with gauze sponges during the procedure. Other than routine preoperative antibiotics, expectant management for shunt infection and failure can be practiced and the shunt does not require externalization. In situations where there is frank contamination of the shunt catheter in the abdomen, externalization of the shunt appears prudent. Laparoscopic procedures have been demonstrated to transiently increase intracranial pressure, but there is no body of literature to suggest that this produces identifiable complications, presumably due to its transient nature. Constipation and ileus, conversely have been suggested to be a source of at least transient shunt dysfunction due to increased abdominal pressure.

Shunt externalization, when necessary, involves palpation of the shunt proximal to its entry into the peritoneum, followed by a sterile prep and, if the patient is awake, local anesthesia. If the shunt has been in place for several years, it may be quite adherent to the surrounding tissues and the procedure is then best performed in the operating room with anesthesia. For recently placed shunts, this is less of an issue and the procedure can be performed at the bedside, assuming a cooperative patient. A cut down is made of over the shunt tract, avoiding laceration of the underlying tubing. The catheter is often encased in a thick sheath of scar that must be teased open to gain access to the catheter. If a specimen of fluid is required from a peritoneal fluid collection, the tubing is withdrawn slightly, then cut and aspirated distally. In a large pseudocyst a liter or more of fluid may be withdrawn. The distal catheter is then withdrawn from the patient and then discarded. The remaining tubing should be observed for CSF drainage and connected to a sterile,

enclosed CSF drainage system. Neurosurgical consultation is advisable before embarking on the procedure. Patients with externalized shunts are draining isotonic CSF and may suffer hyponatremia if appropriate fluid and electrolyte replacement are not performed, particularly in young children.

ONGOING CARE

Patients with VP or ventriculopleural shunts do not require prophylactic antibiotics for surgical or dental procedures in which the shunt is outside the operative field. **Prophylactic antibiotics** may be helpful when the shunt is in the operative field, as described above, or during a planned CSF shunt revision. For patients with ventriculo-atrial CSF shunts in place, an argument can be made for antibiotic prophylaxis before procedures likely to result in bacteremia including dental procedures. Dental practice guidelines suggest this also. American Heart Association guidelines for endocarditis prophylaxis recommend Amoxicillin 2 g 30-60 minutes before the procedure for adults and 50 mg/kg for pediatric patients or Clindamycin 600 mg adult and 20 mg/kg pediatric doses for penicillin allergic patients.

Shunt independence has been reported for children with a prior history of shunt placement. In this situation, a child previously dependent on a CSF shunt becomes once again able to drain CSF independently. Clinically, this issue is often raised when a CSF shunt has gone without a revision for many years or even decades, or a CSF shunt is found disconnected in the absence of clinical symptoms. One series reported that 3% of children with hydrocephalus became shunt independent later in life. However, in the setting of a shunt found to be fractured on x-ray without ventricular enlargement or clinical symptoms of shunt failure, it is clinical experience that CSF can often drain between the fractured catheter segments through the tube of scar tissue that forms around the catheter initially after shunt placement. Such a scarred tract can subsequently close over, even several years after the catheter fracture and separation of the fractured tubing ends. Therefore, caution should be exercised in the presumption of shunt independence unless it has been verified by invasive testing. Patients incidentally found to have broken shunt catheters may reasonably be referred to a neurosurgeon for evaluation.

Shunted hydrocephalus during pregnancy frequently raises concerns over management of headaches during pregnancy, mechanism of delivery, and over the potential impact of hydrocephalus on the pregnancy outcome. Pregnancy, particularly in the third trimester, increases intra-abdominal pressures. For patients with VP shunts, this can lead to a relative decrease in CSF shunt function. In cases series of pregnant patients with hydrocephalus, headaches are not uncommonly reported, particularly during the third trimester. These may herald shunt failure, the evaluation of which may be complicated by a desire to avoid radiation administration during pregnancy. MRI may be a useful option

in these circumstances. In the absence of radiographic manifestations of shunt failure, or additional clinical symptoms, safe observation of headaches has been successfully practiced, but treatment decisions must be individualized and other diagnoses, particularly eclampsia and preeclampsia must be considered. There is little evidence to suggest that the presence of a CSF shunt is a contraindication to labor and vaginal delivery. It has been argued that patients who are suspected of being symptomatic from increased intracranial pressure may benefit from avoiding protracted labor, but no comparative studies exist to provide a clear answer. Hydrocephalus, and the presence of a CSF shunt does not, per se, appear to impact pregnancy outcome. However, recalling that hydrocephalus is coincident with other diagnoses, such as epilepsy and myelomeningocele that do have a significant impact on the potential for birth defects, the importance of prenatal care can be emphasized.

BRAIN ABSCESS

Brain abscesses are an uncommon entity, with approximately 2000 cases reported in the United States each year. There is a higher incidence in developing countries, and men are affected slightly more often than women. Classically, these abscesses arise locally from otorhinolaryngeal infections or hematogenously from distant infections, though opportunistic infections have become an important consideration upon initial presentation as well. The pathogenic organisms most commonly implicated are of the *Streptococcus* family; *Klebsiella*, *Staphylococcus aureus*, and anaerobes are also frequent. In immunocompromised patients, it is important to include *Toxoplasma*, *Listeria*, and *Nocardia* as possible etiologic agents, as well as fungal pathogens.

A patient with a brain abscess can present with nonspecific symptoms. Headache, nausea, vomiting, and altered mental status can occur due to increased intracranial pressure (ICP), while unilateral headache, seizures, and many focal neurological deficits occur due to the presence of a mass lesion. Fever and nuchal rigidity are also seen in many cases. Additional findings in the newborn patient may include cranial enlargement, meningeal signs, irritability, and failure to thrive.

Risk factors for brain abscess include sinus, ear, or dental infections. These sources usually lead to formation of frontal or temporal lobe abscesses through direct spread. Hematogenous spread from intra-abdominal, pelvic, pulmonary, or cardiac seeding occurs most commonly via the middle cerebral artery, leading to microembolic infarcts at the gray-white junction. Risk factors for these types of abscesses include infectious lung processes and congenital cyanotic heart disease. In these conditions, the lungs have a decreased filtering capability, and the associated relative hypoxia promotes abscess formation. Head trauma—blunt, penetrating, or surgical—can introduce a nidus for infection with delayed abscess formation. Parasitic infections such as cysticercosis should be considered more likely in recent foreign travelers.

The differential diagnosis for brain abscess includes subdural empyema, septic emboli, dural sinus thrombosis, mycotic aneurysm, meningitis, focal necrotizing encephalitis (herpes simplex virus), and tumor, as all of these conditions can present with headaches and altered mental status. In the initial evaluation of brain abscess, blood work that should be drawn includes a white blood cell count, cultures, erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP); however, normal test results do not rule out the diagnosis. The key to diagnosing brain abscess is correlating the clinical scenario with an imaging study, such as contrast-enhanced computed tomography (CT) or MRI. The classic finding on CT or MRI is a circular lesion with a strongly contrast-enhancing surround rim. CT images are typically the first obtained on admission, although MRI is the imaging modality of choice as it can provide greater anatomic detail. MRI evaluation for brain abscess should always include diffusion-weighted images (DWI), which can differentiate between ring-enhancing lesions of infectious and neoplastic origin, as abscesses are typically hyperintense on DWI while neoplastic lesions are hypointense.

One general warning is to avoid LP, as cerebrospinal fluid (CSF) results are often nondiagnostic and this procedure is associated with a worsened outcome in patients with brain abscesses. Less than one-quarter of patients have positive CSF cultures, and, with a large enough abscess, there is a real risk for transtentorial or brainstem herniation. CSF sampling should be considered only if parasitic pathogens are suspected. A definitive diagnosis is made by biopsy sampling of the abscess through surgical means.

The treatment of brain abscesses involves both surgical and medical therapy. Treatment should also be aimed at correcting the primary source of infection (ie, draining a pulmonary empyema or repairing a correctable heart defect). Initial surgical treatment usually consists of needle aspiration of the abscess; the abscess can be monitored serially with imaging, and the procedure repeated as necessary. A total excision via a craniotomy can be performed if the abscess is in its chronic, encapsulated form and is located in a surgically amenable region of the brain. It is advisable to perform surgery before starting antibiotics in order to confirm the diagnosis as well as to identify the organisms and their antibiotic sensitivities. Antibiotic therapy typically consists of 6-8 weeks intravenous treatment followed by 4-8 weeks oral treatment. Patients should receive routine follow-up imaging and should also be started on an antiepileptic medication. Glucocorticoids should be considered to counteract symptomatic intracranial hypertension, although their role is less important than in the treatment of brain tumors.

In certain situations, medical therapy can suffice without the need for surgery. These situations include an abscess in its early stages (ie, symptoms for less than 2 weeks), a small (< 2 cm) abscess, or a definite clinical improvement after 1 week of antibiotics only. Medical treatment without surgery should also be considered in poor surgical candidates, patients with multiple abscesses and/or concomitant meningitis, patients with abscesses in eloquent locations, or patients with hydrocephalus and ventricular shunts.

Patients with brain abscess have a reported mortality risk of 0%-30% depending on etiology and presentation. An overall 50% morbidity risk of permanent neurological deficits is conferred, which depends heavily upon the severity of presenting symptoms.

SUBDURAL EMPYEMA

A subdural empyema is a collection of pus that forms in the subdural space. It is less common than brain abscess, but like abscesses, it is more commonly found in men. Subdural empyema is an emergent condition because, unlike the brain parenchyma with abscesses, the subdural space does not pose much of a barrier to prevent the spread of infection. Additionally, antibiotics have poor penetration into the subdural space.

The most common cause of subdural empyema (70%) is paranasal sinusitis, especially in cases involving the frontal sinus. Chronic otitis media accounts for another 15% of cases. As such, the organisms typically cultured from a subdural empyema include *Streptococcus* (aerobic and anaerobic) and *Staphylococcus*. Symptoms present in the majority of patients with subdural empyema include fever, headache, nuchal rigidity, hemiparesis, and altered mental status. Other common symptoms include seizures and sinus tenderness.

Computed tomography or MRI imaging will typically diagnose a subdural empyema. Three-fourths of empyemas are located over the convexity, while 15% are parafalcine (ie, adjacent to the falx cerebri). Just as with brain abscesses, LP should be avoided due to the risk of herniation.

Almost all cases of subdural empyema will require surgical drainage, preferably emergently. The two surgical options are burr-hole drainage and craniotomy. Although burr-hole drainage is less invasive, it is also less effective; thus, craniotomy is the preferred surgical option. Antibiotics are used for a course of 4-6 weeks, and patients are put on therapeutic or prophylactic antiepileptic medication. Medical treatment alone can be effective if the empyema is small, there is minimal neurologic involvement, and antibiotics have an early efficaciousness.

Subdural empyema carries a 15% mortality rate. Half of patients have residual neurological deficits at the time of hospital discharge. Factors known to be associated with poor prognosis include age more than 60 years, obtunded or comatose state at presentation, and empyema formation secondary to surgery or trauma.

OSTEOMYELITIS

Osteomyelitis can affect the skull or the vertebrae. Osteomyelitis of the skull usually results from contiguous spread from an infected sinus or from penetrating trauma (ie, postoperative). The infectious agents are typically *S. aureus* or *epidermidis*, and treatment consists of debridement surgery followed by 6-12 weeks of antibiotics (intravenously for the first 1-2 weeks). Surgical treatment is aimed at removing all infected bone. A cranioplasty or other hardware is not placed until several months later in order to minimize the risk of reseeding an infection.

Vertebral osteomyelitis (VO) represents 3% of all cases of osteomyelitis, and is more common than skull osteomyelitis because of the spine's rich vascular supply. Both anterograde arterial seeding as well as retrograde venous plexus spread have been implicated in VO, with *S. aureus* as the most common organism. VO caused by *Mycobacterium tuberculosis* is known as Pott's disease. Those at higher risk for developing VO include intravenous drug users, diabetics, sickle cell patients, patients on hemodialysis, and the elderly.

The most common presentation in patients with VO is that of back pain (> 90%), usually unaffected by activity. Other typical presenting symptoms include fever, weight loss, radicular pain, and myelopathy. The neurologic symptoms are usually a result of destruction of the vertebral body and subsequent retropulsion of bone into the spinal canal or neural foramen. The most commonly affected segment of the spine is the lumbar region followed by, in order, the thoracic, cervical, and sacral segments. Any source of infection can theoretically put one at risk for developing VO, although important sources include infections of the urinary tract,

respiratory system, and mouth. VO also develops at sites of previous spine surgeries.

Definitive diagnosis of VO is made with positive cultures, either from biopsy of the tissue itself or via blood cultures in the setting of suggestive radiographic findings. MRI has demonstrated excellent diagnostic accuracy of more than 90% of cases and is the preferred diagnostic modality. When unable to obtain MRI, bone scintigraphy with single photon emission computed tomography has also demonstrated excellent sensitivity.

The treatment of VO is nonsurgical in the vast majority of cases, with disease resolution being accomplished via antibiotic therapy alone. The goal of therapy should be to minimize neurologic involvement, and to maintain structural stability of the spine. Surgical treatment is indicated to obtain a tissue diagnosis if closed needle biopsy is unfeasible. In patients with a worsening neurologic deficit, the onset of structural instability, or a failure of medical management, surgery is warranted for abscess drainage, alleviation of compression, and stabilization.

SPINAL EPIDURAL ABSCESS

Spinal epidural abscesses (SEA) are often associated with VO, with the majority of cases arising from *S. aureus*. *Streptococcus* species are the second most commonly implicated organism (Figure 36–27). SEA are located most often in the thoracic region (50%), followed by the lumbar (35%), and cervical (15%) regions. The vast majority of abscesses (80%) are located posterior to the spinal cord.

The primary infection leading to SEA can be from hematogenous spread or direct extension. Hematogenous spread is more common, with skin infections being the usual

originating source. Other mechanisms of hematogenous spread include nonsterile intravenous injections, bacterial endocarditis, urinary tract infections, respiratory infections, and oropharyngeal abscesses. SEA caused by direct extension can be from decubitus ulcers or penetrating trauma, including following spinal procedures.

Patients with SEA are typically middle aged. Risk factors for developing SEA include diabetes, intravenous drug use, chronic renal failure, and alcoholism. Patients often present with back pain, spine tenderness, fever, sweats, and rigors. When motor weakness ensues, there is a very rapid progression to paraplegia. Thus, the diagnosis and treatment of SEA is emergent.

The workup of SEA should include a complete blood count, ESR, CRP, and blood cultures. An LP is contraindicated given the potential to spread infection from the epidural to the intradural space. The imaging modality of choice is MRI, although CT and myelography may also be used to arrive at a diagnosis.

The treatment of SEA, as with most infections of the central nervous system, is surgery plus antibiotics. Surgery is used to drain pus, debride any granulation tissue, and provide stability (usually in cases where there is bony destruction secondary to VO). Antibiotics are given intravenously for 3–4 weeks and then orally for another 4 weeks. Nonsurgical management with antibiotics only is rare and reserved only for very poor surgical candidates, abscesses that are very extensive in length, or cases in which complete paralysis has been present for at least 3 days with irreversible neurologic injury.

The overall prognosis for patients with SEA is relatively poor, with a mortality rate of 20%. In patients that survive, restoration of baseline neurological function is rare.

MULTIPLE CHOICE QUESTIONS

- Intracranial pressure
 - Is normally between 30 and 40 torr
 - Is directly (linearly) related to increasing intracranial mass
 - Cannot be measured directly
 - Is normally maintained at a stable level by displacement of CSF
 - Is often affected by changes in the size of the skull after trauma
- Strategies to reduce intracranial pressure can include all of the following except
 - Drainage of CSF
 - Hyperventilation
 - Treatment with mannitol
 - Trendelenburg position
 - Sedation

3. Spinal cord injury
 - A. Rarely includes the use of systemic corticosteroid therapy
 - B. Is accompanied by initial hyporeflexia
 - C. Is termed complete if there is no motor function below the level of injury
 - D. Is accompanied by priapism and increased anal sphincter tone
 - E. Can cause a Brown–Séguard syndrome, with loss of motor function and loss of pain and temperature sensation below the level of the lesion, with preserved proprioception, vibration, and pressure sensation
4. Peripheral nerve injury recovery
 - A. Occurs with axonal regeneration after wallerian degeneration at a rate of 1 mm per day
 - B. Is best treated by delayed (3 month) repair is the case of acute sharp injury
 - C. Should be treated by segmental resection and nerve graft in cases of apparent stretch injury
 - D. Occurs more quickly with systemic corticosteroid therapy
 - E. Is likely to be functionally successful if a neuroma forms
5. Pituitary tumors
 - A. Are typically adenocarcinomas
 - B. Should be treated by urgent operation in most patients
 - C. Can cause symptoms related to the compression of the pituitary stalk causing increased prolactin levels
 - D. Can cause Cushing syndrome by overproduction of growth hormone
 - E. Cause visual symptoms due to hormonal release

The Eye & Ocular Adnexa

Linda M. Tsai, MD
Ian Pitha, MD, PhD
Stephen A. Kamenetzky, MD

37

Ophthalmology has evolved substantially over the past decade. Innovations in surgical techniques and tissue banking as well as developments in ophthalmic surgical devices and implants, allow an increasingly sophisticated approach to ophthalmic surgery. Advances in imaging the microanatomy of the eye facilitate diagnosis and guide treatment. Nonetheless, the majority of diagnoses in ophthalmology can be made after a targeted history and careful examination without the need for sophisticated equipment.

EXAMINATION OF THE EYE

Evaluation of the eye and its adnexa requires a good history, assessment of visual function and physical examination of the eyes. Occasionally, special examinations may be required to identify specific ocular disorders or to establish the presence of associated systemic disease.

The basic equipment required for an eye examination by a nonophthalmologist includes the following: (1) a visual acuity chart, (2) a handheld flashlight, (3) an ophthalmoscope, and (4) a tonometer.

The basic medications required for an eye examination are (1) a local anesthetic such as proparacaine 0.5% or tetracaine 0.5%; (2) fluorescein strips; and (3) dilating drops, such as phenylephrine 2.5% or tropicamide 0.5%-1%.

► History

In addition to eliciting a chief complaint, determining whether visual loss is monocular or binocular, central or peripheral, and painful or painless is important. Prior ophthalmic history (including known ophthalmic conditions, prior eye surgery or trauma, history of contact lens use, and relevant family history) should be obtained. A review of past medical history and all medications should be included as well.

► Visual Acuity Testing

Central visual acuity, using the patient's glasses if available, should be determined in all patients. The Snellen chart is most commonly used. The patient faces the test chart at a distance of 6 m (20 ft). Each eye should be tested separately. Visual acuity corresponds to the smallest line the patient can read. The patient who is unable to read the largest letter on the chart (typically a 20/200 letter) should be moved progressively closer until that character can be read and that distance recorded in the chart. If no letters are recognizable, the patient should be tested for the ability to count fingers, see hand motion or perceive light. If a vision chart is not readily available, the ability to read small print or a name badge can provide useful information. Preschool children or illiterates can be tested with the E chart or Allen picture chart.

► Visual Field Testing

Confrontation visual fields can be used to detect gross visual field defects such as quadrantanopia, hemianopia, or severe visual field constriction. With one eye occluded, the patient is asked to fixate on the examiner's face and detect finger count or hand motion in each quadrant. Formal visual field testing (perimetry) is used to more carefully examine the central and peripheral visual fields. The technique is performed separately for each eye and measures the function of the retina, the optic nerve and intracranial visual pathway. Perimetry relies on subjective patient responses so results will depend on the patient's alertness and cooperation. Several methods are used to assess visual field functions, including the tangent screen, Goldmann perimetry, and computerized automated perimetry.

► Eye Movements

Ocular motility should be assessed in all positions of gaze. One should also observe the patient for random eye

movement and assess the alignment of the eyes when the patient is looking straight ahead. The position of the light reflection from a penlight (“reflex”) on the cornea is at the same point in each eye when the eyes are properly aligned. The oculocephalic reflex (doll’s head) can be tested. The upward rotation of the cornea in response to resistance to forced eyelid closure (Bell phenomenon) should be noted when clinically appropriate.

▶ Assessment of Pupillary Functions

Examination of the pupils should be performed before any dilating drops are instilled. Both the direct and consensual light reflex should be assessed. The pupils should constrict with accommodation. The size of the pupils should be noted in light and dark conditions and any difference in size (anisocoria) should be recorded. Irregular pupils may indicate traumatic, postsurgical, neurological, or congenital defects. In hospitalized patients and those with neurological disorders requiring monitoring of pupillary reaction to assess clinical status, pupils should be dilated with discretion and only with short-acting mydriatics.

▶ Inspection of Anterior Segment & Adnexa

The eyelids, conjunctiva, cornea, sclera, and lacrimal apparatus should be evaluated. Unusual prominence of the globes (proptosis), abnormal eyelid position and the inability to fully close eyelids are important features that should be documented. Eversion of the upper eyelid to enable inspection of the hidden conjunctival surface should be performed when appropriate. The conjunctiva is inspected for anatomic defects, foreign bodies, lacerations, inflammation, discharge, tearing, dryness, or other abnormalities. In patients who are unconscious, the presence or absence of Bell phenomenon (upward rotation of the cornea during sleep) may be an important measure of neurological function. Corneal sensation should be tested before anesthetic drops are used.

A direct ophthalmoscope focused on the ocular surface can provide magnification for the examination. A magnifying glass and a handheld flashlight can also be used. Shining a light across the eye from the lateral to medial aspects and noting whether or not the nasal iris is shadowed can assess the depth of the anterior chamber. The presence of shadowing may indicate a narrow anterior chamber angle requiring special precautions if dilating drops are to be used.

▶ Ophthalmoscopy

Ophthalmoscopy is important for the diagnosis of both ocular and systemic conditions and can provide critical information in neurologic and neurosurgical contexts. In most instances, the optic nerve head can be clearly seen without dilating the pupils. When describing the optic nerve, it is important to note any nerve head edema and the cup-to-disc ratio. Vessel caliber, tortuosity, arteriovenous nicking, and

the presence of retinal hemorrhages are additional findings that can aid in diagnosis. In hospitalized patients with neurologic and neurosurgical disorders, dilation of the pupils should be performed with discretion.

▶ Tonometry

Tonometry measures intraocular pressure (IOP). The most common instruments used are the Tono-Pen and the Goldmann applanation tonometer. The normal intraocular pressure varies between 10 and 20 mm Hg. IOP measurements can vary slightly with corneal thickness.

SYMPTOMS & SIGNS OF OCULAR DISORDERS

▶ Decrease in Visual Acuity

Efforts should be made to determine if the decrease in visual acuity is unilateral or bilateral, painful or painless, persistent or transient, recent or chronic, isolated or associated with other symptoms. Unilateral acute painful loss of vision may be due to angle-closure glaucoma, endophthalmitis, or uveitis. Painless unilateral loss of vision is often caused by ischemic optic neuropathy, optic neuritis, central retinal artery or vein occlusion, retinal detachment, vitreous hemorrhage or retinal hemorrhages. Transient painless unilateral loss may be due to retinal migraine or amaurosis fugax. Hemispheric strokes are often responsible for visual field loss with preservation of the central visual acuity.

▶ Disturbances in Vision

Disturbances in vision include image distortion, light sensitivity (photophobia), color change, spots before the eyes, visual field defects, night blindness, momentary loss of vision, or halos around lights. Distortion of normal shape (metamorphopsia) is most commonly caused by macular lesions. Photophobia can be due to corneal inflammation, iritis, ocular albinism, or aniridia. Toxicity from systemic medications such as digoxin and certain retinal conditions can cause the patient to complain of abnormally colored vision (chromatopsia). Patients with vitreous opacities or intraocular inflammation may report floating spots in their vision, even if retinal tears and detachment have to be ruled out as a cause. Visual field defects may be due to lid edema, retinal and optic nerve lesions, visual pathway lesions, or cortical abnormalities. Night blindness may be genetic (as in patients with retinitis pigmentosa) or acquired. Important causes of acquired night blindness include vitamin A deficiency, glaucoma, optic atrophy, cataract, or retinal degeneration. Transient loss of vision may imply impending cerebrovascular accident or partial occlusion of the internal carotid artery. Colored halos around lights can be caused by elevated intraocular pressure, most commonly due to acute angle-closure glaucoma. Incipient cataract or incorrect refractive error can cause colorless halos around point light sources.

► Double Vision (Diplopia)

Diplopia can be constant or intermittent, sudden or gradual, painful or painless, horizontal or vertical. It may occur only in certain gaze positions. It is important to first determine if the diplopia is monocular or binocular. Binocular diplopia is only present when both eyes are open and disappears when either eye is closed. Binocular diplopia is most often due to misalignment of the eyes from extraocular muscle dysfunction or neurologic abnormalities. Monocular diplopia (multiple images in a single eye) occurs with refractive error, lenticular changes, macular lesions, malingering, or conversion reactions.

► Ocular & Orbital Pain

Ocular pain may result from corneal lesions, inflammation, rapid increase in intraocular pressure, anterior uveitis, cyclitis, scleritis, or optic neuritis. Other causes of pain include inflammation of the orbital contents, tumors in the orbit and dacryocystitis (lacrimal sac inflammation). Eyelid pain and irritation can also arise from infections of the meibomian glands and the glands of Zeis and Moll.

► Redness of the Eye

Acute redness (injection) of the eye not associated with trauma is caused by conjunctivitis, acute anterior uveitis, acute angle-closure glaucoma, corneal infection or corneal abrasion (Table 37-1). Subconjunctival hemorrhage may

also present as a red eye but this is usually painless and otherwise asymptomatic. Conjunctivitis from bacterial, chlamydial, viral, or allergic causes is a frequent cause of red eye. Nonspecific irritation from exogenous agents or a foreign body can also cause redness. Chemical and thermal injuries cause similar findings. “Dry eye” or ocular surface anomalies can cause redness, a foreign-body sensation, and variable degrees of decreased vision.

► Discharge

Ocular discharge may be described as watery, mucopurulent, purulent, or crusting of the lid margins. When watery discharge is not associated with redness or pain, it may be due to excessive tear production or obstruction of the lacrimal outflow passages. Watery discharge with photophobia, pain, or irritation indicates possible keratitis or keratoconjunctivitis. Purulent or mucopurulent discharge is a sign of bacterial infection, severe inflammation of the conjunctival surface, or bacterial infection of the lacrimal sac or canaliculus. *Pseudomonas* or *Haemophilus* species involvement is common. When the discharge forms mucoid strings, it is characteristic of allergic disorders involving the conjunctiva (vernal conjunctivitis) or dry eye syndrome.

► Swelling of the Eyelids

For unilateral swelling, the cause is often a sty or chalazion. Bilateral swelling suggests blepharitis or allergic dermatitis. Systemic diseases associated with water retention, hyper-

Table 37-1. Differential diagnosis of common causes of inflamed eye.

	Acute Conjunctivitis	Acute Iritis ¹	Acute Glaucoma ²	Corneal Trauma or Infection
Incidence	Extremely common	Common	Uncommon	Common
Discharge	Moderate to copious	None	None	Watery or purulent
Vision	No effect on vision	Slightly blurred	Markedly blurred	Usually blurred
Pain	None	Moderate	Severe	Moderate to severe
Conjunctival injection	Diffuse; more toward fornices	Mainly circumcorneal	Diffuse	Diffuse
Cornea	Clear	Usually clear	Steamy	Change in clarity related to cause
Pupil size	Normal	Small	Moderately dilated and fixed	Normal
Pupillary light response	Normal	Poor	None	Normal
Intraocular pressure	Normal	Normal	Elevated	Normal
Smear	Causative organisms	No organisms	No organisms	Organisms found only in corneal ulcers due to infection

¹Acute anterior uveitis.

²Angle-closure glaucoma.

thyroidism, or hypothyroidism can also cause swelling or puffiness of the eyelids.

► Displacement of the Eyes

The most common cause of both unilateral and bilateral exophthalmos (proptosis) is hyperthyroidism. Other etiologies include tumors of the orbit.

► Strabismus

Strabismus results from misalignment of the eyes due to muscle imbalance. Ocular deviations may be lateral (exotropia), medial (esotropia), upward (hypertropia), or downward (hypotropia). Binocular diplopia is not a frequent complaint in congenital strabismus. Full ocular motility is intact in the majority of strabismus cases.

► Leukocoria

A white pupil in a child indicates a serious eye disorder. The most frequent cause of leukocoria is congenital cataract, which requires urgent management to prevent amblyopia. Other causes include retinoblastoma, retinopathy of prematurity, toxocariasis, persistent hyperplastic primary vitreous, vitreous hemorrhage, retinal detachment, retinal dysplasia, incontinentia pigmenti, Coats disease, and Norrie disease.

► Other Symptoms

Patients may present with other symptoms such as burning, itching, gritty, and foreign-body sensations, or a “sandy” feeling. These symptoms in elderly patients are suggestive of dry eye syndrome. Itching is also frequently associated with allergic disorders.

DISEASES OF THE EYE & ADNEXA

DISEASES OF THE OCULAR ADNEXA

ACUTE HORDEOLUM

Acute hordeolum (stye) is a common infection of the glands of the eyelids. External hordeolum involve the glands of Zeis or Moll. Internal hordeolum is an infection of the meibomian glands. The usual causative agent is *Staphylococcus aureus*. Acute hordeolum is characterized by pain, localized swelling, and redness of the eyelid. A large hordeolum is infrequently associated with a preauricular lymph node.

If there is no abscess formation, treatment with warm compresses three times daily and topical broad-spectrum antibiotic drops such as tobramycin or sulfacetamide 10% three or four times daily for 5-7 days usually suffices. Ophthalmic ointments (erythromycin or bacitracin) twice

daily for 5-7 days are also effective. Oral antibiotics, especially tetracycline derivatives, can be useful for patients with acne rosacea. If the infection does not resolve and is localized, treatment consists of making a local horizontal (skin) or vertical (conjunctiva) incision.

HERPES ZOSTER

Herpes zoster virus (HZV) is caused by a reactivation of latent varicella virus (chickenpox) dormant in the dorsal root ganglion. Approximately 15% of herpes zoster cases arise from the ophthalmic division of the trigeminal nerve (herpes zoster ophthalmicus [HZO]). Hutchinson sign (involvement of the nasociliary nerve which supplies the tip of the nose) occurs in about one-third of patients with HZO. If present, it suggests intraocular involvement. Reactivation is associated with decreased cell-mediated immunity and patients with HIV, blood dyscrasias, neoplasms, or other forms of immunosuppression are at increased risk.

► Clinical Findings

HZO can involve virtually any ocular and adnexal tissues. Reactivation often starts with headache, malaise, fever, and ocular pain without cutaneous findings. Within 24-48 hours, the classic vesicular lesions develop unilaterally in a dermatomal distribution. Corneal involvement presents with the acute event or may follow it by months or years. A corneal pseudodendritic pattern is common. Conjunctivitis, keratitis, episcleritis/scleritis, and uveitis can also occur. Dry eye and poor corneal sensation are common.

► Treatment

Treatments of skin lesions include warm compresses and topical antibiotic ointment. Aggressive lubrication is often needed for maintenance of the ocular surface. Oral antiviral medication is the standard of care. Oral acyclovir (800 mg five times a day) or valacyclovir (1000 mg three times a day) initiated within 72 hours of symptoms has been demonstrated to accelerate the resolution of skin rash and the healing of skin lesions, reduce lesion formation and viral shedding and reduce the incidence of episcleritis, keratitis, and iritis. Oral antivirals appear to reduce both acute zoster-associated pain and postherpetic neuralgia. Topical antiviral medication and steroids are used in certain situations to treat corneal lesions or uveitis. The Zostavax vaccine has been approved for the prevention of herpes zoster in the elderly. In patients without known risk factors for HZO (patients under age 50 without chronic immunosuppression) consider HIV testing.

Oxman MN et al: Vaccination against herpes zoster and postherpetic neuralgia. *J Infect Dis* 2008;197(Suppl 2):S228-S236.

DACRYOCYSTITIS

Dacryocystitis is a common infection of the lacrimal sac. Acute or chronic, it occurs most often in infants and in persons older than 40 years. It is usually unilateral and always secondary to obstruction of the nasolacrimal duct. In rare instances, the nasolacrimal duct may be obstructed by a tumor.

In children the nasolacrimal duct opens spontaneously during the first month of life. Failure of canalization leads to obstruction of the sac and secondary dacryocystitis. The cause of acquired nasolacrimal duct obstruction is often unclear, but trauma to the nose or infection may be responsible. In infants, dacryocystitis leading to obstruction may be due to *Haemophilus influenzae*, staphylococci, or streptococci. In patients with trachoma, nasolacrimal and canalicular obstruction is common. The cause of acute dacryocystitis in adults is usually *S. aureus* or β -hemolytic streptococci. In chronic dacryocystitis, *Streptococcus pneumoniae* is a common pathogen.

► Clinical Findings

A. Symptoms and Signs

Acute dacryocystitis is characterized by pain, swelling, tenderness, and redness in the tear sac area. In chronic dacryocystitis, tearing and discharge are the principal signs. Purulent material can often be expressed through the puncta.

B. Laboratory Findings

Culture and sensitivity of organisms obtained from cotton swab should be performed.

► Treatment

A. Adults

Acute dacryocystitis responds well to systemic antibiotic therapy, but recurrences are common if the obstruction is not surgically relieved.

B. Infants

When ductal obstruction is due to failure of canalicularization in the first month of life, daily vigorous massage of the tear sac is indicated. Topical antibiotics should be instilled in the conjunctival sac four or five times daily. If this is not successful, probing of the nasolacrimal duct is indicated. Most ophthalmologists postpone probing until age 6-9 months to allow sufficient time for the passage to open on its own. Both the upper and the lower canaliculi should be probed. In cases of previous failure or in children older than age 2, balloon dacryocystoplasty at the time of probing may increase chances of success. In recalcitrant cases, stenting of the nasolacrimal system or surgical creation of a new tear drain between the eye and nose (dacryocystorhinostomy) is required.

ORBITAL CELLULITIS

Orbital cellulitis is characterized by an abrupt onset of swelling and redness of the lids, accompanied by proptosis, decreased vision, diplopia, and fever. It is usually caused by staphylococci or streptococci. Immediate treatment with intravenous antibiotics is indicated to prevent abscess formation and rapid increase in the orbital pressure with compromise of the blood supply to the eye. The response to antibiotics is usually excellent, but surgical drainage may be required if an abscess forms. Computerized tomography (CT) is indicated to rule out abscess formation. Preseptal cellulitis is limited to the area anterior to the orbital septum and is treated with oral antibiotics while monitoring closely for progression to full-blown orbital infection.

DISEASES OF THE EYE SURFACE

CONJUNCTIVITIS

Acute conjunctivitis is a common cause of red eye. Infectious causes include bacterial, viral, chlamydial, fungal, and parasitic agents. Noninfectious causes include chemical irritation, allergy, hypersensitivity to topical medications, vitamin A deficiency, dry eye syndrome, floppy eyelid syndrome associated with obstructive sleep apnea and injury.

► Clinical Findings

A. Symptoms and Signs

Patients with conjunctivitis complain of redness, irritation, foreign-body sensation, and conjunctival discharge. One or both eyes may be affected. The eyelids are often stuck together in the morning. Bacterial conjunctivitis has conjunctival hyperemia with purulent or mucopurulent discharge and variable degrees of lid swelling. Gonococcal conjunctivitis is characterized by hyperacute onset of copious mucopurulent discharge and can be a vision-threatening infection. In viral conjunctivitis, follicles are present in the inferior conjunctival fornix and preauricular lymph nodes are often involved. The hallmark symptom of allergic conjunctivitis is itching.

B. Laboratory Findings

If bacterial conjunctivitis is suspected, appropriate microbiologic testing should be performed, including blood and chocolate agar plates, Gram and Giemsa stains, and bacterial cultures.

► Treatment

For patients with suspected bacterial conjunctivitis, topical broad-spectrum antibacterial agents should be prescribed

(eg, sulfacetamide 10% eye drops or ciprofloxacin 0.3% eye drops QID), with the addition of erythromycin or bacitracin ophthalmic ointment at bedtime if clinical indications warrant.

Viral conjunctivitis is usually self-limited and does not require treatment. If the diagnosis is unclear, topical antibiotics are often used. Contact precautions are necessary in all situations of suspected bacterial and viral conjunctivitis because spread of disease occurs through contact with contaminated tears.

Treatment of patients with allergic conjunctivitis consists of topical decongestants (naphazoline 0.1%) and H₁ receptor blocker (levocabastine) or a mast cell stabilizer (cromolyn). Combination mast cell and antihistamine drops such as olopatadine are also available. In severe cases of allergic conjunctivitis, topical corticosteroids or cyclosporine might be required but should be initiated only with the assistance of an ophthalmologist.

CORNEAL ULCERS

Corneal infections leading to ulceration may be due to bacteria, viruses, fungi, or protozoa.

► Clinical Findings

A. Symptoms and Signs

Patients with corneal ulcers complain of pain, photophobia, and blurring of vision. Patients develop conjunctival hyperemia and chemosis with ulceration of the cornea and whitish or yellowish infiltrate. Hypopyon (pus in the anterior chamber) may be present in cases caused by bacterial or fungal infections. Contact lens users and people with diminished corneal sensation or incomplete eyelid closure are at increased risk of developing corneal infections.

B. Laboratory Findings

Laboratory studies include culture and cytologic inspection of corneal scrapings.

► Treatment

Corneal ulceration is a serious condition requiring careful management to avoid permanent visual loss. The most devastating infection of the cornea is caused by *Pseudomonas aeruginosa*. Topical antibiotics should be given on an empirical basis until the results of culture and sensitivity tests are available. Organism-specific antimicrobial treatment should then be started. Patients using topical corticosteroids should stop using them. Central corneal ulcers may leave corneal scars, causing loss of vision. Patients severely affected may require corneal transplantation.

Patients wearing contact lenses (especially extended-wear contacts) are at higher risk of corneal ulcers. Contact lens wear should be stopped if corneal infection is suspected.

HERPES SIMPLEX

Herpes simplex virus (HSV) is a DNA virus that can affect the eye either in a primary ocular reaction or a reactivated state when latent virus travels down the axon of the sensory nerve to its target tissue. HSV is extremely common, with about 90% of the population seropositive for HSV antibodies. HSV-1 usually causes infection above the waist (face, lips, and eyes); HSV-2 infections are usually below. Rarely, HSV-2 is transmitted during birth to the infant eye through infected genital secretions (Table 37-2).

► Clinical Findings

A. Symptoms and Signs

Primary infections usually occur in children between ages 6 months and 5 years, accompanied by generalized symptoms of a viral illness. Ocular HSV is usually self-limited with the most common symptoms being blepharconjunctivitis and a dendritic keratitis.

B. Laboratory Findings

A clinical diagnosis can be made if there is a classic dendritic presentation. However, definitive diagnosis is made using viral culture or Giemsa-stained smears of corneal scrapings

Table 37-2. Herpes simplex virus (HSV) vs. herpes zoster virus (HZV).

	HSV	HZV
Rash	Clear vesicles on erythematous base; crusting	Vesicular rash along dermatomal distribution, not crossing midline; Hutchinson sign (nasociliary branch of V1) may be present
Epithelial lesion	Dendritic epithelial lesions with heaped edges	Pseudodendrites (mucous plaques without true terminal bulbs)
Staining	Edges stain with rose bengal; central ulceration stains with fluorescein	Minimal fluorescein staining
Patient population	Young	Older or immunocompromised

that reveal mononuclear cells, polymorphonuclear neutrophil leukocytes, multinucleated giant epithelial cells, and eosinophilic Lipschütz inclusion bodies in the cell nuclei. Enzyme-linked immunosorbent assay (ELISA) can be used to detect live viral particles.

► Treatment

The mainstays of treatment are topical and oral antiviral medications. Antibiotic ointment may be used at night to help prevent bacterial superinfection. Topical trifluorothymidine 1% (Viroptic) or ganciclovir ophthalmic gel 0.15% (Zirgan) is used to treat keratitis. Oral acyclovir (400 mg five times a day) or valacyclovir (500 mg three times a day) is usually added. Topical steroids can be used to treat corneal scarring or uveitis but only with concurrent topical or systemic antiviral therapy. Cost effectiveness of prophylaxis with valacyclovir or acyclovir has been analyzed but currently they are rarely used unless significant visual loss has occurred from previous herpetic episodes.

Kaufman HE et al: Ganciclovir ophthalmic gel 0.15%: safety and efficacy of a new treatment for herpes simplex keratitis. *Curr Eye Res* 2012;37(7):654-660.

DRY EYE

Dry eye is a disorder of the tear film due to either deficiency of production or excess tear evaporation. The tear film is composed of mucin, aqueous, and lipid components. Abnormalities of any layer lead to a wide variety of symptoms. Dry eye has become one of the most common reasons for visits to ophthalmologists. Symptoms are often exacerbated by weather, climate, reading, and computer use (decreased blink rate). Women have a much higher incidence of symptomatic dry eye. Primary lacrimal deficiency from disease such as Riley-Day syndrome and hypoplastic lacrimal glands is rare. Secondary lacrimal deficiency is more common and can be related to prior radiation therapy, lymphoma, sarcoidosis, graft-versus-host disease, HIV, hemochromatosis, and amyloidosis. Systemic medications such as anticholinergics (including antihistamines and antidepressants), antiadrenergics, and diuretics can cause decreased tear production. Dry eye has also been associated with menopause (presumably due to decreased androgens). Evaporative dry eye problems are usually associated with meibomian gland dysfunction. The protective lipid and mucin layers that normally keep the aqueous layer of tears stable are reduced, leading to a poor-quality tear film that breaks up easily. This problem is often associated with acne rosacea and treated conservatively with warm compresses and oral tetracycline if needed. Oral flax or fish oil supplements may help.

► Clinical Findings

Symptoms of tear deficiency often include foreign-body sensation, redness, decreased vision, and even reflex tearing. Symptoms are usually worse at the end of the day or after prolonged visual tasks.

Symptoms of evaporative tear loss include a chronic “film” over the vision, redness, burning, and itching of the eyelid margin. These symptoms are often worse in the morning. The quick breakup time of the tear film can cause difficulty with reading.

Post-LASIK (laser-assisted in situ keratomileusis) patients have decreased corneal sensation, lower tear production, and diminished blink rate, which may cause dry eye symptoms for 6-18 months or more postoperatively.

► Treatment

Treatment for aqueous deficiency includes tear supplementation. Punctal occlusion may be used in eyes shown to have decreased tear production.

In meibomian gland disease, eyelid hygiene is extremely important. Hot compresses with eyelid scrubs can improve tear quality and prevent evaporative tear loss. Mild topical corticosteroids or systemic tetracycline may also be used, especially if the patient has associated signs of acne rosacea. Topical cyclosporine A, because of its anti-inflammatory action, has been found to dramatically improve dry eye symptoms, although it may take up to 6 weeks for improvement.

PTERYGIUM

Pterygium is a fleshy, triangular conjunctival growth that is usually associated with excessive exposure to wind, sun, sand, and dust. Unilateral or bilateral, it is often on the nasal side of the cornea. There may be a genetic predisposition, but no hereditary pattern has been described.

Treatment is by superficial excision. Excision is indicated if the growth threatens vision by approaching the visual axis. After excising large or recurrent pterygia, autologous conjunctival tissue or amniotic membrane can be used to cover the defect. The conjunctiva is obtained from the upper bulbar conjunctiva and sutured to the denuded area. This leads to rapid restoration of integrity of the epithelial surface and may prevent recurrences. Patients should be advised to wear ultraviolet (UV) protection outdoors. Recurrences can occur. Topical mitomycin eye drops have been used to prevent recurrences of the disease, but serious complications such as scleral thinning and keratitis have been reported.

Zheng K et al: Comparison of pterygium recurrence rates after limbal conjunctival autograft transplantation and other techniques: meta-analysis. *Cornea* 2012 Dec;31(12):1422-1427.

INTRAOCULAR DISEASES**CATARACT**

Cataract is opacity of the lens and is the leading cause of curable blindness in the world. There are three types of cataracts: (1) congenital, (2) those associated with other disorders, and (3) age-related. Some cataracts are rapidly progressive, while others may develop more slowly. Surgical removal is indicated when patients have difficulty with daily activities or if visual development is at risk.

1. Congenital Cataract

Congenital cataract may be genetically determined or may be caused by intrauterine factors that interfere with normal development of the lens. Intrauterine viral infections (most commonly rubella) can cause congenital cataracts. Congenital cataract can be unilateral or bilateral and complete or incomplete. Dense cataract present at birth is an indication for urgent surgical management to ensure proper development of visual function.

Phacoemulsification or simple aspiration with central posterior capsulotomy and limited anterior vitrectomy under general anesthesia is recommended for removal of congenital cataracts. Preservation of the peripheral posterior capsule and zonules is important for future implantation of intraocular lenses. If the cataract is aspirated, leaving the posterior capsule intact, the posterior capsule becomes opaque, requiring capsulotomy at a later stage. Correction with soft contact lenses can be started immediately after surgery. Posterior chamber intraocular lenses can be implanted when the child is older, although children as young as 2 years are being treated with primary intraocular lens implants. Restoration of true binocular vision is seldom achieved after removal of unilateral congenital cataracts.

2. Cataracts Associated With Other Disorders

Many systemic conditions are associated with cataracts, including diabetes mellitus, galactosemia, hypocalcemia, myotonic dystrophy, Down syndrome, and cutaneous disorders such as atopic dermatitis. Certain systemic medications and eye drops containing corticosteroids can also cause cataracts. Other disorders of the eye, such as retinal detachment or chronic uveitis, may also be associated with cataracts. Eyes that have undergone retinal surgical procedures, particularly vitrectomy, have increased risk of cataract development. Physical trauma to the lens as well as injury from thermal and ionizing radiation can cause cataract formation.

3. Age-Related (Senile) Cataract

This is the most common type of cataract. The rate of progression is variable. Diagnosis is by slit-lamp examination.

Nuclear changes of the lens produce a brunescent color and often affect distance vision. In advanced cortical cataracts, a white opacity may be seen in the pupillary area upon gross inspection. Monocular diplopia can occur. Posterior subcapsular cataracts are often in younger patients, causing glare and affecting reading.

► Treatment

Once the cataract causes visual impairment, treatment is by surgical removal of the lens. Clinical trials of agents that might delay or prevent the formation of cataracts are under way, but no pharmacologic means of prevention is currently available.

Phacoemulsification of the cataract is the procedure of choice in most developed countries. Primary lens implant is preferred unless there is a contraindication to its use. In that situation, optical correction can be achieved with eyeglasses or contact lenses.

A. Intracapsular Lens Extraction

Intracapsular extraction, rarely used today, removes the lens entirely with its capsule either by forceps or a cryoprobe. This procedure cannot be performed on children or young adults because of the adhesion between the lens and the vitreous.

B. Extracapsular Extraction

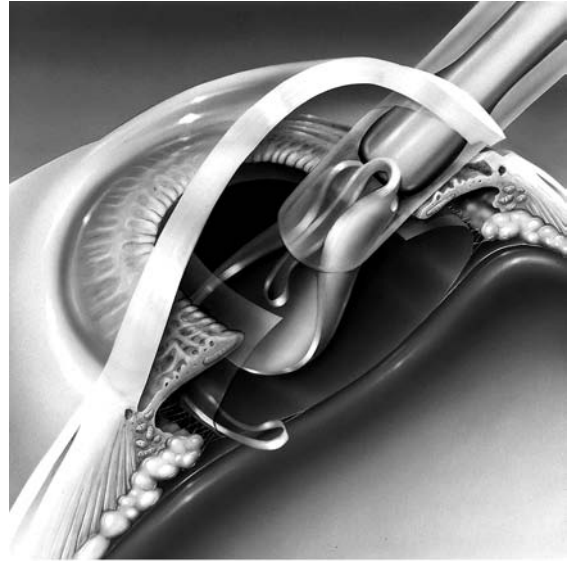

For standard extracapsular cataract extraction, the anterior capsule of the lens is removed, the nucleus of the cataract is expressed, and the residual cortical material is aspirated from the eye through a 9-11 mm incision. Smaller incision techniques that involve manual fracturing the lens nucleus prior to expression are available. The posterior capsule is left intact and an intraocular lens is placed in the capsular bag. The incision is then sutured with 10-0 nylon. In 25%-35% of patients undergoing extracapsular cataract extraction, the posterior capsule will become opacified. This is treated by Nd:YAG laser capsulotomy. If such a laser is not available, surgical incision of the opaque posterior capsule is required.

C. Phacoemulsification

See Figure 37-1. Phacoemulsification is the most common form of extracapsular cataract extraction and involves technology that fragments the nucleus of the lens using a high-frequency ultrasonic probe while simultaneously aspirating these fragments from the eye. The advantage of phacoemulsification is that incision size is reduced, less astigmatism is induced, and the patient can be more quickly rehabilitated. Remaining cortical material is removed by irrigation and aspiration, and an intraocular lens implanted. The insertion of foldable or injectable intraocular lenses through very small incisions is now possible, and often the wound is self-

A

B

sealing. Local anesthesia (either by injection or topically) is used for most adult patients.

D. Laser Assisted

Recently, femtosecond lasers have been utilized to perform multiple steps of cataract surgery including wound creation, opening the anterior lens capsule (capsulotomy), and fragmenting the cataractous lens. Development of this technology for cataract surgery could have a significant impact in the future, but at the present time there is no evidence that this technique (which is more expensive) improves visual outcomes.

Venkatesh R et al: Phacoemulsification versus manual small-incision cataract surgery for white cataract. *J Cataract Refract Surg* 2010 Nov;36(11):1849-1854.

ANGLE-CLOSURE GLAUCOMA

About 1% of people over age 35 have anatomically narrow anterior chamber angles. In such patients, if the pupil dilates spontaneously or is dilated with a mydriatic or cycloplegic

agent, the angle may close and an attack of acute glaucoma precipitated. For this reason, it is wise to estimate the depth of the anterior chamber angle before instilling these drugs.

Acute angle-closure glaucoma is manifested by sudden onset of pain, headache, blurring of vision, and colored halos around lights. Some patients develop nausea and vomiting. The eye is red, the cornea is hazy, and the pupil is mid-dilated and does not react to light. Intraocular pressure is elevated.

The attack can be aborted by use of topical pilocarpine, beta-blockers, apraclonidine and latanoprost drops, systemic acetazolamide and, if necessary, an intravenous hyperosmotic agent such as Mannitol. Definitive treatment consists of peripheral iridotomy, which establishes a communication between the posterior and anterior chambers and reopens the angle. This is usually done with an argon or Nd:YAG laser. Rarely, surgical peripheral iridectomy is required.

OPEN-ANGLE GLAUCOMA

In open-angle glaucoma, the intraocular pressure is elevated, causing gradual cupping (segmental atrophy) of the optic nerve. The damage to the nerve results in loss of vision, ranging in severity from slight constriction of the upper nasal peripheral visual field to complete blindness (absolute glaucoma). The cause of the decreased rate of aqueous outflow that characterizes open-angle glaucoma has not been fully

determined. The disease is bilateral but can be asymmetric and is probably genetically influenced. African Americans are particularly at risk.

► Clinical Findings

Open-angle glaucoma is painless, so patients are often unaware of damage until late in the course of the disease. On examination, there may be cupping of the optic disc. There is loss of peripheral visual field, but central vision acuity is usually preserved even when peripheral field loss is quite advanced. Tonometry, evaluation of the optic nerve and visual field testing are the three principal tests used for the diagnosis and continued clinical evaluation of glaucoma. Central corneal thickness should be assessed and included in risk calculations for glaucoma.

The normal intraocular pressure ranges from 10 to 20 mm Hg. Intraocular pressures higher than 21 is considered ocular hypertension, although this diagnosis should never be made on the basis of a single tonometric measurement. Transient elevations of intraocular pressure do not constitute glaucoma for the same reason that periodic or intermittent elevations of blood pressure do not constitute hypertensive disease. All persons over age 20 should have tonometric and ophthalmoscopic examinations every 3-5 years. If there is a family history of glaucoma or other risk factors, annual examination is indicated. Low-tension glaucoma is an uncommon condition characterized by visual field changes and optic nerve cupping in the presence of intraocular pressure that remains in the normal range.

► Treatment

See Table 37-3. Most patients can be controlled with topical medications including beta-blockers (eg, timolol maleate 0.25%-0.5%, one drop twice daily), α -adrenergic agonists (eg, brimonidine 0.2%, one drop twice daily), carbonic anhydrase inhibitors (eg, dorzolamide 2%, one drop twice daily), or prostaglandins (eg, latanoprost 0.005%, one drop

once daily). Oral carbonic anhydrase inhibitors (eg, acetazolamide) can be used in patients with persistent elevation of intraocular pressures despite topical treatment. Miotics (eg, pilocarpine 1%-4%, one drop four times daily) and epinephrine eye drops (0.5%-2.0%, one drop twice daily) are less commonly used today.

In laser trabeculoplasty, laser energy is applied to the trabecular meshwork. This technique can lead to significant and sustained decreases in intraocular pressure. Argon laser trabeculoplasty (ALT) and selective laser trabeculoplasty (SLT) may be used in place or along with topical medications. SLT produces similar pressure responses to ALT, but studies suggest it can be repeated multiple times in each eye. In those with persistent pressure elevation, surgery is indicated to create an alternate drainage passage for fluid to exit the eye. The most common procedure is trabeculectomy. The success of this procedure has been improved by the use of intraoperative application of mitomycin or 5-fluorouracil to inhibit the fibrosis and closure of the newly created filtering channel.

Drainage devices are also used to facilitate fluid drainage from the eye to lower intraocular pressure. Currently, the most widely used is the Ex-Press glaucoma filtration device. In certain types of glaucoma (such as neovascular glaucoma, aphakic glaucoma or for those with who have failed previous surgery), insertion of a more complex drainage device is required, often referred to as a glaucoma valve or tube shunt. An alternative approach that aims to decrease aqueous production through destruction of ciliary body tissue (diode transscleral cyclophotocoagulation or endophotocoagulation) is also employed in some situations.

de Jong LA: The Ex-PRESS glaucoma shunt versus trabeculectomy in open-angle glaucoma: a prospective randomized study. *Adv Ther* 2009 Mar;26(3):336-345.

de Jong LA et al: Five-year extension of a clinical trial comparing the EX-PRESS glaucoma filtration device and trabeculectomy in primary open-angle glaucoma. *Clin Ophthalmol* 2011;5:527-533.

Table 37-3. Types of glaucoma medications and side effects.

Class	Mechanism	Side Effects	Pregnancy Class
Beta-blockers (eg, timolol)	Decrease aqueous production	Hypotension, bradycardia, asthma exacerbation	C
α_2 -adrenergic agonist (eg, brimonidine, Propine)	Decrease aqueous production	Allergy, tachyphylaxis, CNS depression	B
Cholinergics (eg, pilocarpine)	Increase outflow	Brow ache, cataract formation, retinal detachment	C
Carbonic anhydrase inhibitors (eg, acetazolamide, dorzolamide)	Decrease aqueous production	Sulfa allergy, systemic metabolic acidosis, tingling, aplastic anemia, metallic taste	C
Prostaglandin analogues (eg, latanoprost)	Increase outflow	Bitter taste, iris color change, red eye	C

DIABETIC RETINOPATHY

Diabetes is the leading cause of new blindness in most industrialized countries. Diabetic retinopathy eventually develops in almost half of all diabetics and is a major cause of blindness. There are two clinical classifications: (1) **non-proliferative or background diabetic retinopathy** and (2) **proliferative diabetic retinopathy**. The prevalence of retinopathy increases with the duration of diabetes. Patients who have had type 1 diabetes for 5 years or less are at low risk of retinopathy. However, 27% of those with diabetes for 5-10 years and 71%-90% of those with diabetes for longer than 10 years have some form of diabetic retinopathy. After 20-30 years, the prevalence of retinopathy rises to 95%, with 30%-50% of those patients having proliferative changes. The risk for diabetic retinopathy also increases with duration for type 2 diabetes.

Diabetes can have other effects on the eye. Poor corneal healing and decreased corneal sensation have been noted. Neovascular glaucoma caused by iris neovascularization (which blocks the outflow passage in the anterior chamber angle) is seen in some patients with proliferative disease. Optic neuropathy and cranial neuropathies can also occur.

► Clinical Findings

Microaneurysms, intraretinal hemorrhages, cotton wool spots, and lipid deposits due to vascular leakage are the retinal changes seen in early diabetic retinopathy. Later stages include retinal ischemia and neovascularization with subsequent vitreous hemorrhage often associated with traction or rhegmatogenous retinal detachment. Diabetic retinopathy may be asymptomatic until vision decreases, usually from macular edema or vitreous hemorrhage. The presence of renal microvascular disease correlates well with the presence of diabetic retinopathy.

► Treatment

Careful control of blood sugar and blood pressure appears to reduce the incidence and severity of diabetic retinopathy. Recent epidemiologic studies show that many diabetics fail to have recommended yearly eye examinations. If patients are followed closely and early retinopathy is detected and treated according to the guidelines of the early treatment diabetic retinopathy study (ETDRS), the risk of severe visual loss is less than 5%. Treatment consists of photocoagulation, either of the macula to reduce edema or of the retinal periphery to reduce ischemic neovascular changes. Adjunctive intravitreal injection of triamcinolone with laser treatment has been suggested for macular edema and proliferative retinopathy. Intravitreal injections of agents that neutralize vascular endothelial growth factor (VEGF) now play a central role in treatment of diabetic macular edema. These anti-VEGF agents may also be useful for the treatment of proliferative

disease. Rare complications from these injections include endophthalmitis and steroid-induced glaucoma.

AGE-RELATED MACULAR DEGENERATION

Age-related macular degeneration (AMD) is the leading cause of central visual loss among individuals 65 and older. The pathophysiology is not completely understood although there is a strong genetic component that interacts with aging and environmental influences such as tobacco use. Regardless of the mechanism, the disease appears to affect the retinal pigment epithelium at the level of Bruch membrane. Drusen (yellowish deposits in the retina caused by the thickening, hyalinization, and calcification of the retinal pigment epithelium) are characteristic of AMD.

1. Atrophic ("Dry") Macular Degeneration

Atrophic ("dry") macular degeneration is the most common form of AMD, occurring in approximately 80% of those with the disease. Drusen, pigment changes, and atrophy are present, but there is no leakage of fluid into the subretinal space. Usually, only minimal to moderate visual loss is present although patients may complain of distorted vision (metamorphopsia).

2. Exudative ("Wet") Macular Degeneration

Exudative ("wet") macular degeneration is characterized by the development of a choroidal neovascular membrane that leaks fluid and blood. This causes a serous detachment of the central fovea that can lead to profound vision loss.

► Clinical Findings

Visual loss is caused by geographical atrophy, serous detachment of the retinal pigment epithelium, or choroidal neovascularization. Central visual acuity is primarily affected with the peripheral vision remaining intact. Metamorphopsia is a classic patient complaint. Patients can follow their own progression of disease with an Amsler grid.

► Treatment

The age-related eye disease study (AREDS) is the first large, prospective clinical trial to show the benefit of antioxidant and zinc supplementation on the progression of atrophic AMD and associated visual loss. In evaluating the rate of progression to advanced visual loss, nutritional supplements

benefited only patients who had moderate to severe disease. Supplements were not found to prevent the development of AMD or to prevent progression in patients with mild disease. The AREDS2 study started in 2008 and is examining the use of alternate micronutrients including omega-3-fatty acids in preventing the progression of AMD.

Treatment of exudative AMD was revolutionized through the use of intravitreal injections of anti-VEGF agents. Previously established therapeutic strategies such as standard laser photocoagulation or photodynamic therapy (PDT) reduced the rate of vision loss when compared to controls but did not improve acuity. These treatments remain beneficial in certain specific situations. Intravitreal injection of anti-VEGF agents such as ranibizumab (Lucentis) and bevacizumab (Avastin) has led to actual improvements in visual acuity. Intravitreal injection carries a small risk of infection and treatment resistance can be seen.

Smoking cessation is extremely important in AMD patients and should be stressed. Exercise and control of other systemic diseases such as hypertension and hypercholesterolemia may also help.

RETINAL DETACHMENT

Detachment of the retina is usually spontaneous but may be secondary to trauma. Spontaneous detachment occurs most frequently in persons over 50 years of age. Spontaneous detachments are ultimately bilateral in 20%-25% of cases.

► Clinical Findings

Retinal tears or holes are the most important predisposing factor. Increased risk of retinal detachment is also associated with cataract surgery and high myopia. In the presence of a retinal tear or hole, fluid from the vitreous cavity enters the defect and transudation from choroidal vessels detaches the retina from the pigment epithelium (rhegmatogenous). These small retinal holes may be sealed prophylactically with laser or cryotherapy to prevent detachment.

The superior temporal retina is the most common site of detachment. The area of detachment can rapidly increase

causing progressive visual loss. Central vision remains intact until the macula becomes detached. On ophthalmoscopic examination, the detached retina is seen as an elevated gray membrane.

► Treatment

All cases of retinal detachment should be referred immediately to an ophthalmologist. If the patient must be transported a long distance, the head should be positioned to try to minimize the progression of the detachment. If the upper retina is detached, the head should be kept flat. Patients with an inferior detachment should be kept upright.

Retinal detachment is a true ophthalmic emergency if the macula is threatened. If the macula is detached, permanent loss of central vision may occur even if the retina is successfully reattached by surgery. Treatment consists of drainage of subretinal fluid and closure of retinal tears by cryosurgery, laser, or scleral buckling. This produces an inflammatory reaction that causes the retina to adhere to the choroid. The creation of an inflammatory adhesion between the choroid and the retina helps to prevent future redetachment.

In uncomplicated retinal detachment with a superior retinal tear and healthy vitreous, pneumoretinopexy may be performed. The procedure consists of injection of air or certain gases into the vitreous cavity through the pars plana and positioning the patient to allow the gas bubble to seal the retinal hole and permit spontaneous reabsorption of the subretinal fluid.

About 85% of uncomplicated cases can be reattached with one operation. About 10% will need more than one procedure, and the remainder never reattach. The prognosis is worse if the macula is detached, if the vitreous is not healthy, or if the detachment is of long duration.

Without treatment, retinal detachment almost always becomes total in 1-6 months.

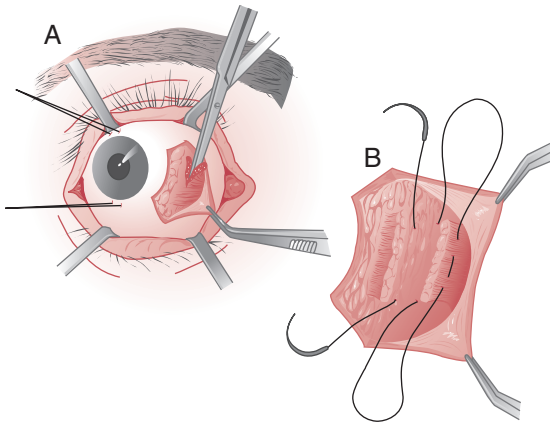

STRABISMUS IN CHILDREN

Any child under age 7 with obvious strabismus should be seen without delay to allow prompt treatment to prevent amblyopia. About 3% of children are born with or develop strabismus. In descending order of frequency, the eyes may deviate inward (esotropia), outward (exotropia), upward (hypertropia), or downward (hypotropia).

► Clinical Findings

Children with manifest strabismus suppress the visual image from the deviating eye to avoid diplopia, and the vision in that eye fails to develop normally. This is the first stage of amblyopia. Most cases of strabismus are obvious, but if the angle of deviation is small or if the strabismus is intermittent, the diagnosis can be missed.

Fortunately, amblyopia due to strabismus can be detected by routine visual acuity testing of all preschool children.

▲ **Figure 37-2.** **A.** Exposure of an extraocular muscle in surgery for strabismus. **B.** Recession of the muscle behind its original insertion followed by suturing to the sclera with absorbable suture.

Those who cannot be tested with a standard eye chart can use visual acuity testing with an illiterate E card or Allen picture chart.

► Treatment

The objectives in the surgical treatment of strabismus in children (Figure 37-2) are to achieve good visual acuity in each eye and align the eyes so that normal binocular vision with fusion can occur. Surgery can be performed in infants, and the earlier the problem is detected and corrected, the better the chance of getting a good result. Correcting the problem in children above age 7-8 often fails to result in visual improvement.

If the child is under age 6 years and has an amblyopic eye and strabismus, patching of the better eye should be instituted to improve the vision before surgery for strabismus is performed. At age 1, patching may be successful within 1 week; at age 6, it may take a year to achieve the same result. Surgery to align the eye is usually performed after the visual acuity has been equalized.

Surgery for correction of strabismus consists of weakening or strengthening the extraocular muscles. To weaken the action of a muscle, it is recessed by detaching it from its insertion site and resuturing it to a more posterior location of the sclera. To strengthen a muscle's action, it is separated at the insertion site from the globe, and a portion of it is resected and then resutured to its original insertion site. Muscles should not be recessed more than 8 mm or resected more than 6 mm.

For correction of exotropia, the lateral rectus muscles in both eyes can be recessed. Alternatively, the lateral rectus muscle can be recessed and the medial rectus muscle

resected in the same eye. The amount of recession and resection and the number of extraocular muscles chosen is determined by the degree of ocular deviation. The decision to involve one or both eyes is influenced by the visual acuity and potential of each eye. In patients with esotropia, the options are to recess the medial recti of both eyes or to recess the medial rectus in combination with resecting the lateral rectus in the same eye.

For vertical deviation, the vertical muscles are recessed, resected, tucked, or weakened by myectomy.

STRABISMUS IN ADULTS

In adults with mature visual systems, development of strabismus usually produces double vision. Strabismus can arise from head trauma, microvascular infarct as in diabetes, intracranial hemorrhage, elevated intracranial pressure, brain tumor, or orbital disease.

► Treatment

Surgical management of strabismus is the same as described for children. Since visual pathways have already been formed, the indications for surgery are for cosmetic reasons or because of diplopia. Care must be taken not to induce diplopia after surgery.

OCULAR MIGRAINE

Migraine is a disorder with multiple clinical presentations. Recurrent headaches are classic, and ocular symptoms are often associated. The pathophysiology of migraine is uncertain and there may be a genetic component. The differential diagnosis for migraine headaches includes stress-tension headache, cluster headache, sinus congestion/pathology, elevated intracranial pressures, orbital inflammation, orbital neoplasia, and temporal arteritis. A thorough headache history and neurologic examination are important diagnostic tools.

Patients with ocular migraine present with visual symptoms; headache and nausea, if present at all, follow. The ocular symptoms can mimic retinal disease, and a dilated ocular examination is needed to rule out retinal pathology when the symptoms are atypical. The flashing lights from retinal disease are primarily unilateral, while migraine presents with bilateral visual distortion. Asking the patient to cover each eye and see if the symptoms are unilateral or bilateral may clarify the situation. Prophylaxis to prevent migraine with oral β -adrenergic blockers, calcium-channel blockers, and tricyclic antidepressants may be used. Triptans such as sumatriptan (Imitrex) are often used to treat the acute episodes. Onabotulinum toxin A (Botox) injections are an effective treatment option for debilitating migraine not controlled by other medications. Acephalgic migraine typically is not treated with systemic agents because of the self-limited nature of the disease.

► Classical Migraines

Classical migraine is characterized by throbbing headaches preceded by visual auras lasting about 20 minutes. The aura may consist of bright or dark spots, zigzag lines (fortification scotoma), heat haze distortions, scintillating scotomas, and tunnel vision. Homonymous or altitudinal hemianopia may rarely occur. The headaches that follow may vary in intensity.

► Retinal Migraine

Retinal migraine is characterized by acute, transient unilateral loss of vision that can be identical to that seen in amaurosis fugax. Vascular etiologies must be ruled out with thorough ocular and medical examination before attributing symptoms to be migraine. Amaurosis is often shorter in duration and has a more “curtain-like” quality.

► Ophthalmoplegic Migraine

Ophthalmoplegic migraine is very rare and typically starts before the age of 10 years. It is characterized by a recurrent transient third nerve palsy that is associated with a typical migraine headache.

► Complicated Migraine

Complicated migraine is associated with neurologic deficits such as tingling in the extremities, hemisensory disturbance and partial visual loss. Rarely, the deficit persists after the headache has resolved. Antiplatelet therapy with aspirin is often recommended.

Diener HC et al: OnabotulinumtoxinA for treatment of chronic migraine: results from the double-blind, randomized, placebo-controlled phase of the PREEMPT 2 trial. *Cephalalgia* 2010;30(7):804-814.

OCULAR BURNS

CHEMICAL BURNS

Apart from the history, the diagnosis of chemical eye burns is usually based on the presence of swelling of the eyelids and marked conjunctival hyperemia and chemosis. The limbal area may show blanched patchy areas and conjunctival sloughing, especially in the interpalpebral area. There is usually corneal stromal haze and diffuse edema, with wide areas of epithelial cell loss and corneal ulcerations. Defects in the corneal epithelium can be better visualized with the instillation of fluorescein dye.

Alkali burns of the eye are particularly serious because the agents tend to rapidly penetrate intraocularly. Retained particles in the conjunctival fornices may continue to release alkaline material and must be promptly removed. Patients are managed by instilling a topical anesthetic agent and then

immediately irrigating copiously (at least several liters) with tap water or any other available solution until a neutral pH is reached. This may require hours of flushing. Double eversion of the upper eyelid should be performed to look for and remove material lodged in the superior fornix. This can be easily done by using a forceps or moist cotton applicator. Topical dilating drops such as atropine 1% or homatropine 5% are instilled, and a topical antibiotic ointment such as ophthalmic erythromycin and bacitracin should be applied. Severe injuries that result in eyelid destruction require hospitalization and specialized care.

Acid burns cause rapid damage but are in general less serious than alkali burns because of lack of intraocular penetration. Irrigation is carried out as described above, the patient is given an analgesic, and the eye is patched for a short time. Close follow-up is needed. Topical antibiotic ointment may also be used.

THERMAL BURNS

The treatment of thermal burns of the eyes is similar to the treatment of burns elsewhere on the body. Adequate systemic analgesia should be provided. A topical anesthetic agent such as proparacaine 0.5% or tetracaine 0.5% is used to minimize pain during manipulation. In cases of burns involving the cornea, topical dilating drops such as atropine 1% or homatropine 5% are instilled. Antibiotic drops are often prescribed for 3-5 days.

BURNS DUE TO ULTRAVIOLET RADIATION

Injuries to the corneal epithelium by UV rays vary in severity. They are described as actinic keratitis, snow blindness, welder's arc burn or flash burn, depending on the source of ultraviolet radiation. Patients present with severe pain, tearing, and photophobia. The examination reveals diffuse punctate staining of the cornea, best seen with fluorescein staining, proper magnification, and a cobalt blue light.

A topical antibiotic such as ophthalmic erythromycin or bacitracin ointment is instilled. Topical nonsteroidal drops such as diclofenac or ketorolac tromethamine can be used for pain.

OCULAR TRAUMA

Eye injuries are common in spite of the protection afforded by the bony orbit. Blunt trauma is the most common injury, but penetrating injuries of the globe, although less frequent, are often more serious. The use of protective eyewear at work helps prevent most serious occupational injuries.

► Clinical Evaluation

A careful history should be obtained from the patient or someone who knows what happened. Visual acuity should

be checked. The eyelids, conjunctiva, cornea, anterior chamber, iris, lens, vitreous, and fundus should be evaluated. Corneal damage (such as abrasions) can be detected by instilling fluorescein dye and using a cobalt blue light to examine the anterior surface. CT scan or x-ray examination is helpful in looking for fractures of the orbital bones or foreign bodies. Patients with severe injuries should have immediate ophthalmic consultation.

PENETRATING OR PERFORATING INJURIES

Penetrating or perforating ocular injuries require immediate treatment and prompt surgical repair to maximize chances for preservation of vision.

Facial injuries—especially those occurring in automobile accidents can be associated with penetrating ocular trauma. Some injuries may be undetected because of eyelid swelling or because the patient's other injuries have demanded the attention of the emergency room staff. Accurate records and a description of how the injury occurred should be obtained. The eye and ocular adnexa should be examined, including vision testing and testing of ocular motility. *Do not apply pressure on the globe.* X-ray examination and CT scan are performed to rule out fractures of orbital bones or the presence of intraocular foreign bodies. An eye with a penetrating injury should be protected from further injury with a Fox or similar shield and light dressing. Parenteral broad-spectrum antibiotics such as cefazolin or gentamicin should be given. Antiemetics (eg, ondansetron, 4 mg intravenously) should be given to the patient when needed to prevent vomiting, which can lead to extrusion of the intraocular contents.

Careful repair and approximation of corneal and scleral lacerations should be performed in the operating room. Magnetic metallic intraocular foreign bodies can be extracted with a magnet in the operating room. The major objectives in management of ocular penetrating or perforating injuries are to relieve pain, preserve or restore vision, and achieve good cosmetic results. Pain relief may be achieved by the administration of intravenous or subcutaneous morphine or meperidine. Sedatives such as diazepam 5 mg may be given orally as required.

LACERATIONS OF THE OCULAR ADNEXA

Lacerations of the eyelids and the periorbital skin should be carefully evaluated. Small linear skin lacerations can be easily repaired with 6-0 nylon sutures. The sutures can usually be removed in 3-5 days. In cases of deep eyelid lacerations, intraocular or orbital damage should be ruled out before the repair is performed. The skin of the eyelids has good elasticity and in adults is frequently present in surplus quantities. This facilitates the development of flaps and grafts. In deep lacerations of the eyelids, if the wound divides the orbicularis muscle parallel to its fibers, only skin sutures are

Table 37-4. Types of ocular injury associated with blunt trauma.

Eyelids	Ecchymosis, swelling, laceration, abrasions, conjunctival, or subconjunctival hemorrhages
Cornea	Edema, lacerations
Anterior chamber	HypHEMA, recession of angle, secondary glaucoma
Iris	Iridodialysis, iridoplegia, rupture of iris sphincter
Ciliary body	Hyosecretion of aqueous humor
Lens	Cataract, dislocation
Vitreous	Vitreous hemorrhage
Ciliary muscle	Paralysis
Retina	Comotio retinae, retinal edema, choroidal breaks in Bruch membrane, choroidal hemorrhage

generally required. When the muscle fibers are transversely divided, they should be approximated with 6-0 absorbable synthetic sutures. The skin can be approximated with nylon sutures. In patients with lacerations resulting in round or oval losses of skin, the skin is undermined and the laceration approximated. For larger defects, reconstruction with flaps may be required. Flaps used in reconstruction of the eyelids are advancement flaps, rotational flaps, transposition flaps, island flaps, and Z-plasty flaps.

When flaps cannot be used, free skin grafts may be obtained from behind the ear or from the skin of the inner upper arm. Special care should be taken with repair of lacerations of the lower lid to be certain that the lid is not closed under tension to prevent eversion and distortion of the lid margin.

BLUNT TRAUMA TO THE OCULAR ADNEXA & ORBIT

Contusions of the eyeball and ocular adnexa may result from blunt trauma (Table 37-4). The extent of damage to the vision may not be obvious upon initial examination. A careful dilated eye examination is needed for all patients with this type of injury.

BLOWOUT FRACTURE OF THE FLOOR OF THE ORBIT

Blowout fracture of the floor of the orbit can be associated with enophthalmos, double vision in primary position or upgaze, restriction of ocular movement, hypotropia, and decreased or absent sensation over the maxillary area in the distribution of the infraorbital nerve. CT scan of the orbit will document the extent of the orbital injury that can involve the medial wall as well as the floor. There may be air

noted in the sinuses. Evaluation and management of patients with blowout fractures may involve both an ophthalmologist and an otolaryngologist because of potential associated fractures of the maxilla or zygoma. Patients are usually treated with a systemic antibiotic (cephalothin or amoxicillin/potassium clavulanate), told not to blow their nose and reassessed within 1 week by an ophthalmologist. Many blowout fractures do not require surgical correction. Operative management is recommended if there is significant enophthalmos, continued diplopia in primary gaze or significant instability of the orbital floor.

CORNEAL & CONJUNCTIVAL FOREIGN BODIES

Patients often give a history of working with high-speed tempered steel tools, drilling, or hammering against a hard object. There may be no history of trauma to the eye, and the patient may not be aware of a foreign body. In most cases, however, the patient complains of foreign-body sensation in the eye or under the eyelid with associated pain, tearing, and photophobia.

A corneal foreign body can be seen with the aid of a loupe and diffuse light. Conjunctival foreign bodies often become embedded in the inner surface of the upper lid, which must be everted to facilitate inspection and removal. A topical anesthetic such as proparacaine 0.5% or tetracaine 0.5% is applied. Sterile fluorescein should be instilled to assist in the visualization of small foreign bodies. Some loose foreign bodies can be removed with a moist cotton applicator; others require use of the tip of a hypodermic needle. Topical antibiotic ointment should be instilled (eg, erythromycin or bacitracin) and the eye patched for a few hours if necessary. Patients with continued foreign-body sensation, pain, or decreased vision need to be referred to an ophthalmologist for the possibility of corneal ulceration.

Use of the topical anesthetic by the patient will decrease healing and increase risk of corneal ulceration. Topical anesthetics should be used only for examination purposes, *never* for treatment. If there is any suspicion of penetrating trauma or history consistent with that type of injury, appropriate ultrasound and radiologic tests should be performed.

OCULAR TUMORS

Tumors of the adnexal structures can often be recognized early because they are usually visible and cause local disfigurement, interference with vision or displacement of the globe. Intraocular tumors are more difficult to diagnose, but in children ocular tumors such as retinoblastoma that affect visual function may present with strabismus or leukocoria. Tumors of the eye may be primary (affecting only the ocular or adnexal tissues) or secondary to metastatic tumors. In the eye, the highly vascular choroid is most frequent site of metastasis is the choroid. The tumors that

most frequently metastasize to the eye are carcinoma of the breast and lung.

The history of growth of the lesion is extremely important, as well as recent changes in its size or appearance. Excisional biopsy of lesions of the skin or conjunctiva is indicated if cancer is suspected.

LID TUMORS

► Benign Tumors of the Eyelids

The most frequent benign tumors of the eyelids are melanocytic nevi. Excision is indicated primarily for cosmetic reasons (Figure 37-3). Xanthelasma represent lipid deposits in histiocytes in the dermis of the skin of the eyelid. In such patients, a lipid profile is indicated. Treatment is indicated for cosmetic reasons and consists of simple excision. The lesions tend to be larger than the surface size would indicate and recurrences are common. Care must be taken not to foreshorten the eyelid skin and impair eyelid closure.

▲ **Figure 37-3.** Tumor of the left lower eyelid involving the lid margin. **A.** Two vertical incisions are made. **B.** The defect after removal of the tumor. **C.** Suturing of the tarsus and orbicularis with absorbable sutures. **D.** Approximation of the eyelid margin. Skin is approximated with 6-0 silk sutures.

Hemangiomas of the eyelids consist of two types: capillary and cavernous. Capillary hemangiomas consist of dilated capillaries and proliferation of endothelial cells. The lesions appear as bright red spots. They may show rapid growth in early childhood but later often undergo involution and subside spontaneously. Treatment of hemangiomas in infancy and early childhood is not indicated unless they cause interference with vision that may lead to amblyopia. Low-dose oral steroids, local injection of steroids, or systemic use of beta-blockers may cause rapid involution. Cavernous hemangiomas are venous channels in the subcutaneous tissue. They appear bluish in color and are distended. Surgical excision may be required. Radiation is not recommended because it leads to excessive scarring of the eyelid.

Other benign tumors of the eyelids include verrucae and molluscum contagiosum. These lesions are caused by viruses.

Missoi TG et al: Oral propranolol for treatment of periocular infantile hemangiomas. *Arch Ophthalmol* 2011 Jul;129(7):899-903.

► Malignant Tumors of the Eyelids

Squamous cell carcinoma has a tendency to grow slowly and painlessly. It begins as a small lesion covered by a layer of keratin. The lesion may erode, causing an ulcer with hyperemic edges. It may enlarge to form a fungating mass and invade the orbit. Early excision can result in cure. If early treatment is not provided, squamous cell carcinoma can involve the lymphatic system to the preauricular and submandibular lymph nodes.

Basal cell carcinoma begins as a slowly growing, locally invasive tumor forming the so-called “rodent ulcer” with raised nodular borders. It is the most common malignant eyelid tumor. Inner canthal basal cell carcinoma invades locally and can extend into the orbit. Treatment should include complete excision to prevent recurrence. Mohs is usually performed to assure clean margins prior to eyelid reconstruction. Often, the lesions are more extensive than they appear visually. Systemic metastasis is rare.

Malignant melanomas of the eyelids behave similar to malignant melanomas of the skin.

CONJUNCTIVAL TUMORS

Benign tumors of the conjunctiva include melanocytic nevi (pigmented or nonpigmented), papillomas, granulomas, dermoids, and lymphoid hyperplasia. Malignant tumors of the conjunctiva include carcinoma, malignant melanoma, and lymphoma. Carcinoma of the conjunctiva arises frequently at the limbus or the inner canthus in the exposed area of the bulbar conjunctiva. Early in the course of the disease, the lesion can resemble a pterygium. The tumor is

slightly elevated, with a gelatinous surface and may spread over the corneal surface. These grow slowly. Treatment is by wide excisional biopsy and cryotherapy or topical interferon alpha.

Shah SU et al: Topical interferon alfa-2b for management of ocular surface squamous neoplasia in 23 cases: outcomes based on American Joint Committee on Cancer classification. *Arch Ophthalmol* 2012 Feb;130(2):159-164.

INTRAOCULAR TUMORS

► Benign Intraocular Tumors

Melanocytic nevi of the iris, ciliary body, or choroid are common. No treatment is required. Retinal angioma may be seen in patients with phacomatoses (eg, Bourneville disease). Choroidal hemangioma is another less frequently encountered benign intraocular tumor.

► Malignant Intraocular Tumors

Malignant intraocular tumors include malignant melanoma of the uvea, retinoblastoma, and a rare tumor of the ciliary body known as diktyoma or medulloepithelioma.

Malignant melanoma of the uvea is the most common primary intraocular tumor in adults. It typically occurs in the fifth or sixth decade and is almost always unilateral. The most frequent site is the choroid, but malignant melanoma can occur also in the ciliary body or iris. Malignant melanomas of the choroid often do not cause decrease in vision. Necrosis of the tumor can lead to intraocular inflammation. Histopathologic examination shows spindle-shaped cells with or without prominent nuclei and large epithelioid tumor cells. Intraocular malignant melanomas may spread directly through the sclera by local invasion or directly into the central nervous system via optic nerve extension.

Malignant melanomas can be detected by ophthalmoscopy after pupillary dilation.

Treatment of malignant melanoma consists of enucleation or radiotherapy with radioactive plaques or charged particles. Extension outside the eye may require exenteration of the orbit. Patients with small melanomas—less than 10 mm in diameter—can be followed with serial fundus photos. Similarly, small melanomas of the iris that have not invaded the iris root can be safely followed and observed until growth is documented. If there is growth of the iris tumor, treatment is by local iridectomy. If the iris malignant melanoma invades the root and ciliary body, it can be removed surgically by iridocyclectomy.

Retinoblastoma is a rare but life-threatening condition in childhood. It is the most frequent intraocular malignant tumor in children. It arises from embryonic cone cells of

the photoreceptor layer. Most patients with retinoblastoma present in the first or second year of life. Patients present with leukocoria or strabismus. Retinoblastoma may be unilateral or bilateral and is often multifocal. There are both sporadic and inherited forms of the disease. It may grow slowly to fill the intraocular space and undergo necrosis, leading to calcific deposits. Tumor cells may seed on the iris and in the anterior chamber, causing fluffy whitish exudates.

Spontaneous remission of retinoblastoma has been reported. Treatment options include radiotherapy, cryotherapy, chemotherapy, intra-arterial chemotherapy, and enucleation.

Abramson DH: Chemosurgery for retinoblastoma: what we know after 5 years. *Arch Ophthalmol* 2011 Nov;129(11):1492-1494.

ORBITAL TUMORS

Orbital tumors are of two types: primary and secondary. Benign primary orbital tumors include dermoid cysts, hemangiomas, lipomas, fibromas, osteomas, chondromas, neurofibromas, and lacrimal gland tumors. Malignant tumors include rhabdomyosarcoma, adenocarcinoma of the lacrimal gland and lymphomas. In children, rhabdomyosarcoma often presents with acute, painless unilateral proptosis and needs to be evaluated immediately. Secondary tumors include malignant melanoma and retinoblastoma from the intraocular structures and malignant melanomas and carcinomas from the skin of the eyelids and conjunctiva. Metastatic lesions commonly are from the lung or breast. Neuroblastoma can also metastasize to the orbit in children. Meningiomas of the cranial nerves may invade the orbit through the optic canal.

Treatment and prognosis in all cases depend on the type of tumor.

LASER TREATMENTS FOR OCULAR DISEASE

The laser has many useful applications in ophthalmology. Using various gases, a single-wavelength beam can be produced that can be absorbed by specific tissues in the eye.

FOCAL DIABETIC TREATMENT

Macular edema occurs in the preproliferative stage of diabetic retinopathy and is characterized by retinal thickening (with or without exudates) within the central macular area. This procedure is performed with a slit-lamp laser delivery system using a contact lens and is aided by fluorescein angiography. Improvement may not occur for several months. Long-term studies by the National Institutes of Health have shown that treatment with an argon laser may improve visual outcome by as much as 50%.

PANRETINAL PHOTOCOAGULATION

Panretinal photocoagulation is indicated for treatment of proliferative diabetic retinopathy. Using a contact lens and a slit-lamp delivery system, extensive destruction of peripheral retina is undertaken to decrease production of vasoproliferative factors and increase retinal oxygenation, causing regression of abnormal blood vessels.

LASER SURGERY FOR CORRECTION OF REFRACTIVE ERROR

LASIK is a lamellar refractive surgical procedure, which involves creation of a partial-thickness corneal flap under high suction. The flap is then lifted and an ArF (argon-fluoride) excimer beam is used to ablate stromal tissue with minimal thermal effect. The flap is then replaced and allowed to heal. The combination of precision, minimal postoperative discomfort, and quick visual recovery make this the most popular refractive technique. A newer technology of flap creation with femtosecond laser instead of microkeratome blades is becoming more popular.

MULTIPLE CHOICE QUESTIONS

1. A 61-year-old Caucasian woman presents with sudden-onset right-sided head pain, right eye redness, and blurred vision. Examination of the right eye is difficult due to the patient's nausea and vomiting, but reveals visual acuity of 20/400, a mid-dilated, unreactive pupil, a hazy cornea, and an intraocular pressure of 57. What is the best course of action at this time?
 - A. Obtain an immediate head CT to rule out orbital abscess.
 - B. Arrange for follow-up with an ophthalmologist within the next 1-2 weeks.
 - C. Medically manage the patient's pain and nausea and arrange an urgent ophthalmology consult.
 - D. Start the patient on oral acyclovir as this is likely herpes simplex-induced uveitis.
2. A 42-year-old man with a history of chronic sinusitis presents with worsening left eyelid swelling over the preceding 3 days and intermittent double vision for the past 8 hours. Examination reveals swollen, red, and warm left eyelids. Visual acuity is 20/20 in both eyes and pupillary reactions are normal; however, extraocular motility is limited on lateral gaze in the left eye. What is the best course of action at this time?
 - A. Start the patient on a course of oral antibiotics.
 - B. Arrange for an outpatient CT scan and endocrine follow-up as this is likely thyroid ophthalmopathy.
 - C. Obtain a maxillofacial CT scan and start on IV antibiotics.

- D. Start the patient on a course of valacyclovir 1000 mg three times daily.
3. Which statement regarding herpes simplex virus is TRUE?
- A. Eye infections are most commonly caused by the HSV-2 virus.
 - B. If a vesicular lesion is seen on the tip of the nose this suggests intraocular involvement of HSV.
 - C. Early use of antivirals may help reduce the risk of postherpetic neuralgia.
 - D. HSV keratitis classically presents with a dendritic corneal lesion.
4. Which of the following conditions is not treated with VEGF (vascular endothelial growth factor)-targeting agents?
- A. Diabetic macular edema.
 - B. Exudative “wet” macular degeneration.
 - C. Nonexudative “dry” macular degeneration.
 - D. Neovascular glaucoma.
5. A 25-year-old man reports from his job as a janitor after “ammonia” splashed in his right eye. What is the best course of action at this time?
- A. Send out for special ophthalmic solution, perform a complete dilated exam, and call for an ophthalmology consult.
 - B. Use artificial tears to rinse out remaining ammonia.
 - C. Instill tetracaine 0.5% and irrigate with ~2 liters of saline (or any other immediately available fluid) immediately.
 - D. Instill topical dilating drops and antibiotic ointment.

Urology

Christopher S. Cooper, MD

Fadi N. Joudi, MD

Mark H. Katz, MD

EMBRYOLOGY OF THE GENITOURINARY TRACT

A basic understanding of genitourinary embryology facilitates learning many aspects of urology. Embryologically, the genital and urinary systems are intimately related. Associated anomalies of the two systems are commonly encountered.

► The Kidneys

The kidneys pass through three embryonic phases (Figure 38–1): (1) The **pronephros** is a vestigial structure without function in human embryos that, except for its primary duct, disappears completely by the fourth week. (2) The pronephric duct gains connection to the **mesonephric tubules** and becomes the mesonephric duct. While most of the mesonephric tubules degenerate, the mesonephric duct persists bilaterally; from where it bends to open into the cloaca, the ureteral bud grows cranially to interact with the metanephric blastema. (3) This forms the **metanephros**, which is the final phase. The metanephros develops into the kidney. During cephalad migration and rotation, the metanephric tissue progressively enlarges, with rapid internal differentiation into the nephron and the uriniferous tubules. Simultaneously, the cephalad end of the ureteral bud expands and divides within the metanephros to form the renal pelvis, calices, and collecting tubules.

► The Bladder & Urethra

Subdivision of the cloaca (the blind end of the hindgut) into a ventral (urogenital sinus) and a dorsal (rectum) segment is completed during the seventh week and initiates early differentiation of the urinary bladder and urethra. The urogenital sinus receives the mesonephric duct and absorbs its caudal end, so that by the end of the seventh week, the ureteral bud and mesonephric duct have independent openings. The ureteral orifice migrates upward and laterally. The mesonephric duct orifice moves downward and medially,

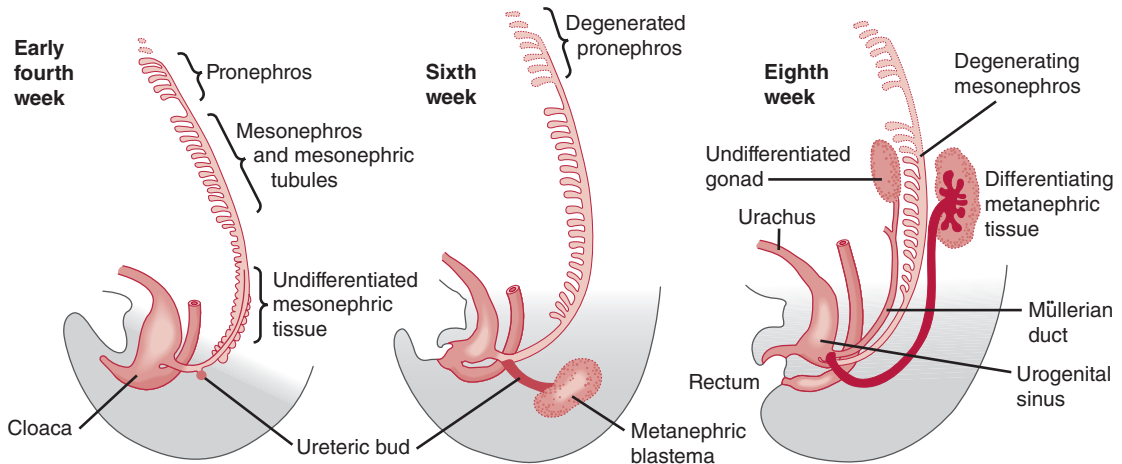

and the structure in between (the trigone) is formed by the absorbed mesodermal tissue, which maintains direct continuity between the two tubes (Figure 38–2).

The fused müllerian ducts also meet the urogenital sinus at Müller's tubercle. The urogenital sinus above Müller's tubercle differentiates to form the bladder and the part of the prostatic urethra proximal to the seminal colliculus in the male or the bladder and the entire urethra in the female (Figure 38–3). Below Müller's tubercle, the urogenital sinus differentiates into the distal part of the prostatic urethra and the membranous urethra in the male or the distal vagina and vaginal vestibule in the female. The rest of the male urethra is formed by fusion of the urethral folds on the ventral surface of the genital tubercle. In the female, the genital folds remain separate and form the labia minora.

The prostate develops at the end of the 11th week as several groups of outgrowths of urethral epithelium both above and below the entrance of the ejaculatory duct (distal vas deferens). The developing glandular element (seminal colliculus) incorporates the differentiating mesenchymal cells surrounding it to form the muscular stroma and capsule of the prostate. The seminal vesicles form as duplicate buds from the distal end of the mesonephric duct (vas deferens).

► The Gonads

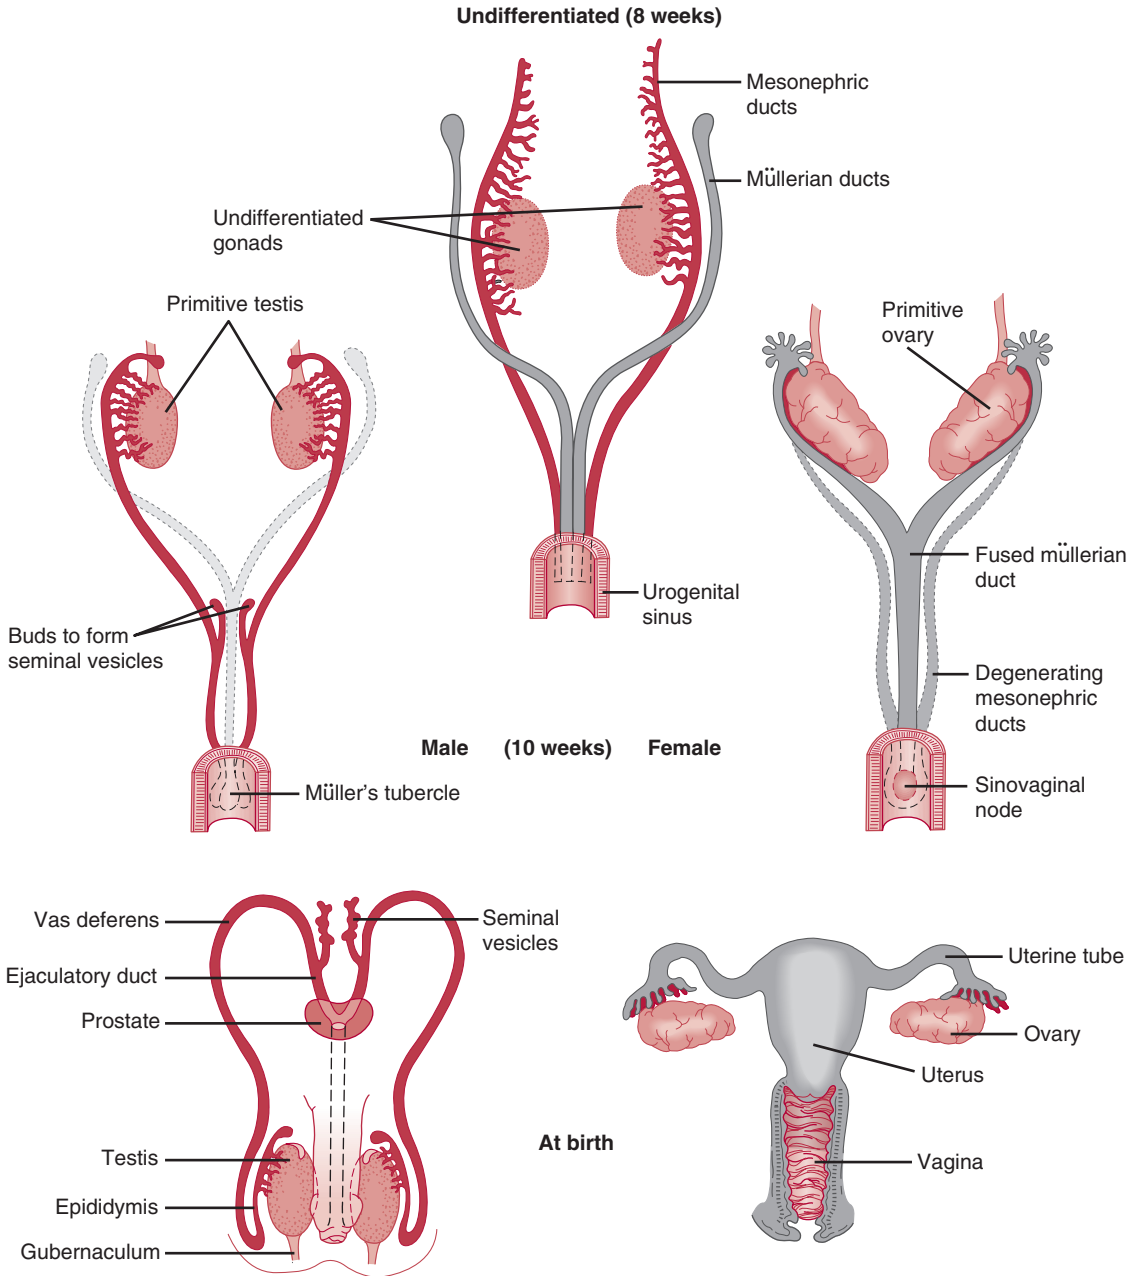

The potential to differentiate along male or female lines is present in every embryo initially. The development of one set of sex primordia and the gradual involution of the other are determined by the genetic sex of the embryo and differential secretion of numerous hormones. The *SRY* gene—or testis-determining factor—on the Y chromosome drives the gonad to differentiate into a testicle. Gonadal differentiation begins during the seventh week (Figure 38–3). If the gonad develops into a testis, the germinal epithelium progressively grows into radially arranged, cord-like seminiferous tubules. The production of müllerian-inhibiting factor by the testicle

▲ **Figure 38-1.** Schematic of the development of the nephric system. Only a few of the tubules of the pronephros are seen early in the fourth week, while the mesonephric tissue differentiates into mesonephric tubules that progressively join the mesonephric duct. The first sign of the ureteral bud from the mesonephric duct is seen at 4 weeks. At 6 weeks, the pronephros has completely degenerated and the mesonephric tubules start to do so. The ureteral bud grows dorso-cranially and has met the metanephric blastema. At the eighth week, there is cranial migration of the differentiating metanephros. The cranial end of the ureteral bud expands and starts to show multiple successive outgrowths (renal calices).

▲ **Figure 38-2.** The development of the ureteral bud from the mesonephric duct and their relationship to the urogenital sinus. The ureteral bud appears at the fourth week. The mesonephric duct distal to this ureteral bud is gradually absorbed into the urogenital sinus, resulting in separate endings for the ureter and the mesonephric duct. The mesonephric tissue that is incorporated into the urogenital sinus expands and forms the trigonal tissue. The mesonephric duct forms the vas deferens in the male and Gartner's duct (if present) in the female.

▲ **Figure 38–3.** Transformation of the undifferentiated genital system into the definitive male and female systems.

causes regression of the müllerian duct and acts in a local (paracrine) fashion so that only the ipsilateral müllerian duct is affected. The subsequent production of testosterone by the testicle leads to masculinization of the mesonephric (wolffian) duct structures (ie, epididymides, vas deferens, seminal

vesicles, and ejaculatory duct). If the gonad develops into an ovary, it becomes differentiated into a cortex and a medulla; the cortex later differentiates into ovarian follicles containing ova. The lack of testosterone leads to the disappearance of the mesonephric duct.

The testes remain in the abdomen until the seventh month and then pass through the inguinal canal to the scrotum, following the path of the gubernaculum. The mechanism of descent remains uncertain. Lack of complete testicular descent is known as cryptorchidism; descent to an abnormal site beyond the external inguinal ring is known as testicular ectopia.

The ovary, which is attached to ligaments, undergoes internal descent to enter the pelvis.

In the female, the genital duct system develops from the müllerian ducts, which fuse at their caudal ends and differentiate into the uterine tubes, the uterus, and the proximal two-thirds of the vagina.

The external genitalia start to differentiate by the eighth week. The genital tubercle and genital swellings develop into the penis and scrotum in the male and the clitoris and labia majora in the female. The external genitalia are masculinized by dihydrotestosterone (DHT), which is created from testosterone under the influence of 5 α -reductase.

With the breakdown of the urogenital membrane in the seventh week, the urogenital sinus achieves a separate opening on the undersurface of the genital tubercle. The expansion of the infratubercular part of the urogenital sinus forms the vaginal vestibule and the distal third of the vagina. The two folds on the undersurface of the genital tubercle unite in the male to form the penile urethra; in the female, they remain separate to form the labia minora.

ANATOMY OF THE GENITOURINARY TRACT: GROSS & MICROSCOPIC

► The Kidneys

The kidneys lie retroperitoneally in the posterior abdomen and are separated from the surrounding renal fascia (Gerota's fascia) by perinephric fat. The renal vascular pedicle enters the renal sinus; the vein is anterior to the artery, and both are anterior to the renal pelvis. The renal artery divides just outside the renal sinus into anterior and posterior branches that undergo further subdivisions with variable extents of distribution. They are end arteries and thus result in segmental infarction when occluded. The venous tributaries anastomose freely and usually drain into one renal vein.

► The Renal Parenchyma

The renal parenchyma consists of more than 1 million functioning units (nephrons) and is divided into a peripheral cortex containing secretory elements and a central medulla containing excretory elements. The nephron starts as Bowman's capsule, which surrounds the glomerulus and leads to elongated proximal and distal convoluted tubules with the loop of Henle in between, ending in a

collecting duct that opens into a minor calix at the tip of a papilla.

► The Renal Pelvis & Calices

The renal pelvis and calices are within the renal sinus and function as the main collecting reservoir. The pelvis, which is partly extrarenal and partly intrarenal (but occasionally is totally extrarenal or intrarenal), branches into three major calices that in turn branch into several minor calices. These calices are directly related to the tips of the medullary pyramids (the papillae) and act as a receiving cup to the collecting tubules. The pelvicaliceal system is a highly muscular structure; the fibers run in many directions and are directly continuous from the calices to the pelvis, allowing synchronization of contractile activity.

► The Ureter

The ureter connects the renal pelvis to the urinary bladder. It is a muscularized tube; its muscle fibers lie in an irregular helical arrangement and function primarily in peristaltic activity. Ureteral muscle fibers are directly continuous from the renal pelvis cranially to the vesical trigone distally.

The blood supply to the renal pelvis and ureters is segmental, arising from multiple sources, including the renal, gonadal, and vesical arteries, with rich subadventitial anastomoses.

► The Bladder

The bladder is primarily a reservoir with a meshwork of muscle bundles that not only change from one plane to another but also branch and join each other to constitute a synchronized organ. Its musculature is directly continuous with the urethral musculature and thus functions as an internal urethral sphincteric mechanism in spite of the lack of a true circular sphincter.

The ureters enter the bladder posteroinferiorly through the ureteral hiatus; after a short intravesical submucosal course, they open into the bladder and become continuous with the trigone, which is superimposed on the bladder base though deeply connected to it.

► The Urethra

The adult female urethra is about 4 cm long and is muscular in its proximal four-fifths. This musculature is arranged in an inner longitudinal coat that is continuous with the inner longitudinal fibers of the bladder and an outer circular coat that is continuous with the outer longitudinal coat of the bladder. These outer circular fibers comprise the sphincteric mechanism. The striated external sphincter surrounds the middle third of the urethra.

In the male, the prostatic urethra is heavily muscular and sphincteric. The membranous urethra is within the urogenital

diaphragm and is surrounded by the striated external sphincter. The penile urethra is poorly muscularized and traverses the corpus spongiosum to open at the tip of the glans.

► The Prostate

The prostate surrounds the proximal portion of the male urethra; it is a fibromuscular, cone-shaped gland about 2.5 cm long and normally weighing about 20 g in the adult. It is traversed from base to apex by the urethra and is pierced posterolaterally by the ejaculatory ducts from the seminal vesicles and vas deferens that converge to open at the verumontanum (seminal colliculus) on the floor of the urethra.

The prostatic glandular elements drain through about 12 paired excretory ducts that open into the floor of the urethra above the verumontanum. The prostate is surrounded by a thin capsule, derived from its stroma, which is rich in musculature, and part of the urethral musculature and the sphincteric mechanism. A rich venous plexus surrounds the prostate, especially anteriorly and laterally. Its lymphatic drainage is into the hypogastric, sacral, obturator, and external iliac lymph nodes.

► The Testis, Epididymis, & Vas

The testis is a paired organ surrounded by the tunica albuginea and subdivided into numerous lobules by fibrous septa. The extremely convoluted seminiferous tubules gather to open into the rete testis, where they join the efferent duct and drain into the epididymis. The epididymis drains into the vas deferens, which courses through the inguinal canal into the pelvis and is joined by the duct from the seminal vesicle to form the ejaculatory duct, which opens before opening into the prostatic urethra on either side of the verumontanum.

Arterial supply is via the spermatic, vas deferential, and external cremasteric arteries. Venous drainage is through the pampiniform plexus, which drains into the internal spermatic veins; the right spermatic vein joins the vena cava, and the left joins the renal vein.

Testicular lymphatics drain into the retroperitoneal lymph nodes; the right primarily into the interaortocaval area, the left into the para-aortic area, both just below the renal vessels.

PHYSIOLOGY OF THE GENITOURINARY TRACT

► The Kidneys

The kidneys maintain and regulate homeostasis of body fluids by glomerular filtration, tubular reabsorption, and tubular secretion.

A. Glomerular Filtration

This mechanism is dependent on glomerular capillary arterial pressure minus plasma colloid osmotic pressure plus

Bowman's capsular resistance. The resultant glomerular filtration pressure (about 8-12 mm Hg) forces protein-free plasma through the capillary filtering surface into Bowman's capsule. Normally, about 130 mL of plasma is filtered every minute through the renal circulation; the entire volume of plasma recirculates through the kidney and is subjected to the filtration process once every 27 minutes.

B. Tubular Reabsorption

About 99% of the filtered volume is reabsorbed through the tubules, together with all the valuable constituents of the filtrate (chlorides, glucose, sodium, potassium, calcium, and amino acids). Urea, uric acid, phosphates, and sulfates are also reabsorbed to varying degrees. The process of reabsorption is a combination of active and passive transport mechanisms. Reabsorption of water and electrolytes is under the control of adrenal, pituitary, and parathyroid hormones.

C. Tubular Secretion

Tubular secretion helps (1) to eliminate certain substances and thus maintain their plasma levels and (2) to exchange valuable ions from the filtrate for less desirable ions in the plasma (eg, a sodium ion from the urine for a hydrogen ion in the plasma). Failure of adequate secretory function leads to the acidosis commonly encountered in chronic renal disease.

► The Ureteropelvic System

This system is one continuous tubular structure with a syncytial type of smooth musculature that is imperceptibly in motion from one segment to the other. Waves of peristaltic contractions start from the calices and are propagated along the smooth muscle cells to the renal pelvis. At normal urine flow rates, many of these contraction waves are terminated at the ureteropelvic junction; however, some are transmitted to the ureter and down toward the urinary bladder. These peristaltic waves occur at a rate of about 5-8/min, involve a 2-cm to 3-cm segment at a time, and usually proceed at the velocity of 3 cm/s. Frequency, amplitude, and velocity are influenced by urine output and flow rate. In a state of diuresis, there may be a 1:1 relationship between caliceal contractions and ureteral contractions. Ureteral filling is primarily passive and occurs by reception of a bolus of urine from a renal pelvis contraction. The ureteropelvic junction closes after passing a bolus of urine, preventing back-pressure and back-flow of urine into the renal pelvis secondary to the elevated ureteral contraction pressure. A contraction ring forms in the proximal ureter, and as it migrates down the ureter, it pushes the bolus of urine antegrade. In states of diuresis, the size of the bolus increases and the pressure in the bolus may be greater than the pressure in the contraction ring ahead of it. In this case, the ureteral walls cannot

coapt, and urine is transported as an uninterrupted column of fluid.

► The Ureterovesical Junction

The ureterovesical junction allows flow of urine from the ureter to the bladder and at the same time prevents retrograde flow. The continuity and the specific muscular arrangement of the intravesical ureter and the trigone provide a muscularly active valvular mechanism that can efficiently adapt itself to the variable phases of bladder activity during filling and voiding.

The normal resting pressure of the ureterovesical junction (10-15 cm H₂O) is greater than the more cephalad ureteral resting pressure (0-5 cm H₂O). Progressive bladder filling leads to firm occlusion of the intravesical ureter against retrograde urine flow and to increased resistance to antegrade flow resulting from trigonal stretching. During voiding, trigonal contraction completely seals the intravesical ureter against any antegrade or retrograde flow of urine.

► The Urinary Bladder

The urinary bladder functions primarily as a reservoir that can accommodate variable volumes without increasing its intraluminal pressure. When the bladder reaches full capacity, the detrusor muscle voluntarily contracts following relaxation of the external sphincter and maintains its contraction until the bladder is completely empty. Funneling of the bladder outlet with progressive downward movement of the dome ensures complete emptying.

The vesical sphincteric mechanism is primarily a smooth muscle sphincter in the bladder neck and male prostatic urethra and in the proximal four-fifths of the female urethra. There is no purely circular sphincteric entity, but there are abundant circularly oriented smooth muscle fibers that are directly continuous with the outer coat of the detrusor muscles. The sphincter has an abundance of alpha receptors that respond to sympathetic neural input from the pelvic nerve to maintain urethral closure. Parasympathetic input from the pelvic nerve facilitates bladder contracture and voiding.

There is a voluntary striated muscle sphincter that is part of the urogenital diaphragm and surrounds the mid urethra in the female and the membranous urethra in the male. It responds to somatic neural input from the pudendal nerve. It is essential for continence when the internal sphincter is nonfunctional. Its pathologic irritability or spasticity can lead to obstructive manifestations.

DEVELOPMENTAL ANOMALIES OF THE GENITOURINARY TRACT

Genitourinary tract anomalies constitute about one-third of all congenital abnormalities and occur in over 10% of the population. The severity varies from lesions incompatible

with life to insignificant findings detected during diagnostic studies for unrelated reasons. The anatomic abnormalities are often not intrinsically harmful, yet they may predispose to infection, stone formation, or chronic renal failure.

RENAL ANOMALIES

Bilateral absence of the kidneys is rare and is associated with oligohydramnios, Potter facies, and pulmonary hypoplasia. It occurs more often in males and results in death shortly after birth. Unilateral renal agenesis is seen more often but is not usually associated with illness. **Renal agenesis** is thought to be due to both lack of a ureteral bud and lack of subsequent development of the metanephric blastema. The trigone is absent on the affected side. Because adrenal gland development is unrelated to kidney development, both adrenals are usually present in the normal position. Rarely, more than two kidneys are seen, a condition clearly dissimilar to ureteral duplication, as described later.

Abnormal ascent of the metanephros leads to an **ectopic kidney**, which may be unilateral or bilateral. Lumbar, pelvic, and the less common thoracic and crossed ectopic varieties are seen. Ectopic kidneys are associated with genital anomalies in 10%-20% of cases. Fusion abnormalities are also associated with failure of normal ascent and include fused pelvic kidneys and **horseshoe kidneys** (the most common), which are typically fused at the lower poles. Intravenous urography typically establishes the diagnosis. The relationship of the kidneys to the psoas muscles is abnormal: Instead of an oblique orientation with the medial border of the kidney parallel to the psoas muscle, the kidneys are vertical and the medial border intersects and crosses the psoas muscle. Horseshoe kidneys have an elevated incidence of vesicoureteral reflux and are at increased risk of ureteropelvic junction obstruction (UPJO). The latter may be related to a high ureteral insertion in the renal pelvis, crossing of the ureter over the isthmus, or compression by one of many anomalous arteries. Failure of rotation during ascent results in "malrotated" kidneys and is rarely significant.

► Polycystic Kidneys

Parenchymal anomalies include a variety of cystic and dysplastic lesions. Polycystic kidney disease is hereditary and bilateral. The autosomal recessive polycystic kidney disease (ARPKD), previously called infantile PKD, has numerous small cysts that arise only from the collecting ducts and result in bilateral symmetrical enlargement of the kidneys. The autosomal dominant ADPKD, previously called adult PKD, has cysts arising from all areas of the nephron, which are usually larger and more variable in size than the ARPKD cysts. ARPKD occurs in 1 in 40,000 births and may be detected in utero by the presence of enlarged hyperechoic kidneys and oligohydramnios. Infants usually die of respiratory failure rather than renal problems; however,

the 1-year survival probability after the first month is over 85%. These children have declining renal function as well as severe hypertension and hepatic periportal fibrosis with portal hypertension leading to hypersplenism and esophageal varices.

The genes mutated in ADPKD may include the *PKD1* gene (located on chromosome 16p13.3) in 85% of patients or the *PKD2* gene (on chromosome 4q21-23) in 12%-15% of patients. These genes code for the polycystin-1 and polycystin-2 proteins, respectively. ADPKD occurs in 1 in 1000 individuals and is a major cause of end-stage renal disease in adults. Cysts may also be present in the liver, pancreas, and spleen, and cerebral arterial aneurysms may occur. Renal cystic enlargement exerts pressure on normal parenchyma, leading to its gradual destruction and glomerulosclerosis.

The diagnosis is often made during a workup for hypertension or uremia discovered in the third to sixth decades. Hematuria with or without flank pain is a common finding. An intravenous urogram reveals the enlarged kidneys, with marked elongation of the calices, which are compressed by large cysts. Ultrasonography or CT scan readily makes the diagnosis.

Surgery is rarely warranted. Therapy is medical and ultimately includes dialysis. The median age for reaching end-stage renal disease is 54 years in PKD1 and 74 years in PKD2. Renal transplantation is often indicated, though potential family donors must be carefully screened to determine whether they have the same disorder. The leading cause of death in ADPKD is cardiovascular disease, which may relate to early untreated hypertension.

► Medullary Sponge Kidney

Medullary sponge kidney results from collecting tubular ectasia (see section on Polycystic Kidneys) and is associated with recurrent urolithiasis and an increased incidence of infection in 50% of patients. The lesion is often bilateral and may involve all of the calices. Intravenous urograms reveal dilated collecting tubules as a “blush” in the renal papilla. Microscopic hematuria is common. Specific antibiotics should be given for documented infections, and prophylactic therapy for renal stones should be recommended on the basis of metabolic stone evaluation.

► Simple Renal Cysts

Simple renal cysts are common (approximately 50% after age 50) and are thought to arise from tubular dilation. They may be solitary or bilateral and multiple. They rarely have pathologic significance except in the differentiation from solid renal masses. (See the section on Renal Adenocarcinoma.)

► Multicystic Dysplastic Kidney

Multicystic dysplastic kidney is a congenital abnormality consisting of macroscopic cysts of variable sizes compressing dysplastic renal parenchyma. It is usually associated with

an atretic proximal ureter. The disorder occurs in about 1 in 3000 live births and is frequently noted on prenatal ultrasound. Rarely, it may occur bilaterally and is associated with oligohydramnios and renal failure. It may be distinguished from other causes of hydronephrosis by the absence of any renal function on renal scan. There is an increased incidence of contralateral UPJO (5%-10%) and reflux (18%-43%), either of which increases the patient's risk of subsequent chronic renal insufficiency.

The chance of developing a malignancy in multicystic dysplastic kidney appears to be no greater than 1 in 2000. There may also be an increased incidence of hypertension. These two factors constitute a rationale for treatment by nephrectomy. However, conservative management with routine ultrasound examinations at intervals of 6-12 months is reasonable practice, since about half involute within 5 years.

► Renal Vascular Abnormalities

Multiple renal arteries occur in 15%-20% of patients and are significant only when they cause UPJO. Congenital **renal artery aneurysms** are infrequent; they are differentiated from acquired lesions by their location at the bifurcation of the main renal artery or at a distal branch point. The lesions are usually asymptomatic, but they can cause hypertension. They require surgical treatment only if hypertension is uncontrolled, if they are incompletely calcified, or if they have a diameter of more than 2.5 cm. **Congenital arteriovenous fistulas** are rare but may result in hematuria, hypertension, or cardiac failure necessitating operative treatment.

► Renal Pelvis Anomalies

UPJO is the most common cause of antenatal hydronephrosis. The condition may be associated with compression by anomalous renal arteries or intrinsic stenosis of the junction. The diagnosis is not uncommonly made when gross hematuria follows minor trauma. Symptoms include intermittent flank pain, particularly with orally induced diuresis. There is a bimodal age at presentation, with an initial peak in infancy and a secondary presentation in early adulthood. Renal ultrasound provides a safe screening technique in patients suspected of having UPJO. Diuretic renal scan may confirm the diagnosis and suggest functional significance. Intravenous pyelogram or retrograde pyelography may further define the anatomy. Bilaterality is not uncommon, and the condition requires surgical repair if symptomatic or severe. With the advent of laparoscopic and robotic surgery, minimally invasive repair of UPJO with dismembered pyeloplasty has become standard of care. Success rates with pyeloplasty are superior to endoscopic approaches in the primary setting. Percutaneous or ureteroscopic incision of the obstruction with short-term stenting has been successful in adults, but endoscopic incision is most useful in the setting

of recurrent UPJO, when redo pyeloplasty becomes much more difficult, or when patients are poor surgical candidates due to comorbidities.

Buffi NM et al: Robot-assisted, single-site, dismembered pyeloplasty for ureteropelvic junction obstruction with the New da Vinci platform: A Stage 2a Study. *Eur Urol* 2014 Mar 13; pii:S0302-S2838(14)00210-00213. doi: 10.1016/j.eururo.2014.03.001.

URETERAL ANOMALIES

► Congenital Obstruction of the Ureter

Congenital obstruction of the ureter may be due to ureterovesical and UPJO or to neurologic deficits such as sacral agenesis or myelomeningocele. Functional ureteral obstruction—also known as **primary obstructive megaureter**—is not uncommon. Symptoms are renal pain during diuresis or resulting from pyelonephritis. Excretory urograms depict dilation above the obstruction. Vesicoureteral reflux is uncommonly associated with megaureter. Milder forms without symptoms or significant hydronephrosis are the rule and do not require treatment if renal function is normal. When treatment is necessary, it consists of division of the ureter proximal to the obstruction and reimplantation of the ureter into the bladder, often involving ureteral tapering or plication.

► Duplication of Ureters

Bifurcation of the ureteral bud before it interacts with the metanephric blastema results in incomplete ureteral duplication, commonly in the mid or upper ureter. A second ureteral bud from the metanephric duct leads to complete ureteral duplication (Figure 38–4; right kidney) draining one kidney. This represents the most common ureteral anomaly, occurring in 1 in 125 people. It occurs twice as often in females. The presence of more than two ureters on each side is not common, but bilaterality of ureteral duplication occurs in 40%. Usually, all of the duplicated ureters enter the bladder; the ureter draining the upper pole of the kidney enters closest to the bladder neck (due to its later reabsorption into the bladder). Because of this relationship, the ureter draining the lower pole often has a short intramural tunnel and an inadequate surrounding musculature and is thus prone to vesicoureteral reflux. The ureter draining the upper pole may be ectopic (because of its late absorption) and thus empty into the bladder neck, urethra, or genital structures (vagina or vestibule in the female and seminal vesicle or vas deferens in the male [Figure 38–4; left kidney]). The ureter draining the upper pole is prone to obstruction and may be associated with a ureterocele, which is a common cause of obstruction. Duplication becomes significant when hydronephrosis or pyelonephritis occurs. The diagnosis is

▲ **Figure 38–4.** Duplication of ureters and ectopic ureteral orifice. Complete duplication with obstruction to one ureter with ectopic orifice on left. The ureter with the ectopic opening always drains the upper pole of the kidney.

made by intravenous urography. Ureteral reimplantation to prevent recurrent infection is necessary in some cases. An anastomosis between the upper pole renal pelvis and the lower pole ureter or a low ureteroureterostomy are alternatives in selected cases. The upper pole of the kidney and its ureter may require removal if obstruction is severe and renal function of that segment is poor.

► Ectopic Ureteral Orifice

Ureteral ectopia can occur in the absence of duplication and drain into any of the abnormal positions mentioned previously. If the orifice lies proximal to the external urinary sphincter, no incontinence ensues, but vesicoureteral reflux is common. In contradistinction to the female, the ectopic orifice in the male never lies distal to the external sphincter, making incontinence an extremely rare presentation. Should the ectopic orifice in the female drain into the vagina or at the vestibule, there may be continuous leakage of urine apart from voiding. Most ectopic orifices involve the ureter draining the upper pole of a duplicated system, and most are observed in females. Hydroureteronephrosis of the involved segment frequently occurs due to ureteral obstruction as it traverses the muscle of the bladder neck.

An ectopic orifice may be seen beside the urethral orifice or in the roof of the vagina on endoscopy. Renal ultrasound or intravenous urograms often demonstrates hydroureteronephrosis of the upper renal segment. Cystography may show reflux into the ectopic orifice but may require cyclic voiding first to decompress the obstructed segment with bladder neck relaxation and subsequently to permit reflux. In the rare case when there is significant upper pole renal function, the ureter can be divided and reimplanted into the bladder or lower pole ureter. Usually, however, heminephroureterectomy is necessary.

► Ureterocele

A ureterocele is a ballooning of the distal submucosal ureter into the bladder. This structure commonly has a pinpoint orifice and therefore leads to hydroureteronephrosis. If large enough, it may obstruct the vesical neck or the contralateral ureter. It is most common in females with ureteral duplication and always involves the ureter draining the upper renal pole.

Most ureteroceles are now detected by prenatal ultrasound. Symptoms are usually those of pyelonephritis or

obstruction. Intravenous urograms may show a negative shadow in the bladder cast by the ureterocele. The ureter and renal calices may be normal or may reveal marked dilation or no excretory function at all. A cystogram may show reflux into the ipsilateral lower pole ureter.

Treatment of ureteroceles depends on multiple factors, including the presence or absence of reflux in any or all of the ureters as well as whether or not the ureterocele is completely contained within the bladder (intravesical/orthotopic) or if a portion is at the bladder neck or urethra (extravesical/ectopic). A simple method of establishing drainage involves cystoscopy and puncture of the ureterocele. Associated reflux, if present, can be managed with prophylactic antibiotics until the child has grown larger, at which time a technically easier ureteral reimplant may be performed with a decompressed ureter. In the relatively uncommon situation when there is no associated reflux, an upper pole heminephrectomy is considered. Minimally obstructive ureteroceles within the bladder in adults do not require treatment.

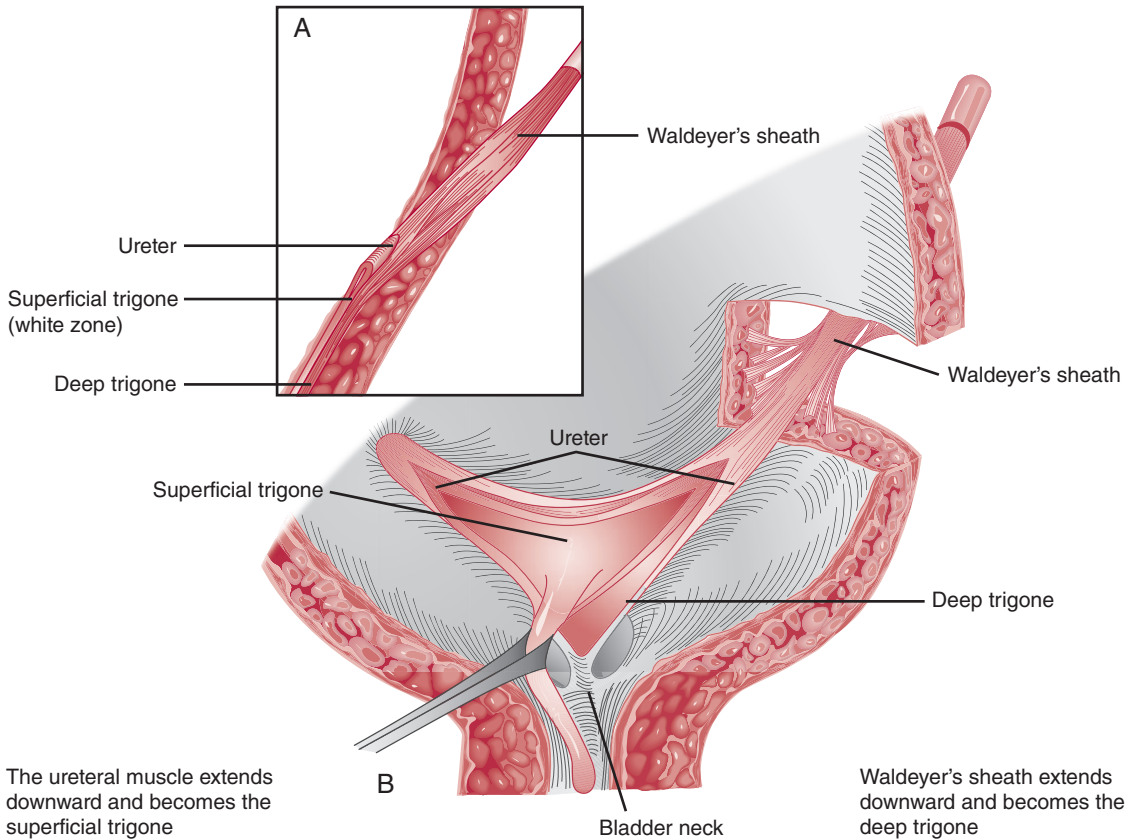

Patel MN et al: Robot-assisted management of congenital renal abnormalities in adult patients. *J Endourol* 2010 Apr;24(4):567-570. doi: 10.1089/end.2009.0313.

VESICoureTERAL REFLUX

The main function of the ureterovesical junction is to permit free drainage of the ureter and simultaneously prevent urine from refluxing back from the bladder. Anatomically, the ureterovesical junction is well equipped for this function, because the ureteral musculature continues uninterrupted into the base of the bladder to form the superficial trigone. Additionally, the terminal 4-5 cm of ureter are surrounded by a musculofascial sheath (Waldeyer's sheath) that follows the ureter through the ureteral hiatus and continues into the base of the bladder as the deep trigone (Figure 38-5).

▲ **Figure 38-5.** Vesicoureteral reflux. The length and fixation of the intravesical ureter and the appearance of the ureteral orifice depend on the muscular development and efficiency of the lower ureter and its trigone. **A:** Normal structures. **B:** Moderate muscular deficiency. **C:** Marked deficiency results in a golf hole distortion of the submucosal ureter.

▲ **Figure 38-6.** Normal ureterotrigoanal complex. **A:** Side view of ureterovesical junction. The Waldeyer muscular sheath invests the juxtavesical ureter and continues downward as the deep trigone, which extends to the bladder neck. The ureteral musculature becomes the superficial trigone, which extends to the verumontanum in the male and stops just short of the external meatus in the female. **B:** Waldeyer's sheath is connected by a few fibers to the detrusor muscle in the ureteral hiatus. This muscular sheath, inferior to the ureteral orifices, becomes the deep trigone. The musculature of the ureters continues downward as the superficial trigone. (Adapted, with permission, from Tanagho EA, Pugh RCB: The anatomy and function of the ureterovesical junction. *Br J Urol.* 1963 June;35(2):151-165.)

Direct continuity between the ureter and the trigone offers an efficient, muscularly active, valvular function. Any stretch of the trigone (with bladder filling) or any trigonal contraction (with voiding) leads to firm occlusion of the intravesical ureter, thus increasing resistance to flow from above downward and sealing the intravesical ureter against retrograde flow (Figure 38-6).

► Etiology & Classification

Vesicoureteral reflux may be classified as primary reflux due to developmental ureterotrigoanal weakness or associated with ureteral anomalies such as ectopic orifice or ureterocele, and secondary reflux due to bladder outlet or urethral obstruction, neuropathic dysfunction, iatrogenic causes, and

inflammation, especially specific infection (eg, tuberculosis). Primary reflux is associated with some degree of congenital muscular deficiency in the trigone and terminal ureter.

Reflux is associated with an increased incidence of pyelonephritis and renal damage. It also allows bacteria free access from the bladder to the kidney.

Reflux is the most common cause of pyelonephritis and is found in 30% to 50% of children presenting with urinary tract infection. It is present in over 75% of patients with radiologic evidence of chronic pyelonephritis and is responsible for end-stage renal disease in a large percentage of patients requiring chronic dialysis or renal transplantation.

In primary reflux, the child (on average, between 2 and 3 years of age) usually presents with symptoms of pyelone-

phritis or cystitis. Vague abdominal pain is not uncommon. Renal pain and pain with voiding are relatively uncommon. On rare occasions, the patient may present with advanced renal failure with bilateral renal parenchymal damage. Significant reflux and its sequelae are more common in females and are usually detected after a urinary tract infection. About one-third of the siblings of a child with reflux will also have reflux, and one-half of the children of a mother with reflux will also have reflux.

In secondary reflux, manifestations of the primary disease (neuropathic, obstructive, etc) are usually the presenting symptoms.

► Clinical Findings

A. Symptoms and Signs

With acute pyelonephritis, fever, chills, and costovertebral angle tenderness may be present. Children usually do not have renal pain but may complain of vague abdominal pain. Occasionally, daytime frequency, incontinence, or enuresis may be caused by infection associated with reflux. In cases of obstruction or neuropathic deficit, a palpable hydronephrotic kidney or a distended bladder may be found. The diagnosis may be elusive in infants who present with ill-defined symptoms.

B. Laboratory Findings

Urinalysis usually reveals evidence of infection (pyuria and bacteriuria). Urine cultures are mandatory when infection is suspected. Renal function tests may be abnormal if reflux and infection have caused renal scarring.

C. Imaging Studies

The most useful study for conclusive diagnosis of reflux continues to be voiding cystourethrography (Figure 38–7). This study demonstrates the grade of reflux as well as the urethral anatomy. Radionuclide voiding studies are extremely sensitive at detecting reflux but do not demonstrate the anatomic detail seen with a voiding cystourethrogram. Radionuclide voiding studies are often performed as follow-up after an initial voiding cystourethrogram because they offer the advantage of decreased radiation exposure.

Radioisotopic renal scanning provides accurate differential renal function data and detection of renal scars. Ultrasound can provide accurate measurement of renal size and may demonstrate the presence of renal scarring and ureteral or caliceal dilation. In many cases, there may be no abnormality visible in the upper urinary tract, or only mild distal ureteral dilation may be seen.

D. Urodynamic Considerations

A significant number of children with dysfunctional voiding present with urinary tract infections and are subsequently

▲ **Figure 38–7.** Voiding cystourethrogram showing total (grade IV) left vesicoureteral reflux.

found to have reflux. These children contract the bladder against a closed external sphincter. Elevated voiding pressures associated with dysfunctional voiding may increase renal damage with an associated urinary tract infection and may also lessen the chance for either spontaneous or surgical resolution of reflux. When the history suggests the possibility of voiding dysfunction (incontinence, frequency, urgency), urodynamic studies are conducted to evaluate the voiding dynamics. Treatment of voiding dysfunction may result in resolution of the reflux.

► Treatment

Although some children with lower grades of reflux may not require antibiotics, traditionally any child with reflux was maintained on prophylactic antibiotics to attempt to decrease the incidence of urinary tract infections. Several recent studies suggest that the practice of daily antibiotic prophylaxis in all children with reflux may be of limited benefit in preventing urinary tract infection. Prompt treatment of pyelonephritis prevents renal scar formation. Factors causing secondary reflux—such as dysfunctional voiding or obstruction—should be corrected.

In many children, reflux resolves with time. Reflux is graded as seen on voiding cystourethrography as follows:

Grade I: Contrast enters ureter

Grade II: Contrast enters the renal collecting system

Grade III: Slight dilation of the calices or ureter

Grades IV and V: Progressively increased amounts of caliceal dilation and ureteral dilation or tortuosity

Reflux most likely to resolve is of lower grade or detected at a younger age. Over 70% of children with grades I, II, or unilateral grade III reflux will have resolution within 5 years. Resolution in children with grade V or bilateral grade IV reflux can be anticipated in less than 10% of cases. Other factors that appear to negatively affect the chance for reflux resolution include early reflux during bladder filling, presentation with a febrile urinary tract infection, renal scars, and voiding dysfunction.

In obstructive secondary reflux (eg, posterior urethral valves), release of obstruction may cure reflux. Occasionally, surgical reimplantation is still required. In neuropathic reflux, intermittent catheterization for control of infection may allow return of valvular competence. However, many cases require bladder augmentation for a noncompliant bladder and ureteral reimplantation. In reflux associated with ectopic orifices, duplication with ureterocele, and other congenital malformations, reimplantation is generally required.

The aim of surgery is to correct the reflux. This is accomplished by the creation of a longer submucosal tunnel for the ureter. With bladder filling and increased pressure, the ureter is compressed between the mucosa and underlying detrusor muscle. This flap valve prevents reflux of urine. The necessary length of the tunnel to stop reflux depends on the diameter of the ureter, with a 5:1 length-to-diameter ratio being ideal. One of three methods is used in most cases: (1) in suprahial repair (Politano-Leadbetter procedure), a new ureteral hiatus is developed about 2.5 cm above the original one, and the ureter—after passing through a submucosal tunnel—is sutured to the cut edge of the trigone at the level of the original orifice. (2) In the cross-trigonal repair (Cohen procedure), the original hiatus is maintained, and the ureter is advanced through a submucosal tunnel, extending across the trigone to the contralateral bladder wall. (3) A totally extravesical ureteral advancement procedure (extravesical ureteroplasty) achieves results similar to those achieved with the intravesical methods, with a shorter hospital stay and shorter convalescence.

Injections of subureteric bulking agents have also been used to increase submucosal support of the ureter. With proper placement beneath the ureteral orifice under endoscopic vision, these injections act to bolster the deficient antireflux mechanism. Concern regarding late sequelae of Teflon injections (eg, particle migration) has prevented use of this approach in the United States. Currently, hyaluronic acid/dextranomer (NASHA/Dx) gel (Deflux) is the only FDA-approved material for endoscopic injection to manage vesicoureteral reflux in children. Short-term success in stopping reflux with the injection techniques appears to be around 75% overall, with most success with grades I-III reflux. The long-term success rates still need to be evalu-

ated, as many studies only have short term (ie, 3 month) follow up.

Routh JC, Inman BA, Reinberg Y: Dextranomer/hyaluronic acid for pediatric vesicoureteral reflux: systematic review. *Pediatrics* 2010 May;125(5):1010-1019. doi: 10.1542/peds.2009-2225. Epub 2010 Apr 5. Review. PMID: 20368325.

► Prognosis

The long-term prognosis is excellent for patients with mild to moderate reflux successfully treated with antibiotic prophylaxis. There are few instances of recurrent infection or renal insufficiency. Patients with more significant reflux or persistent urinary tract infections may benefit from subureteric injection or surgical reimplantation; the success rate is approximately 95% with the open surgical technique (cessation of reflux, clearance of renal infection, and absence of obstruction). Unfortunately, for patients with advanced disease (irreversible ureteral decompensation and severe bilateral scars), the prognosis is less favorable. These patients account for a significant proportion of patients with end-stage renal disease who ultimately require chronic dialysis, renal transplantation, or both.

BLADDER ANOMALIES

Anomalies of the bladder are infrequent and include the following: (1) **agenesis**, or complete absence, which results in a persistent cloaca; (2) bladder **duplication**, which may be complete, with separate ureteral openings drained by duplicated urethras, or incomplete, with a septum or hourglass deformity; and (3) **urachal anomalies**, which in the most severe forms appear as a patent opening at the umbilicus and are usually associated with some form of bladder outlet obstruction. In less severe forms, a **urachal diverticulum** may be present at the dome of the bladder or a **urachal cyst** along the course of the partially obliterated urachus. These latter conditions may cause abdominal pain and umbilical or bladder infection requiring surgical treatment. Occasionally, adenocarcinoma develops in a urachal remnant (see section on Tumors of the Bladder).

Failure of cloacal division results in a persistent cloaca. Incomplete division is more frequent (though still rare) and results in a rectovesical, rectourethral, or rectovestibular fistula (usually with imperforate anus or anal atresia).

► Exstrophy of the Bladder

Exstrophy of the bladder is the most severe bladder anomaly—the result of a complete ventral defect of the urogenital sinus and the overlying inferior abdominal wall musculature and integument. The lower central portion is devoid of skin and muscle. The anterior bladder wall is absent, and the posterior wall is contiguous with surrounding skin. Urine

drains onto the abdominal wall, the rami of the pubic bones are widely separated, and the open pelvic ring may affect gait. In males, the penis is shortened and the urethra is epispadiac. The exposed bladder mucosa tends to be chronically inflamed.

Currently, the favored treatment is bladder salvage, which includes closure of the bladder in the newborn period. Urethral closure and penile reconstruction have also been advocated at the time of the initial bladder closure. Ureteral obstruction or vesicoureteral reflux may develop and require ureteral reimplantation. The closed bladder may have a small capacity, and incontinence is often a complication. Patients frequently require multiple operations, including bladder augmentation and bladder neck reconstruction. Good results have been observed in more than half of all patients treated, with preservation of renal function and continence.

► Prune Belly Syndrome

Prune belly syndrome consists of a triad of abnormalities: deficient abdominal wall musculature, bilateral cryptorchidism, and variable amounts of dilation of the urogenital tract. The cause is not known. Almost all children with prune belly syndrome have reflux. The incidence of eventual renal failure is 25%-30%. Risk factors for renal failure include bilateral abnormal kidneys on ultrasound or renal scan, a serum creatinine that never falls below 0.7 mg/dL, and clinical pyelonephritis. These children are managed with prophylactic antibiotics and frequent urine cultures, followed by prompt treatment of any urinary tract infections. Abdominoplasty may be performed to help correct the abdominal wall defect.

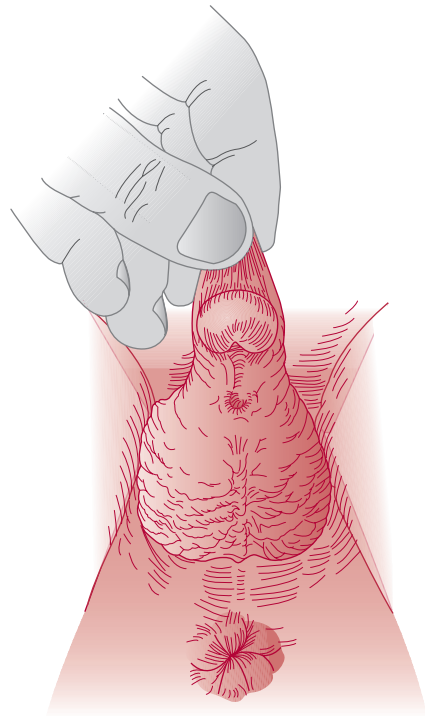

► Congenital Neurovesical Dysfunction

Congenital neurovesical dysfunction frequently accompanies a posterior myelomeningocele or sacral agenesis, with associated spinal abnormalities. Both conditions may result in incontinence and recurrent urinary infection with late sequelae (ureteral reflux, pyelonephritis, and renal failure). These children require frequent evaluation of their kidneys and kidney function because high bladder storage pressures may harm the kidneys.

PENILE & URETHRAL ANOMALIES

► Hypospadias

Hypospadias results from failure of fusion of the urethral folds on the undersurface of the genital tubercle. The urethral meatus is ventrally displaced on the glans on the shaft of the penis or more proximal at the level of the scrotum or perineum. With more proximal displacement, chordee (ventral curvature of the penile shaft) frequently occurs and

▲ **Figure 38-8.** Hypospadias, penoscrotal type. Redundant dorsal foreskin that is deficient ventrally; ventral chordee.

requires treatment, or it precludes straight erections and normal intercourse (Figure 38-8). The midscrotal hypospadiac penis may resemble female external genitalia with an enlarged clitoris and labia. Sexual assignment in these latter infants requires hormonal and chromosomal analysis.

In hypospadias with the meatus positioned proximal to the corona, the prepuce is abnormal—not forming a complete cylinder due to a ventral defect. Circumcision should not be done in these patients, as the prepuce can be used later in surgical repair.

The degree of hypospadias dictates the need for repair. If the opening is glandular or coronal (85% of patients), the penis is usually functional both for micturition and procreation, and repair is done primarily for cosmetic reasons. Openings that are more proximal on the shaft require correction to allow voiding while standing, normal erection, and proper sperm deposition during intercourse. Surgical plastic repair of hypospadias is currently accomplished by a variety of highly successful one-stage operations and is routinely performed between 6 and 18 months of age. The most common complications of hypospadias surgery include meatal stenosis and fistula formation; however,

improved techniques have decreased the incidence of these complications.

► **Epispadias**

Epispadias is a rare congenital anomaly that is commonly associated with bladder exstrophy. When it occurs alone, it is considered a milder degree of the exstrophy complex.

The urethra opens on the dorsum of the penis, with deficient corpus spongiosum and loosely attached corpora cavernosa. If the defect is extensive, it may extend to the bladder neck, causing incontinence because of deficient sphincter muscles. The pubic bones are separated, as in exstrophy. Marked dorsiflexion of the penis is usually present.

Treatment consists of correction of penile curvature, reconstruction of the urethra, and reconstruction of the bladder neck in incontinent patients.

► **Urethral Strictures**

Congenital urethral strictures are rare but when present are most common in the fossa navicularis (just proximal to the meatus) and in the bulbomembranous urethra. Commonly, these strictures are thin diaphragms that may respond to simple dilation or to direct vision internal urethrotomy. Rarely is open surgical repair necessary. Congenital urethral strictures in girls and meatal stenosis in boys are uncommon. When the latter does occur, it appears to be acquired, as it is seen only in circumcised boys.

► **Urethral Diverticulum**

In males, urethral diverticula are nearly always in the pendulous or bulbous urethra. They are often associated with an obstructive flap of the urethral mucosa (anterior urethral valve), thought to represent incomplete closure of the urethral folds. Treatment by endoscopic unroofing is usually successful, though most diverticula are small and require no therapy. In females, they occur in adult life and are usually manifested by irritative symptoms and recurrent infection. The cause is unknown, but the disorder is most likely congenital. Treatment is usually by transvaginal excision. Diverticula may occasionally harbor stones or tumors.

► **Posterior Urethral Valves**

Posterior urethral valves are the most common obstructive urethral lesion in newborn and infant males and the most common cause of end-stage renal disease in boys. They consist of obstructive folds of mucosa, which originate at or are attached at some point to the verumontanum in the prostatic urethra. The embryologic derivation is indefinite. They are partially obstructive and thus lead to variable degrees of back-pressure damage to the urinary bladder and

upper urinary tract. Dilation and obstruction of the prostatic urethra are always present. Spontaneous urinary ascites from the kidneys is often seen in neonates. This clears when the obstruction is relieved.

About one-third of children with posterior urethral valves are now diagnosed by prenatal ultrasound. Another one-third are diagnosed in the first year of life, with the remaining third presenting later. Clinical manifestations consist of difficult voiding, a weak urinary stream, and a midline lower abdominal mass that represents a distended bladder. In some cases, the kidneys are palpable and the child may have signs and symptoms of uremia and acidosis. Urinary incontinence and urinary tract infection may occur. Laboratory findings include elevated serum urea nitrogen and creatinine and evidence of urinary infection. Ultrasound shows evidence of bladder thickening and trabeculation, hydroureter, and hydronephrosis. Demonstration of urethral valves on a voiding cystourethrogram establishes the diagnosis, as does endoscopic identification of valves. Up to 70% of children with valves may have vesicoureteral reflux.

Treatment consists of destruction of the valves by endoscopic incision. In a premature infant with a small urethra prohibiting transurethral resection, a temporary cutaneous vesicostomy may be required to provide drainage and improve impaired kidney function.

The prognosis depends on the original degree of kidney damage and the success of efforts to prevent or treat infection. Rates of chronic renal failure or end-stage renal disease range from 25% to 67% of boys with valves. Poor prognostic factors include the presence of bilateral reflux or an elevated nadir serum creatinine in the first year of life. Many of these children have delayed development of urinary continence due to bladder changes and impaired urinary concentration.

SCROTAL & TESTICULAR ANOMALIES

► **Testicular Torsion**

Neonatal testicular torsion (extravaginal torsion) is an extremely rare condition. The entire testicle and the tunica vaginalis are twisted. No trigger mechanism associated with the torsion has been identified. Although the vast majority are necrotic and nonsalvageable, several studies have reported salvage of testicular tissue when torsion is detected immediately following birth. Any scrotal swelling in the neonate requires close follow-up. Intravaginal testicular torsion in adolescents is described later in this chapter.

► **Scrotal Lesions**

Congenital scrotal lesions include hypoplasia of the scrotum (unilateral or bilateral) in association with cryptorchidism and bifid scrotum with extensive hypospadias. Midline inclusion cysts may also occur.

CRYPTORCHIDISM

► Etiology & Classification

True undescended testicles stop along the normal path of descent into the scrotum. They may remain in the abdominal cavity (least common), in the inguinal canal (canalicular), or just outside the external ring (suprascrotal, most common). Testes may also pass through the external ring and then be located ectopically, most commonly in a superficial inguinal pouch. The incidence of undescended testicles increases from 3% to 5% in full-term infants to 30% in premature infants. Most undescended testicles descend within the first 6 months of life, and by 1 year of age the prevalence is 1%. The left testicle is affected more often, and 1%-2% of children with cryptorchidism will have both testicles affected. Twenty percent of boys who present with cryptorchidism have one nonpalpable testis. Of nonpalpable testes, 20% are intra-abdominal; 40% are canalicular, scrotal, or ectopic testes; and 40% are atrophic or absent.

► Clinical Findings

The diagnosis of cryptorchidism relies on physical examination. Absence of an identifiable testicle with ultrasound, computed tomography, or magnetic resonance imaging (MRI) does not prove testicular agenesis and therefore does not alter the need for surgical exploration. Testicular examination in the infant and young child requires two hands, with the first hand being swept from the anterior iliac spine along the inguinal canal to gently express any retained testicular tissue into the scrotum, which is palpated with the other hand. A true undescended or ectopic inguinal testis may slip or “pop” under the examiner’s fingers. To distinguish a retractile testicle, the testicle is brought into the scrotal position, holding it in place for a minute to fatigue the cremaster muscle. After this, a retractile testicle remains in the scrotum, whereas an ectopic or undescended testis immediately snaps back out of the scrotum. If a testis cannot be palpated in the inguinal canal or the scrotum, or in the typical ectopic sites, evaluation for a nonpalpable testis must be performed.

A child with bilateral nonpalpable testes should undergo hormonal evaluation for testicular absence. Elevations in luteinizing hormone (LH) and follicle-stimulating hormone (FSH) and absence of detectable müllerian-inhibiting substance suggest testicular absence. Testicular absence is confirmed by a negative human chorionic gonadotropin (hCG) stimulation test. The hCG stimulation test is performed by the administration of intramuscular hCG (2000 IU/day for 3-4 days). Raised gonadotropin levels (FSH and LH) and a lack of a testosterone rise from hCG indicate bilateral absent testes, and a formal surgical exploration is unnecessary. When one or both components are lacking or there is detectable müllerian-inhibiting substance, surgical exploration is warranted.

► Surgical Therapy

Treatment of the undescended testicle offers the possibility of improved fertility, correction of patent processus vaginalis, prevention of testis torsion, and improvement in body image. There is controversy whether orchidopexy decreases the risk of malignancy, but placement of an undescended testicle in the scrotum assists physical examination of the testis. Histologic changes related to infertility occur in the undescended testicle as young as 1 year of age, and spontaneous descent rarely occurs after 6 months of age, making this the optimal time for surgical correction.

Almost 90% of undescended testes have an associated patent processus vaginalis, which predisposes to formation of a hydrocele or hernia. Occult inguinal hernia in patients with untreated undescended testis can present at any time with the typical symptoms or complications, including incarceration.

Prior to any surgical intervention, the patient is reexamined while under anesthesia because on occasion a retractile testicle descends under anesthesia or a previously nonpalpable testicle becomes palpable. For a palpable testicle, an open inguinal approach is performed. For the nonpalpable testicle in a child, a laparoscopic approach is preferred, but an open inguinal approach may be performed.

► Outcomes

Success rates following orchidopexy are 74% for the abdominal testis, 87% for canalicular, and 92% for those distal to the external ring. The most significant complication is testicular atrophy, which occurs in 1%-2% of cases of orchidopexy, while complete devascularization of the testis is rare. Paternity rates have been reported at 65%, 90%, and 93% in men with bilateral cryptorchidism, unilateral cryptorchidism, and normally descended testicles, respectively. If only one testis is undescended, the sperm count is subnormal in 25%-33% patients, and serum FSH concentration is slightly elevated. These abnormalities suggest that both testes are abnormal, perhaps congenitally, although only one fails to descend. If both testes are undescended, sperm count usually is severely subnormal, and serum testosterone may be reduced.

► Alternative Therapy

Hormonal therapy is an option in the treatment of cryptorchidism because the condition may be related to hypogonadotropic hypogonadism. hCG is the only hormone approved for use in the treatment of cryptorchidism in the United States. Side effects of hCG treatment include enlargement of the penis, growth of pubic hair, increased testicular size, and aggressive behavior during administration. The likelihood of success with hormonal therapy is greatest for the most distal undescended testes or for testes that have been

previously descended. Some suggest that hormonal therapy is effective only for retractile and not truly undescended testes. Although hormonal therapy may not be effective in achieving testicular descent, it may improve fertility in cryptorchid boys.

ACQUIRED LESIONS OF THE GENITOURINARY TRACT

OBSTRUCTIVE UROPATHY

Obstruction is one of the most important abnormalities of the urinary tract, since it eventually leads to decompensation of the muscular conduits and reservoirs, back-pressure, and atrophy of renal parenchyma. It also invites infection and stone formation, which cause additional damage and can ultimately end in complete unilateral or bilateral destruction of the kidneys.

Both the level and the degree of obstruction are important to an understanding of the pathologic consequences. Any obstruction at or distal to the bladder neck may lead to back-pressure affecting both kidneys. Obstruction at or proximal to the ureteral orifice leads to unilateral damage unless the lesion involves both ureters simultaneously. Complete obstruction leads to rapid decompensation of the system proximal to the site of obstruction. Partial obstruction leads to gradual progressive muscular hypertrophy followed by dilation, decompensation, and hydronephrotic changes.

► Etiology

Acquired urinary tract obstruction may be due to inflammatory or traumatic urethral strictures, bladder outlet obstruction (benign prostatic hyperplasia or cancer of the prostate), vesical tumors, neuropathic bladder, extrinsic ureteral compression (tumor, retroperitoneal fibrosis, or enlarged lymph nodes), ureteral or pelvic stones, ureteral strictures, or ureteral or pelvic tumors.

► Pathogenesis

Regardless of its cause, acquired obstruction leads to similar changes in the urinary tract, which vary depending on the severity and duration of obstruction.

A. Urethral Changes

Proximal to the obstruction, the urethra dilates and balloons. A urethral diverticulum may develop, and dilation and gaping of the prostatic urethra and ejaculatory ducts may occur.

B. Vesical Changes

Early detrusor and trigonal thickening and hypertrophy compensate for the outlet obstruction, allowing complete bladder emptying. This change leads to progressive develop-

ment of bladder trabeculation, cellules, saccules, and, finally, diverticula. Subsequently, bladder decompensation occurs and is characterized by the above changes plus incomplete bladder emptying (ie, postvoid residual urine). Trigonal hypertrophy leads to secondary ureteral obstruction owing to increased resistance to flow through the intravesical ureter. With detrusor decompensation and residual urine accumulation, there is stretching of the hypertrophied trigone, which appreciably increases ureteral obstruction. This is the mechanism of back-pressure on the kidney in the presence of vesical outlet obstruction (while the ureterovesical junction maintains its competence). Catheter drainage of the bladder relieves trigonal stretch and improves drainage from the upper tract.

A very late change with persistent obstruction (more frequently encountered with neuropathic dysfunction) is decompensation of the ureterovesical junction, leading to reflux. Reflux aggravates the back-pressure effect on the upper tract by transmitting abnormally high intravesical pressures and favors the onset or persistence of urinary tract infection.

C. Ureteral Changes

The first change noted is a gradual increase in ureteral distention. This increases ureteral caliber and stimulates hyperactive ureteral contraction and ureteral muscular hypertrophy. Because the ureteral musculature runs in an irregular helical pattern, stretching of its muscular elements leads to lengthening as well as widening, causing the dilated ureter to assume a tortuous, serpiginous course, weaving back and forth across the relatively straight course of the ureteral vessels, which are unaffected by the ureteral obstruction. This is the start of ureteral decompensation, where tortuosity and dilation become apparent. These changes progress until the ureter becomes atonic, with infrequent, ineffective, or completely absent peristalsis.

D. Pelvicaleical Changes

The renal pelvis and calices, subjected to increased volumes of retained urine, distend. The pelvis shows evidence first of hyperactivity and hypertrophy and then of progressive dilation and atony. The calices show similar changes to a variable degree, depending on whether the renal pelvis is intrarenal or extrarenal. In the latter, caliceal dilation may be minimal in spite of marked pelvic dilation. In the intrarenal pelvis, caliceal dilation and renal parenchymal damage are maximal. The successive phases seen with obstruction are rounding of the fornices, followed by flattening of the papillae and finally clubbing of the minor calices.

E. Renal Parenchymal Changes

With continued pelvicaleical distention, there is parenchymal compression against the renal capsule and, more

importantly, compression of the arcuate vessels results in a marked drop in renal blood flow leading to parenchymal ischemic atrophy. With increased intrapelvic pressure, there is progressive dilation of the collecting and distal tubules, with compression and atrophy of tubular cells.

► Clinical Findings

A. Symptoms and Signs

The findings vary according to the site of obstruction.

1. **Infravesical obstruction**—Infravesical obstruction (eg, due to urethral stricture, benign prostatic hypertrophy, bladder neck contracture) leads to difficulty in initiation of voiding, a weak stream, and a diminished flow rate with terminal dribbling. Burning and frequency are common associated symptoms. A distended or thickened bladder wall may be palpable. Urethral induration due to stricture, benign prostatic hypertrophy, or cancer of the prostate may be noted on rectal examination. Meatal stenosis and impacted urethral stones are readily diagnosed by physical examination.
2. **Supravesical obstruction**—Renal pain or renal colic and gastrointestinal symptoms are commonly associated. Supravesical obstruction (eg, due to ureteral stone, UPJO) may be completely asymptomatic when it develops gradually over a period of months. An enlarged kidney may be palpable. Costovertebral angle tenderness may be present.

B. Laboratory Findings

Evidence of urinary tract infection, hematuria, or crystalluria may be seen. Impaired renal function may be noted in cases of bilateral obstruction. Postrenal azotemia (serum changes reflecting impaired renal function due primarily to obstruction) is suggested by elevation of serum urea nitrogen and serum creatinine with a ratio greater than 10:1.

C. Imaging Studies

Radiologic examination is usually diagnostic in cases of stasis, tumors, and strictures. Dilation and anatomic changes occur above the level of obstruction, whereas distal to the obstruction, the configuration is usually normal. This helps in localizing the site of obstruction. Combined antegrade imaging by intravenous urograms and retrograde imaging by ureterograms or urethrograms is sometimes needed to demonstrate the obstructed segment. In supravesical obstruction, demonstration of stasis and delayed drainage is essential to establish and quantitate the severity of obstruction.

1. **Ultrasonography**—Ultrasonography reveals the degree of dilation of the renal pelvis and calices and allows for diagnosis of hydronephrosis even in the prenatal period. Color Doppler ultrasound can reveal blood

flow and restrictive indices to help determine functional impairment.

2. **Isotope studies**—A technetium-99m DTPA scan or MAG-3 scan portray the degree of hydronephrosis as well as renal function. Use of diuretics during the scan can provide specific data on the significance of the obstruction and the need for treatment. Multiple studies can reveal ongoing functional changes.
3. **CT scan**—CT scan is of particular value in revealing the degree and site of obstruction as well as the cause in many cases. The use of contrast (CT urogram) agents allows estimation of residual renal function.
4. **MR urogram**—MRI provides anatomic images and identification of the site of obstruction. With dynamic contrast-enhanced MR urography, functional information is also obtained without the use of ionizing radiation.
5. **Antegrade urography**—Antegrade urography via percutaneous needle or tube nephrostomy is valuable when the obstructed kidney fails to excrete the radiopaque material on excretory urography. The Whitaker test requires percutaneous catheter access to the collecting system above the site of suspected obstruction. This permits fluid introduction into the renal pelvis and simultaneous measurement of urine flow rate and pressures in the bladder and renal pelvis, thus providing a quantitative assessment of the degree and severity of obstruction. The fluid transport can be measured and the degree of obstruction estimated by the use of a pressure monitor.

► Complications

The most important complication of urinary tract obstruction is renal parenchymal atrophy as a result of back-pressure. Obstruction also predisposes to infection and stone formation, and infection occurring with obstruction leads to rapid kidney destruction.

► Treatment

The first goal of therapy is relief of the obstruction (eg, catheterization for relief of acute urinary retention). Definitive therapy often requires surgery, but minimally invasive techniques are becoming utilized more often. Simple urethral stricture may be managed by dilation or internal urethrotomy (incision of the stricture under direct vision through the resectoscope). However, urethroplasty (open surgical graft or flap of skin or buccal mucosa to replace urethral diameter) may be required and have better long-term success. Benign prostatic hyperplasia classically requires excision, but laser techniques are providing satisfactory outcomes with less morbidity. Impacted ureteral stones may either be removed or bypassed by a catheter unless it is thought that they may pass spontaneously.

Ureteral or UPJO requires surgical repair; however, endoscopic approaches within the ureter or by laparoscopy

may be equal to open repair. Renal stones may be removed instrumentally via retrograde or antegrade percutaneous approach by direct extraction with baskets or by ultrasonic or laser lithotripsy or by irrigation through a tube placed directly into the kidney.

Preliminary drainage above the obstruction is sometimes needed to improve kidney function. Occasionally, intestinal urinary diversion or permanent nephrostomy is required. If damage is advanced, nephrectomy may be indicated.

► Prognosis

The prognosis depends on the cause, site, duration, and degree of kidney damage and renal decompensation. In general, relief of obstruction leads to improvement in kidney function except in seriously damaged kidneys, especially those destroyed by inflammatory scarring.

Padmanabhan P, Nitti VW: Primary bladder neck obstruction in men, women, and children. *Curr Urol Rep* 2007;8:379.

URETEROPELVIC JUNCTION OBSTRUCTION

Stenosis of the renal pelvis outlet is commonly due to congenital narrowing of the junction or compression by anomalous vessels. However, the lesion may be acquired. Presentation in adults often includes the abrupt onset of flank pain usually following ingestion of large amounts of fluids. Presentation in childhood is now most often made following the diagnosis of hydronephrosis by prenatal ultrasonography.

The diagnosis may be confirmed with a diuretic nuclear renal scan or intravenous urography, which reveals hydronephrosis with a dilated renal pelvis and slow drainage of either radiotracer or contrast medium. Occasionally, patients present with intermittent hydronephrosis and normal urograms, except during attacks of pain, when x-rays show typical obstruction. These patients generally have normal renal parenchyma. Retrograde ureteropyelography is usually needed in patients with chronic moderate to severe obstruction to determine the extent of the lesion and to provide assurance that the distal ureter is normal. Marked obstruction may make it difficult to determine whether kidney function is surgically salvageable. In these cases, it may be necessary to perform either (1) differential radioisotope renography with use of a diuretic during the study or (2) percutaneous nephrostomy and creatinine clearance by 24-hour urine collection.

Severe obstruction with minimal remaining renal function is best treated by unilateral nephrectomy. If renal function is adequate (> 10%-15% of total renal function or > 10 mL/min creatinine clearance), surgical repair of the stenosis, either by creation of a renal pelvis flap or by resection of the stenotic area and reanastomosis (dismembered repair), is warranted. Laparoscopic and/or robotic pyeloplasty has emerged as the standard of care in adults for the repair of

UPJO. The use of ureteroscopy or percutaneous nephroscopy with endopyelotomy, incising the strictured ureteropelvic junction, offers an alternative method of therapy and is most useful in secondary UPJO, after primary repair has failed. Endoscopic approaches are less successful in the presence of a crossing vessel, poor renal function, and significant hydronephrosis. The surgical results of all the above methods are excellent in terms of functional preservation, improvement of urine flow, and relief of symptoms, but dilation of the calices may persist.

Singh I, Hemal AK: Robot-assisted pyeloplasty: review of the current literature, technique and outcome. *Can J Urol* 2010 Apr;17(2):5099-5108.

URETERAL STENOSIS

Ureteral stenosis can be secondary to congenital or acquired lesions. Congenital causes can include compression by an anomalous vessel such as a lower pole renal artery in UPJO or a retroperitoneal vein or primary megaureter where the distal ureter is partially obstructed. More commonly, the ureter is secondarily obstructed due to acquired conditions such as inflammation from chronic ureteral stones, trauma secondary to gynecologic or vascular surgery, or external penetrating trauma from a knife or gunshot wound. Enlarged pelvic lymph nodes or an iliac artery aneurysm or retroperitoneal fibrosis may obstruct the ureter, as can intrinsic ureteral cancer or bladder cancer infiltrating the ureter at its insertion into the bladder. Finally, infection such as urinary tuberculosis can cause distal ureteral strictures, and bilateral ureteral obstruction can occur from bladder neck obstruction with urinary retention secondary to benign prostatic hyperplasia.

Chronic conditions with slow development may not cause symptoms, whereas acute obstruction such as that from a stone will cause severe flank pain that may radiate to the groin or testes/labia. Diagnosis is most often made by a CT urogram with contrast that will show delayed function and a dilated renal pelvis and ureter down to the site of the obstruction. This is often an unsuspected finding on a CT done for other reasons in an asymptomatic patient.

Treatment depends entirely on the cause. Severe stenosis may require resection of the lesion and spatulated end-to-end anastomosis of the ureter. Less-severe obstruction may be managed by cystoscopy and ureteral or balloon dilation of the narrowed area under direct vision via a ureteroscope. Placement of an indwelling ureteral stent may dilate the stenosis over time and be a useful treatment as well in selected patients.

RETROPERITONEAL FIBROSIS

See also Chapter 22.

One or both ureters may be compressed by a chronic inflammatory process, usually of unknown cause, which

involves the retroperitoneal tissues of the lumbosacral area. When the source of fibrosis is unknown, the entity is known as idiopathic retroperitoneal fibrosis. Patients treated for migraine with methysergide may develop this fibrosis. Sclerosing Hodgkin disease and fibrosis from metastatic cancer have also been implicated. Symptoms include flank pain, lower back and abdominal pain (from ureteral obstruction), and those associated with uremia. Some patients present with complete anuria. Urinary infection is unusual. If both ureters are obstructed, the serum creatinine is elevated, but unilateral renal obstruction from fibrosis may present with normal or slightly elevated creatinine levels.

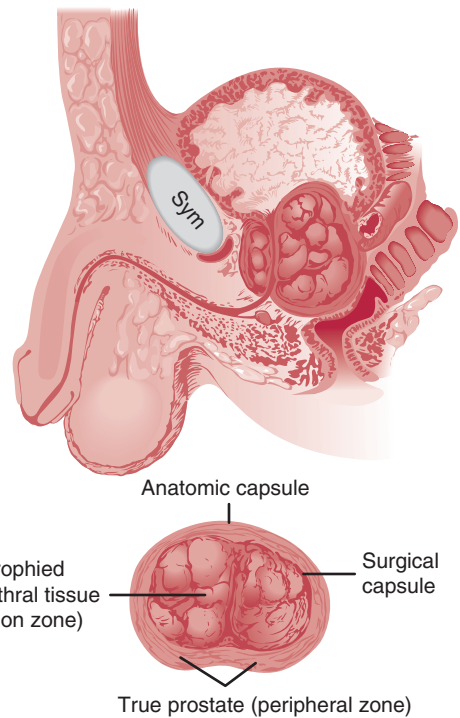

Excretory urograms show hydronephrosis and a dilated ureter down to the point of obstruction. The ureters are displaced medially in the lumbar area. Retrograde ureterograms show a long segment of ureteral stenosis, though a catheter usually passes easily through the ureter. Ultrasound lacks the anatomic specificity to make the diagnosis, but obstruction proximal to the fibrotic mass yields hydronephrosis and hydroureter. Large areas of fibrosis can be identified with ultrasound. CT scans and MRI offer the most diagnostic information about the fibrotic mass and both the degree and level of obstruction. If the patient has significant worsening of renal function, indwelling ureteral stent(s) or percutaneous nephrostomy tube(s) should be placed. When the patient's condition has improved, definitive therapy can be accomplished. If methysergide is suspected to be the causative agent, fibrosis may subside when the drug is discontinued. When malignancy is in the differential diagnosis, a percutaneous or laparoscopic biopsy should be considered prior to treatment. These patients may benefit from administration of corticosteroids and/or other immunosuppressive agents. Chronic indwelling ureteral stents have also been used successfully. If these methods fail, ureterolysis must be performed to free the ureter from the fibrous plaque. The involved ureter should be dissected from the plaque, moved to a lateral position, and wrapped with omentum to prevent recurrent entrapment. This has been accomplished quite successfully with laparoscopic and robotic approaches.

Keehn AY et al: Robotic ureterolysis for relief of ureteral obstruction from retroperitoneal fibrosis. *Urology* 2011 Jun;77(6):1370-1374.

BENIGN PROSTATIC HYPERPLASIA

► General Considerations

The cause of benign prostatic enlargement is not known but is probably related to hormonal factors. The mechanism for opening and funneling the vesical neck at the time of voiding is altered by hyperplasia of the prostate, which causes increased outflow resistance. Consequently, a higher intra-

▲ **Figure 38-9.** Benign prostatic hyperplasia. The enlarged periurethral glands are enclosed by the surgical capsule. The true prostate has been compressed.

vesical pressure is required to accomplish voiding, causing hypertrophy of the vesical and trigonal muscles. This may lead to the development of bladder diverticula—outpocketings of vesical mucosa between the detrusor muscle bundles. Hypertrophy of the trigone causes excessive stress on the intravesical ureter, producing functional obstruction and resulting in hydroureteronephrosis in late cases. Stagnation of urine can lead to infection; the onset of cystitis exacerbates the obstructive symptoms. The periurethral and subtrigonal prostate enlargement produces the most significant obstruction.

The prostate in young men has an anatomic capsule like an apple peel. In men with prostatic enlargement, there is a thick “surgical” capsule similar to an orange peel, composed of peripherally compressed true prostatic tissue (“peripheral zone”). The hyperplastic benign periurethral glands correspond to the “transition zone” and are the cause of the obstruction (Figure 38-9).

► Clinical Findings

A. Symptoms and Signs

Typically, the patient has lower urinary tract symptoms and notices hesitancy and loss of force and caliber of the

stream. The urgent need to void when the bladder is nearly full may be an early sign. He may also be awakened by the urge to void several times at night (nocturia). Postvoid dribbling (“terminal dribbling”) is particularly disturbing. The complication of infection increases the degree of obstructive symptoms and is often associated with burning on urination. Acute urinary retention may supervene. This is associated with severe urgency, suprapubic pain, and a distended, palpable bladder.

The size of the prostate rectally is not of primary diagnostic importance, since there is a poor correlation between the size of the gland and the degree of symptoms and amount of residual urine. The American Urological Association (AUA) developed a 7-item, self-administered questionnaire (AUA symptom score) that can assist the patient and physician in evaluating the patient’s lower urinary tract symptoms.

B. Laboratory Findings

Urinalysis may reveal evidence of infection. Residual urine is commonly increased (> 50 cc), and a timed urinary flow rate is decreased (< 10-15 cc/s). The serum creatinine may be elevated in cases with prolonged severe obstruction.

C. Imaging Studies

Pelvic ultrasound can easily identify post-void urine residual as well as estimate prostate size and anatomy, in particular, the presence or absence of median lobe tissue. Bladder wall thickness, trabeculation, and diverticula can also be identified with ultrasound. Renal ultrasound can identify hydronephrosis in advanced cases of BPH. Transrectal ultrasound of the prostate provides better imaging of the prostate than the transabdominal approach but is more invasive and typically not required. Computerized tomography (CT), MRI, and excretory urography also provide anatomical information for an enlarged prostate, but are more time consuming and costly and should only be utilized in unusual circumstances (eg, ruling out malignancy).

D. Cystoscopic Examination

Cystourethroscopy reveals secondary vesical changes (eg, trabeculation and diverticula) and enlargement of the prostatic urethra. Lateral lobe hypertrophy (so-called “kissing lobes”) as well as median lobe tissue can be easily visualized. Although cystoscopy is not required to make the diagnosis of BPH, it may identify other conditions in the differential diagnosis (eg, urethral stricture, bladder neck contracture, malignancy) as well as complications secondary to BPH (eg, bladder stones).

E. Urodynamic Studies

Simultaneous physiologic monitoring of bladder filling and emptying, urethral sphincter activity, abdominal pressure,

and pelvic floor muscle activity (electromyography) can be extremely useful in documenting whether bladder outlet obstruction, poor bladder function, or other causes are responsible for lower urinary tract symptoms. While urodynamic studies are not required for diagnosis in all cases, they are helpful in cases with large postvoid residual volumes or underlying neurologic disease to help determine appropriate management.

► Differential Diagnosis

Neurogenic bladder may produce a similar syndrome. A history suggesting a neuropathic etiology, such as diabetes mellitus, stroke, Parkinson’s disease, or spinal cord injury or compression, may be obtained. Neurologic deficit involving the spinal nerves S2-4 is particularly significant.

Cancer of the prostate also causes symptoms of vesical neck obstruction. Serum prostate-specific antigen (PSA) may be elevated in patients with benign prostatic hypertrophy, and the level increases as the volume of the prostate increases. Thus, an absolute value is not diagnostic, but in general, if it is over 10 ng/mL, the possibility of cancer should be evaluated.

Acute prostatitis may cause symptoms of obstruction, but the patient is septic and has infected urine. The prostate is exquisitely tender.

Urethral stricture diminishes the caliber of the urinary stream. There is usually a history of gonorrhea or local trauma. A retrograde urethrogram or cystoscopy shows the stenotic area. A stricture blocks the passage of an instrument or catheter.

► Complications

Obstruction and residual urine lead to vesical and prostatic infection and occasionally pyelonephritis; these may be difficult to eradicate. Long-term obstruction can lead to renal failure.

The obstruction may lead to the development of bladder diverticula. Infected residual urine may contribute to the formation of calculi.

Functional obstruction of the intravesical ureter, caused by the hypertrophic trigone, may lead to hydroureteronephrosis.

► Treatment

The indications for operative management are impairment of or threat to renal function and bothersome symptoms. Because the degree of obstruction progresses slowly in most patients, conservative treatment may be adequate. Drugs that relax the prostatic capsule and internal sphincter (α -adrenergic blocking agents) or decrease the volume of the prostate (5 α -reductase inhibitors or antiandrogens) have been tried with considerable success.

A. Conservative Measures

Treatment of chronic prostatitis may reduce symptoms. The resolution of a complicating cystitis usually affords some relief. In order to protect vesical tone, the patient should be cautioned to void as soon as the urge develops. Forcing fluids over a short time causes rapid vesical filling and decreasing vesical tone; this is a common cause of sudden acute urinary retention and thus should be avoided. Patients with urinary obstructive symptoms should avoid the use of cold remedies, including antihistamines and alpha agonists, because they are also a common cause of urinary retention. These conservative measures are of only temporary help—in any—in patients with BPH. There has been recent great interest, particularly by patients, in the use of phytotherapy for treatment of lower urinary tract symptoms, including saw palmetto, pumpkin seeds, and other plant extracts. Despite previous claims of efficacy based on small retrospective studies, a recent large, multicenter randomized trial of 369 men comparing placebo versus saw palmetto showed no improvement in AUA symptom score or secondary outcomes (eg, peak flow and PVR) in the saw palmetto group. Thus, the use of saw palmetto extracts for the treatment of BPH is not recommended.

Barry MJ, et al: Effect of increasing doses of saw palmetto extract on lower urinary tract symptoms: a randomized trial. *JAMA* 2011 Sep 28;306(12):1344-1351.

Controversy surrounds choices in the treatment of benign prostatic hyperplasia. No treatment (watchful waiting) may be appropriate in patients who complain of mild to moderate symptoms and thus have low AUA symptom scores and residual urine less than 70-100 cc. Interest has also focused on nonoperative medical therapy for those with more significant symptoms. α -Adrenergic blocking agents relax the internal (bladder neck) sphincter and prostatic capsule. Selective agents that are long-acting and preferentially work for this purpose include tamsulosin and silodosin. 5 α -Reductase inhibitors block conversion of testosterone to DHT (the androgen active in promoting prostate growth) and are useful for large glands, particularly in combination with an alpha-blocker, which has been shown to best prevent urinary retention and other common progressive symptoms of prostatic obstruction. More recently, daily tadalafil, a PDE-5 inhibitor commonly used in the treatment of erectile dysfunction, has been shown to have efficacy in treating symptoms related to BPH.

Catheterization is mandatory for acute urinary retention. Spontaneous voiding may return, but a catheter should be left indwelling for at least a few days and preferably one week while detrusor tone returns. Several studies have documented improved success of voiding trials after retention if α -blockers are initiated for at least 48 hours prior to catheter

removal. If several voiding trials fail, additional treatment is indicated.

Zeif HJ et al: Alpha blockers prior to removal of a catheter for acute urinary retention in adult men. *Cochrane Database Syst Rev* 2009 Oct 7;(4):CD006744.

B. Surgery

Surgery for BPH is offered to men in whom medical therapy fails to provide adequate symptom relief and/or objective parameters such as post-void residual fail to improve. Additionally, men may request surgery because of poor compliance with medical therapy or desire to stop medications. Absolute indications for BPH surgery include recurrent infections, development of bladder stones, renal failure due to BPH, and persistent urinary retention due to obstruction. Men with large amounts of median lobe tissue (intra-vesical protrusion) tend to have a poor response to medical therapy and benefit most from early surgery.

There are two common approaches used in surgery for BPH: transurethral and transabdominal (open vs. minimally invasive). The transurethral route is by far the most common and preferred in patients with glands weighing less than 100 g because morbidity rates are lower and the hospital stay is shorter. With new technology, even larger glands can be managed with the transurethral approach. Larger glands, however, may require open surgery (suprapubic or retropubic enucleation), depending on the preference and experience of the urologist. Open surgery for BPH is the exception rather than the rule because of increased morbidity.

Transurethral approaches are the least invasive and require the shortest hospital stay (typically ambulatory or one night). The gold standard is the monopolar transurethral resection of the prostate (TURP), by which a resectoscope with a monopolar loop electrode is utilized to remove the obstructing BPH tissue. Hypotonic irrigation solution is required and hyponatremia due to excess systemic absorption ("TURP Syndrome") is a unique complication of this approach. Additional complications of TURP include hematuria, UTI, stress incontinence, impotence, retrograde ejaculation, urethral stricture, and bladder neck contracture. Incontinence and impotence are rare complications in the hands of experienced surgeons (< 5%). TURP has reliably demonstrated improvement in AUA symptom score, flow rate, and PVR in randomized controlled trials. The more recent use of bipolar energy has allowed for the use of saline irrigation during TURP, eliminating the risk of hyponatremia.

Transurethral laser vaporization of the prostate with holmium or KTP (potassium titanyl phosphate) laser technology has demonstrated similar efficacy to TURP in well-selected patients with smaller glands. The major advantage of the laser approaches is less risk of bleeding, and even the ability to perform the procedure while patients remain on

anticoagulation. Holmium-laser enucleation of the prostate (HOLEP) utilizes laser energy to enucleate the prostate adenoma (rather than vaporize the tissue). The tissue must then be morecellated to be removed via the resectoscope. HOLEP has similar efficacy to TURP and laser vaporization but may be more technically challenging.

An alternative transurethral approach for the treatment of BPH is transurethral incision of the prostate (TUIP). This procedure consists of a linear incision starting at the bladder neck and ending distally at the verumontanum, allowing expansion of the entire prostatic urethra. Typically two incisions are made with a cutting current at the 5 and 7 O'clock positions. TUIP is typically reserved for men with a steep/high bladder neck or small, obstructive prostates of 30 g or less in size.

Open and robotic enucleation of the prostate for BPH is reserved for larger glands where transurethral approaches would be unable to remove sufficient tissue to provide long-term relief of the obstruction.

► Prognosis

Most patients with marked symptoms receive considerable relief and substantial improvement in urine flow following surgical treatment; however, those with milder forms may benefit from drug therapy. Unless absolute indications for surgery exist (see above), most men begin with medical therapy and progress to surgical interventions if substantial symptoms persist.

American Urological Association Guideline: Management Of Benign Prostatic Hyperplasia (BPH). Available at www.auanet.org. Accessed May 10, 2014.

URETHRAL STRICTURE

Acquired urethral strictures in men may be due to external trauma or to prior instrumentation (most common). Strictures may be inflammatory, due to gonorrhea, tuberculous urethritis, or schistosomiasis, or may rarely be a complication of cancer. The common presenting symptoms are dysuria, weak stream, splaying of the urinary stream, urinary retention, and urinary tract infection. Evidence of scarring due to trauma or induration and perineal fistula may be seen. Urethroscopy reveals the degree of narrowing. A retrograde urethrogram delineates the site and degree of stricture.

Urethral stricture must be differentiated from bladder outlet obstruction due to BPH, impacted urethral stones, urethral foreign bodies, and tumors.

Initial treatment consists of transurethral direct-vision internal urethrotomy (incision of the stricture). Successful results are obtained in 75% of patients. For long, dense strictures or those failing to respond to an initial internal urethrotomy, open surgical repair is indicated. This is probably

best achieved by the transpubic or perineal route if the lesion involves the membranous urethra. If the bulbar urethra is involved, the perineal approach is indicated; if the distal/penile urethra is involved, the ventral penile approach is appropriate. End-to-end anastomosis is satisfactory for short segment strictures, usually 2 cm or less, with a more than 90% success rate. Longer strictures often require pedicle flaps for distal urethral strictures or onlay grafts (eg, buccal mucosa) for proximal strictures.

Lee YJ et al: Current management of urethral stricture. *Korean J Urol* 2013 Sep;54(9):561-569.

HEMATURIA

Hematuria, gross or microscopic, is a common urologic consult because it can be a presenting sign for underlying urologic malignancies. Red-colored urine may not necessarily include blood, and microscopic examination looking for red blood cells is prudent. Microscopic hematuria is defined as three or more red blood cells per high-powered field on urine microscopy in two of three properly collected specimens. The degree of hematuria bears no relation to the seriousness of the underlying cause. Urine dipstick test is the simplest method to check for blood and has a sensitivity of 91%-100% and a specificity of 65%-99%. Caution should be taken because false positives (menstrual blood, myoglobin, and hemolysis, among others) and false negatives (dipstick exposed to moisture and presence of reducing agents like ascorbic acid) can lead to confusing results. For this reason, further evaluation of microscopic hematuria performed only when microscopic analysis confirms the diagnosis. Knowledge of the medical history and medications can help rule out other causes of colored urine. Beets, rifampin, and phenazopyridine, among other substances, can cause urine discoloration. Anticoagulation at normal therapeutic levels does not predispose to hematuria, and patients should be evaluated for the hematuria, because 13%-45% of these patients may have significant urologic disease.

Ideally, a clean-catch midstream sample should be collected. If that is not possible, a catheterized specimen is indicated. It is important to note that hematuria can be due to urologic or renal parenchymal disease. The differential diagnosis thus includes benign causes like renal or bladder stones, papillary necrosis, urinary tract infections, prostatitis, or instrumentation, and malignant causes like renal, renal pelvis, bladder, prostate, or urethral cancer. Renal parenchymal causes of hematuria include glomerular and interstitial renal disease. These patients may have proteinuria and casts on the urinalysis, and the red blood cells are typically dysmorphic. Nephrology evaluation is required for hematuria associated with glomerular or interstitial renal disease.

Patients with hematuria referred to urology are classified into low-risk and high-risk groups. High-risk groups include smokers, age older than 40 years, history of exposure to pelvic radiation or cyclophosphamide, occupational exposure to chemicals or dyes, and history of urinary tract infections or other urological disorders. It is recommended that a complete workup be performed for all patients with symptomatic hematuria, all patients with gross hematuria, and high-risk patients with microscopic hematuria. The workup includes history and physical examination, serum creatinine, upper tract imaging (typically CT urogram), cystoscopy, and urine cytology. Asymptomatic patients younger than 40 years who have microscopic hematuria and have no risk factors can be evaluated with upper tract imaging and either cystoscopy or voided cytology, as the risk of significant pathology in this population is very low. If the workup is negative, it is recommended that the patient be evaluated with urinalysis, voided cytology, and blood pressure check at 6, 12, 24, and 36 months.

URINARY TRACT INFECTIONS

Urinary tract infection is the second-most common type of infection in humans and is frequently encountered by primary care physicians as well as urologists.

These infections are caused by a variety of pyogenic bacteria that typically produce a nonspecific tissue response. The most common organisms are gram-negative bacteria, particularly *Escherichia coli*. Less common are *Enterobacter aerogenes*, *Proteus vulgaris*, *Proteus mirabilis*, *Pseudomonas aeruginosa*, and *Enterococcus faecalis*.

Owing to the short length of the female urethra and bacterial colonization of the introitus, ascending infection is a common occurrence in young girls and in sexually active women. In men, ascending infection is often a consequence of urethral instrumentation.

Although relatively uncommon, descending or hematogenous urinary tract infection is usually associated with local urinary tract disorders—most commonly, obstruction and stasis; less commonly, trauma, foreign bodies, or tumors.

Lymphatic spread occasionally occurs from the large bowel or from the cervix and adnexa in the female through the perivesical and periureteral lymphatics.

Direct extension to the urinary bladder of nearby inflammatory processes (eg, appendiceal abscess, enterovesical fistula, or pelvic abscess) may occur.

► Predisposing Factors

Infection is usually initiated or sustained by predisposing factors. Predisposing systemic factors include diabetes mellitus, immunosuppression, and malnutrition; these disorders likely interfere with normal bladder and body defense mechanisms. Predisposing local factors include incontinence,

constipation, organic or functional obstruction, stasis (residual urine), foreign bodies (especially catheters and stones), tumors, or necrotic tissue. Vesicoureteral reflux facilitates transport of bacteria from the bladder to the kidney, which subsequently predisposes to pyelonephritis.

► Classification of Urinary Tract Infection

Urinary tract infection is classified as (1) upper urinary tract infection (most commonly acute or chronic pyelonephritis or infection due to renal abscess), (2) lower urinary tract infection (cystitis or urethritis), or (3) genital infection (prostatitis, epididymitis, seminal vesiculitis, or orchitis).

► Urologic Instrumentation or Surgery & Urinary Tract Infection

In the absence of urinary tract infection, surgery of the upper urinary tract should require only short-term prophylactic antibacterial therapy. In the presence of infection, one attempts to sterilize the system before operation. If stenting or tube drainage is required and there are no symptoms of infection, colonization does not call for antibacterial therapy until the stent or tube is to be changed or removed. Broad-spectrum antibacterial prophylaxis is started at that time.

With lower urinary tract surgery, antibacterial therapy is advised before operations involving the urethra and the bladder, especially for women in whom contamination from vaginal organisms is likely. Men undergoing prostatectomy for obstructive prostatism often have urinary tract infection, particularly when catheter drainage is used preoperatively. In these cases, antimicrobial therapy is necessary before and after surgery to prevent bacteremia.

In the presence of urinary tract infection, any urethral instrumentation poses a threat of bacteremia, and possibly sepsis—more apt to occur in men than in women. Appropriate antibacterial coverage should be instituted before manipulation.

A. Principles of Catheterization

After a short-term single catheterization, the rate of infection is 1%-5%. However, in certain patients—pregnant women, elderly, or debilitated patients—and in the presence of urologic disease, the risk is much higher. An indwelling catheter often leads to bacterial colonization, especially in women. The incidence is proportionate to the duration of catheterization and reaches approximately 95% after 5 days.

Strict aseptic technique is of critical importance in catheterization. Proper cleansing of the genitalia is essential. Iodophor preparations may be used for cleaning the vaginal introitus or the glans penis. Many common urinary tract pathogens are present in normal colonic flora, and these organisms often gain access to the urinary tract of catheterized patients. Cross-contamination of urinary catheters (passive transmission of bacteria from patient to patient

on the hands of hospital personnel) is a frequent mode of transfer of resistant organisms. Measures directed to the prevention of catheter cross-contamination are essential. Closed catheter drainage is probably the best way to reduce cross-contamination.

With sterile technique during catheterization and a closed drainage system, most catheters can be kept sterile for 48-72 hours. In a closed drainage system, an added airlock or one-way valve preventing reflux of urine from the collecting bag to the draining tubes also helps prevent infection. The general principles are as follows: (1) Indwelling catheters should be used only when absolutely necessary. (2) Catheters should be inserted with strict aseptic technique. (3) A closed drainage system, preferably with a one-way valve, is advisable. (4) Nonobstructed dependent drainage is essential. (5) Unnecessary irrigation of the system should be avoided. (6) If the catheter is needed for a prolonged period, it should be changed every 2-4 weeks to minimize encrustation and stone formation. (7) Catheterized patients with asymptomatic catheter colonization should be given antibiotics just before the catheter is changed or removed—not during the period of catheterization unless symptomatic infection occurs.

B. Evaluation

Imaging of the urinary tract is recommended in every febrile infant or young child following the first urinary tract infection. Imaging includes a renal and bladder ultrasound and a voiding cystourethrogram. The renal ultrasound may detect hydronephrosis, duplication anomalies, stones, or abnormalities of the bladder wall and should be obtained at the earliest convenient time. A cystogram may be obtained by instillation of contrast medium with fluoroscopy or by instillation of a radionuclide. Radionuclide cystography has the advantage of decreased radiation, while the contrast-voiding cystourethrogram has the advantage of providing better anatomic detail, which may help detect bladder or urethral abnormalities. Either method should include a voiding phase because reflux is the most likely abnormality to be detected and may only occur with voiding. The cystogram should be obtained once the child is free of infection.

Imaging recommendations in adults with a urinary tract infection vary depending on the patient's past history and present symptoms. Renal/bladder ultrasound is a good initial study to identify upper- (eg, hydronephrosis, stones, or abscess) and lower- (eg, urinary retention or bladder calculi) tract sources of infection. CT scan with intravenous contrast can identify stigmata of pyelonephritis (see below).

C. Antibacterial Therapy

The choice of antibiotics depends on the type of organism and its sensitivity, as determined by urine cultures. For uncomplicated infection, adequate urine concentrations of the antibiotic determine efficacy, but in cases of bacte-

remia and septic shock, serum concentrations are crucial. Commonly used oral medications are sulfonamides, nitrofurantoin, ampicillin, trimethoprim-sulfamethoxazole, fluoroquinolones, and oxytetracycline. For parenteral therapy, aminoglycosides and cephalosporins are effective against the most common organisms (ie, *P. mirabilis*, *E. aerogenes*, and *P. aeruginosa*).

ACUTE PYELONEPHRITIS

► General Considerations

Except in the presence of stasis, foreign bodies, trauma, or instrumentation, pyelonephritis is an ascending type of infection. Pathogenic organisms usually reach the kidney from the bladder, often via an incompetent ureterovesical junction.

► Clinical Findings

A. Symptoms and Signs

In acute attacks, pain is present in one or both flanks. Diagnosis in infants requires a high index of suspicion, since they may present with nonspecific symptoms such as fever and failure to thrive. Young children commonly present with poorly localized abdominal pain; irritative lower urinary tract symptoms may be present. Chills and fever are common. Severe infection may produce hypotension, peripheral vasoconstriction, and acute renal failure. Gross hematuria is not common but can be observed more frequently in women and the elderly.

B. Laboratory Findings

Pyuria and bacteriuria are consistent findings. Leukocytosis with a shift to the left is common. Urine culture identifies the organism.

C. Imaging Studies

In acute attacks, only minimal changes such as delayed visualization and poor concentrating ability are noted on intravenous urography. CT scans may demonstrate zones of decreased enhancement in the renal parenchyma as well as perinephric fat stranding. Renal or ureteral calculi may be seen on plain abdominal x-rays or nonenhanced CT scans. Chest x-ray may show a small ipsilateral pleural effusion.

► Differential Diagnosis

Pneumonia, acute cholecystitis, or splenic infarction can be confused with pyelonephritis. Acute appendicitis sometimes causes pyuria and microhematuria. Any acute abdominal illness such as pancreatitis, diverticulitis, or intestinal ischemia can simulate pyelonephritis. Appropriate history, examination, urinalysis and imaging usually make the distinction.

► Complications

If the diagnosis is missed in the acute stage, the infection may become chronic. Both acute and chronic pyelonephritis may lead to progressive renal damage and abscess formation.

► Treatment

Specific antibiotic therapy should be given for at least 7 days to eradicate the infecting organism after proper identification and sensitivity determination. Symptomatic treatment is indicated for pain and irritative voiding symptoms. Adequate fluid intake to assure optimum urinary output is required. Failure to simultaneously identify and treat predisposing factors (eg, obstruction) is the principal cause of failure to respond to therapy, leading to progressive infection, chronic pyelonephritis, and possibly sepsis. Patients not responding to culture-sensitive antibiotics should be imaged, looking for intrinsic (eg, calculi) or extrinsic obstruction or renal abscess.

► Prognosis

The prognosis is good with adequate treatment of both the infection and its predisposing cause, depending on the degree of preexisting renal parenchymal damage.

EMPHYSEMATOUS PYELONEPHRITIS

Emphysematous pyelonephritis is a form of acute necrotizing pyelonephritis secondary to a gas-producing bacteria (*E. coli* in 66% of cases and *Klebsiella* in 26%). It is commonly seen in patients with poorly controlled diabetes (over 90% of cases) or in patients with upper urinary tract obstruction. The diagnosis is made by the usual signs of acute pyelonephritis and by the presence of gas in the renal collecting system and parenchyma seen on plain films, ultrasound, or CT. The condition is life threatening, with a mortality rate of 40%-80% with intravenous antibiotics alone. Obstruction requires drainage either percutaneously or by stent placement. Operative treatment, including nephrectomy and drainage along with antibiotics, decreases the mortality rate to less than 20%.

CHRONIC PYELONEPHRITIS

Chronic pyelonephritis is the result of inadequately treated or recurrent acute pyelonephritis. The diagnosis is primarily made by x-ray, since patients rarely have signs or symptoms until late in the course, when they develop chronic flank pain, hypertension, anemia, or renal failure. Pyuria is not a consistent finding. Because chronic pyelonephritis may be a progressive, localized immune response initiated by bacteria long since eradicated, urine cultures are usually sterile. Early cases may have no findings on intravenous urography, whereas in late cases it may reveal small kidneys with typical caliceal

deformities (clubbing), with evidence of peripheral scarring and a thin cortex. Voiding cystourethrography may document vesicoureteral reflux as the cause. Complications include hypertension, stone formation, and chronic renal failure.

Antibiotic treatment is not helpful in these patients unless ongoing infection can be documented. The prognosis depends on the status of renal function but is generally not good, particularly when the disease is contracted in childhood. Progressive deterioration of renal function usually occurs.

Xanthogranulomatous pyelonephritis is a form of chronic pyelonephritis seen most frequently in middle-aged diabetic women and rarely in children. The disease is usually unilateral and is associated with prolonged obstructing nephrolithiasis. Patients often have nonspecific symptoms similar to those of acute pyelonephritis but have an enlarged kidney with calculi and a mass often indistinguishable from tumor. *Proteus* species are common causative agents. Nephrectomy is usually the treatment of choice, though a partial nephrectomy may be performed for focal disease. Histologic examination confirms the diagnosis following nephrectomy by the demonstration of foamy lipid-laden macrophages.

PAPILLARY NECROSIS

This disorder consists of ischemic necrosis of the renal papillae or of the entire pyramid. Excessive ingestion of analgesics, sickle cell trait, diabetes, obstruction with infection, and systemic conditions decreasing renal blood flow are common predisposing factors.

The symptoms are usually those of chronic cystitis with recurring exacerbations of pyelonephritis. Renal pain or renal colic may be present. Azotemic manifestations may be the presenting symptoms. In acute attacks, localized flank tenderness and generalized toxemia may occur. Laboratory findings consist of pyuria, hematuria, occasionally glycosuria, and acidosis. Impaired kidney function is shown by elevated serum creatinine and urea nitrogen. Intravenous urography usually shows impaired function and poor visualization in advanced cases. Evidence of ulceration, cavitation, or linear breaks in the base of the papillae and radiolucent defects due to sloughed papillae may be seen; the latter may become calcified. Retrograde urograms may be needed for proper imaging if kidney function is markedly impaired.

Preventive measures consist of proper management of diabetic patients with recurrent infections and avoidance of chronic use of analgesic compounds containing phenacetin and aspirin.

Intensive antibacterial therapy may be needed, though it is commonly unsuccessful in eradicating infection. Little can be done surgically except to remove obstructing papillae and correct predisposing factors (eg, reflux, obstruction) if identified.

In severe cases, the prognosis is poor. Renal transplantation may be required.

RENAL ABSCESS

While renal abscess is occasionally due to hematogenous spread of a distant staphylococcal infection, most abscesses are secondary to chronic nonspecific infection of the kidney, often complicated by stone formation. The onset may be acute, with high fever, but occasionally low-grade fever and general malaise are the presenting symptoms. Localized costovertebral angle tenderness and a palpable flank mass may be present. A mass may be evident on intravenous urograms, DTPA scans, sonograms, CT scans, or renal angiograms. If the abscess is due to hematogenous spread, the urine does not contain bacteria unless the abscess has broken into the pelvicaliceal system. More frequently, gram-negative organisms are found, as would be expected in light of the preponderance of ascending infection.

If organism sensitivity can be established by appropriate tests (blood and urine cultures and sensitivity tests), treatment with the proper antibiotic is indicated. Many infections have responded to percutaneous drainage and irrigation with antibiotic solutions, especially in cases of unilocular abscess cavity seen on either ultrasound or CT examination. In multilocular abscess or persistent bacteremia despite percutaneous drainage, surgical drainage or even heminephrectomy may be necessary.

When the abscess is found to be secondary to chronic renal infection, nephrectomy is usually indicated because of advanced destruction of the kidney.

PERINEPHRIC ABSCESS

Abscess between the renal capsule and the perirenal fascia most often results from rupture of an intrarenal abscess into the perinephric space. *E. coli* is the most common causative organism. The pathogenesis usually begins with severe pyonephrosis secondary to obstruction, as with renal or ureteral calculi. Clinical findings are similar to those of renal abscess. A pleural effusion on the affected side and signs of psoas muscle irritation are common. Abdominal plain films may show obliteration of the psoas muscle shadow, and an intravenous urogram may show poor concentration of contrast medium and hydronephrosis. CT scan is the current study of choice for diagnosis.

Treatment involves prompt drainage of the abscess and use of appropriate systemic antibiotics, including coverage of anaerobes. Percutaneous drainage is often successful; however, open surgical drainage is necessary if percutaneous drainage is incomplete.

CYSTITIS

Cystitis is more common in females and is usually an ascending infection. In males, it usually occurs in association

with urethral or prostatic obstruction, prostatitis, foreign bodies, or tumors. The urinary bladder is normally capable of clearing bacterial inoculation unless an underlying pathologic process interferes with its defensive mechanisms.

In the acute phase, the principal symptoms of cystitis are dysuria, frequency, urgency, and hematuria; low-grade fever and suprapubic, perineal, and low back pain may be present. In chronic cystitis, irritative symptoms are usually milder.

Evidence of prostatitis, urethritis, or vaginitis may be present. Laboratory findings, in addition to hematuria, consist of bacteriuria and pyuria. Leukocytosis is not common. Urine culture identifies the organism. Cystoscopy is not advisable in the acute phase. In chronic cystitis, evidence of mucosal irritation may be present.

In any documented recurrent lower urinary tract infection (particularly in males), a complete urologic workup is indicated. Instrumentation is contraindicated in the acute phase, but cystoscopy is essential to identify the predisposing factor in chronic or recurrent bacterial cystitis. Upper tracts should be investigated with renal ultrasound when a lower tract source of infection is not identified.

Specific antibacterial therapy is given according to sensitivity testing of recovered organisms (*E. coli* in > 80% of cases). Sterilization of urine should usually be followed by a variable period of continuous antibiotic therapy (depending on the predisposing factor or the chronicity and recurrence of the disease). Prolonged suppressive medication is usually indicated in cases associated with voiding dysfunction.

In females with recurrent postcoital cystitis, premedication (eg, sulfonamides, nitrofurantoin) on the night of intercourse and the following day in addition to immediate postcoital voiding decreases recurrences.

PROSTATITIS

▶ Acute Bacterial Prostatitis

Acute bacterial prostatitis is a severe acute febrile illness caused by ascending coliform bacteria, which frequently colonize the male urethra. Symptoms include high fever, chills, low back and perineal pain, and urinary frequency and urgency with diminished stream or retention. On examination, the prostate is extremely tender, swollen, and warm to the touch. A fluctuant abscess may be palpable. The prostate must be examined cautiously, because vigorous palpation may cause acute septicemia. Laboratory findings include pyuria, bacteriuria, and leukocytosis.

Transurethral manipulation by catheter or cystoscopy should be avoided if possible; urinary retention should be treated by gently introducing a urethral catheter or introducing a percutaneous suprapubic tube. Treatment with systemic antibiotics (fluoroquinolones or aminoglycosides and ampicillin-cephalosporin) should be started immediately and should be adjusted later when results of urine culture or blood culture (or both) and sensitivity tests are known.

E. coli is found in 80% of cases. Treatment with oral antibiotics for several weeks after the initial phase has subsided is necessary to eradicate the bacteria completely.

Prostate abscess can develop from a smoldering acute prostatitis (typically gram negative bacteria) or from hematogenous seeding, often from gram-positive staphylococcus species. Pelvic imaging (CT, MRI, or ultrasound) identifies a hypodense fluid collection within the prostate parenchyma. Treatment includes a long course of culture-sensitive antibiotics and drainage of the abscess. Transrectal needle drainage and transurethral unroofing of the abscess are both successful modalities. Ultrasound-guided transrectal needle drainage can be done under local anesthesia, with or without intravenous sedation, whereas transurethral unroofing is performed with a resectoscope in the operating room, typically under general anesthesia. Thus, if feasible, it seems reasonable to attempt transrectal drainage first, and if the abscess recurs or persists then proceed to transurethral unroofing.

▶ Chronic Prostatitis

Chronic prostatitis is a common and complex problem. With differential diagnosis including urethritis, bacterial and nonbacterial prostatitis, prostatodynia (chronic pelvic pain syndrome [CPPS]), and seminal vesiculitis, assigning the correct diagnosis may challenge even the expert. The symptoms are varied and include suprapubic pain, low back pain, orchialgia, dysuria at the tip of the penis, and urinary frequency and urgency. The urinalysis may be normal. There may be a clear white urethral discharge. Prostate examination may be normal or reveal a soft, boggy prostate.

Expressed prostatic secretions may contain numerous leukocytes (> 10 per high-power field) in clumps as well as macrophages. Cultures of urine are usually sterile, but cultures of expressed prostatic secretions and urine obtained after prostatic massage are usually positive in bacterial prostatitis. *Chlamydia* or *Ureaplasma* may be an offending organism, particularly in men under age 35. Determination of the site of infection may require differential cultures. The first part of the voided urine stream is collected as VB₁ and the midstream specimen as VB₂. The prostate is then massaged to obtain expressed prostatic secretions, and the post-massage urine is collected as VB₃. The differential leukocyte and bacterial counts from each of these specimens can help localize the site of infection. If VB₁ has high levels of leukocytes and bacteria relative to the other specimens, urethritis is likely; if VB₂ has high levels, a site above the bladder neck is likely; and if the expressed prostatic secretions, VB₃, or both have high counts, prostatitis is likely.

For chronic bacterial prostatitis, at least a 4- to 6-week course of a fluoroquinolone or trimethoprim-sulfamethoxazole is often given. Surgical treatment for prostatitis is rarely indicated or helpful. Some patients improve following discontinuation of caffeine and alcohol, and a few respond to repeated

prostatic massage. Patients with no evidence of bacterial infection or obstructive findings, and those who have recurrent pelvic pain in association with voiding dysfunction (eg, intermittent or weak urinary stream) may be treated with α -adrenergic blocking agents or biofeedback to decrease the internal and external sphincter tone. 5 α -Reductase inhibitors may be helpful.

ACUTE EPIDIDYMITIS

Acute epididymitis is most commonly a disease of young males, caused by bacterial infection ascending from the urethra or prostate. The disease is less common in older males, but when it does occur, it is most often due to infection secondary to urinary tract obstruction or instrumentation.

The symptoms are sudden pain in the scrotum, rapid unilateral scrotal enlargement, and marked tenderness that extends to the spermatic cord in the groin and may be relieved by scrotal elevation (**Prehn's sign**). Fever is present. An acute hydrocele may result, and secondary orchitis with a swollen, painful testicle may occur. Laboratory studies reveal pyuria, bacteriuria, and marked leukocytosis.

Epididymitis must be differentiated from torsion of the testis, testicular tumor, and tuberculous epididymitis. A technetium-99m pertechnetate scan reveals increased uptake with epididymitis but decreased uptake with torsion. Scrotal ultrasound distinguishes between the solid mass of a testicular tumor and an enlarged, inflamed epididymis and can also identify epididymal or testicular abscess, which requires operative treatment. Increased blood flow on Doppler ultrasound also helps distinguish epididymitis from torsion, though it is not completely reliable.

Cultured aspirates from inflamed epididymides of males under age 35 tend to show gonococci and chlamydiae; in men older than 35, *E. coli* is most common. Epididymal aspiration for culture is not required routinely, however. Pyuria with a negative urine culture suggests the presence of chlamydial infection in both prostate and epididymis. (See also section on Tuberculosis.)

Treatment consists of antibiotics, usually ceftriaxone and doxycycline in males under age 35 and fluoroquinolones in those over age 35. In some patients, pain is relieved by scrotal hypothermia, and consideration should be given to infiltration of the spermatic cord by 1% bupivacaine. Nonsteroidal anti-inflammatory drugs are recommended to aid in pain relief. In most instances, prompt treatment results in rapid resolution of pain, fever, and swelling. Patients must refrain from exertion for 1-3 weeks.

Exacerbations can be controlled by treating the predisposing factor. Chronic epididymitis rarely resolves completely; it has no consequences except, occasionally in bilateral cases, sterility due to scarring and obstruction of the delicate epididymal tubules. Rarely, epididymectomy is necessary for severe and refractory pain.

TUBERCULOSIS

Tuberculosis is a commonly missed genitourinary infection that should be considered in any case of pyuria without bacteriuria or in any case of urinary tract infection that does not respond to treatment.

Genitourinary tuberculosis is always secondary to pulmonary infection, though in many cases, the primary focus has healed or is quiescent. Infection occurs via the hematogenous route. The kidneys and (less commonly) the prostate are the principal sites of urinary tract involvement, though any part of the genitourinary system can be affected.

► Pathology

Renal tuberculosis usually starts as a tuberculoma that gradually enlarges, caseates, and finally ulcerates, breaking into the pelvicaliceal system. Caseation and scarring are the principal pathologic features of renal tuberculosis. In the ureter, tuberculosis usually leads to distal strictures, periureteritis, and mural fibrosis.

In the bladder, the infection is characterized by areas of hyperemia and a coalescent group of tubercles, followed by ulcerations. Bladder wall fibrosis and contraction are the end results.

Urethral involvement in the male is uncommon but when present leads to urethral stricture, usually in the bulbous portion. Periurethral abscess and fistula are possible complications.

Genital tuberculosis may involve the prostate, seminal vesicles, and epididymides, either separately or in association with renal involvement. Tubercle formation with later caseation and fibrosis is the basic pathologic feature. The prostate becomes enlarged, with palpable nodules and an irregular consistency. The affected seminal vesicle is fibrotic and distended. Induration and thickening of the epididymis and beading of the vas deferens are characteristic findings. The testicles are rarely involved.

► Clinical Findings

A. Symptoms and Signs

The patient commonly presents with lower urinary tract irritation, usually with pyuria. Less common manifestations are hematuria, renal pain, and renal colic.

B. Laboratory Findings

“Sterile” pyuria is the rule, but 15% of cases have secondary bacterial infection (eg, *E. coli*). Mycobacteria can be identified on an acid-fast stain of the centrifuged sediment of the first morning urine collected on three successive days (positive in 90% of cases). Culture of the sediment should yield the mycobacteria, which may then be speciated by niacin and nitrate tests, both of which must be positive for a diagnosis of *Mycobacterium tuberculosis*.

C. Imaging Studies

Radiologic findings that suggest genitourinary tuberculosis include moth-eaten, caseous renal cavities, or bizarre, irregular calices. Strictures in straight, rigid, moderately dilated ureters and a contracted bladder with vesicoureteral reflux are all suggestive evidence.

► Treatment

A. Medical Treatment

Tuberculosis must be treated as a systemic disease. Once the diagnosis is established, medical treatment is indicated regardless of the need for surgery. Whenever possible, medical treatment should be continued for at least 3 months before surgery is considered.

Active medications against tuberculosis include rifampin, isoniazid, pyrazinamide, ethambutol, and streptomycin. Standard initial treatment is with rifampin, isoniazid, and pyrazinamide for 8 weeks. Pyridoxine, 100 mg/d, is given in divided doses to counteract the vitamin B₆ depletion effect of isoniazid. In patients with more severe infections, ethambutol or streptomycin may be added to the initial treatment. Following the initial 8 weeks of therapy, rifampin and isoniazid are continued in combination three times per week for another 8 weeks. Liver function tests must be followed in view of the hepatotoxicity of rifampin, isoniazid, and pyrazinamide.

B. Surgical Measures

If medical therapy fails to cure a unilateral lesion, nephrectomy may be necessary. However, this is rare. In bilateral disease that has seriously damaged one kidney and is in an early stage in the other, unilateral nephrectomy may be considered; in localized polar lesions, partial nephrectomy may be done.

In unilateral epididymal involvement, epididymectomy plus contralateral vasectomy is indicated to prevent descent of the infection to the prostate; bilateral epididymectomy should be done if both sides are involved.

For a severely contracted bladder, augmentation enterocystoplasty increases vesical capacity following eradication of the infection.

► Prognosis

In a high percentage of cases, cure is obtained by medical means. Unilateral renal lesions have the best prognosis.

CALCULI

RENAL STONE

► General Considerations

Stone disease is common, with the lifetime risk of stone formation in the United States exceeding 12% in males and 6% in females. Prevalence of stone disease varies by racial background and geographic location within the United States, with older white males and southeastern states having the highest prevalence. Seventy-five percent of most stones are composed of calcium salts (oxalate and phosphate), while uric acid and struvite stones (magnesium-ammonium phosphate stones that form secondary to urea-splitting organisms) constitute 10% each. Formation of calcium stones can be due to one or multiple factors that include hypercalciuria, hypocitraturia, hyperoxaluria, and hyperuricosuria. In patients with hyperparathyroidism or those who ingest large amounts of calcium or vitamin D or in patients who are dehydrated or immobilized, hypercalciuria promotes stone formation.

Uric acid stones form in acidic urine. Cystine stones, which make up 1% of all stones, usually form secondary to impaired renal reabsorption of cystine. Owing to the radiodensity of sulfur, cystine stones are radiopaque (albeit less so than calcium stones), whereas uric acid stones are radiolucent. Stones that obstruct the ureteropelvic junction or ureter lead to hydronephrosis and possibly infection.

► Clinical Findings

A. Symptoms and Signs

If the stone acutely obstructs the ureteropelvic junction or a calix, moderate to severe renal pain is noted, often accompanied by nausea, vomiting, and ileus. The pain starts in the upper lateral back and may radiate anteriorly and inferiorly toward the groin. Gross or microscopic hematuria is common. Symptoms of infection, if present, are exacerbated. Nonobstructing calculi are usually painless. This includes staghorn calculi, which may form a cast of all calices and the pelvis. In the symptomatic patient, there may be costovertebral angle tenderness and a quiet abdomen. Infection secondary to obstruction may lead to high fever and a rigid abdomen.

B. Laboratory Findings

With acute infection, leukocytosis is to be expected. Urinalysis may reveal red and white blood cells and bacteria. A pH of 7.6 or higher implies the presence of urea-splitting organisms. A pH consistently below 5.5 is compatible with the formation of uric acid or cystine stones. If the pH is fixed between 6.0 and 7.0, renal tubular acidosis should be considered as a cause of nephrocalcinosis. Crystals of uric acid (rhomboid) or cystine (hexagonal) in the urine are suggestive. A 24-hour urine collection can help identify the metabolic effect that predisposes to stone formation (hypercalciuria, hypocitraturia, hyperoxaluria). Hypercalciuria can be resorptive (due to hyperparathyroidism), absorptive (increased gastrointestinal absorption), or renal (increased urine loss of calcium). Citrate is a stone inhibitor and hypocitraturia predisposes to stone formation.

Increases in urine calcium and phosphate plus hypercalcemia (and hypophosphatemia) suggest the presence of hyperparathyroidism, and measurement of serum parathyroid hormone is helpful. Excessive urinary uric acid is compatible with uric acid stone formation.

A qualitative test for urinary cystine should be part of the routine evaluation. If levels are elevated, a 24-hour quantitative measurement should be made. Hyperchloremic acidosis suggests distal renal tubular acidosis with secondary renal calcifications. Total renal function is impaired only if the stones are bilateral, and particularly if chronic infection complicates the clinical presentation.

C. Imaging Studies

About 90% of calculi are radiopaque; the majority are calcium stones and can be seen on plain x-ray. However, stones smaller than 5 mm can be difficult to see on plain x-ray, and bowel gas may obscure stone visualization as well.

Renal ultrasound can be an excellent initial and follow-up imaging modality to identify renal calculi, although results depend on the quality of the sonographer. Stones are hyperechoic and cast an acoustic shadow. Small stones can be missed on ultrasound and sizing estimates can be poor. Hydronephrosis implies a downstream obstruction in the ureter, possibly from obstructing calculus, but ureteral stones are poorly visualized with ultrasound.

Spiral (helical) CT has become the study of choice, because the entire urinary tract can be scanned rapidly and without contrast injection (Figure 38–10). Calculi can be readily identified and distinguished from clot or tumor. Stones are accurately sized and localized with CT, and the anatomic detail is very helpful prior to operative intervention. CT scans deliver significant doses of ionizing radiation, making ultrasound an attractive initial modality to look for stones or obstruction, followed by CT for confirmation and more anatomic detail.

▲ **Figure 38–10.** CT scan without intravenous contrast demonstrating a left renal calculus (arrow).

D. Stone Analysis

If a stone has previously been passed or if one is recovered, its chemical composition should be analyzed. Such information may be useful when planning a preventive program.

► Differential Diagnosis

Acute pyelonephritis may begin with acute renal pain mimicking that of renal stone. Urinalysis reveals pyuria, and urograms or CT fails to reveal a calculus.

Renal adenocarcinoma may bleed into the tumor, causing acute pain mimicking that of an obstructing stone. Imaging can make the differentiation.

Transitional cell tumors of the renal pelvis or calices mimic uric acid stone; both are radiolucent. CT scan without contrast or ultrasound reveal the stone by virtue of increased density compared with adjacent soft tissues.

Renal tuberculosis is complicated by stone formation in 10% of cases. Pyuria without bacteriuria is suggestive. Urography reveals the moth-eaten calices typical of tuberculosis.

Papillary necrosis may cause renal colic if a sloughed papilla obstructs the ureteropelvic junction. Imaging (particularly CT) settles the issue.

Renal infarction may cause renal pain and hematuria. Evidence of a cardiac lesion, nonfunction of the kidney on urography, and exclusion of a calculus help in differentiation. Infarction is confirmed by angiography, radioisotopic renography, or color Doppler ultrasound.

Other conditions to be considered in the differential diagnosis include UPJO, obstruction due to blood clots, ureteral strictures or fungal bezoars, and renal abscess.

► Complications

Acting as a foreign body, a stone increases the probability of infection. However, primary infection may incite stone formation. A stone lodged in the ureteropelvic junction leads to progressive hydronephrosis. A staghorn calculus, as it grows, may destroy renal tissue by pressure, and the infection that is usually present also contributes to renal damage. The presence of an obstructed renal unit with associated infection should be considered a urologic emergency. Drainage of the kidney should be performed promptly with insertion of a ureteral stent or percutaneous nephrostomy tube. Obstruction without infection can be managed without immediate drainage if renal function is preserved and pain is controlled (see ureteral calculi section below). Persistent obstruction for longer than 2–4 weeks requires intervention because permanent renal damage can ensue.

► Prevention

An effective preventive regimen depends on stone analysis and chemical studies of the serum and urine.

A. General Measures

Ensure a high fluid intake (3–4 L/d) to keep solutes well diluted. This measure alone may decrease stone-forming potential by 50%. Treat infection, relieve stasis or obstruction, and advise the patient to avoid prolonged immobilization.

B. Specific Measures

1. Calcium stones—Remove the parathyroid tumor, if present. High dietary sodium promotes renal calcium absorption, and restriction to 100 mEq/d may be helpful. Limitation of proteins and carbohydrates may also reduce hypercalciuria. Recent randomized trials have shown that in men with recurrent calcium oxalate stones and hypercalciuria, restricted intake of animal protein and salt, combined with a normal calcium intake, provides greater protection than the traditional low-calcium diet. Potassium citrate can decrease stone formation by increasing urine levels of citrate, which is a stone inhibitor.

Oral orthophosphates are effective in reducing the stone-forming potential of urine by decreasing urine calcium and increasing inhibitor activity. Thiazide diuretics such as hydrochlorothiazide, 50 mg twice daily, decrease the calcium content in urine by 50%. If hyperuricosuria is coincident with calcium urolithiasis, then allopurinol and urinary alkalization can reduce the formation of urate crystals, which may act as a nidus for calcium crystallization.

For a patient with primary absorptive hypercalciuria, cellulose sodium phosphate can be given. This substance combines with calcium in the gut to prevent absorption.

2. Oxalate stones (calcium oxalate)—Consider a phosphate or a thiazide diuretic (see above). Elimination of excessive oxalate in coffee, tea, colas, leafy green vegetables, and chocolate may also be helpful. Excess vitamin C can be metabolized to oxalate and thus should be avoided.

3. Magnesium-ammonium-phosphate stones—These stones are usually secondary to urinary tract infection due to bacteria that produce urease (primarily proteus species). Eradication of the infection prevents further stone formation but is impossible when stones are present. Acetohydroxamic acid, a urease inhibitor, can be used for oral chemolysis and can potentiate antibiotic action. After all calculi have been removed, prevention of stone growth is best accomplished by urinary acidification and suppression antibiotic therapy.

4. Metabolic stones (uric acid, cystine)—These substances are most soluble at a pH of 7.0 or higher. Give potassium citrate, 10-20 mEq by mouth three times a day, and monitor the urine pH with a litmus paper indicator or urine dipstick test. For uric acid stone formers, limit purines in the diet and give allopurinol if they have hyperuricemia. Patients with mild cystinuria may need only urinary alkalinization, as described previously. For severe cystinuria, penicillamine, 30 mg/kg/d orally, reduces urinary cystine to safe levels. Penicillamine should be supplemented with pyridoxine, 50 mg/d orally. Tiopronin, which has fewer side effects than D-penicillamine and captopril, can be used as well.

► Treatment

A. Conservative Measures

Intervention is not required for small, nonobstructive, asymptomatic caliceal stones. Hydration and dietary management may be sufficient to prevent growth of existing or new calcium stones in patients without metabolic abnormalities. Those with identifiable metabolic disorders may benefit from the specific measures described previously. Patients with known uric acid stones can be treated with hydration and urinary alkalinization, which can help dissolve the stone. Patients with active infection, obstruction, or intractable nausea or pain may need definitive treatment. In the acute setting, a ureteral stent or percutaneous nephrostomy tube can be inserted.

B. Ureteroscopic Intervention

Patients with small stones can be managed with ureteroscopic and laser lithotripsy or basketing of the

stones. The presence of a ureteral stent several days prior helps passively dilate the ureter and facilitates the procedure, but new, smaller caliber ureteroscopes preclude the need for elective preoperative stenting. As described above, stents should be placed emergently in the setting of infection/sepsis with obstructing calculus. After stenting and an appropriate course of antibiotics (typically 10-14 days), the definitive stone surgery is undertaken. Post-operatively, a ureteral stent is often left in place for several days to prevent acute obstruction secondary to edema or small stone fragments.

C. Percutaneous Intervention (Endourology)

In selected patients with symptomatic or large upper tract stones, percutaneous stone removal may be indicated. A percutaneous tract enters the renal collecting system through an appropriate calix (**percutaneous nephrostomy**). The tract is subsequently dilated, and endoscopic extraction of the stones (**percutaneous nephroscopy** and **percutaneous nephrolithotomy [PCNL]**) is done. Pulverization of the fragments is accomplished by means of ultrasonic, electrohydraulic, or laser probes passed through the nephrostomy tract. For cystine and uric acid stones, alkaline or other irrigants that increase the specific crystal solubility may be used (eg, *N*-acetyl-L-lysine or propionyl glycine for cystine stones). Specific antibiotic treatment for infection must be given before irrigation to prevent sepsis.

Success with these endourologic methods approaches 100%. The advantages over surgical procedures include no incision and rapid recovery and return to full activity. Disadvantages include the occasional need for multiple treatments to completely remove the calculi and the uncommon occurrence of significant hemorrhage, collecting system perforation, or stricture.

D. Extracorporeal Shock Wave Lithotripsy

With this technique, patients are positioned in the path of shock waves focused on the renal calculi with the aid of fluoroscopy or ultrasound. General or regional anesthesia is required in selected patients, but sedation may be sufficient. The shock waves (more than 1500 are usually given) pulverize the stones, and the small particles pass spontaneously in the postoperative period. With appropriate patient selection, results are excellent. Lower pole renal stones have lower success rates because pulverized fragments are less likely to completely pass. In addition, stones greater than 1.5 cm may produce too many fragments to successfully pass. PCNL is the treatment of choice for larger stones greater than 1.5-2.0 cm. Calcium stones and magnesium-ammonium-phosphate stones have been treated successfully. Because of the physical properties of the crystal lattice, extracorporeal shock wave lithotripsy (ESWL) is not as

effective in fragmenting cystine stones. Radiolucent uric acid stones, which can be visualized using contrast medium are amenable to ESWL treatment. A variety of ESWL devices now effectively pulverize stones using less energy and thus can be used with only intravenous sedation; an increased number of pulses are required to obtain the same results as with previous higher energy devices. Some instruments use ultrasound instead of x-ray for stone localization. Complications include incomplete fragmentation and need for secondary procedures, ureteral obstruction from stone fragments, and perinephric hematoma.

E. Open and Laparoscopic Surgical Removal of Stones

Endourologic intervention and ESWL have markedly decreased the indications for open surgery. Rarely, both percutaneous nephrolithotomy and ESWL are contraindicated, and open nephrolithotomy is necessary. The goal of any approach is to remove all stone fragments, and the approach chosen must allow for intraoperative localization by radiography or ultrasonography. Incisions into the renal pelvis (pyelolithotomy) or the renal parenchyma (radial nephrotomy or anatomic nephrolithotomy) may be required for complete stone removal. Instillation of a mixture of thrombin and calcium into the kidney causes the fragments to become trapped in a dense clot, which is removed through a pyelotomy incision (coagulum pyelolithotomy). Operative nephroscopy allows a full view of all the calices and removal of all fragments. “Bench” surgery with autotransplantation of the kidney may be required in very few instances. Rarely, poorly functioning kidneys containing symptomatic stones require nephrectomy, especially in cases of XGP. Laparoscopic and robotic pyelolithotomy have been used with excellent success and decreased morbidity compared with open surgery. This is especially the case in patients undergoing concomitant robotic pyeloplasty for UPJ obstruction.

► Prognosis

The recurrence rate of renal stone can be as high as 40% and can be decreased with sufficient attention to measures for prevention of stone formation. The danger of recurrent stones is progressive renal damage due to obstruction and infection.

URETERAL STONE

► General Considerations

Ureteral stones originate in the kidney. When symptoms occur, ureteral obstruction is implicit and renal function endangered. Complicating infection may occur. Most ureteral stones pass spontaneously, or with the assistance of medical expulsive therapy, especially if they are less than 0.5 cm in greatest dimension.

► Clinical Findings

A. Symptoms and Signs

The onset of pain is usually abrupt. Pain is felt in the costovertebral angle and radiates to the ipsilateral lower abdominal quadrant. Nausea, vomiting, abdominal distention, and gross hematuria are common. When the stone approaches the bladder, symptoms mimic cystitis, with frequency and urgency. If the kidney is infected, acute ureteral obstruction exacerbates the infection.

The patient is usually in such agony that only parenteral opioids and NSAIDs will give relief. Costovertebral angle tenderness and guarding may be evident. Absence of bowel sounds and abdominal distention signify ileus. Fever may occur as a result of complicating renal infection.

B. Laboratory Findings

Laboratory findings are similar to those for renal stone. Unilateral obstruction secondary to ureteral stone may cause acute exacerbation of renal function, but not in all cases.

C. Imaging Studies

CT stone protocol is the gold standard to confirm stone size, location and degree of obstruction (Figure 38–11). Plain films may reveal an opacity in the region of the ureter and ultrasound will demonstrate ipsilateral hydronephrosis. Excretory urograms and retrograde urography reveal a filling defect (lack of dye) at the location of the stone. Almost all

▲ **Figure 38–11.** CT scan without intravenous contrast demonstrating a left ureteral calculus (arrow).

stones are radiopaque on CT scan. The density (hardness) of the stone can be estimated using the Hounsfield Units (HU). Calcium based stones are, on average, more than 1000 HU. Uric acid and struvite (infection) stones have lower HU.

Differential Diagnosis

A tumor of the kidney or renal pelvis may bleed, and passage of a blood clot may cause ureteral colic. Urograms may reveal a radiolucent area in the ureter surrounded by the radiopaque urine. A CT scan with and without contrast agents reveals no radiopacity in the ureter and helps define the renal parenchymal or renal pelvis tumor.

A primary tumor of the ureter may cause obstructing pain and hematuria. The urogram reveals the ureteral filling defect, often with secondary obstruction. A CT scan can differentiate a stone from tumor. Urinary cytologic study may reveal malignant urothelial cells.

Acute pyelonephritis may cause pain as severe as that seen with stone. Pyuria and bacteriuria are found but do not rule out stone. Stone is absent on noncontrast CT or urography.

A sloughed papilla (consequent to conditions such as diabetes mellitus) traversing the ureter may cause colic and produces a urogram compatible with uric acid stone. Papillary sloughs should be evident, however.

► Complications

If obstruction from the ureteral stone is prolonged, progressive renal damage may ensue. Bilateral stones may cause oliguria or anuria, requiring immediate drainage of the proximal collecting system with indwelling ureteral stents or percutaneous nephrostomy. Unilateral obstructing stone in patients with a solitary kidney requires immediate drainage.

Infection may supervene, but many renal infections are iatrogenic (ie, introduced at the time of stone manipulation).

► Prevention

See Renal Stone.

► Treatment

A. General Measures

Most ureteral stones pass spontaneously—particularly those less than 0.5 cm in diameter. Once the diagnosis has been established, analgesics should be given and the patient hydrated. Recent reports have found alpha-antagonist therapy useful in expulsion of distal ureteral stones by relaxing smooth muscle. Randomized controlled trials have confirmed shorter time to stone passage with the use of alpha antagonists when compared with placebo. Periodic plain films should be taken to follow the progress of the stone and interval renal ultrasound studies obtained to assess the

degree of hydronephrosis. The urine should be strained until the stone passes in order to recover the calculus for analysis. With larger stones, acute obstruction can be temporarily relieved by inserting an indwelling ureteral stent.

B. Specific Measures

If the stone causes intractable pain, progressive hydronephrosis, or acute infection, it should be removed. Obstructing stones in the upper two-thirds of the ureter can often be successfully treated by ureteroscopy or ESWL, with or without ureteral stent insertion to help facilitate stone passage. Ureteroscopy permits laser fragmentation or stone basket retrieval under direct vision. Open and laparoscopic/robotic surgical removal (ureterolithotomy) is only very rarely required for very large ureteral stones. ESWL has been applied to ureteral stones in the proximal ureter but is more problematic in the distal ureter owing to bone interference by surrounding pelvis, which interferes with imaging and attenuates shock wave force. Ureteral stones which have not spontaneously passed with medical expulsive therapy after 4 weeks should be considered for surgical removal with the above techniques.

► Prognosis

About 80% of ureteral stones pass spontaneously. Stones larger than 1 cm rarely pass spontaneously. Periodic clinical evaluation, plain films, and renal ultrasound should be performed to document ureteral stone passage and prevent long-term renal damage from obstruction. Patients often do not witness small stones pass if a strainer is not utilized. If still uncertain about definitive stone passage, repeat CT scan can be obtained with the caveat of additional radiation exposure.

VESICAL STONE

Primary vesical calculi are rare in the United States but are common in Southeast Asia and the Middle East. The cause is probably dietary. Secondary stones usually complicate vesical outlet obstruction with residual urine and infection; 90% of those affected are men. Other causes of bladder stasis such as neurogenic bladder, and bladder diverticula also promote vesical stone formation. They are common in vesical schistosomiasis or in association with radiation cystitis. Foreign bodies in the bladder may act as a nidus for the precipitation of urinary salts. Most stones contain uric acid or struvite (in infected urine).

► Clinical Findings

A. Symptoms and Signs

Symptoms of bladder neck obstruction are elicited. There may be sudden interruption of the stream and urethral pain if a stone occludes the bladder neck during voiding.

Hematuria is common. Vesical distention may be noted; evidence of urethral stricture or an enlarged prostate is usually found.

B. Laboratory Findings

Pyuria and hematuria are almost always present.

C. Imaging Studies

Vesical calculi may be missed on plain x-rays due to the high component of radiolucent uric acid. Excretory urograms reveal a filling defect in the bladder and ultrasound reveals a large echogenic shadowing focus. CT scan easily identifies the number and size of the stones. Cystoscopy directly visualizes the stone(s) and also evaluates the entire urethra for stricture and/or prostate hypertrophy.

► Differential Diagnosis

A pedunculated vesical tumor may suddenly occlude the vesical neck during voiding. Excretory urograms, pelvic ultrasound, CT scan, or cystoscopy leads to definitive diagnosis.

Extravesical opacifications may simulate stones on a plain film.

► Complications

Acting as foreign bodies, bladder stones exacerbate urine infection and can cause obstruction at the level of the bladder neck. Antibiotic therapy for concomitant UTI is often unsuccessful given that the stones harbor persistent bacteria.

► Prevention

Prevention requires relief of the primary obstruction, removal of the stones, and sterilization of the urine.

► Treatment

A. General Measures

Analgesics should be given for pain and antimicrobials for control of infection until the stones can be removed.

B. Specific Measure

Small stones can be removed or crushed transurethrally (**cystolitholopaxy**). Larger stones are often disintegrated by transurethral electrohydraulic lithotripsy (shock wave-generating probe) or laser destruction, or they may require suprapubic transvesical removal (vesicolithotomy). If the nidus for stone formation is urinary stasis due to BPH, concomitant TURP or suprapubic transvesical prostatectomy should be performed at the time of stone removal.

► Prognosis

Recurrent vesical stone is uncommon if the obstruction and infection are treated.

NEPHROCALCINOSIS

Nephrocalcinosis is a precipitation of calcium in the tubules, parenchyma, and, occasionally, the glomeruli. It always causes renal functional impairment, often severe. Stones may be found in the calices and pelvis. The common causes are primary or secondary hyperparathyroidism, excessive milk-alkali or vitamin D intake, or they may be found with severe renal damage associated with renal tubular acidosis, or sarcoidosis. Calcifications may also be seen in the skin, lungs, stomach, spleen, and corneas, or around the joints.

► Clinical Findings

A. Symptoms and Signs

There are no specific symptoms. In childhood, the patient may merely fail to thrive. Stones or sand may be passed. The complaints are usually those of the primary disease. Physical examination may reveal an enlarged parathyroid gland, corneal calcifications, and pseudorickets.

B. Laboratory Findings

The urine may be infected. In renal tubular acidosis, the pH is fixed between 6.0 and 7.0. Urinary calcium is high in hyperparathyroidism, both primary and secondary. Tests of renal function are depressed; uremia is common. Hypercalcemia and hypophosphatemia are seen with primary hyperparathyroidism; secondary hyperparathyroidism may be associated with a low serum calcium and an elevated serum phosphate. Hyperchloremic acidosis and hypokalemia accompany renal tubular acidosis.

C. Imaging Studies

A plain x-ray reveals punctate calcifications in the papillae of the kidneys. Caliceal or pelvic stones may also be noted. The pattern of calcification may have to be differentiated from renal tuberculosis and medullary sponge kidney.

► Complications

Complications include renal damage caused by the calcifications and renal and ureteral calculi. Chronic renal infection may complicate the primary disease.

► Treatment & Prognosis

The primary cause should be treated if possible (eg, parathyroidectomy). Hydration with isotonic saline along with furosemide can help enhance calcium excretion. Discontinue vitamin D and milk-alkali producers if the primary cause was due to excessive intake. With hyperchloremic acidosis, alkalize the urine with potassium citrate. Osteomalacia requires administration of vitamin D and calcium even though nephrocalcinosis is present.

If nephrocalcinosis is secondary to primary renal disease, the outlook is poor. If the cause is correctable and renal function is fairly good, the prognosis is more favorable.

Aboumarzouk OM, Kata SG, Keeley FX, McClinton S, Nabi G: Extracorporeal shock wave lithotripsy (ESWL) versus ureteroscopic management for ureteric calculi. *Cochrane Database Syst Rev* 2012 May 16;5:CD006029. doi: 10.1002/14651858.CD006029.pub4. Review. PMID: 22592707.

GENITOURINARY TRACT TRAUMA

INJURIES TO THE KIDNEY

► General Considerations

Renal injury is uncommon but potentially serious and often accompanied by multisystem trauma. The most common causes are athletic, industrial, or automobile accidents. The degree of injury may range from contusion to laceration of the parenchyma or disruption of the renal pedicle.

► Clinical Findings

A. Symptoms and Signs

Gross hematuria following trauma means injury to the urinary tract. Pain and tenderness over the renal area may be significant but could be due to musculoskeletal injury. Hemorrhagic shock may result from renal laceration and lead to oliguria. Nausea, vomiting, and abdominal distention (ileus) are the rule. Physical examination may reveal ecchymosis or penetrating injury in the costovertebral angle or flank. Extravasation of blood or urine may produce a palpable flank mass. Other injuries should be sought.

B. Laboratory Findings

Serial hematocrit determinations will give clues to persistent bleeding. Hematuria is to be expected, but the absence of hematuria does not exclude renal injury (as in renal vascular injury).

C. Imaging Studies

A plain film may reveal obliteration of the psoas shadow; this suggests the presence of a retroperitoneal hematoma or urinary extravasation. Bowel gas may be displaced from the area. Evidence of transverse vertebral process or rib fractures may be noted. In the past, the excretory urogram was used for evaluating renal trauma. Excretory urograms may show a normal kidney if it is mildly contused or may show extravasation of contrast medium if the kidney is lacerated. Nonfunction suggests injury to the vascular pedicle. The

excretory urogram should demonstrate that the contralateral kidney is normal. CT scan with intravenous contrast medium is now the method of choice for staging a patient with hemodynamically stable renal trauma. CT scans may miss urinary extravasation if performed too rapidly following intravenous contrast administration—before the contrast is excreted into the collecting system and ureter. Therefore, trauma protocol CT scans should include a delayed phase of imaging, allowing time for contrast to be excreted in to the collecting system. If renal vascular damage is suspected and the patient's condition is stable, preoperative renal angiography may facilitate planning of renovascular reconstruction or permit arterial stenting. In special circumstances, selective renal artery embolization may control segmental arterial bleeding. Renal imaging is indicated in any adult with gross hematuria or microscopic hematuria with shock. Imaging is also required with deceleration injuries and is indicated in children with gross or microscopic hematuria in the setting of trauma.

► Differential Diagnosis

Bony fractures or contusion of soft tissues in the region of the kidney may cause confusion. Hematuria might be secondary to ureteral or vesical injury. The absence of a perirenal mass (ie, hematoma or urinoma) or contrast extravasation on urograms or CT scan would rule out significant trauma.

► Complications

A. Early

The most serious complication is continued perirenal hemorrhage, which may be fatal. Serial hematocrit, blood pressure, and pulse determinations are essential. Serial CT scans may also be useful. Evidence of an enlarging flank mass implies persistent bleeding. In most cases, bleeding stops spontaneously, probably as a result of tamponade by the perirenal fascia. Delayed bleeding 1 or 2 weeks later is rare. Infection of the perirenal hematoma may occur.

B. Late

History, examination, and imaging are recommended 1-3 months after management of renal trauma to look for persistent renal damage from prolonged perinephric hematoma, obstruction, and/or urinary extravasation. Ultrasound is a good imaging modality to evaluate the integrity of the kidney and to assess for residual perinephric fluid collections and/or hydronephrosis. The blood pressure should be checked at regular intervals, because hypertension may be a late sequela.

► Treatment

Treat shock and hemorrhage with fluids and transfusion. Most patients with blunt renal trauma stop bleeding and heal

spontaneously. Bed rest is indicated until hematuria resolves and blood counts stabilize. If bleeding persists, angiography with possible segmental arterial embolization is an option if the patient is hemodynamically stable. Persistent hemodynamic instability requires laparotomy with renorrhaphy or nephrectomy.

Penetrating renal trauma usually requires exploration. Lacerations may be sutured, the collecting system closed, and urinary extravasation drained. Nephrectomy or partial nephrectomy may be necessary to remove devitalized tissue and secure the collecting system.

Late complications may occur. Perinephric abscess/infected hematoma should be drained. Hypertension may be due to renal ischemia and requires medical or surgical correction.

► Prognosis

Most injured kidneys heal spontaneously, though the patient must be examined at intervals for the onset of hypertension due to renal ischemia or progressive hydronephrosis due to secondary ureteral stricture. Many patients with genitourinary trauma have associated injuries. In most cases, death is due to associated injury rather than renal injury.

INJURIES TO THE URETER

► General Considerations

Most ureteral injuries are iatrogenic in the course of pelvic surgery. Ureteral injury may occur during transurethral bladder or prostate resection or ureteral manipulation for stone or tumor. Ureteral injury is rarely a consequence of penetrating trauma. Unintentional ureteral ligation during operation on adjacent organs may be asymptomatic, though hydronephrosis and loss of renal function results. Ureteral division leads to extravasation and urinoma.

► Clinical Findings

A. Symptoms

If the ureteral injury is not recognized at surgery, the patient may complain of flank and lower abdominal pain on the injured side. Ileus and pyelonephritis may develop. Later, urine may drain through the wound (or through the vagina following transvaginal surgery) or there may be increased output through a surgical drain. Wound drainage may be evaluated by comparing creatinine levels found in the drainage fluid with serum levels; urine exhibits very high creatinine levels when compared with serum. Intravenous administration of 5 mL of indigo carmine causes the urine to appear blue-green; therefore, drainage from a ureterocutaneous fistula becomes blue, compared to serous drainage. Anuria following pelvic surgery not responding to intravenous fluids may rarely signify bilateral ureteral ligation or

injury. Peritoneal signs may occur if urine leaks into the peritoneal cavity.

B. Laboratory Findings

Microscopic hematuria is usually found but may be absent. Tests of renal function may be normal unless both ureters are occluded. Drainage fluid will have increased levels of creatinine when compared with serum creatinine.

C. Imaging Studies

Excretory urograms may show evidence of ureteral occlusion. Extravasation of radiopaque fluid may be seen in the region of the ureter. Retrograde ureterography depicts the site and nature (occlusion or division) of the injury.

Ultrasonography may reveal hydroureter and hydronephrosis or a fluid mass representing urinary extravasation. CT urography (including delayed phase imaging) identifies the location of the ureteral injury, surrounding urinary extravasation, and potential urinoma or fistula.

► Differential Diagnosis

Ureteral injury may mimic peritonitis if urine leaks into the peritoneal cavity. Excretory urography reveals the ureteral involvement.

Oliguria may be due to dehydration, transfusion reaction, or bilateral incomplete ureteral injury. A survey of fluid and electrolyte intake and output, including serial body weights, should prove helpful in delineating a medical versus surgical etiology for oliguria. Nephrology consultation should be considered. Total anuria may signify bilateral ureteral injury and indicates the need for immediate urologic evaluation.

Vesicovaginal and ureterovaginal fistulas may be confused. Methylene blue solution instilled into the bladder stains the vaginal drainage in the case of vesicovaginal fistula. Cystoscopy may show the vesical defect. Retrograde ureterography should reveal a ureteral fistula. The presence of both injuries occurring simultaneously should also be considered and evaluated.

► Complications

These include urinary fistula, ureteral obstruction or stenosis with hydronephrosis, renal infection, peritonitis, and uremia (with bilateral injury).

► Prevention

Before operation for large pelvic masses, which may cause displacement of the ureters, catheters should be placed in the ureters to facilitate their identification at surgery. Although the catheters may not prevent injury, they facilitate recognition of a ureteral injury intraoperatively and allow for immediate repair.

► Treatment

A. Injury Recognized at Surgery

1. Ureteral division—Repair of a ureter inadvertently cut during surgery consists of anastomosis of the ends over an indwelling stent (ureteroureterostomy), reimplanting the ureter into the bladder if the injury is juxtavesical (neoureterocystostomy), or anastomosing the proximal segment of divided ureter to the side of the contralateral ureter (transureteroureterostomy). The anastomosis must be tension free, and the area of repair must be drained. Injuries resulting from cautery must be adequately debrided prior to reanastomosis.

2. Ureteral resection—Repair of a ureter from which a substantial segment has been removed requires interposition of a ureteral substitute or mobilization of the proximal and distal ureter to provide a tension-free anastomosis. With loss of the distal ureter, the bladder may be hitched cephalad to the psoas muscle, or a bladder flap may be created to facilitate a ureteral implant. In extreme cases, autotransplant of the kidney to the pelvis or bowel interposition may be necessary.

B. Injury Discovered After Surgery

Early intervention is recommended as soon as the ureteral injury is recognized. Depending on the findings, any of the procedures noted above may be utilized. If a long segment of ureter is not viable, an intestinal ureter may be constructed. If hydronephrosis is advanced or if sepsis develops, percutaneous nephrostomy should precede repair. When the patient's condition is stable, definitive repair can be accomplished. If the injury is partial or incomplete, attempted ureteral stent placement for 4-6 weeks followed by repeat evaluation may obviate the need for laparotomy and open repair. Delayed nephrectomy may be indicated if the repair is unsuccessful and the contralateral kidney is normal.

► Prognosis

In cases of iatrogenic injury, the results are best if the injury is recognized at the time of surgery. Late repair, if severe periureteral fibrosis has developed, is less likely to afford a good outcome.

INJURIES TO THE BLADDER

► General Considerations

The most common cause of vesical injury is an external blow over a full bladder. Rupture of the organ is seen in 15% of patients with pelvic fracture. The bladder may be inadvertently opened during pelvic surgery or injured by cystoscopic maneuvers (eg, transurethral resection of bladder tumor). If the injury is intraperitoneal (40% of all bladder ruptures), blood and urine will extravasate into the perito-

neal cavity, producing signs of peritonitis. If it is extraperitoneal (54% of all bladder ruptures), a mass develops in the pelvis. About 6% of all bladder ruptures have a combination of both intraperitoneal and extraperitoneal extravasation.

► Clinical Findings

A. Symptoms and Signs

There is usually a history of hypogastric or pelvic trauma. Hematuria and suprapubic pain and possible inability to void are expected. Associated injury may cause hemorrhagic shock. There is suprapubic tenderness and guarding. Intraperitoneal extravasation causes peritoneal signs, while extraperitoneal extravasation results in formation of a pelvic urinoma.

B. Laboratory Findings

A falling hematocrit reflects continued bleeding. Hematuria is expected in patients who are able to void. A patient who cannot void should be catheterized unless pelvic fracture (and urethral injury) is suspected or blood is noted at the urethral meatus.

C. Imaging Studies

A plain film may reveal fracture of the pelvis. An extraperitoneal collection of blood and urine may displace the bowel gas laterally or out of the pelvis. If bladder trauma is suspected, cystography should precede excretory urography. Extravasation is most reliably demonstrated by a postdrainage cystogram film showing persistent contrast outside the area of the suspected bladder. If one suspects urethral trauma, a retrograde urethrogram should precede catheter insertion. The excretory urogram may suggest the diagnosis of bladder perforation but by itself is insufficient to exclude bladder injury. A CT cystogram is diagnostic for bladder injury and urinary extravasation. It also reliably distinguishes between intra- and extraperitoneal injury. A catheter is placed, the bladder filled by gravity with diluted contrast (350-400 mL), and subsequently the CT scan is performed.

► Differential Diagnosis

Renal injury is also associated with bladder trauma and usually presents with hematuria. Imaging shows changes compatible with renal trauma; the cystogram is negative.

Injury to the membranous urethra can mimic extraperitoneal rupture of the bladder. A urethrogram reveals the site of injury. Urethral disruption is a contraindication to urethral catheterization.

► Complications

Extraperitoneal extravasation may lead to pelvic abscess. Intraperitoneal extravasation causes delayed peritonitis, oliguria, and azotemia.

► Treatment

Treat shock, hemorrhage, and other life-threatening injuries. Marked extraperitoneal extravasation should be drained, the bladder decompressed by either a suprapubic or urethral catheter, and appropriate antibiotics administered. Small extraperitoneal extravasations are treated nonoperatively by urethral catheter.

Intraperitoneal extravasation of bladder urine requires exploratory laparotomy, midline cystotomy, bladder closure, and bladder catheter drainage. Penetrating injuries (ie, gunshot, stabbing) require exploration, +/- debridement, and closure of the bladder. The ureters should also be evaluated in all cases of bladder injury by preoperative imaging or intraoperative assessment, which may be done by injecting indigo carmine and looking for ureteral extravasation or by retrograde passage of 5F feeding tubes through the ureteral orifice. A closed surgical drain is left in place.

► Prognosis

Early diagnosis minimizes morbidity and mortality rates. The prognosis depends chiefly on the severity of associated injuries.

INJURIES TO THE URETHRA

► Membranous Urethra

Injury to the membranous urethra is usually a consequence of pelvic fracture and thus is associated with hemorrhage and multiorgan injury. The mechanism of injury is blunt trauma and deceleration resulting in shearing forces applied to the prostate and urogenital diaphragm. Penetrating injuries result from external missiles or laceration by bone fragments acting as secondary projectiles.

If the urethral disruption is incomplete, the patient may be able to void, and hematuria would be inevitable. Urethral injury is suspected if blood is expressed from the urethral meatus. In cases of complete avulsion, extravasation causes a suprapubic mass. Rectal examination may reveal a nonpalpable or upwardly displaced prostate.

X-ray reveals a fractured pelvis; urethrography delineates any extravasation, and cystography identifies an associated bladder injury. An immediate excretory urogram or CT scan should be obtained in all cases to assess kidney and ureteral function.

Treatment must be coordinated with care of associated injury. Once a membranous urethral injury with urinary extravasation has been identified, suprapubic cystostomy should be performed either at the time of laparotomy or percutaneously before placement of external pelvic fixation. Definitive urethral repair may be delayed until the patient has recovered from the acute injury and pelvic fractures have healed. Occasionally, when urethral disruption is

incomplete, late repair is unnecessary. Primary repair may be indicated in cases of severe prostatomembranous dislocation, major bladder neck laceration, or concomitant pelvic vascular or rectal injury.

Late sequelae are urethral stricture, impotence, and incontinence. Urethral stricture must be identified by retrograde urethrography and may be treated by transurethral incision of the stricture or urethroplasty. Impotence due to injury of nerves to the corpora cavernosa that course adjacent to the membranous urethra may resolve without treatment during the year following injury. Vascular injury of the hypogastric or pudendal arteries may cause impotence following trauma. Cavernosometry and arteriography confirms the diagnosis; appropriate treatment may include vascular reconstruction. Incontinence depends on the neurologic status of the patient. Medical or surgical therapy is utilized to increase bladder capacity and bladder outlet resistance.

► Bulbous Urethra

The bulbous urethra may be injured as a result of instrumentation or, more commonly, falling astride an object (straddle injury). Urethral contusion may cause a perineal hematoma without injury to the urethral wall. Laceration leads to urinary extravasation.

Perineal pain and some urethral bleeding are to be expected. Sudden swelling in the perineum may develop following attempted urination. Examination reveals a perineal mass; swelling due to extravasation of blood and urine involves the penis and scrotum and may spread onto the abdominal wall.

If the patient can void well and the perineal hematoma is small, no treatment is necessary. If urethrography reveals significant extravasation, suprapubic cystostomy should be performed. Minor injury without extravasation (contusion, compression by hematoma) may be managed by careful insertion of a urethral catheter.

The only serious complication is stricture, which requires subsequent internal urethrotomy or surgical repair.

► Pendulous Urethra

External injury to this portion of the urethra is not common, since the penis is so mobile. The erect organ, however, is vulnerable, and pendulous urethral injury often occurs in conjunction with penile fracture (see below). Injury during urethral instrumentation (eg, urethral catheter and urethroscopy) is another common etiology.

Urethral bleeding and penile swelling are to be expected. A urethrogram reveals the site and severity of injury.

If voiding is normal, no treatment is required. A large hematoma may require drainage. If significant injury is present, a suprapubic tube should be inserted and delayed surgical repair performed after swelling and inflammation have resolved.

INJURIES TO THE PENIS

Mechanisms of penile injury include penetration, blunt trauma to the erect penis during sexual activity (eg, fracture of corpora cavernosa), avulsion of skin, and amputation.

Tourniquet injury is also uncommon; the circumferential compression may be due to a rubber band, a steel ring, string, or a hair and may be exacerbated by subsequent erection. The tourniquet may have been applied unintentionally, but child abuse cases have been reported in which the penis has been ligated as punishment for enuresis.

Treatment includes assessment and care of urethral injuries if present. Removal of tourniquet, split-thickness skin grafting of avulsion injuries, and primary closure of corporal lacerations are principles of therapy. Penile fracture is considered a urologic emergency and immediate repair minimizes the inherent risk of future impotence and penile curvature. The penis may be acutely reimplanted up to 16 hours following amputation using microsurgical techniques.

INJURIES TO THE SCROTUM & TESTIS

Avulsion of the scrotal skin may require a meshed split-thickness skin graft. If the avulsion is severe, involving the skin and dartos muscle, then the testes may be implanted in the subcutaneous tissue of the thigh and dressed outside the wound with 0.25% acetic acid-soaked gauze. Scrotal reconstruction is performed at a later time, frequently by using skin grafts.

Penetrating trauma rarely injures the mobile testes. Lacerations should be explored, debrided, and closed primarily. If hemorrhage into the tunica vaginalis is noted, drainage is indicated.

Blunt trauma to the testes may cause contusion or rupture. Rupture of the tunica albuginea may be demonstrated by ultrasonography as abnormal echotexture of the parenchyma. In cases of rupture, scrotal exploration is imperative allows debridement and closure of the tunica albuginea. The testes may ultimately undergo atrophy despite these efforts.

TUMORS OF THE GENITOURINARY TRACT

Tumors of the genitourinary tract are among the most common neoplastic diseases found in adults. Prostate cancer, for example, is the most common cancer in men (33%), and renal and bladder cancer account for nearly 10% of all malignant tumors in men, but only about 3% in women. Even though excellent diagnostic methods are available, one-third of all genitourinary tumors are not found until regional or distant spread has occurred. Advances in diagnosis and treatment of genitourinary tract tumors have occurred in recent years, and the prognosis has improved in conditions such as Wilms tumor, testicular cancer, and bladder cancer. The mainstay of diagnosis continues to be physical examination, complete urinalysis, CT urography and cystoscopy

whenever indicated. Curative treatment of these tumors continues to be surgical in most instances.

RENAL ADENOCARCINOMA (RENAL CELL CARCINOMA)

► General Considerations

Malignant tumors of the kidney account for approximately 3% of all tumors in adults. Often, the diagnosis is found incidentally on ultrasound, CT scan, or MRI. Microscopic or gross hematuria evaluation can also identify renal cell carcinoma (RCC). Advanced or metastatic disease can present with flank mass, weight loss, or pathologic fracture. Risk factors for RCC include cigarette smoking, obesity, and hypertension. The disease occurs in men three times more commonly than in women. A suppressor gene on chromosome 3p has been shown to be present in von Hippel–Lindau renal cancers as well as in most sporadic RCC. The most common cell type is clear cell (also called conventional) carcinoma, accounting for 70%-80% of renal carcinomas. The cell of origin is in the proximal convoluted tubule. Other cell types include papillary (10%-15%), chromophobe (3%-5%), and collecting duct renal carcinoma (1%). The tumor metastasizes commonly to the lungs (50%-60%), adjacent renal hilar lymph nodes (25%), ipsilateral adrenal (12%), opposite kidney (2%), and lytic lesions in mainly long bones (30%-40%).

Numerous conditions predispose to renal cell cancer, including von Hippel–Lindau syndrome (cerebellar hemangioblastomas, retinal angiomas, and bilateral RCC), tuberous sclerosis, and acquired renal cystic disease developing in patients with end-stage renal disease. Paraneoplastic syndromes are common in RCC and are often what suggests the diagnosis, yet they rarely have prognostic significance. These syndromes include hypercalcemia, erythrocytosis, hypertension, fever of unknown origin, anemia, and elevated liver enzymes (**Stauffer's syndrome**). RCC has a predilection for producing occlusive tumor thrombi in the renal vein and the inferior vena cava (particularly from the right kidney), manifested by signs of lower extremity edema and acute scrotal varicocele when occluding the left renal vein. This phenomenon of inferior vena cava thrombus occurs in approximately 5%-10% of patients. Occasionally, the tumor thrombus reaches up to the right atrium.

► Clinical Findings

A. Symptoms and Signs

Painless gross or microscopic hematuria throughout the urinary stream (“total hematuria”) occurs in some patients. The degree of hematuria is not necessarily related to the size or stage of the tumor. Although a triad of hematuria, flank

pain, and a palpable flank mass suggests RCC, fewer than 10% of patients will so present. Both pain and a palpable mass are late events occurring only with tumors that are very large or invade surrounding structures or when hemorrhage into the tumor has occurred. Symptoms due to metastases may be the initial complaint (eg, bone pain, respiratory distress). Localized disease is often identified incidentally on imaging.

B. Laboratory Findings

Microscopic urinalysis reveals hematuria in most patients. The erythrocyte sedimentation rate may be elevated but is nonspecific. Elevation of the hematocrit and levels of serum calcium, alkaline phosphatase, and aminotransferases occur in fewer than 10% of patients. These findings nearly always resolve with curative nephrectomy and thus are not usually signs of metastases. Anemia unrelated to blood loss occurs in 20%-40% of patients, particularly those with advanced disease.

C. Imaging Studies

The diagnosis of RCC is often made by CT (and, less frequently, by intravenous urography) performed as an initial step in the workup of hematuria, an enigmatic metastatic lesion, or suspicious laboratory findings (Figure 38-12). Ultrasonography and CT scan often reveal incidental renal masses, which now account for 50% of the initial diagnoses of RCC in patients without manifestations of renal disease. Plain abdominal x-rays may reveal a calcified renal mass, but only 20% of renal masses contain demonstrable calcification. (Twenty percent of masses with peripheral calcification are malignant; more than 80% with central calcification are malignant.) The initial technique for workup of hematuria is currently CT urography which can accurately identify an enhancing renal mass which is diagnostic for RCC. CT scan is also helpful in local staging and can reveal tumor penetration of perinephric fat; enlargement of local hilar lymph nodes, indicating metastases; or tumor thrombi in the renal vein or inferior vena cava. CT angiography can delineate the renal vasculature, which is helpful in surgical planning for partial nephrectomies.

1. Ultrasonography—Occasionally, some masses detected on CT require further characterization by ultrasound. Abdominal ultrasonography can define the mass as a benign simple cyst or a solid mass in 90%-95% of cases. Abdominal ultrasound can also identify a vena caval tumor thrombus and its cephalad extent in the cava.

2. MRI—MRI is not more accurate than CT and is much more expensive. It is, however, the most accurate noninvasive means of detecting renal vein or vena caval thrombi. With the further refinement of pulse sequencing and the use of paramagnetic contrast agents, MRI has become one

of the primary techniques for staging solid renal masses. Magnetic resonance angiography (MRA) has become particularly useful for mapping the blood supply and the relationship to adjacent structures in candidates for partial nephrectomy.

▲ **Figure 38-12.** **A:** Adenocarcinoma of the left kidney. CT scan of the abdomen shows an exophytic lesion from the midpolar kidney (arrow). **B:** CT scan showing a large left renal mass (arrow) incidentally found on imaging done to evaluate nonspecific abdominal pain. Final pathology revealed clear cell renal carcinoma.

D. Other Diagnostic or Staging Techniques

Isotopic bone scanning is useful in patients with bone pain, elevated alkaline phosphatase, or known metastases. Chest x-ray is sufficient if negative, but if equivocal, then CT scan of the chest can be used to detect metastases. Identification of metastatic disease in the thorax warrants consideration of brain imaging to rule out occult disease. There are currently no tumor markers specific for RCC. Occasionally, biopsy of the mass can be useful in when imaging is not definitive, or when metastases from another primary malignancy are a possibility. Previously, such procedures were discouraged because of fear of disseminating the tumor along the needle tract, but this has proved to be rare, and the technique is safe. False negative results and insufficient tissue for diagnosis are limitations of renal mass biopsy. Fortunately, imaging is diagnostic in most cases.

► Differential Diagnosis

A variety of lesions in the retroperitoneum and kidney other than renal cysts may simulate renal cancer. These include lesions due to hydronephrosis, adult polycystic kidney disease, tuberculosis, xanthogranulomatous pyelonephritis, metastatic cancer from another primary cancer, angiomyolipoma or other benign renal tumors, or adrenal cancer and retroperitoneal lipomas, sarcomas, or abscesses. In general,

one or more imaging techniques described above should make the differentiation. Percutaneous biopsy is necessary in rare instances when imaging cannot make the diagnosis.

Hematuria may be caused by renal, ureteral, or bladder calculi; renal pelvis, ureteral, or bladder tumors; or many other benign conditions usually delineated by the studies described. Cystoscopy is obligatory in hematuric patients with a normal CT scan or intravenous urogram to rule out disease of the bladder and to determine the source of the hematuria.

► Complications

Occasionally, patients may present with acute flank pain secondary to hemorrhage within a tumor or colic secondary to obstructing ureteral clots. Tumor in the renal vein or vena cava may cause an acute left varicocele or lower extremity edema associated with proteinuria. Pathologic fractures are due to osteolytic metastases in long bones. Brain metastases can present with seizure or other neurologic symptoms.

► Treatment

Staging is the key to designing the treatment plan (Table 38–1). Patients with disease confined within the renal fascia (Gerota's fascia) or limited to nonadherent renal vein or vena caval tumor thrombi (stages T1, T2, and T3a) are best treated

Table 38–1. TNM staging classification and prognosis of renal cell cancer.

Robson Stage	T	N	M	Five-Year Survival (%)
I. Tumor confined by renal capsule	T1 (< 7.0 cm tumor) T2 (> 7.0 cm tumor)	N0 (nodes negative)	M0 (lack of distant metastases)	80-100
II. Tumor extension to perirenal fat or ipsilateral adrenal but confined by Gerota's fascia	T3a	N0	M0	50-60
IIIa. Renal vein or inferior vena cava involvement	T3b (renal vein involvement) T3c (renal vein and caval involvement below the diaphragm) T4b (caval involvement above the diaphragm)	N0	M0	50-60 (renal vein) 25-35 (vena cava)
IIIb. Lymphatic involvement	T1-3	N1 (single regional node involved) N2 (multiple regional, contralateral, or bilateral nodes involved)	M0	15-35
IIIc. Combination of IIIa and IIIb	T3-4	N1-2	M0	15-35
IVa. Spread to contiguous organs except ipsilateral adrenal	T4	N1-2	M0	0-5
IVb. Distant metastases	T1-4	N0-2	M1	0-5

by surgical extirpation with either radical nephrectomy or partial nephrectomy. Radical nephrectomy traditionally includes en bloc removal of the kidney and surrounding Gerota fascia (including the ipsilateral adrenal), the renal hilar lymph nodes, and the proximal half of the ureter. However, adrenal-sparing radical nephrectomy is routinely performed for mid- and lower-pole renal tumors with equivalent outcomes.

In patients with very large or central tumors and a normal contralateral kidney, radical nephrectomy is recommended. In all other cases, attempts should be made for nephron-sparing surgery. Successful partial nephrectomy with negative surgical margins offers the same survival benefit as radical nephrectomy. Typically hilar-vessel occlusion with bulldog or satinsky clamp(s) is performed to allow for resection in a relatively bloodless field.

Laparoscopic radical or partial nephrectomy has been advocated as a method equal to the open approach with the advantages of less blood loss, shorter hospitalization, and earlier return to normal function. It is the gold standard in institutions with appropriate expertise. Laparoscopic or percutaneous cryoablation of RCC has also shown considerable promise. Alternatively, radiofrequency ablation has been utilized for small renal tumors. These ablative technologies do not provide pathologic diagnosis; so percutaneous biopsy can be performed before the procedure or intraoperatively.

Nephrectomy has not been associated with improved survival rates in patients with multiple distant metastases (stage IV), and the procedure is not recommended unless patients are symptomatic or a promising therapeutic protocol is being studied. Flanigan and others have shown, however, that up to a 6-month improvement in survival can be achieved with nephrectomy—even with soft tissue metastasis—in selected patients who also receive interferon alpha systemic therapy. Patients with solitary pulmonary metastases have benefited from joint surgical removal of both the primary lesion and the metastatic lesion (30% survival at 5 years). Preoperative arterial embolization in patients with or without metastases does not improve survival rates, though it may be helpful as a single treatment measure in patients with symptomatic but nonresectable primary lesions. Radiation therapy is of little benefit except as treatment for symptomatic bone metastases. Medroxyprogesterone for metastatic RCC has given an equivocal 5%-10% response rate of short duration. Vinblastine has also had a response rate of approximately 20%, again of minimal duration. There are no other cytotoxic chemotherapeutic agents of benefit.

Immunotherapy with interferon alpha has had a 15%-20% response rate. Other interferons, alone (interferon beta, interferon gamma) or in combination with chemotherapeutic agents, have been less effective than interferon alpha. Adoptive immunotherapy—using lymphocytes (lymphokine-activated killer cells) from exposure of the

patient's own peripheral blood lymphocytes to interleukin-2 (IL-2) *in vitro* followed by reinfusion into the patient along with systemic IL-2 infusion—has shown up to 33% objective response rates. High-dose intravenous IL-2 causes a profound capillary leak syndrome and substantial toxicity. Subsequent studies have shown only a 16% response rate.

Recent advances in research on the von Hippel-Lindau tumor suppressor gene has led to identification of growth factors including vascular endothelial growth factor (VEGF) and platelet-derived growth factor as molecular targets in treating advanced renal cancer. Initial studies using bevacizumab, an anti-VEGF antibody, have shown promising results. Sorafenib, a tyrosine kinase inhibitor that blocks the pathway leading to the production of several growth factors, has been studied in patients with metastatic renal cancer and shown longer median progression-free survival than placebo (24 weeks vs. 6 weeks). Sunitinib, another tyrosine kinase inhibitor, has shown longer progression-free survival and higher response rates than interferon alpha in patients with metastatic renal cancer. These oral agents are currently used as first-line therapy in this group of patients.

Temsirolimus is another targeted agent that is a specific inhibitor of the mammalian target of rapamycin kinase (mTOR inhibitor) and has shown promising results. It is now used as first-line therapy in poor prognosis patients. Many other agents are currently being studied.

► Prognosis

Patients with localized RCC (stages T1, T2, and T3a) treated surgically have 5-year survival rates of approximately 70%-80%, whereas rates for those with local nodal extension or distant metastases are 15%-25% and less than 10%, respectively. Most patients who present with multiple distant metastases succumb to disease within 15 months (Table 38-1). The advent of new agents for RCC may improve the outcome in these patients.

RENAL SARCOMA

Renal sarcomas include rhabdomyosarcoma, liposarcoma, fibrosarcoma, and leiomyosarcoma; the latter is the most common, though all are very uncommon. Sarcomas are highly malignant and are usually detected at a late stage and thus have a poor prognosis. The diagnostic approach is similar to that of RCC. The histology of the lesion is rarely suspected preoperatively, although local invasion into surrounding retroperitoneal structures is more common than with RCC. These tumors have a tendency to surround the renal vasculature and do not exhibit neovascularity on MRA.

Treatment is surgical, with wide local excision; however, local recurrence and subsequent distant metastases are the rule. There is no therapy of proved benefit for metastatic disease.

SECONDARY MALIGNANT RENAL TUMORS

Metastatic tumors to the kidney are more common than primary renal tumors and often develop from primary tumors of distant sites, most commonly the lung, stomach, and breast. It is rare for the diagnosis to be made before autopsy; this suggests that renal metastasis is a late event. There are usually no symptoms, though microscopic hematuria occurs in 10%-20% of cases. Imaging reveals a renal mass, often difficult to distinguish from RCC. Contiguous spread of a tumor adjacent to the kidney is not infrequent (eg, tumors of the adrenal, colon, and pancreas and retroperitoneal sarcomas). Tumors such as lymphoma, leukemia, and multiple myeloma may also infiltrate the kidney. Routine radiologic, hematologic, and chemical examinations should demonstrate the primary tumor in most cases. Percutaneous biopsy may be appropriate in certain circumstances.

BENIGN RENAL TUMORS

► Renal Oncocytoma

Renal oncocytomas are benign renal neoplasms. The tumors are generally asymptomatic and not associated with the paraneoplastic syndromes. The finding of a central stellate scar on CT or a spoke-wheel pattern of feeding arteries on angiography may suggest the diagnosis, although these findings have been found to be unreliable. Oncocytomas can coexist with renal carcinoma in the same lesion or in other lesions in the same kidney (7%-30%). This finding, along with difficulty differentiating oncocytoma from clear cell or chromophobe renal cancers on fine-needle aspirates, make it difficult to make a definitive diagnosis preoperatively. Consequently, definitive treatment of these lesions with radical or partial nephrectomy, or with ablation (cryoablation or RFA) has been recommended.

► Mesoblastic Nephroma

Mesoblastic nephroma is a benign congenital renal tumor seen in early childhood, which must be distinguished from the highly malignant nephroblastoma, or Wilms tumor. Unlike Wilms tumor, mesoblastic nephroma is commonly diagnosed within the first few months of life. Histologically, it is distinguished from Wilms tumor by cells resembling fibroblasts or smooth muscle cells and by the lack of epithelial elements. The prognosis is excellent; complete surgical resection is curative, and neither chemotherapy nor radiotherapy is required.

► Angiomyolipoma

Angiomyolipoma is a benign hamartoma seen most often bilaterally in adults with tuberous sclerosis (which also includes adenoma sebaceum, epilepsy, and mental retardation).

The tumor is also common in middle-aged women, but only unilaterally. These tumors can be detected following spontaneous retroperitoneal hemorrhage, though 50% of these lesions are currently diagnosed incidentally. CT scan can be diagnostic, with negative Hounsfield units detected in the fat-containing area of the tumor. Occasionally, an angiomyolipoma eludes diagnosis preoperatively and requires resection (especially the lipid-poor angiomyolipoma). Asymptomatic patients with small (< 4 cm) tumors and typical findings on CT scan of fat within the tumor do not require surgery, as the prognosis is excellent without treatment. These patients can be followed with serial imaging. Those presenting with a retroperitoneal hemorrhage or a size greater than 4 cm should have the tumor removed surgically with partial nephrectomy or embolized via angioinfarction, which has been shown to be effective.

► Other Benign Renal Tumors

Other benign renal tumors include (1) **fibroma**, a renal parenchymal capsular or perinephric fibrous mass; (2) **lipoma**, an adipose deposit within or around the kidney, often perihilar or within the renal sinus; (3) **leiomyoma**, a common retroperitoneal tumor that may arise from the renal capsule or renal vascular walls; and (4) **hemangioma**, which is occasionally found to be the elusive cause of hematuria. Hemangiomas are generally quite small, and the diagnosis can be confirmed by direct vision of the lesion in the renal collecting system on ureteroscopy.

TUMORS OF THE RENAL PELVIS & CALICES

► General Considerations

In over 90% of cases, tumors involving the collecting system of the kidney are urothelial (or transitional cell) carcinomas. Fewer than 5% of tumors in this location are squamous carcinomas (often in association with chronic inflammation and stone formation) or adenocarcinomas. The cause of urothelial carcinoma of the upper urinary tract is similar to that of epithelial tumors in the ureter or bladder; there is a strong association with cigarette smoking and exposure to industrial chemicals. Excessive use of phenacetin-containing analgesics and the presence of Balkan nephritis are also predisposing factors.

► Clinical Findings

A. Symptoms and Signs

Gross or microscopic painless hematuria occurs in over 70% of patients. The lesions are usually asymptomatic unless bleeding causes acute flank pain secondary to obstructing clots. Presenting symptoms can often be due to metastases to bone, the liver, or the lungs. Physical examination is usually negative for any positive findings.

B. Laboratory Findings

Microscopic hematuria on urinalysis is the rule. Pyuria is not seen. Cytologic examination of voided urine specimens may be diagnostic in high-grade tumors. Urine obtained from the ureter by retrograde catheterization or by brushing with specialized ureteral instruments can improve the diagnostic accuracy of cytologic examinations. Direct biopsy during ureteroscopy is the most accurate. There are no commonly associated paraneoplastic syndromes or diagnostic serum tumor markers in urothelial carcinoma. A large number of urine markers are currently being studied, but only *in situ* hybridization studies identifying abnormalities in chromosomes 3, 7, 17, and 9p21 can be recommended at present.

C. Imaging Studies

The diagnosis is commonly made on CT urography or intravenous urography and confirmed by retrograde pyelography and ureteroscopy with biopsy. Renal ultrasound or CT scan can be used to rule out calculus. CT scan is also useful in local staging of the tumor. The tumors metastasize to the lungs, liver, and bone, so chest x-ray, CT scan of the lungs and liver, and a bone scan are useful to determine the presence of metastases. Urothelial carcinoma tends to be multifocal in the urinary tract, involving the opposite kidney (1%-2%), ipsilateral ureter, or bladder (38%-50%). Surveillance of these potential sites is important.

D. Endoscopic Findings

Cystoscopy is necessary when gross hematuria is present to determine the location of the bleeding. Lateralizing hematuria can be identified with cystoscopy (bloody efflux from one ureteral orifice). Retrograde pyelography and ureteral cytologic studies or brushing, as described previously, can be useful, though mildly abnormal cytologic findings may occur in patients with upper tract inflammation or calculi. Rigid or flexible ureteroscopes can be used to view the upper ureter and renal pelvis directly. Biopsy of upper tract lesions is possible through these instruments. Although percutaneous approaches to the renal collecting system have been perfected, their use for diagnosis or treatment of suspected urothelial carcinoma in routine cases is not recommended, because of the possibility of spreading tumor cells outside the kidney.

► Differential Diagnosis

A variety of conditions may mimic transitional cell carcinoma of the renal pelvis, including calculi, sloughed renal papillae, tuberculosis, and RCC with pelvic extension of the tumor. These can usually be ruled out by the diagnostic studies described previously.

► Complications

Occasionally, bleeding may be severe enough to require immediate nephrectomy. Infection may develop, particularly when there is obstruction and hydronephrosis, requiring prompt use of systemic antibiotics.

► Treatment

Renal urothelial carcinoma is treated by nephroureterectomy (perifascial nephrectomy and removal of the entire ureter, down to and including the ureteral orifice within the bladder). Transureteral or percutaneous endoscopic techniques for resection of selected low-grade lesions have been successful, particularly in patient with significant chronic kidney disease and/or solitary renal units. Upper tract instillation of bacille Calmette-Guérin (BCG) or mitomycin C has been reported with modest results. High recurrence rates and the potential for local tumor spread would argue against this approach in high-grade or extensive lesions. Laparoscopic nephroureterectomy has become common practice, but management of the distal ureter and bladder cuff by this technique has been the subject of controversy. Regional lymph node dissections have not been traditionally performed, although recent reports have shown some benefit for patients with aggressive disease. Because 50% of these patients will develop urothelial carcinoma of the bladder, cystourethroscopy must be performed postoperatively; it is usually done quarterly during the first year, twice the second year, and then annually.

► Prognosis

Because most of these tumors are low grade and noninvasive, the 5-year tumor-free survival rate is higher than 90% for lesions treated with complete removal of the ipsilateral upper urinary tract. Survival rates are much lower for lesions that invade the renal parenchyma or are of high histologic grade. A poor prognosis is associated with tumors having histologic features of squamous carcinoma or adenocarcinoma. These tumors are mildly radiosensitive, but preoperative or postoperative radiotherapy has not been particularly helpful. Metastatic lesions are particularly problematic, and survivors are rare. Chemotherapy combinations, which have shown benefit in urothelial carcinoma of the bladder (methotrexate, vinblastine, Adriamycin, and cisplatin [MVAC] or gemcitabine and cisplatin), are also efficacious in urothelial carcinoma of the upper urinary tract.

TUMORS OF THE URETER

► General Considerations

Ureteral tumors are rarely benign, but benign fibroepithelial polyps do occasionally occur within the ureter. More than 90% of ureteral tumors are urothelial carcinomas. The cause is unknown, but tobacco smoking and exposure to industrial chemicals are known to be associated. Ureteral urothelial carcinoma is often found in association with renal pelvis urothelial carcinoma and slightly less often with bladder urothelial carcinoma. The lesions develop in persons aged 60-70 years and are twice as common in men as in women. More than 60% of these tumors occur in the lower ureter.

► Clinical Findings

A. Symptoms and Signs

Gross or microscopic hematuria is the rule (80% of cases). Because ureteral tumors grow slowly, they may not cause symptoms even though they completely obstruct the kidney. Occasionally, gross hematuria may cause acute obstruction because of clots. The initial presentation may be due to symptomatic metastases to bone, lungs, or liver.

B. Laboratory Findings

Urinalysis commonly reveals hematuria. There are no biochemical markers specific to the diagnosis, though patients with metastases may have abnormal liver function tests or anemia. Serum creatinine levels may be elevated with complete unilateral obstruction in elderly patients. Cytologic studies of voided urine or ureteral urine or brush biopsy studies may be diagnostic.

C. Imaging Studies

The diagnosis may be made on CT or intravenous urography, though the tumor often obstructs the ureter completely, so that cystoscopy and retrograde pyelography are required for definition of the lesion. These studies often reveal a filling defect in the ureter (classically described as a goblet sign). The ureter is dilated proximal to the lesion. CT scan is useful in ruling out nonopaque calculi and in abdominal tumor staging. Chest x-ray, CT scans, and bone scans are helpful in determining the presence of metastases.

D. Endoscopic Findings

Cystoscopy is necessary when gross hematuria is present to determine the site of bleeding. Retrograde pyelography may then be necessary. Ureteroscopy may provide a direct view of the tumor and access for biopsy.

► Differential Diagnosis

Nonopaque calculi, sloughed renal papillae, blood clots, or extrinsic compression by retroperitoneal masses or nodes

may all produce signs, symptoms, and x-ray findings similar to those with ureteral tumors. The radiographic, cytologic, and endourologic studies listed above should make the distinction, but surgical exploration is required occasionally.

► Treatment

Most ureteral transitional cell carcinomas are not associated with metastases and can be definitively treated with nephroureterectomy. Selected patients with noninvasive low-grade lesions may be treated by segmental ureteral resection with end-to-end anastomosis (ureteroureterostomy), or ureteral reimplantation for lesions in the distal one-third of the ureter. In some patients carefully selected with low-grade noninvasive tumors, resection or laser ablation can be considered. Regional lymph node dissections have not been traditionally performed, although recent reports have shown some benefit. Preoperative or postoperative radiation therapy appears to be of no benefit. As with renal pelvis and bladder urothelial carcinoma, cystoscopy should be performed periodically postoperatively. Patients with metastases are rarely helped by removal of the primary tumor. These tumors are responsive to chemotherapy. Traditional agents that have been used include cisplatin with gemcitabine or MVAC. These have shown reasonable response rates but poor long-term outcomes.

► Prognosis

The 5-year survival rate for patients with low-grade noninvasive lesions treated surgically approaches 100%. Those with high-grade or invasive lesions have a poorer prognosis, and those with metastases have a 5-year survival rate of less than 10%.

TUMORS OF THE BLADDER

► General Considerations

Vesical neoplasms account for nearly 6% of all cancers in men and are the second-most common cancer of the genitourinary tract in men. In women, these tumors account for 2% of all cancers and are the most common cancer of the genitourinary tract. Men are affected twice as often as women. More than 90% of tumors are urothelial carcinomas, while a few are squamous cell carcinomas (associated with chronic inflammation, as in bilharziasis) or adenocarcinomas (often seen at the dome of the bladder in patients with a urachal remnant).

Most urothelial carcinomas (70%-80%) are nonmuscle invasive (not invasive into the bladder detrusor musculature) when recognized. Only 10%-15% of recurrent tumors become invasive.

The cause of urothelial carcinoma is unknown; there is a strong association with chronic cigarette smoking and exposure to chemicals prevalent in dye, rubber, leather, paint, and other chemical industries.

Table 38–2. Treatment and prognosis of tumors related to stage of disease.

Conventional Stage	TNM Stage	Tumor Involvement	Treatment	Five-Year Survival (%)
0	Ta	Mucosa only	Transurethral resection	85-90
A	T1	Submucosal invasion (lamina propria)	Transurethral resection and intravesical chemoimmunotherapy	60-80
B1	T2a	Superficial muscle invasion	Total cystectomy and pelvic lymphadenectomy	50-55
B2	T2b	Deep muscle invasion		30-50
C	T3	Perivesical fat invasion		30-40
D1	T3-4N+	Regional lymph node invasion	Systemic chemotherapy	6-35
D2	T3-4M1	Distant metastases		0-10

The treatment and prognosis depend entirely on the degree of anaplasia (grade) and the depth of penetration of the bladder wall or beyond (Table 38–2). Most of these tumors develop on the trigone and the adjacent posterolateral wall; thus, ureteral involvement with obstruction is a possibility. Tumors tend to be multifocal within the bladder. Approximately 5% of patients develop upper urinary tract urothelial carcinoma as well.

► Clinical Findings

A. Symptoms and Signs

Gross or microscopic hematuria is a common finding that leads to the diagnosis. Patients with diffuse noninvasive tumors, particularly carcinoma *in situ*, may have urinary frequency and urgency. Occasionally, large necrotic tumors become secondarily infected, and patients exhibit symptoms of cystitis. Pain secondary to clot retention, tumor extension into the bony pelvis, or ureteral obstruction may occur but are not frequent presenting complaints. When both ureters are obstructed, azotemia with attendant secondary symptoms may be the finding that requires diagnostic studies.

External physical examination is not generally revealing, though occasionally a suprapubic mass may be palpable. Rectal examination may reveal large tumors, particularly when they have invaded the pelvic sidewalls. Thus, bimanual examination is a necessary part of staging evaluation.

B. Laboratory Findings

Microscopic hematuria is the only consistent diagnostic finding. Patients with bilateral ureteral obstruction may have azotemia and anemia. Liver metastases may cause elevation of serum transaminases and alkaline phosphatase. There are no paraneoplastic syndromes or tumor markers consistently present in patients with urothelial carcinoma. Urinary markers currently being studied are various tumor-associated antigens, growth factors, and nuclear matrix proteins, but

none are proved to be accurate enough to obviate cystoscopy for diagnosis.

C. Imaging Studies

Small bladder tumors are not seen on intravenous urography but may be seen on CT. Larger tumors usually produce filling defects in the bladder on both urography or CT (Figure 38–13). Ureteral obstruction with hydronephrosis may occur as well. Invasion of the bladder wall may be predicted in patients with asymmetry or marked irregularity of the bladder wall. Noninvasive lesions seen on CT or intravenous urography tend to be exophytic within the bladder, without evidence of bladder wall distortion.

Ultrasonography by external, transrectal, or transurethral routes can accurately define moderate-sized bladder tumors and can often depict deep invasion.

CT scan can be useful for staging, but the depth of bladder wall penetration and delineation of tumor deposits

▲ **Figure 38–13.** Noncontrast CT scan showing space-occupying lesion (transitional cell carcinoma) on the posteroinferior of the bladder (arrow).

in adjacent nonenlarged lymph nodes are not accurately defined. In patients with nodal metastases suspected on CT scans, fine-needle aspiration and cytologic studies may confirm the diagnosis and eliminate the need for surgical exploration. MRI is helpful in the pelvis, where motion artifacts are minor and the scant pelvic fat is just enough to provide organ differentiation. However, the information is not superior to that obtained with CT.

D. Urinary Cytologic Studies

Urothelial tumors shed neoplastic cells into the urine in large numbers. Low-grade tumor cells may not appear abnormal on cytologic examination, but higher-grade tumor cells can be detected by cytologic study with high specificity. These studies are most useful in checking for recurrence of urothelial carcinoma. Flow cytometry (differential staining of DNA and RNA within urine cells to measure the amount of nuclear protein and thus the relative number of aneuploid [abnormal] cells) has been used to screen patients with some success. This technique may be useful for early diagnosis of recurrence. The urinary fluorescence *in situ* hybridization assay is more sensitive and comparably specific for bladder cancer cells as compared to cytology.

E. Endoscopic Findings

Cystoscopy is mandatory in any adult patient with unexplained hematuria and a normal upper-tract imaging study. Many urothelial carcinomas are not identified on CT or intravenous urography. Cystoscopic examination should detect nearly all tumors in the bladder (Figure 38-14). Only a few patients will have carcinoma *in situ* (high-grade non-invasive tumor) that is not visible. Any tumor seen should be biopsied and preferably resected to completion if the patient

▲ **Figure 38-14.** Transitional cell (papillary) carcinoma of the bladder with minimal invasion of the bladder wall.

is under anesthesia. The entire bladder, including the bladder neck, should be routinely scrutinized in all patients with microscopic hematuria. In patients without visible tumor and no other causes of hematuria, random biopsies may be diagnostic of carcinoma *in situ*. A bimanual examination should be done during cystoscopy in all patients with urothelial carcinoma to be certain that the bladder is not fixed, signifying extensive extravesical extension.

F. Staging

Therapy depends on the stage of the tumor as seen on histologic sections and examinations for metastases. Table 38-2 sets forth the stage, treatment, and prognosis of patients with urothelial carcinoma of the bladder. The histologic grade of the tumor is also important in determining treatment and prognosis, but in general, low- and high-grade histologic characteristics tend to occur in low- and high-stage tumors, respectively.

As previously discussed, CT scan, MRI, or both may be helpful in predicting the stage of the tumor. Isotope bone scanning, chest x-ray, and chest CT scan evaluate the possibility of bone or pulmonary metastases and should be done before determining therapy in patients with invasive lesions.

► Treatment

A. Transurethral Resection, Fulguration, and Laser Therapy

Endoscopic transurethral resection of superficial and submucosally invasive low-grade tumors can be curative. Nevertheless, because the tumor recurs in more than 50% of patients, cystoscopy should be performed periodically. Quarterly examinations are recommended during the first year following tumor resection, every 6 months during the second year, and annually thereafter. Periodic urinary cytologic examinations can be helpful as well. Upper tract surveillance with CT urography is recommended for high-grade tumors, typically every 2 years. Low-grade tumors do not require upper tract surveillance unless hematuria recurs without evidence for tumor recurrence in the bladder. Recurrent small tumors without obvious invasion may be treated by fulguration only, though biopsy is recommended to document the stage and grade.

Neodymium:YAG lasers have been used for desiccation of low-grade, low-stage tumors. There is as yet no proven advantage to this approach except that patients can be treated under local anesthesia as outpatients and perhaps that tumor cells are rendered nonviable and thus incapable of reimplantation elsewhere in the bladder or urethra. Biopsies for diagnosis and staging are still required.

B. Intravesical Therapy

A variety of chemotherapeutic agents have been used in patients with recurrent low-grade, low-stage tumors.

Mitomycin C is instilled into the bladder by catheter (40 mg in 40 mL of water) and left indwelling for 1-2 hours. Patients are treated once a week for 6 weeks and may undergo a less frequent maintenance regimen. Treatment results in decreased frequency of recurrence or no recurrence in nearly 50% of patients. Other agents include thiotepa and doxorubicin.

Immunotherapeutic drugs, which include BCG, are effective in prophylaxis (60%) of recurrent papillary tumors and curative (70%) in carcinoma *in situ*, a highly malignant lesion less responsive to the cytotoxic agents described earlier. Intravesical BCG is the gold-standard first line therapy for carcinoma *in situ* of the bladder. Side effects of BCG include vesical irritability (90%), low-grade fever, and systemic BCG-osis (1%). Although the mechanism of action of BCG is not entirely known, it is suspected to induce T-cell recruitment and subsequent cytokine release locally at the tumor site. It is the most effective agent currently used. Interferon alpha has also been studied and is effective (nearly 50% of cases) for carcinoma *in situ*, with less toxicity than BCG; however, its durability as a single agent is poor. The combination of BCG and interferon alpha has shown nearly 50% response rates and is occasionally used in patients who have failed BCG. BCG is contraindicated in immunocompromised patients due to risk of systemic BCG infection and the likely decreased efficacy.

Immediate instillation of Mitomycin C after transurethral resection has shown a substantial decrease in recurrence rates and is now standard of care.

C. Radiation Therapy

Definitive radiation therapy should be reserved for patients who have inoperable muscle-invasive bladder cancer localized to the pelvis or who refuse surgical treatment, as the 5-year survival rate is only 30%. In some patients with recurrence after radiation therapy, salvage cystectomy can be curative (in at least 30% of cases), though surgical morbidity rates are high. Radiation, when used, is combined with systemic chemotherapy.

D. Surgical Therapy

Occasional patients are seen with muscle-invasive lesions (T2) localized to an area in the bladder well away from the bladder base or orifices and without tumor in other sites of the bladder (proved by multiple biopsies) or beyond. Partial cystectomy (removal of the tumor with a cuff of normal bladder) may be appropriate in these patients. Such tumors are rare, and patients must be selected carefully for partial cystectomy. All other patients with high-grade or invasive (T2 and T3) lesions without distant spread or a fixed pelvis on bimanual examination are best treated by radical cystectomy and pelvic lymph node dissection. This includes removal of the bladder and the prostate in men. Removal of

the entire urethra may be necessary in selected patients with tumors at the bladder neck or in the prostate or in those with diffuse carcinoma *in situ* in the bladder. In women, the uterus, ovaries, fallopian tubes, urethra, and the anterior vaginal wall are usually removed *en bloc* with the bladder. Vaginal-sparing cystectomy can be performed as well.

Urinary diversion is required and is accomplished with the use of intestinal conduits, pouches or neobladders. Ileal conduit urinary diversion creates a urostomy on the skin and requires continuous bag drainage. This is the most common urinary diversion with the lowest complication rates. Continent cutaneous urinary diversions requiring intermittent cutaneous catheterization rather than cutaneous bag drainage became popular in the late 1980s. The basic principles are large-volume reservoirs with detubularization of bowel to maintain low intrapouch pressures and construction of an intussuscepted or plicated ileal segment to provide cutaneous continence. Orthotopic neobladder reservoirs also have been devised using bowel configurations similar to those described above to connect directly to the membranous urethra in men and in the distal two thirds of the female urethra, permitting the patient to void normally. These procedures are appropriate in both men and women and have been shown to be safe, with minimal increase in morbidity over cutaneous diversions.

Robotic cystectomy has been done in large numbers at select centers in the United States and Europe. With short-term follow up, oncologic outcomes appear equivalent to open surgery with potentially less blood loss and faster convalescence postoperatively. In most cases, the urinary diversion is done via open surgery, but more recently, ileal conduit and neobladder urinary diversions have been performed intracorporeally with robotic assistance.

E. Systemic Chemotherapy

Chemotherapy in the form of CMV (cisplatin, methotrexate, and vinblastine) or MVAC (CMV plus doxorubicin [Adriamycin]) has been used precystectomy (neoadjuvant) or postcystectomy (adjuvant) for muscle-invasive tumors or as treatment of metastatic urothelial cancer. More recently, gemcitabine and cisplatin have become standard of care after a randomized trial showed similar efficacy to MVAC with fewer side effects. A recent randomized trial showed improved survival in patients with locally advanced bladder cancer who received neoadjuvant chemotherapy and cystectomy compared to those who underwent cystectomy alone. Adjuvant chemotherapy has been shown in randomized trials to help patients with locoregional disease but not patients with localized disease (stage T1-T2). Several reports of efficacy with either CMV or MVAC for treatment of metastatic disease have shown a 60% overall objective response rate with a 30% complete response rate. A few long-term survivors with apparent cure have been reported (10%-15%), and either of these regimens thus appears to be a

definite advance in the treatment of urothelial cancer. Other chemotherapeutic agents used in urothelial cancer include paclitaxel and carboplatin in various regimens that appear to have similar efficacy with less toxicity.

► Prognosis

Approximately half of the low-grade superficial tumors are controlled by transurethral surgery or intracavitary use of chemotherapeutic agents (Table 38–2). Following radical cystectomy, the 5-year survival rate varies with the extent, stage, and grade of the tumor, but with T2N0M0 tumors averages about 50%-70%. The complications of urinary diversion (ureteral obstruction with hydronephrosis, pyelonephritis, and nephrolithiasis) also influence the outcome.

CARCINOMA OF THE PROSTATE

► General Considerations

In adult men, prostate cancer is the most common neoplasm (after skin cancer) and the second-most common (after lung cancer) cause of death due to cancer. The tumor is more prevalent in black men than in any other group in the United States. The tumor rarely occurs before age 40, and the incidence increases with age such that more than 75% of men older than age 85 have prostate cancer on autopsy. In most of these older men, however, the disease is not clinically apparent; only 10% of men over age 65 develop clinical evidence of the disease. Ninety-five percent of tumors are adenocarcinomas. The tumor arises primarily in the peripheral zone (85%), an area that differs in embryologic derivation from the periurethral (transition) zone, which is the site of formation of benign prostatic hyperplasia. The cause of prostate cancer is unknown, but many factors appear to be involved, including genetic, hormonal, dietary (particular high-fat diets), and perhaps environmental carcinogenic influences.

► Screening

Screening with PSA monitoring and digital rectal examination (DRE) has been controversial due to conflicting evidence regarding a decrease in mortality. Two very large randomized controlled trials examining the effects of PSA screening on mortality have recently been completed, one in the United States and one in Europe. The US trial did not show a survival benefit in the screening group, although the control group was significantly contaminated with men who had some previous PSA testing. The European study showed a relative survival benefit of 20% in the screening group after 10 years of follow-up, and the data will be reanalyzed with longer follow-up.

Based on all available evidence, the US Preventive Services Task Force released a recommendation against routine screening for prostate cancer in 2011. The American

Urological Association recommends a shared decision making discussion about prostate cancer screening with men between the ages 55–69, and at a younger age for those men with a positive family history in a first degree relative or for African Americans. If screening is agreed upon, serum PSA level and DRE are performed annually or every two years based on the clinician's discretion.

► Clinical Findings

A. Symptoms and Signs

Nonpalpable (T1) carcinoma of the prostate presents without physical signs and is only diagnosed by the pathologist when prostate tissue is removed as treatment for symptomatic bladder outlet obstruction presumed to be caused by benign prostatic hyperplasia or is found by an elevated PSA (T1c). Patients T2 or higher disease have a hard nodule on the prostate that can be felt during rectal examination (Table 38–3). T3 disease is palpable (or visible by imaging) beyond the capsule of the prostate or demonstrates seminal vesicle involvement. T4 disease invades adjacent organs including the rectum and pelvic sidewall. Previously, 50% of patients presented with evidence of metastases, including weight loss, anemia, bone pain (commonly in the lumbosacral area), or acute neurologic deficit in the lower limbs. Today, however, fewer than 20% of patients present in this way because of earlier diagnosis due to wide use of PSA screening (stage migration).

B. Laboratory Findings

Patients with extensive metastases may have anemia due to bone marrow replacement by tumor. Those with bilateral ureteral obstruction secondary to trigonal compression by tumor may exhibit azotemia and uremia. Serum alkaline phosphatase is often elevated in patients with bone metastases but not in those with localized disease.

PSA is elevated in the serum of most men with prostate cancer, but high-grade (Gleason 8–10) cancers and ductal variant adenocarcinomas can present with normal PSA levels. Values above 4 ng/mL are considered abnormal but rise normally with age and significant benign prostatic hypertrophy. PSA can also be falsely elevated due to cystoscopy, prostate biopsy, urethral catheterization, and urinary tract infection. Routine DRE does not usually affect PSA levels.

Methods for enhancing PSA specificity include the following: (1) age-specific PSA (younger men [$<$ age 50 years], normal $<$ 2.5 ng/mL; older men [$>$ age 70 years], normal $>$ 6.5 ng/mL); (2) PSA density (PSA divided by prostate volume), where less than 0.15 ng/mL suggests cancer; (3) percent-free PSA (total PSA minus complexed PSA), where lower values signify an increased risk of cancer (useful for total PSA levels between 4 and 10). While total PSA is useful for staging, it is not absolute. PSA appears to be most helpful

Table 38–3. Treatment and prognosis of prostate cancer related to tumor stage.

Conventional Stage	TNM Stage 1997	Clinical Findings	Treatment	Fifteen-Year Recurrence-Free Survival (%)
A1	T1a	Nonpalpable tumor; incidental finding at transurethral prostatectomy (low-grade cancer seen in < 5% of prostate)	Observation	100
A2	T1b	Same as above except tumor is high-grade, or > 5% of prostate is involved, or both	Radical prostatectomy with pelvic lymphadenectomy	70-80
B1	T2a	Tumor involves one lobe or less	External beam radiation	85
B2	T2b	Tumor involves more than one lobe	Brachytherapy	60-70
C	T3a	Unilateral extraprostatic extension	Radiation with or without pelvic lymphadenectomy	20-60
C2	T3b T3c T4a T4b	Bilateral extraprostatic extension Seminal vesicle invasion Invades bladder neck or rectum Invades levator muscle and/or fixed to pelvic sidewall	Hormonal therapy (orchiectomy or LHRH/antiandrogen) when symptomatic Irradiation for isolated bone pain	0-10
D	N+ or M+	Pelvic lymph node involvement or distant metastases	Hormonal therapy (orchiectomy or LHRH/antiandrogen) when symptomatic Irradiation for isolated bone pain	0-10

in following up on patients after treatment, as levels fall to undetectable after surgery and decrease dramatically after radiation therapy when there is a complete response. There are several new prostate cancer markers currently being investigated, but none have become widely used to date. PCA3 urinary assay shows promise in men with persistently elevated PSA levels and previous negative biopsies.

C. Imaging Studies

Transrectal ultrasound has become very useful for evaluating prostate volume and guiding biopsy needles into the peripheral zone and other specific areas, such as the base, the apex, and the transition zone of the prostate. The study can also reveal typical hypoechoic peripheral zone lesions in 70% of patients with palpable lesions. Because many prostate cancers are not hypoechoic and not all hypoechoic lesions are cancer, transrectal ultrasound alone for screening for prostate cancer is not recommended. CT scan may reveal urinary retention, distal ureteral obstruction with resultant hydronephrosis, and pelvic lymphadenopathy. Locally advanced disease and bony metastases can also be visualized on CT scan. A chest x-ray or CT may help in identifying the uncommon lung metastases but more often shows typical osteoblastic metastases in the thoracic spine or ribs. An abdominal x-ray may reveal metastases in the lumbosacral spine or ilium. Abdominopelvic CT is not usually recom-

mended unless the disease is palpable, Gleason score is 7 or more, or PSA level is more than 20 ng/mL.

Endorectal MRI (eMRI) appears to be more helpful than CT scan in the staging of prostate cancer. This study allows for localization of malignant lesions within the prostate as well as assessment for extracapsular extension, seminal vesical invasion, involvement of adjacent organs, and lymph node involvement. eMRI is useful for clinical staging and preoperative planning but is reliant upon having a radiologist with expertise in this field.

Positron emission tomography is not typically utilized for prostate cancer staging.

D. Biopsy

The diagnosis is established by transrectal ultrasound-guided biopsies in most instances. Because the great majority of patients have biopsies due to an elevated serum PSA (stage T1c) and no abnormal findings on exam or imaging, biopsies of the base, middle, and apex of the prostate—concentrating on the peripheral zone, with 6 biopsies per side of the prostate—are required for accurate diagnosis.

Differentiation of the tumor is graded by the pathologist using the Gleason score, which assigns a grade of 1-5 (low to high grade) for both the primary and secondary forms of the tumor. The two numbers are added, and the cancer can thus

be Gleason sum 2-10, with 10 being the most poorly differentiated cancer. Gleason score is an independent predictor of disease recurrence. Typically, pathologists give Gleason scores between 6 and 10.

E. Staging

Rectal examination can provide initial staging in patients with palpable tumors (Table 38–3). Needle biopsy is confirmatory, and histologic grading (Gleason score) can fairly accurately predict the metastatic potential of the tumor. Imaging as described above can be useful for staging of the primary tumor (eMRI) and to rule out metastatic disease (eMRI, bone scan).

► Differential Diagnosis

Nodules caused by benign prostatic hyperplasia may be difficult to distinguish from cancer; benign nodules are usually rubbery, whereas cancerous nodules have a much harder consistency. Fibrosis following a prior prostatectomy for benign disease or secondary to chronic prostatitis or prior biopsies may be associated with lesions indistinguishable from cancerous nodules and require biopsy for definition. Occasionally, phleboliths or prostatic calculi on the surface of the prostate may be confusing; however, transrectal ultrasound can be helpful in the differentiation and for biopsy guidance.

► Treatment

A. Curative Therapy

Curative treatment for localized prostate cancer includes radical prostatectomy and various forms of radiation therapy (external beam radiation therapy, transperineal radioactive seed placement [brachytherapy with ^{125}I , ^{103}Pd , or ^{192}Ir], and cyberknife). Complete staging is important so that appropriate candidates will be selected. Patients with localized prostate cancer are stratified into three risk groups (Table 38–4). Low-risk patients have similar 5-year recurrence survival rates irrespective of the curative treatment

Table 38–4. Localized prostate cancer risk groups.

Low risk	PSA ≤ 10 ng/mL Clinical stage T1c-T2a Gleason score 2-6
Intermediate risk	PSA 10-20 ng/mL Clinical stage T2b Gleason score 7
High risk	PSA > 20 ng/mL Clinical stage \geq T2c Gleason 8-10

modality. Intermediate-risk and high-risk patients have better recurrence-free rates with prostatectomy or external beam radiation compared to brachytherapy. None of these modalities have been compared in randomized trials. The only reported randomized trial compared watchful waiting to radical prostatectomy and showed improved disease-free as well as overall survival in the prostatectomy group. Studies have shown that compared to external beam radiotherapy alone, combined androgen deprivation (for 6 months to 3 years) and external beam radiation improve survival in patients with localized prostate cancer, especially patients in the intermediate and high-risk groups. Patients with grossly positive pelvic lymph nodes are not candidates for curative therapy. Recent advances in surgical technique have led to a low incidence of incontinence (1%-4%) and preservation of potency in up to 70% of patients. Alternative procedures include external beam pelvic irradiation plus brachytherapy and transperineal cryoablation of the prostate for primary and recurrent disease after radiation.

For the past decade, robotic-assisted radical prostatectomy has increased in popularity and has been shown to have decreased blood loss and length of hospital stay and more rapid return to normal activity than open surgery. Oncological and functional (continence and potency) outcomes are equivalent to open surgery. More than 80% of prostatectomies in the United States are now performed with the da Vinci™ Robot.

B. Palliative Therapy

Patients with metastatic disease cannot be cured, but significant palliation can be offered. Androgen deprivation therapy in the form of luteinizing hormone-releasing hormone (LHRH agonist or bilateral orchiectomy) is effective in 70%-80% of symptomatic patients. Estrogen-based treatments are less commonly used due to the numerous side effects (in about 25% of patients), including congestive heart failure, thrombophlebitis, and myocardial infarction, and thus should not be used except in selected patients. These hormonal treatments are not additive, and use of both treatments simultaneously has no advantages over use of either alone. LHRH agonists have shown efficacy comparable to that of estrogen or orchiectomy, with reduced side effects, and are preferred by patients who find bilateral orchiectomy unacceptable. The drug must be given by injection every 1-6 months (depending on dosage) or via subcutaneous pellet annually. Studies have also shown that if an LHRH agonist is used, concomitant administration of an antiandrogen (flutamide or bicalutamide) may slightly improve survival. Studies to determine if orchiectomy plus an antiandrogen is more effective than orchiectomy alone have not shown an advantage to the combination. Antiandrogens should be administered for at least one week prior to inception of LHRH agonists to prevent the short-term flare that occurs with initiation of LHRH monotherapy. LHRH antagonists have more recently

become available and have a faster onset to castration, and do not require pre-treatment with antiandrogens.

Hot flashes, osteoporosis, cardiac disease, and cognitive impairment are all potential long-term side effect of androgen deprivation.

Controversy continues concerning whether to treat asymptomatic patients at the time of diagnosis or to wait until symptoms develop. Because either approach is palliative only and there are no definitive studies showing survival advantages with early treatment, it is recommended that treatment be withheld until PSA is relatively high (> 20 ng/mL) or symptoms occur except in patients who cannot accept a no-treatment philosophy. Recent studies do show that patients who have had a radical prostatectomy and have node-positive disease do have a slight survival advantage with early hormonal treatment.

Patients whose prostate cancer becomes hormone refractory (median of 18 months after starting treatment) can be treated by ketoconazole (which inhibits adrenal androgen production) with oral corticosteroids for short-term response. Radiation therapy for symptomatic bone lesions can be helpful, as can local irradiation for an obstructing or bleeding prostate tumor. On occasion, transurethral prostatectomy is required to relieve bladder outlet obstruction. Chemotherapy with docetaxel and prednisone has shown a slight survival advantage in phase III trials.

► Prostate Cancer Prevention

Because the etiology of prostate cancer is not known, prevention is difficult to determine. However, there is evidence that a low-fat diet and lycopene (found in processed tomatoes) decrease the growth of prostate cancer cells *in vitro* and *in vivo* in animals. Further large-scale epidemiologic studies suggest a decrease in prostate cancer in humans who consumed vitamin E and selenium. However, these studies were not planned specifically for this purpose, and thus the results were questionable. A current randomized trial comparing selenium and vitamin E (SELECT) was recently halted due to the lack of evidence of prostate cancer prevention. The largest chemoprevention trial (Prostate Cancer Prevention Trial [PCPT]), with over 18,000 men, compared finasteride (5 α -reductase) to placebo and found a 25% reduction in prostate cancer with finasteride but also showed an increased risk of high-grade cancer in the finasteride-treated patients. While this is thought to be an artifact of the study, these results have limited enthusiasm for recommending prevention therapy with finasteride routinely.

► Prognosis

Radical prostatectomy cures 70%-80% of the patients suitable for that operation, but its use should be limited to those with a reasonable life expectancy (Table 38-3). Currently, about 60%-70% of patients with prostatic cancer

are amenable to curative therapy when their disease is discovered.

TUMORS OF THE URETHRA

Malignant tumors of the urethra are rare. The disease is more common in women than in men (4:1). Squamous cell types are seen most often in both sexes.

In women, urethral bleeding is the most common symptom. Distal urethral lesions of low grade and without extension can be treated by radiotherapy or wide local excision. Advanced disease is best treated by combination radiotherapy, chemotherapy, and surgery to achieve good local and distant disease control. Surgery includes anterior exenteration (removal of the bladder, uterus, adnexa, and urethra with the anterior vaginal wall), including pelvic lymphadenectomy and urinary diversion. The prognosis is excellent for distal lesions without extension, but 5-year survival rates are less than 50% for those with proximal lesions.

In men, the lesion is most commonly in the bulbomembranous urethra and is associated with a history of chronic urethral strictures, often secondary to gonorrheal infection. Patients present with urethral bleeding, a weak urinary stream, and a perineal mass. The diagnosis is made by urethroscopy and biopsy. Distal penile urethral lesions can be treated by partial or total penectomy. Lesions in the bulbous urethra or more proximal lesions require extensive surgical resection, including en bloc removal of the penis, urethra, prostate, bladder, pelvic lymph nodes, and urinary diversion. In both men and women with distal lesions, inguinal lymphatics may be involved, but node dissection is required only when gross disease is palpable. Prophylactic node dissection is controversial. Five-year survival rates are 60% for distal urethral tumors but less than 40% for the more common proximal lesions.

Primary irradiation—other than to distal lesions in the female—is rarely helpful. Patients with metastatic disease may respond to methotrexate or cisplatin alone or in combination, but objective remissions are usually of short duration.

TUMORS OF THE TESTIS

► General Considerations

Most testicular tumors are malignant germ-cell tumors. Non-germ-cell tumors such as Sertoli cell tumors and

Leydig cell tumors are rare and usually benign. Germ-cell tumors are categorized as either seminomatous (35%) or nonseminomatous (embryonal, 20%; teratocarcinoma, 38%; teratoma, 5%; and choriocarcinoma, 2%). Cryptorchidism predisposes to testicular cancer, with the incidence increasing inversely with the level of testicular descent (ie, testicles remaining in the abdomen have a much higher incidence of cancer). Metastases first develop in the retroperitoneal nodes; right-sided tumors metastasize primarily to the inter-aortocaval region just below the renal vessels and left-sided tumors primarily to the left para-aortic area at the same level. Distant spread is to supraclavicular areas (left, primarily) and the lungs. Almost 50% of patients have metastases when first evaluated, and this is more common for nonseminomatous tumors.

► Clinical Findings

A. Symptoms and Signs

Testicular tumors present as a painless firm mass within the testicular substance. They often have been present for several months before the patient seeks consultation. Occasionally (10%), a hydrocele is present, obscuring palpation of the mass. A few patients have spontaneous bleeding into the mass, causing pain. Patients with high serum levels of hCG may have gynecomastia. Patients with extensive abdominal metastases may present with abdominal pain, anorexia, and weight loss. Examination may reveal palpable retroperitoneal nodes when spread is extensive or palpable supraclavicular nodes, particularly on the left side.

B. Laboratory Findings

In general, testicular tumors do not alter the usual laboratory parameters, but serum tumor markers are diagnostically helpful. Patients with extensive retroperitoneal metastases may have bilateral ureteral obstruction that causes azotemia and anemia.

Serum lactic dehydrogenase, particularly isoenzyme I, is elevated in approximately 60% of patients. β -HCG, a particularly sensitive marker, is a glycoprotein produced by 65% of nonseminomatous testicular tumors but only 10% of seminomas. The alpha-subunit of the molecule is identical to LH, but the beta-subunit is unique to testicular tumors in adult men. There is cross-reactivity in some assays between the alpha- and beta-subunits; treated patients who develop modest elevations should have simultaneous assay of LH to be certain the marker detected is β -hCG.

α -Fetoprotein is elevated in 70% of patients with nonseminomatous testicular cancer but is *not* elevated in patients with seminoma. Patients in whom histologic study has shown seminoma but in whom serum AFP is elevated should be suspected of having nonseminomatous elements in the primary specimen or metastatic lesions.

Approximately 85% of patients demonstrate elevation of one of these markers at presentation. Serum levels decrease when the tumor is completely removed or regresses. Markers are used mainly to follow tumor regression or predict recurrence, as even minute amounts of tumor may cause serum elevations; however, tumor may be present without elevation of serum markers.

C. Imaging Studies

Abdominal CT scan defines enlarged lymph nodes in approximately 90% of cases when they are present. Chest x-ray and CT scan will detect most pulmonary metastases.

Scrotal ultrasound is useful for identifying the typical hypoechoic lesion in the testicle. Regardless of the findings on ultrasound, however, a young man with an intratesticular mass on palpation requires surgical definition of the mass.

► Differential Diagnosis

Testicular masses in men aged 18-40 are frequently malignant and should be treated accordingly. Confusion can occur with scrotal hydroceles, cord hydroceles, epididymal masses or cysts, or epididymitis. Most of these can be differentiated from masses within the testicle by palpation, but if not, scrotal ultrasound is usually helpful.

► Treatment

See also Table 38-5.

Inguinal orchiectomy with high ligation of the cord at the internal ring is proper initial treatment for all subtypes of testicular cancer. Rarely is incisional biopsy of the testicle advisable. Recommendations for further therapy (retroperitoneal node dissection, chemotherapy, radiation therapy) are then based on the pathologic findings. A staging workup, including postoperative measurement of serum markers, chest x-ray, and chest and abdominal CT scan, is conducted to determine the extent of disease.

A. Nonseminomatous Tumors

Following orchiectomy, three management options are available: (i) active surveillance, (ii) retroperitoneal lymph node dissection (RPLND), and (iii) systemic chemotherapy. Treatment is based on clinical staging and pathology from the orchiectomy specimen. Patients with no evidence of metastatic disease on imaging and normal serum tumor markers postorchiectomy are candidates for close surveillance with the knowledge that about 20% will relapse and require salvage therapy. This strategy avoids the adverse effects of RPLND and/or systemic chemotherapy. Surveillance, however, is rigorous and should only be offered to motivated and reliable patients.

RPLND is recommended for clinical stage I patients (no evidence of metastatic disease on imaging) or for those with

Table 38–5. Treatment and prognosis of testicular cancer related to tumor stage.

Conventional Stage	TNM Stage	Clinical Findings	Treatment	Five-Year Survival (%)
I	T1	Confined to testicle	Nonseminoma: RPLND vs. surveillance; Seminoma: irradiation	>95
IIA	N1	Regional nodes < 2 cm	Adjuvant chemotherapy Nonseminoma: RPLND or chemotherapy; Seminoma: XRT or chemotherapy	>90
IIB	N2	Nodes 2–5 cm	Adjuvant chemotherapy Nonseminoma; RPLND or adjuvant chemotherapy; Seminoma: XRT or chemotherapy	>85
IIC III	N3 M+	Nodes > 5 cm Distant metastases	Chemotherapy followed by resection of residual disease	~70

All patients undergo inguinal orchiectomy.
RPLND: Retroperitoneal lymph node dissection.

retroperitoneal lymphadenopathy that is not bulky (stage IIA–IIB). The extent of lymphadenectomy depends on the testicle involved but in general includes para-aortic and paracaval nodes from the renal vessels down to the aortic bifurcation and along the external iliac artery to the internal inguinal ring on the involved side. Adverse effects of RPLND include severe hemorrhage from vascular injury to the vena cava, aorta or major branches, chylous ascites, loss of seminal emission, and damage to surrounding structures. If necessary, adjacent organs involved are removed *en bloc* with the lymph node tissue (eg, nephrectomy). Seminal emission can be preserved with modified templates or nerve sparing techniques that prospectively identify and preserve the sympathetic fibers that coalesce near the bifurcation of the aorta.

Patients with any nonseminomatous cell type who have extensive retroperitoneal or chest metastases are best treated after orchiectomy by multiagent chemotherapy—typically bleomycin, etoposide, and cisplatin. Residual masses post-chemotherapy are surgically excised. Combination chemotherapy with bleomycin, etoposide, and cisplatin achieves over a 90% cure rate in stage II patients and a 70% cure rate in stage III patients. Patients who do not respond may be treated with ifosfamide, doxorubicin, or both, with some expectation of success.

B. Seminoma

In the absence of extensive distant spread, patients with pure seminoma should be treated with external beam radiation therapy (2500 cGy) to the retroperitoneum following orchiectomy. A recent study showed that one cycle of carboplatin is equivalent to radiation therapy for stage I seminoma. In the presence of bulky abdominal disease or more distant metastases, survival rates are better with multiagent chemotherapy (described earlier) given initially *in lieu* of radiation

therapy. Patients with substantial residual retroperitoneal tumor (> 3 cm) after chemotherapy may benefit from surgical removal of the remaining tumor.

► Prognosis

Even in the presence of metastases, many of these patients can be cured, with overall survival rates more than 90%. The only exception is patients with pure choriocarcinoma, who still have a poor survival rate (35% at 5 years) despite extensive chemotherapy.

TUMORS OF THE PENIS

Cancer of the penis is a rare disease occurring in the fifth to sixth decades. The cause is uncertain. The disease is rarely seen in circumcised men. The lesion commonly is on the glans penis or foreskin. Early cases may exhibit a painless red, velvety lesion, but most often the lesion is an exophytic nodular or wart-like growth with secondary infection. The initial diagnosis is made by a generous incisional biopsy of the lesion, which reveals squamous cell carcinoma in over 95% of cases. The tumors tend to metastasize to superficial or deep inguinal nodes, though the attendant infection may cause enlarged, tender nodes, which may be difficult to differentiate from metastatic cancer.

The differential diagnosis includes syphilitic chancre, soft chancre due to *Haemophilus ducreyi* infection, and simple or giant condyloma. Biopsy usually differentiates among these conditions.

Small, noninfiltrating lesions (carcinoma *in situ*) can be treated with fluorouracil cream, external beam radiation, or laser therapy. However, close follow-up is mandatory in patients so treated. Larger lesions not involving deep structures that are limited to the distal penis are treated

by partial penile amputation at least 2 cm proximal to the lesion, leaving enough of the penis for adequate direction of the urinary stream. Deeply infiltrating and proximal lesions require total penectomy, with formation of a perineal urethrostomy.

Patients with high-risk features (high T stage, high grade, or presence of lymphovascular invasion) are at risk of inguinal nodal metastases. Prophylactic node dissection has been associated with improved survival.

Palpable inguinal nodes should be treated with antibiotics for 6 weeks following treatment of the primary lesion to eliminate infection. Persistently palpable nodes require bilateral ilioinguinal lymphadenectomy. An alternative would be fine-needle aspiration of the palpable nodes and node dissection if positive for metastases. Even those who undergo delayed node dissection when the nodes become palpable can be cured, though this is a lower percentage. Radiation therapy for palpable nodes or as prophylaxis for nonpalpable nodes has been occasionally effective, but mostly in the palliative setting.

Patients with distant metastases (to the pelvic nodes, lungs, or bone) have a poor prognosis, though cisplatin and methotrexate have shown objective but not durable responses. Five-year survival rates for patients with noninvasive lesions localized to the penis are 80%; for those with inguinal node involvement, 50%; and for those with distant metastases, nil.

NEUROPATHIC (NEUROGENIC) BLADDER

A neuropathic bladder has abnormal activity secondary to a neurologic condition. To understand the variety of neuropathic bladder conditions, a basic understanding of the normal innervation and myoneurophysiology is required.

► Myoneural Anatomy

The urinary bladder and its involuntary sphincter develop and differentiate from the tubular urogenital sinus. The

differentiation of the encasing mesenchymal cells forms the musculature of the detrusor and urethral sphincter.

► Innervation

The innervation of the bladder and its involuntary sphincter is via the autonomic nervous system. The parasympathetic supply to the bladder and the sphincter is via the pelvic nerves, which arise from S2-4. These fibers also carry the stretch sensory receptors to the same spinal cord center (S2-4).

The sensory supply for pain, touch, and temperature is carried via the sympathetic fibers arising from the thoracolumbar segments (T11-L2).

Motor and sensory supply of the trigone is via the thoracolumbar sympathetic fibers.

The striated external sphincter, as well as the entire urogenital diaphragm, receives its motor and sensory innervation from the somatic fibers arising from S2-4 (via the pudendal nerve).

It is clear that the S2-4 segment is the origin of the motor supply to the bladder musculature, to the involuntary sphincter, and to the striated external sphincter. The trigone is the only structure that is partly independent in its innervation. This is why segment S2-4 is called the spinal cord center for micturition. It is located at the level of the T12 and L1 vertebral bodies. There are connections between the spinal reflex center and the midbrain and cerebral cortex. Through these connections, inhibition, and control of the spinal cord reflexes can be maintained. The micturition reflex is coordinated in the pontine micturition center.

► Myoneurophysiology

The primary functions of the urinary bladder are to store and empty urine at a safe pressure and in a continent fashion. Intact myoneural elements are essential for these functions. The primary reservoir function is possible because of the specialized detrusor muscle arrangement and because of the bladder compliance phenomenon. The normal adult bladder can accommodate volumes up to 400 mL without increasing intravesical pressure. Bladder fullness is perceived through increases in stretching of bladder mechanoreceptors.

Distention and stretch initiate detrusor activity that can be controlled and inhibited by the high cortical centers or can be allowed to progress to active detrusor contraction and voiding. Normally during voiding, detrusor contraction continues until the bladder is completely empty unless voiding is voluntarily interrupted or inhibited.

Before voiding begins, the pelvic floor and the striated external sphincter relax, the bladder base descends, and the bladder outlet assumes a funnel shape. As a result, urethral resistance decreases. This is followed by detrusor muscle contraction and a rise in intravesical pressure to 20-40 cm

of water, which results in a urine flow of about 15-30 mL/s. When the bladder is completely empty, the pelvic floor and striated external sphincter contract, elevating the bladder base, increasing urethral pressure, and ending voiding. Intact nerve pathways are essential for these synchronized activities to occur.

► Cystometry

Cystometry is a simple method for testing the bladder's storage function and gives the following information: bladder capacity, extent of accommodation or compliance, the ability to sense bladder filling and temperature, and the presence of an appropriate detrusor muscle contraction. In addition, postvoid residual urine can be measured at the same time. A normal cystometrogram is shown in Figure 38-15A.

► Uroflowmetry

Uroflowmetry is the measurement of urine flow rate. If detrusor contraction is properly coordinated with sphincter

relaxation, then the outlet resistance falls as the bladder pressure increases, and the flow rate is adequate. Normally, the flow rate changes with age but is more than 20 mL/s in men under 60 and more than 25 mL/s in women under 50 years of age. Any flow rate below 12 mL/s suggests obstruction or detrusor dysfunction. A flow rate under 10 mL/s strongly suggests underlying pathology.

► Urodynamics

Urodynamic studies require measurement of bladder pressure during micturition. The pressure measured within the bladder (intravesical pressure) is a combination of the intra-abdominal pressure and the pressure generated by the detrusor. To determine the detrusor pressure, the intra-abdominal pressure is measured with a rectal catheter, and this pressure is subtracted from the total intravesical pressure (measured by the bladder catheter). The urine flow rates may then be assessed in light of the detrusor pressure. No consensus exists on a critical value for pressure and flow that is diagnostic of obstruction. Nomograms have been developed for evaluating the pressure-flow relationship and thus to categorize these values as obstructed, equivocal, or unobstructed.

► Electromyographic Recording

Needle or patch electrodes may be employed to record the activity of the external sphincter. This information is useful when obtained during micturition. Increased activity in the sphincter after voiding begins suggests detrusor-sphincter dyssynergia.

► Classification & Clinical Findings

Several classification systems exist that describe the variety of pathologic bladder conditions that develop secondary to neuropathies. Many bladder conditions are predictable on the basis of the neurologic lesion. A lesion above the brain stem (ie, stroke) affecting micturition frequently results in involuntary bladder contractions (detrusor hyperreflexia) with coordinated (synergistic) sphincter relaxation. These patients have urge incontinence.

A complete lesion of the spinal cord (ie, trauma) above the T12 vertebral body may leave the spinal reflex center intact. This often leads to what has been categorized as an upper motor neuron lesion. These patients have detrusor hyperreflexia and uncoordinated sphincter activity (detrusor-sphincter dyssynergia). Although detrusor contractions can generate abnormally high intravesical pressure, they are not effective in producing adequate urine flow because of the spastic external sphincter. Thus, there is residual urine. Bladder capacity is reduced. Detrusor contraction and mass reflexes can be initiated from certain trigger areas.

Figure 38-15B is a typical cystometrogram of a hyperreflexic bladder.

▲ **Figure 38-15.** Cystometrograms. **A:** Normal cystometrogram. **B:** Cystometrogram in a patient with hyperreflexic bladder caused by transection of the spinal cord above S2. **C:** Cystometrogram in a patient with an areflexic flaccid neuropathic bladder caused by a myelomeningocele.

An injury to the spinal reflex center or below often leads to what has been categorized as a lower motor neuron lesion. These patients often develop detrusor areflexia. Trauma is the most common cause, but tumors, ruptured intervertebral disks, and meningomyelocoele may also cause this type of neuropathic bladder. Both motor and sensory fibers are usually affected, and there is loss of sense of fullness (Figure 38–15C). These contractions are usually weak and unsustainable, and bladder emptying is incomplete, resulting in large amounts of residual urine.

The bladder dynamics in a person with a neuropathic bladder often change over time. This may occur secondary to changes in innervation (ie, tethering of spinal cord, multiple sclerosis, recovery from spinal shock) or changes in the bladder. For example, a patient with a hyperreflexic bladder and dyssynergic sphincter often develops a trabeculated, noncompliant bladder over time. These changes require periodic reevaluation of all patients with neuropathic bladders regardless of the initial classification.

► Differential Diagnosis

Cystitis, interstitial cystitis, and organic obstruction (eg, due to BPH or urethral stricture) are occasionally confused with neuropathic bladder, but associated neurologic lesions usually help make the diagnosis of neuropathic bladder. Psychosomatic disturbances can cause spasm of the external sphincter, incomplete voiding, retention, or incontinence.

► Complications

Common complications include urinary tract infection, stone formation, and incontinence. The most serious consequences of these lesions are the hydrodynamic back-pressure on the kidneys, hydronephrosis, infection, decompensation of the ureterovesical junction, and loss of renal function.

► Treatment

Immediately following spinal cord injury, there is a shock phase that may last a few weeks up to 2–3 years. The average time is 2–3 months. The bladder is completely dissociated from nervous control and thus has no sensation and is areflexic.

Treatment is aimed at avoiding the aforementioned complications in the hope of partial or complete recovery. During the shock phase, continuous closed drainage or, preferably, clean intermittent (every 4–6 hours) catheterization should be instituted until bladder activity is restored.

A. Hyperreflexic Bladder

In the hyperreflexic bladder, attaining a functional bladder depends on mobilizing residual urine and increasing the

bladder capacity. Residual urine volume can be decreased by reducing urethral resistance by several methods: alpha antagonists, surgery (eg, TURP), or clean intermittent catheterization.

Functional capacity can be increased by decreasing detrusor instability with anticholinergic drugs (eg, oxybutynin), Botox injection into the bladder with cystoscopic guidance, or by operative bladder augmentation. This is often performed with small or large intestine (enterocystoplasty).

Conversion to a flaccid areflexic bladder can be achieved by cord rhizotomy. The storage function of the bladder is preserved, and the patient can be managed by clean intermittent catheterization.

Supravesical urinary diversion may be called for in patients with upper tract deterioration due to elevated storage pressures or female incontinence. Male incontinence may be controlled by a condom catheter.

B. Areflexic Bladder

Function of the flaccid bladder can be improved by measures that facilitate complete emptying; these include voiding by the Credé maneuver (suprapubic pressure), transurethral resection of the bladder neck to reduce outlet resistance, and timed voiding or timed clean intermittent catheterization. An indwelling urethral catheter or suprapubic cystostomy is required in a few cases, but chronic indwelling tubes should be avoided if possible.

Suprapubic urinary diversion (ileal or colon conduit, etc) can circumvent deterioration of upper tracts. Implantable prosthetic sphincters, periurethral bulking agent injections, or urethral slings may also improve urinary control.

A new technique of microanastomosis of a lumbar ventral nerve root to the S3 ventral root has generated promising results in children with spina bifida. This technique is reported to result in improved bladder function in children with an areflexic bladder as well as those with a hyperreflexic bladder.

► Prognosis

Renal injury from elevated bladder pressure and infection are the most serious consequences of neuropathic bladder. When diversion or bladder augmentation is required, proper timing of the operation is essential for preservation of kidney function. Patients with a neuropathic bladder require close follow-up of their kidneys with renal ultrasound and serum creatinine determinations.

Van Arendonk KJ et al: Improved efficacy of extended release oxybutynin in children with daytime urinary incontinence converted from regular oxybutynin. *Urology* 2006;68:862.

OTHER DISEASES & DISORDERS OF THE GENITOURINARY TRACT

SIMPLE RENAL CYST

A simple renal cyst is usually unilateral and solitary but may be multiple and bilateral. The cause of this disorder is unclear. The cyst can compress and destroy adjacent parenchyma. Cysts contain fluid that resembles (but is not) urine. Most are diagnosed in patients after the fourth decade. Occasionally, what appears to be a simple cyst may in fact be a papillary cystadenocarcinoma—an uncommon form of renal cancer with both solid and cystic components. In those cases, however, ultrasound usually demonstrates a complex mass with both cystic and solid components.

Flank pain may be a presenting symptom, though most renal cysts are found incidentally on imaging for other purposes. CT scan and ultrasound are the most common imaging modalities. A mass may be felt in the flank or upper quadrant and must be distinguished from tumor. Urinalysis and tests of renal function are normal. If the CT scan or ultrasound reveals an equivocal cystic mass, cyst aspiration may be performed, the fluid submitted for cytologic examination, and the cyst filled with contrast material to delineate its wall. A simple cyst must be distinguished from adenocarcinoma of the kidney; ultrasonography or CT scan usually makes that distinction.

Complications are rare, but bleeding into or infection of a cyst may occur.

If the diagnosis of cyst is established, surgery is not necessary unless the lesion causes pain due to mass effect or endangers renal function. Simple percutaneous aspiration with instillation of 95% ethanol may suffice. If sclerosis fails, laparoscopic or open cyst decortication may be performed.

RENAL ARTERY ANEURYSM

Aneurysm of the renal artery is relatively rare. It results from weakening of the artery wall by arteriosclerosis, poststenotic dilation, intimal or perimedial fibroplasia, or trauma. If the aneurysm causes stenosis of the artery, hypertension may ensue secondary to ischemia and activation of the renin-angiotensin system. A plain abdominal x-ray may reveal a ring-like calcification in the wall. Angiography or CT scan is diagnostic.

Surgery is indicated in the following situations: (1) secondary renal ischemia and hypertension, (2) dissecting aneurysm, (3) aneurysm associated with pain or hematuria, (4) anticipation of pregnancy, (5) aneurysm coincident with significant stenosis, (6) radiographic evidence of incomplete calcification or increase in size on serial films, and (7) aneurysm containing thrombus with evidence of distal embolization. If the aneurysm ruptures, emergency nephrectomy may be necessary.

RENAL INFARCTION

The common causes of renal artery occlusion include emboli due to subacute infective endocarditis, atrial or ventricular thrombi, arteriosclerosis, polyarteritis nodosa, trauma, and, in the neonate, umbilical artery catheterization. Multiple emboli are common and lead to patchy renal ischemia. Occlusion of a main renal artery causes renal total infarction.

The patient may suffer from severe flank pain, or the lesion may be silent. Hematuria is common. Excretory urograms may reveal no excretion of radiopaque material or may only opacify a portion of the kidney. With complete acute occlusion of the main renal artery, a ureteral catheter drains no urine, yet the retrograde urogram reveals normal anatomy. Renal angiography, color Doppler ultrasound, or MRA makes the diagnosis by revealing occlusion of the artery or arterioles; a renal scan shows similar findings. CT scan after the intravenous injection of radiopaque medium shows no concentration in the ischemic area. Ureteral stone may mimic renal infarction, but urograms, CT scan, or angiograms distinguish one from the other. Following renal infarction, hypertension may develop secondary to renal ischemia; it may later resolve spontaneously.

If the diagnosis is made promptly (within 5-8 hours), thrombectomy or endarterectomy should be considered. Otherwise, anticoagulation therapy should be instituted (eg, heparin). Thrombolytic therapy (eg, streptokinase) may be used to lyse the clot. If permanent hypertension develops, definitive treatment of the arterial occlusion or nephrectomy (preferably laparoscopic) should be performed.

RENAL VEIN THROMBOSIS

Thrombosis of the renal vein affects both infants and adults and can be either acute or chronic. In children, thrombosis may be caused by severe dehydration (eg, due to ileocolitis and diarrhea or the nephrotic syndrome). In adults, it may be secondary to renal infection, ascending thrombosis of the vena cava, or caval occlusion due to tumor thrombus. There is usually flank pain and a palpable distended kidney. If renal vein thrombosis is secondary to infection, the patient is septic and urinalysis reveals pus cells and bacteria. In noninfectious cases, the urine may reveal microhematuria and mild proteinuria. The patient with bilateral involvement is azotemic. Nephrotic syndrome may develop. Excretory urograms show delayed opacification in an enlarged kidney. The calices are elongated. Later, the kidney may become atrophic. Renal angiography reveals stretching and bowing of arterioles. Selective renal venography demonstrates the thrombus, as does renal ultrasound.

Treatment should attempt to eliminate the underlying cause whenever possible. If the diagnosis of unilateral infected renal vein thrombosis can be established, nephrectomy should be performed. In bilateral disease, anticoagulant or thrombolytic therapy (or both) is required.

VESICAL FISTULAS

Vesical fistulas may be congenital or acquired. Congenital fistulas usually involve the urachus. Acquired fistulas may be iatrogenic or due to trauma, tumor, or inflammation.

The most common types of vesical fistulas are vesicovaginal, vesicointestinal, and vesicocutaneous. Vesicovaginal fistulas are commonly secondary to gynecologic or birth trauma; rarely, they occur as a complication of infiltrating cervical carcinoma. Vesicointestinal fistulas are most often due to inflammatory bowel disease: Crohn disease, diverticulitis, and appendicitis. Cystostomy in the presence of bladder outlet obstruction, bladder cancer, or foreign body may result in vesicocutaneous fistula.

Diagnostic maneuvers include cystoscopy, conventional cystography, barium enema or barium swallow, and CT scan with contrast infusion. Oral charcoal may be useful for detecting a urinary intestinal fistula, as the granules can be seen in spun urine under the microscope.

Therapy for vesicovaginal fistula requires surgical closure, with placement of an omental flap between the bladder and the vagina. For vesicointestinal fistula, the primary intestinal lesion must be resected and the bladder closed. An indwelling urethral catheter is necessary during the healing period.

INTERSTITIAL CYSTITIS

This lesion is most commonly found in middle-aged women. Urinary frequency both day and night is most often accompanied by suprapubic pain with bladder distention. The cause is uncertain, though some suggest an autoimmune collagen disease, while others have documented the presence of mast cells and mast cell mediators (histamine and prostaglandin) in bladder biopsy specimens of affected patients.

The diagnosis is based on the history and the results of cystoscopy under general anesthesia. Cystoscopy reveals a small-capacity bladder and punctate hemorrhage following hydrodistention. (Studies suggest this is a nonspecific finding.) Biopsy may reveal lymphocytic infiltration, mast cell infiltration, and submucosal fibrosis. In patients suspected of having interstitial cystitis, one must rule out carcinoma *in situ* with cystoscopy, urine cytologic study, and possible bladder biopsies of suspicious areas.

Treatment of established cases of interstitial cystitis often fails. First line treatment is with dietary modification of foods that can irritate the bladder mucosa (eg, caffeine, spicy foods). If poorly controlled by diet alone, pharmacotherapy with several different agents has shown utility. Pentosan polysulfate sodium is FDA approved for the treatment of interstitial cystitis. Antidepressants, antihistamines, and anticholinergics have also been utilized with some benefit. Temporary response has been obtained with bladder hydrodistention and intravesical instillations with agents such as dimethylsulfoxide. Systemic corticosteroids have their

proponents as well, and BCG has been tried with limited success. Some patients who are refractory to the above therapies undergo operative intervention. Neuromodulation with Interstim has demonstrated limited success. Finally, the last resorts of therapy include augmentation of bladder capacity by enterocystoplasty or, rarely, cystectomy and permanent urinary diversion.

URINARY STRESS INCONTINENCE

Involuntary loss of urine during stress (coughing, sneezing, or physical strain) is a common complaint of postmenopausal women. The cause is related to pelvic relaxation with age, resulting in descent of the trigone and proximal urethra. There is obliteration of the urethrovesical angle, which normally provides resistance at the bladder outlet. The diagnosis is made by the history and physical examination and urodynamic evaluation. When the bladder is full, the patient should be asked to cough while in both the supine and upright positions, producing incontinence. Digital pressure applied to the paraurethral tissues in an anterior direction through the vagina reestablishes the urethrovesical angle and prevents stress incontinence (Marshall test).

Treatment in patients with normal bladder function and low residual urine is initiated with behavioral therapy and Kegel exercises; if unsuccessful, pharmacologic methods include anticholinergics to minimize any concomitant urge incontinence. Definitive management is surgical. Currently, the most effective surgical approach is a transvaginal sling procedure with a piece of autologous fascia or synthetic mesh placed at the level of the bladder neck or mid-urethra. Other approaches include the use of bulking agents (eg, calcium hydroxylapatite) injected into the periurethral tissues, resulting in increased urethral outflow resistance.

FEMALE URETHRITIS & PERIURETHRITIS

Urethritis in the female may be acute or chronic. Acute urethritis can be gonorrheal in origin. Chemical urethritis is occasionally acquired from exposure to soap or bath oils. Chronic urethritis is a common problem in women, since the female urethra is exposed to pathogenic bacteria because of its anatomic location. Urethral trauma, instrumentation, and increase in the number of pathogenic organisms lead to infection and overt urethritis. Urethritis usually precedes cystitis.

Hormonal changes associated with menopause cause vaginal and urethral mucosal changes, leading to irritative symptoms and increased susceptibility to inflammation.

Urethritis usually causes irritative voiding symptoms similar to those of cystitis and, occasionally, functional obstructive symptoms. Examination may reveal urethral discharge, marked tenderness, or congested everted mucosa at the external meatus. Induration of the urethra may be associated with vaginitis and cervicitis. Endoscopy may reveal

obstruction, mucosal congestion, and inflammatory polyps. Urethral calibration rarely reveals obstruction. Spasm of the external sphincter may be noted.

Treatment is directed to the underlying cause. Estrogen cream is indicated for senile vaginitis. Surgical treatment consists of urethral dilation and opening and draining infected periurethral ducts. Alpha-blockers given orally may also help decrease urethral resistance. Correction of vaginitis, cervicitis, and cervical erosions helps in ameliorating symptoms.

FEMALE URETHRAL CARUNCLE

Urethral caruncle, commonly seen after menopause, represents granulomatous overgrowth of the posterior lip of the external meatus. The caruncle is tender and causes pain with intercourse and urination. The primary concern is exclusion of urethral cancer. Treatment is complete excision.

FEMALE URETHRAL DIVERTICULUM

Urethral diverticulum in the female commonly presents as recurrent lower urinary tract infection. It should be suspected whenever urinary infection fails to resolve with treatment. Symptoms are urinary dribbling and cystic swelling in the anterior vaginal wall during voiding. If diverticulum is suspected, it can usually be identified during panendoscopy and opacified by contrast medium on a voiding cystourethrogram while occluding the external meatus. Pelvic MRI provides excellent diagnostic detail. These lesions occasionally contain stones or tumors. Treatment consists of transvaginal diverticulectomy.

SPERMATOCELE

Spermatocele is a retention cyst of a tubule of the rete testis or the head of the epididymis. The cyst is distended with a milky fluid that contains sperm. Located at the superior pole of the testis and caput epididymidis, the spermatocele is soft and fluctuant and can be transilluminated. No treatment is needed unless the spermatocele is painful, in which case surgical excision may be performed.

VARICOCELE

Varicocele is due to incompetent valves in the testicular vein, permitting transmission of hydrostatic venous pressure; distention and tortuosity of the pampiniform plexus results. Varicocele is found in 15% of male adolescents with left-sided predominance (90%), presumably because of venous drainage of the left testes to the left renal vein, causing increased retrograde venous pressure. Bilateral varicoceles are palpable in fewer than 2% of male adults.

Mild varicoceles are commonly asymptomatic, but a dragging scrotal sensation may be noted. Varicocele may lead to infertility in some men.

Asymptomatic varicocele is best untreated unless it is a suspected factor in male infertility. Treatment then consists of operative ligation of the spermatic vein at or above the internal inguinal ring. In recurrent varicocele, transfemoral catheterization and occlusion or ablation of the spermatic vein may be performed with a detachable balloon or sclerosing agents. The technical success rate is high.

TORSION OF THE SPERMATIC CORD

Torsion of the spermatic cord (intravaginal torsion or torsion within the space of the tunica vaginalis) is most common in adolescent boys. A twist in the spermatic cord interferes with testicular blood supply. If torsion is complete, testicular infarction may occur within 4-6 hours. The cause is unknown, but an underlying anatomic abnormality (spacious tunica vaginalis, loose epididymotesticular connection, undescended testis) is usually present.

Clinical findings consist of precipitous onset of lower abdominal and scrotal pain and scrotal swelling. There may be a history of previous trauma in young adolescents. The testis is swollen, tender, and retracted. The pain is not relieved by testicular support. The cord above the swelling is normal. The cremasteric reflex is usually absent on the affected side.

Torsion must be differentiated from orchitis, epididymitis, and pain due to testicular trauma. Technetium 99m pertechnetate scan may differentiate orchitis-epididymitis from testicular torsion if performed early in the course of symptoms: The former demonstrates increased blood flow, in contrast to the ischemic pattern of torsion. Color Doppler ultrasound is more definitive and less time consuming and can delineate the lack of testicular blood flow. No radiologic study is completely accurate, and imaging should be used to confirm the clinical decision that the cause of the acute scrotum is not torsion. If the diagnosis cannot be established by examination, history, and imaging, exploration is required.

Torsion of the spermatic cord is a surgical emergency! Contralateral orchiopexy is always necessary because of frequent bilateral involvement (ie, the “bell clapper” deformity: lack of fixation of the cord structures by the testicular mediastinum) and the high incidence of recurrent torsion and infertility in bilateral cases.

TORSION OF TESTICULAR APPENDAGES

The epididymis and the testicle often have a vestigial remnant of embryologic ducts known as an appendix testis or appendix epididymis. These structures can undergo spontaneous infarction usually in young boys, causing acute testicular pain and swelling that may be difficult to differentiate from testicular torsion. With torsion of the appendix testis or epididymis, physical examination often demonstrates point tenderness at the site of the torsed appendage. Occasionally, the infarcted appendage can be seen through

the scrotal wall as a “blue dot” sign on the scrotum. This sign is only visible early in the course, prior to hydrocele formation and onset of scrotal edema. Scrotal ultrasound occasionally delineates the enlarged appendage and a normal testicle, establishing the diagnosis. In most cases—and certainly in equivocal ones—immediate scrotal exploration and removal of the infarcted appendage is required to rule out testicular torsion. Although the appendages often occur bilaterally, appendiceal torsion does not; thus, removal of the opposite appendage is not indicated.

MALE INFERTILITY

Male infertility accounts for 30%-50% of infertile couples (10%-15% of marriages). Both partners should be evaluated for causes of infertility.

The causes of male infertility include the following: congenital anomalies (genetic, such as Klinefelter’s syndrome, or developmental, such as absent vas deferens); trauma (both testicular, resulting in atrophy, and neurologic, resulting in erectile or ejaculatory dysfunction); infections (either systemic or reproductive organ specific); endocrine disorders (pituitary insufficiency, androgen deficiency); acquired anatomic abnormalities (varicocele, vasectomy); or drug side effects (nitrofurantoin, estrogens, antineoplastic agents).

► Diagnosis

The most important aspect of infertility evaluation is the history, which uncovers the cause in many patients. The physical examination is no less important and may reveal small testicles, a varicocele, or absence of the vas deferens.

A. Semen Analysis

Semen analysis is essential in evaluation of male factor infertility. At least two samples should be analyzed, since values may vary over time and with the method of collection. The specimen is produced by masturbation after 3 days of ejaculatory abstinence and collected in a clean wide-mouth container and examined within 2 hours. Determination of the volume, pH, liquefaction, sperm count, viability, abnormal forms, and motility constitutes a complete analysis. Normal values include volume of more than 2.0 mL, concentration greater than 20 million sperm per mL, more than 50% motile sperm, and 75% or more viable sperm (World Health Organization criteria).

B. Hormone Studies

Patients with no sperm in the ejaculate (azoospermia) or very low counts (oligospermia, < 10 million sperm/mL) should have serum FSH, LH, and testosterone levels measured. Patients with low testosterone should have prolactin levels checked and, if elevated, should be investigated for

pituitary tumor. A significant elevation of FSH represents a problem with spermatogenesis.

C. Testicular Biopsy

Testicular biopsies are indicated in azoospermic patients to distinguish obstructive versus parenchymal disease. Testicular biopsy should be performed in patients with unexplained oligospermia to establish a histologic diagnosis, to assess prognosis, and to direct treatment. If the serum FSH is more than two times normal, one may presume the presence of severe and irreversible testicular damage without confirmatory testis biopsy.

Vasography requires injection of contrast material into the vas. The purpose of this study is to delineate obstruction of the vas, epididymis, seminal vesicle, or ejaculatory duct. Vasography is used in patients who are azoospermic and have no evidence of retrograde ejaculation while demonstrating normal spermatogenesis on testicular biopsy. Seminal fructose levels should be obtained before operative exposure of the vas. Absence of fructose would indicate obstruction of the ejaculatory duct, and if this diagnosis is confirmed by vasography, the obstructing tissue may be resected by transurethral methods.

D. Other Diagnostic Studies

The **sperm penetration assay**, performed by incubation of sperm with hamster eggs whose zona pellucida has been enzymatically removed, offers an objective method of determining the ability of sperm to penetrate the ovum. The **cervical mucus penetration test** compares sperm motility in cervical mucus with a known standard. Although these two important parameters of sperm function can be evaluated, neither test alone can establish the cause of male factor infertility.

Antisperm antibodies can be measured in the serum of either the male or female partner or in the seminal fluid. This assessment is indicated when spontaneous sperm agglutination or decreased sperm motility is noted on semen analysis. If antisperm antibodies are found, immunosuppressive therapy in the form of steroids may be effective in reducing agglutination (clumping) and increasing motility. Another method of treating antisperm antibodies is *in vitro* sperm washing with immunobeads coated by antihuman antibody. The sperm not bound by antibody remain in the supernatant and can be used for intrauterine insemination.

Studies to detect a nonpalpable varicocele are not recommended except in cases in which the physical examination is inadequate. Physical examination is the most effective method of detecting clinically significant varices. Venography is reserved for patients with recurrent varices, since identification of collateral venous channels would direct choice of therapy.

Transrectal ultrasound is used to support the diagnosis of ejaculatory duct obstruction in the azoospermic patient. Absence of the seminal vesicles or distention due to distal obstruction can be identified. This study should be preceded by measurement of fructose in the ejaculate (lack of fructose suggests obstruction of the ejaculatory duct) and examination of postejaculate urine (to determine the presence of sperm, suggesting retrograde ejaculation).

► Treatment

A. Nonoperative Treatment

Primary male infertility may be caused by hypogonadotropic hypogonadism, diagnosed by demonstrating low serum levels of FSH, LH, and testosterone. Spermatogenesis may be stimulated by administration of hCG followed by FSH. Isolated absence of either FSH or LH is rare; the LH deficiency is overcome by administration of testosterone, and lack of FSH is treated by administration of menotropins. Hyperprolactinemia may contribute to male infertility and would be treated with bromocriptine.

Infection of the reproductive organs should be treated when found during evaluation of male infertility. Infection may cause infertility immediately by several mechanisms: decreased spermatogenesis due to hyperthermia, immune interaction with sperm causing agglutination and decreased motility, as well as later sequelae such as obstruction of the ejaculatory tract. Pyospermia suggests the diagnosis, and treatment should be designed to eliminate the common pathogens: *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, and *Ureaplasma urealyticum* (all are sensitive to tetracycline).

If antisperm antibodies are found in either partner, steroids may be used to suppress the immune system. One must use steroids with caution and after thorough discussion of possible side effects with the patient; acne, hypertension, gastrointestinal bleeding, and avascular necrosis of the hip have been reported with steroid administration. Response to treatment is assessed by repeat semen analysis and measurement of antisperm antibodies in the patient's serum. Sperm washing in an attempt to remove cytotoxic antibodies may improve motility and decrease clumping; washed semen may then be instilled into the uterus (artificial insemination of the husband's semen) or used in conjunction with *in vitro* fertilization (IVF) techniques.

Retrograde ejaculation or lack of seminal emission—usually due to spinal cord injury or sympathetic nerve injury during retroperitoneal surgery leading to bladder neck (ie, internal sphincter) incompetence—can be treated with α -adrenergic drugs or antihistamines to reestablish internal sphincter function and antegrade ejaculation. Alternatively, alkalized postejaculate urine can be collected and centrifuged and the concentrated sperm instilled into the female partner's uterus.

Clomiphene and tamoxifen are antiestrogens that are currently used in patients with idiopathic oligospermia, though the efficacy of these medications has been doubted.

B. Operative Therapy

Ligation of varicocele yields pregnancy in 30%-50% of patients. Several approaches are available, including inguinal and retroperitoneal. Transvenous occlusion of the spermatic vein by balloon is useful especially in cases of recurrent varicocele.

Obstruction of the epididymis-vas system may be amenable to vasovasostomy or vasoepididymostomy. Currently, these procedures are performed with the aid of the operating microscope, and patency is established in 50%-90% of cases.

Obstruction of the ejaculatory ducts is rare. When this diagnosis is made, transurethral resection of the ducts may establish patency.

C. Assisted Reproductive Techniques

These include the following: artificial insemination with husband's sperm (AIH), gamete intrafallopian transfer, and IVF using intracytoplasmic sperm injection after retrieving eggs by transvaginal ultrasound guidance and sperm by testicular aspiration in selected partners. In cases of male factor infertility not amenable to treatment, artificial insemination by donor sperm is also available.

PRIAPISM

Priapism is a rare disorder in which prolonged, painful erection occurs, usually not associated with sexual stimulation. The blood in the corpora cavernosa becomes hyperviscous but not clotted. About 25% of cases are associated with leukemia, metastatic carcinoma, sickle cell anemia, or trauma. In most cases, the cause is uncertain.

If the erection does not subside, needle aspiration of the sludged blood of the corpora followed by lavage with alpha-adrenergic agents such as phenylephrine should be performed. Delayed or unsuccessful treatment may result in impotence. Unsuccessful treatment calls for the Winter procedure, in which a biopsy needle is passed through the glans into one of the corpora, creating a fistula between corpora cavernosa and corpus spongiosum. If this procedure is successful, then potency is usually maintained. Other procedures include excising the tunica albuginea at the tip of the corpora cavernosum, proximal cavernosal-spongiosum shunt, and saphenous vein-cavernous shunt. If priapism persists, impotence results.

In sickle cell anemia, hydration and hypertransfusion often give relief and should constitute initial therapy.

PEYRONIE'S DISEASE

Fibrosis of the dorsal covering sheaths of the corpora cavernosa occasionally occurs without known cause in men over age 45. Trauma to the penis during intercourse has been implicated in the etiology of Peyronie's disease. The fibrosis does not permit the involved surface to lengthen with erection.

tion, thus leading to dorsal chordee. The disorder may be due to vasculitis in the connective tissues. Palpation of the penile shaft reveals a raised, firm plaque dorsally. There is an association with Dupuytren contracture.

Controversy exists regarding treatment. Expectant therapy or medical treatment, including vitamin E, para-aminobenzoic acid, colchicine, and intralesional verapamil may limit progression of disease. Operative therapy is necessary for patients who do not respond or for impotent patients. In the potent patient, either plication of the tunica albuginea on the opposite side of the plaque or a Nesbit procedure—excision of an ellipse of the tunica albuginea from the ventral convex aspect of the shaft and suture closure—or plaque excision and dermal grafting have been used successfully. If the patient is impotent, insertion of a penile prosthesis is the procedure of choice.

Taylor FL, Levine LA: Peyronie's disease. *Urol Clin North Am* 2007;34:517.

PHIMOSIS & PARAPHIMOSIS

Phimosis—inability to retract the foreskin to expose the glans—may be congenital but is more often acquired. At birth, the foreskin cannot be easily retracted, but by age 3, the prepuce becomes pliant and the glans can be exposed and cleansed. If the foreskin is then retractable, circumcision is not necessary. Acquired phimosis is usually a result of chronic and recurrent bacterial balanitis (infection of the prepuce), common in patients with diabetes or balanitis xerotica obliterans. These patients are best treated by circumcision.

Paraphimosis is the inability to reduce a previously retracted foreskin. The prepuce becomes fixed in the retracted position proximal to the corona. With prolonged retraction, lymphedema of the prepuce exacerbates the condition and increases the circumferential pressure of the shaft proximal to the glans. Manual reduction can usually be accomplished using the index fingers to pull the prepuce distally while pushing the glans into the prepuce. If this measure fails, the preputial cicatrix may be incised (dorsal slit) and the foreskin reduced with relative ease. Circumcision may be performed as an elective procedure once the edema has subsided.

CONDYLOMATA ACUMINATA

Condylomata acuminata are wart-like lesions that occur on the penis, scrotum, urethra, and perineum in men and the vagina, cervix, and perineum in women. They are caused by human papillomavirus and are usually transmitted by sexual contact. Pain and bleeding are common presenting complaints. Warts outside the urethra can be treated with excision, application of podophyllum resin, liquid nitrogen, or CO₂ laser. Urethroscopy is needed to determine the proximal extent of lesions in the urethra. Intraurethral fulgura-

tion, CO₂ laser treatment, injection of fluorouracil solution, or interferon- α can be therapeutic.

IMPOTENCE

Impotence is the inability to obtain and sustain an erection satisfactory for sexual intercourse.

► Causes of Impotence

Causes can be grouped into the following categories: neurologic, vascular, endocrine, systemic, pharmacologic, and psychological. Treatment is directed accordingly.

A. Neurologic

Reflex erections are mediated by the afferent fibers of the pudendal nerve and efferent fibers of the parasympathetic outflow (S2-4). Psychogenic erections are initiated via cerebral centers. Specific neurologic diseases that may cause impotence may be congenital (spina bifida), acquired (cerebrovascular accident, Alzheimer disease, multiple sclerosis), iatrogenic (electroshock therapy), neoplastic (pituitary or hypothalamic tumors), traumatic (cord compression), infectious (tabes dorsalis), and nutritional (vitamin deficiency).

B. Vascular

Vascular causes of impotence may be cardiac (anginal syndromes, congestive failure), aortoiliac disease (Leriche syndrome, atherosclerosis, and other embolic phenomena), microangiopathy (diabetes, radiation injury), and abnormal venous drainage.

C. Endocrine

The accepted endocrine causes of impotence are hypogonadism, hyperprolactinemia, pituitary tumors, hypothyroidism, Addison disease, Cushing syndrome, acromegaly, and testicular feminizing syndrome.

D. Pharmacologic

Impotence is a common and often unsuspected complication of many therapeutic and illicit drugs. Major groups that may cause sexual dysfunction are the following: tranquilizers, antidepressants, anti-anxiety agents, anticholinergic drugs, antihypertensives, and many drugs with abuse potential. One should recognize that virtually all antihypertensives (including diuretics) can be associated with impotence or ejaculatory dysfunction. Drugs with abuse potential include alcohol (both as a direct affect and secondary to cirrhosis) and cocaine.

E. Psychogenic

Up to 50% of cases of impotence are related to psychogenic factors. Establishing an organic cause of impotence is impor-

tant in choosing appropriate therapy. Factors that indicate a psychogenic cause are the following: selective erectile dysfunction (episodic, normal nocturnal erections, normal erections with masturbation), sudden onset, associated anxiety or external stress, affect disturbances (anger, anxiety, guilt, fear), and patient convinced of an organic cause.

► **Diagnosis**

The history and physical examination suggest the cause in most cases. Confirmatory tests are necessary to ensure an appropriate choice of therapy.

In investigating a possible neurologic cause of impotence, the neurologic examination should include review of systems with respect to bladder and bowel function. More invasive studies include a cystometrogram, electromyography of the external urethral sphincter, and bulbosphincteric reflex latency.

Vascular impotence is suggested by signs of peripheral vascular disease as well as a history of atherosclerotic heart disease. Noninvasive diagnostic testing is performed with penile duplex Doppler studies to assess arterial inflow. Venous leak can be evaluated with cavernosography and cavernosometry. Arteriography is rarely required but may be indicated in patients with a history of pelvic trauma and those considering microvascular arterial revascularization.

Endocrine evaluation mandates measurement of serum testosterone and prolactin; many investigators include assessment of FSH and LH. Routine automated chemical screening may suggest other hormonal abnormalities that require additional testing. These studies should also detect systemic disease capable of causing impotence: cirrhosis, renal failure, scleroderma, and diabetes.

Psychogenic impotence may be established by nocturnal penile tumescence monitoring or outpatient snap-gauge cuffs. Additional testing includes one of the following: Minnesota Multiphasic Personality Inventory, DeRogatis Sexual Function Inventory, and Walker Sex Form.

► **Treatment**

A. Nonoperative Treatment

First-line treatment includes oral phosphodiesterase inhibitors (sildenafil, vardenafil, tadalafil). These medications are contraindicated in men with heart disease who are taking nitroglycerin. These medications work in patients who have normal blood flow and neurologic innervation. In patients without arterial-vascular causes of impotence, intracorporal injections of papaverine, phentolamine, or prostaglandin E_1 (or all three) offer a nonoperative means of restoring sexual function. Intractable psychogenic impotence may also respond to this treatment. Intraurethral pellets of alprostadil (prostaglandin E_1) can also be used; however, they often cause pain and are not favored by most patients. Finally, a vacuum erection device can be used to sustain erection.

Endocrine disturbances responsible for impotence include low testosterone and hyperprolactinemia. Testosterone deficiency is treated by replacement therapy using a once-daily topical testosterone gel or depot testosterone intramuscular injection every 2-3 weeks. Hyperprolactinemia is treated by bromocriptine therapy; the patient should be evaluated to assess the presence of a pituitary tumor.

Pharmacologic causes of impotence require altering medical treatment to ameliorate or eliminate secondary impotence. The ability to change medications depends on the severity of the underlying disease.

Psychogenic impotence is treated by a trained sex therapist, and response may be anticipated in most cases. The importance of eliminating organic causes of impotence before embarking on psychological therapy is obvious. The best psychological methods applied to organic impotence do not resolve the dysfunction but serve to frustrate both the therapist and patient.

B. Operative Treatment

Penile prosthesis insertion is currently the most common operative method for treatment of impotence. Two categories of prosthesis are in use: semirigid and inflatable. The semirigid prostheses are composed of a rigid shaft and a flexible hinge at the penile-pubic junction or a malleable soft metal case within the prosthesis; the erection is constant and is satisfactory to effect vaginal penetration, but the penile circumference is not equal to that of a natural erection.

Inflatable prostheses offer erections more similar in size to those experienced by the patient prior to the onset of impotence when compared to those achieved by semirigid prostheses. Two types of inflatable prostheses are available. The standard inflatable prosthesis consists of two corporal inflatable rods, a reservoir situated in the retropubic space, and a pump placed in the scrotum; the new inflatable rods combine the simplicity of two corporal rods with the sophistication of a self-contained pump and reservoir system (FlexiFlate and Hydroflex), permitting the convenience of inflation and deflation without tubing and multiple components.

Satisfactory results are achieved in 85% of patients. Complications common to both types of prostheses are infection and erosion of skin or urethra. The inflatable prostheses are also at risk for mechanical failure of the pump, tubing or reservoir leak, and aneurysm or rupture of the corporal cylinders.

Arterial revascularization of the penile arteries has met with limited success. Aortoiliac reconstruction improves erectile function in only 30% of cases. Microsurgical revascularization of the penile arteries (dorsal artery of the penis or deep corporal arteries) is successful in about 60% of patients. While these methods avoid the risks of prosthetic infection and offer the advantage of reestablishing the natural physiologic mechanisms or erection, the mediocre

success rate (when compared with the results of prosthetic insertion) would suggest that microsurgical penile revascularization be reserved for carefully selected cases.

MULTIPLE CHOICE QUESTIONS

1. During development, the kidneys pass through three embryonic phases, including all of the following except
 - A. Prenephros
 - B. Pronephros
 - C. Mesonephros
 - D. Metanephros
2. The most common site for an undescended testis to reside is
 - A. Just outside the external ring
 - B. Inside the abdomen
 - C. In the inguinal canal
 - D. In the wall of a sliding hernia sac
 - E. None of the above
3. Patients evaluated for hematuria are considered low risk for malignancy based upon all of the following except
 - A. Less than 40 years of age
 - B. No history of pelvic irradiation or cyclophosphamide exposure
 - C. Non-smokers
 - D. Have a history of urinary tract infections
 - E. Microscopic hematuria
4. Renal stones composed of calcium salts can be promoted by
 - A. Hyperoxaluria
 - B. Hypercitrauria
 - C. Hypocalciuria
 - D. Hypouricosuria
 - E. All of the above
5. Palliative therapy for prostate cancer can include
 - A. LHRH antagonists
 - B. Estrogen blockade
 - C. Transurethral prostatectomy
 - D. Somatostatin agonists
 - E. Depot testosterone therapy

Gynecology

39

R. Kevin Reynolds, MD

PERTINENT HISTORY & PHYSICAL EXAM FOR GYNECOLOGIC DISEASES

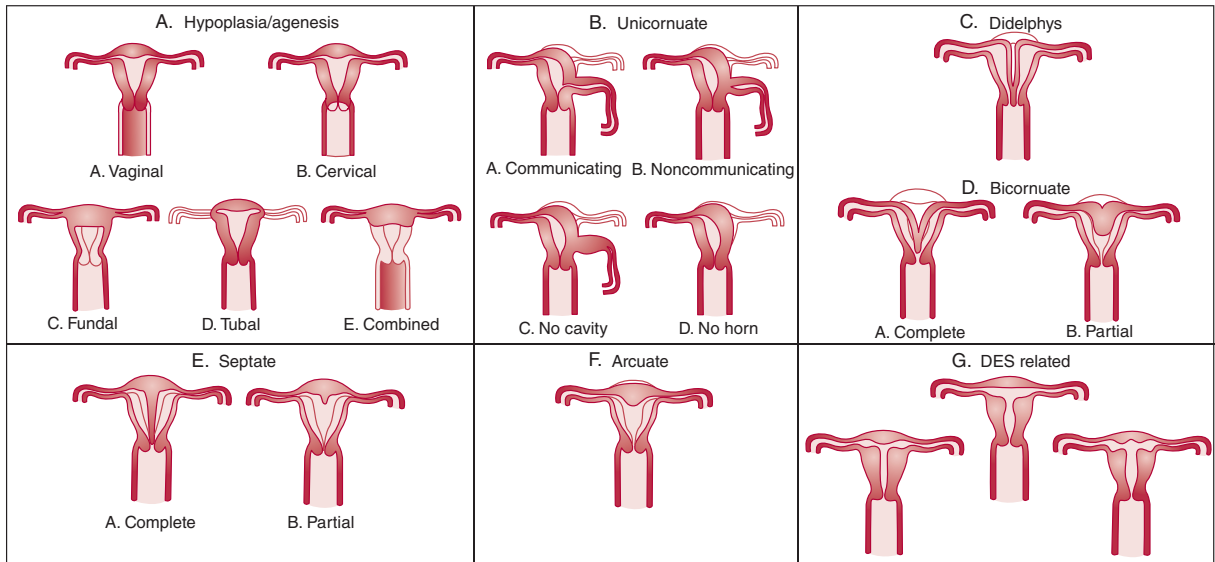

Accurate diagnosis and treatment of gynecologic disease begins with obtaining a complete history and physical examination. A thorough history should include

- First day of the most recent menstrual cycle
- Current genital tract symptoms
- Age at first menses (menarche)
- Interval from starting one menses to the next (cycle length)
- Duration and amount of menstrual flow
- Presence or absence of irregular or unexplained bleeding
- Symptoms associated with each menstrual cycle such as cramping before or during menses
- Other genital tract symptoms such as urinary or fecal incontinence, prolapse, dyspareunia, discharge, or pruritus
- Sexual history including assessment of risk factors such as knowledge of safe sex practices, age of first intercourse (coitarche), number and gender of partners, and presence of any history of abuse
- Number of pregnancies and subsequent outcome including term delivery, mode of delivery, preterm delivery, miscarriage, or abortion
- Contraceptive use including type, duration
- History of sexually transmitted disease such as infection with human papillomavirus (HPV), gonorrhea, or Chlamydia
- Adequacy of cervical cancer screening with Pap tests including date of most recent screen and any prior history of abnormal screens
- History of any gynecologic surgery including type, date, and indication
- Age of menopause
- Presence of postmenopausal bleeding regardless of amount of flow
- Hormone therapy of any type including oral contraceptives, postmenopausal estrogen replacement therapy, hormone therapy of breast cancer, etc
- Family history of pertinent cancer sites including ovarian cancer, endometrial cancer, breast cancer, and colorectal cancer. Determine the age at time of cancer diagnosis and relationship of the affected individual to the patient
- Determine the ethnicity of the patient regarding potential for hereditary diseases

Perform a complete pelvic examination. Inspect external genitalia including vulva and urethra for development, symmetry, and visible lesions. Place a vaginal speculum to inspect the vagina and cervix for symmetry, or visible lesions and perform Pap test, cultures, or wet mount tests as indicated to evaluate symptoms or update screening. Bimanual examination is then performed with careful compression of pelvic viscera between the examiner's hand on the abdominal wall and the finger(s) in the vagina. The process is repeated with the rectovaginal examination whereby one finger is placed in the vagina and one is inserted into the rectum. The rectovaginal exam allows the examiner to feel higher into the pelvis and may improve the ability to feel the cardinal and uterosacral ligaments, cul de sac peritoneum, ovaries, rectocele, and sphincter integrity. The rectovaginal exam is particularly important for assessing pelvic masses or malignancies, rectocele, and fecal incontinence.

EMBRYOLOGY & ANATOMY

Development of the reproductive tract in the female fetus results from fusion and differentiation of the Müllerian ducts and the urogenital sinus. Fusion defects may result in duplication, malformation, or absence of genital tract structures.

▲ **Figure 39–1.** Classification of müllerian anomalies. DES, diethylstilbestrol. (From Schorge JO, Williams JW: *Williams Gynecology*, New York: McGraw-Hill, 2008.)

The most common defects are imperforate hymen, presence of longitudinal or transverse septae within the vagina, congenital absence of the vagina, and duplication defects of the uterus (Figure 39–1). The etiology of most of these congenital defects is idiopathic, but some cases arise as a result of teratogens such as androgen exposure to the developing fetus during the first and second trimesters.

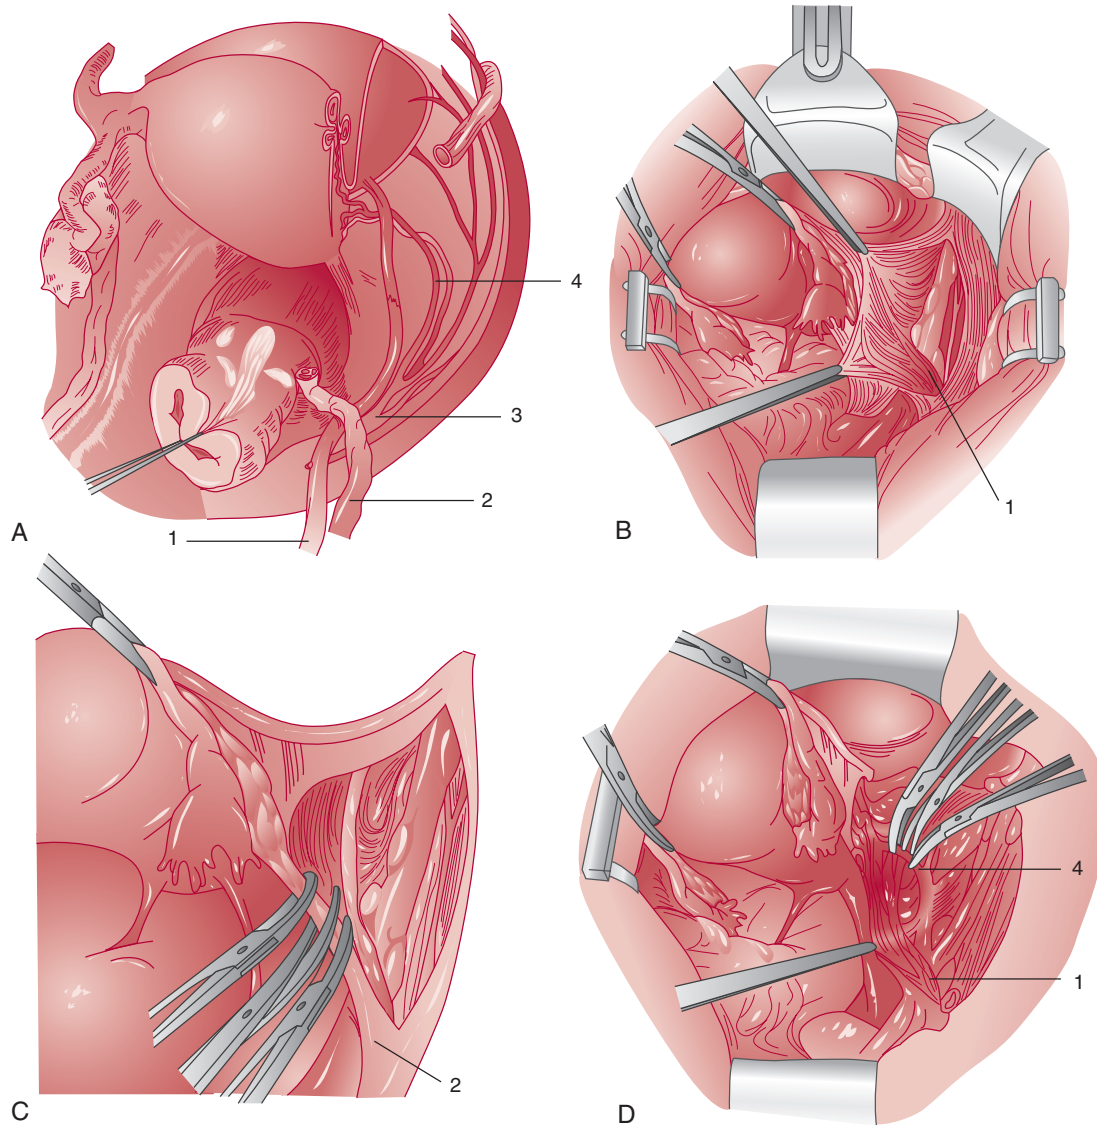

Careful examination of the newborn is necessary. cursory examination of the genital structure of the newborn may result in errors of gender assignment. Ultrasound and/or MRI, examination under anesthesia, and possible laparoscopy or hysteroscopy provide information for accurate diagnosis. One-third or more of children diagnosed with genital tract anomalies will have associated with anomalies of the urinary tract such as absent kidney, horseshoe kidney, and duplication of ureters.

The pelvis is a space constrained by bony architecture and filled with gastrointestinal urologic and gynecologic viscera. The blood supply is rich, including the external and internal iliac arteries and veins, and numerous branches within the pelvis. Motor nerves including the sciatic, obturator, and femoral nerves transit the pelvis along the pelvic sidewall. Sensory nerves including the genitofemoral nerve are superficially located and easily injured. The ureter is closely placed to the uterine artery and is at risk for injury during hysterectomy procedures (Figures 39–2A and 39–2B). A pelvic surgeon must be intimately familiar with the close spacing of critical pelvic structures to minimize risk of injury.

THE LOWER GENITAL TRACT: VULVA, VAGINA, & CERVIX

SCREENING & TREATMENT OF PREMALIGNANT LOWER GENITAL TRACT NEOPLASIA

As recently as 1945, cervical cancer and related lower genital tract cancers were the most common cancers in women. With the advent of the Pap test in the 1940s, cervical cancer incidence began to fall with more than an 80% reduction of risk of mortality in the ensuing six decades. It is now understood that virtually all cervical cancers and some vaginal and vulvar cancers are caused by persistent infection with oncogenic strains of the human papillomavirus (HPV). There are more than 75 HPV types identified, with types 6 and 11 most commonly associated with condyloma and types 16 and 18 associated with preinvasive and invasive carcinoma. Prevalence of HPV infection is as high as 80% of the population, but most infections are transient in nature. With appropriate screening and treatment to detect individuals with persistent high-risk HPV infection, the risk of developing invasive cervical cancer is low. In parts of the world without screening, cervical cancer remains prevalent and is the second most common cancer diagnosis for un-screened women. FDA approval of vaccination effective for the prevention of oncogenic HPV strains occurred in 2006 and has the potential to greatly reduce HPV mediated lower genital tract cancers in women.

▲ **Figure 39-2.** Pelvic retroperitoneal anatomy. **A:** Dissected right retroperitoneal space illustrating the course of the pelvic ureter. The right uterine adnexa are transected adjacent to the uterus, the ovarian vessels are severed just distal to the pelvic brim, and the peritoneum is removed from the right pelvic sidewall and the right portion of the bladder. The ureter (1) enters the pelvis by crossing over the bifurcation of the common iliac artery just medial to the ovarian vessels (2). It then descends medial to the branches of the internal iliac artery (3). The ureter then courses through the cardinal ligament and passes under the uterine artery (4, “water under the bridge”) approximately 1–2 cm lateral to the cervix at the level of the internal cervical os. The origin of the uterine artery from the internal iliac artery (3) is shown. The ureter then courses medially toward the base of the bladder. The distal part of the ureter is associated with the upper portion of the anterior vaginal wall. **B:** The retroperitoneal space is entered, and the peritoneum is retracted medially to show the ureter (1) crossing over the external and internal iliac artery bifurcation. Note that the ureter remains attached to the peritoneum of the pelvic sidewall and the medial leaf of the broad ligament. **C:** The ovarian vessels (2) are clamped and transected after visualization of the ureter. **D:** The uterine artery (4) is being clamped and transected. Note the ureter (1) crossing under this vessel lateral to the cervix.

A number of professional groups, including the American Cancer Society, American College of Obstetricians and Gynecologists, American Society for Clinical Pathology, American Society for Colposcopy and Cervical Pathology (ASCCP), and the National Comprehensive Cancer Network have issued consensus guidelines for cervical cancer screening that were updated in 2012. The US Preventive Services Task Force issued nearly identical recommendations in 2012. The guidelines address initiation of screening, screening interval, and discontinuation of screening.

When to initiate screening

Begin at age 21

When to discontinue screening

1. Age > 65 with adequate negative prior screening
2. Hysterectomy
3. Discontinuation of screening should not occur if the patient has a history of CIN2, CIN3, or adenocarcinoma *in situ*. In this case screening should continue for 20 years

Screening interval

1. Women aged 21-29 years
 - a. Cytology alone every 3 years
 - b. Liquid-based or glass-smear cytology is acceptable
2. Women aged 30-65 years
 - a. Cytology with high-risk HPV cotest every 5 years (preferred)
 - b. Cytology alone every 3 years (acceptable)
3. Women vaccinated against HPV

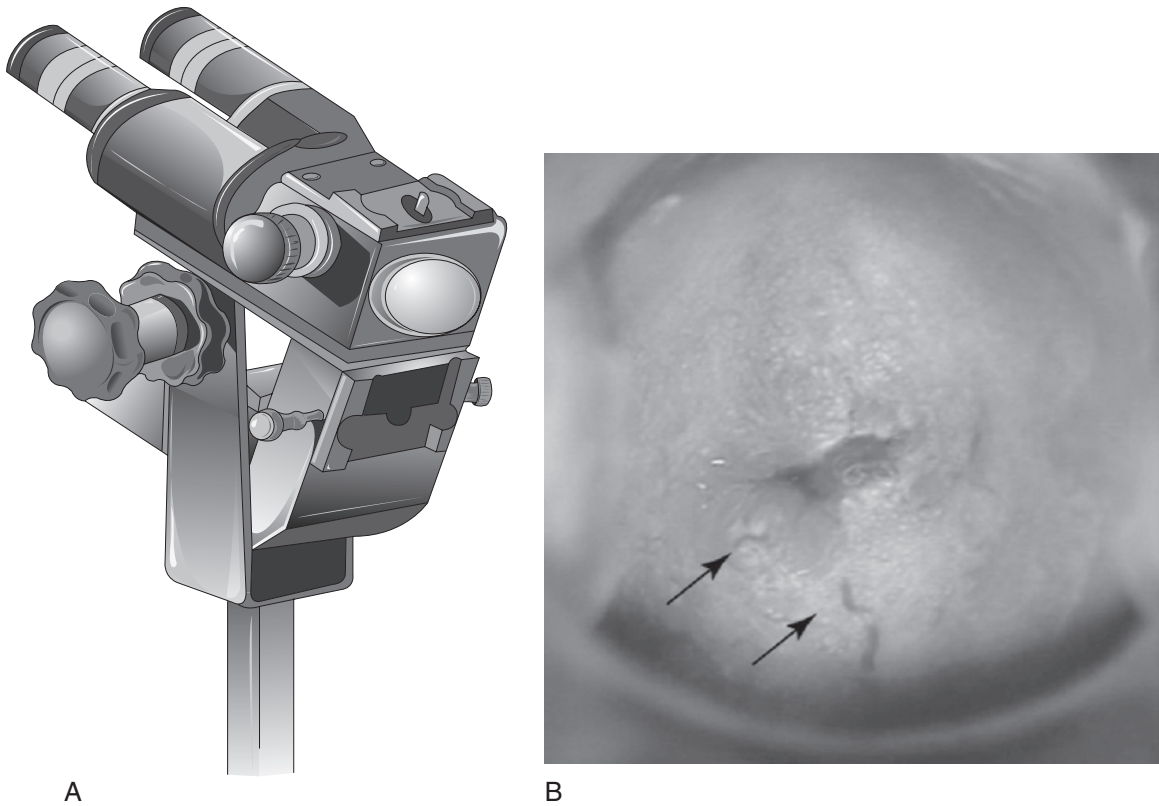

Follow age-specific guidelines

If cytology or HPV testing results are abnormal, then further evaluation is warranted. The ASCCP issued guidelines in 2013 that addressed triage and treatment for women with screening test abnormalities. Key points are as follows:

1. Cytologic tests should be reported using standard nomenclature defined by the Bethesda System. Key preinvasive diagnoses with which the clinician should be familiar include
 - a. Atypical squamous cells (ASC). The report will indicate either “uncertain significance” (ASC-US), or “cannot rule out high-grade dysplasia” (ASC-H). ASC-US should be further tested by ordering a reflex hybrid capture assay for high-risk HPV DNA unless the patient is an adolescent. ASC-H has a high risk of high-grade dysplasia and must be evaluated with colposcopy
 - b. Low-grade squamous intraepithelial lesion (LSIL) is virtually always caused by HPV, and HPV

testing has been shown not to be cost effective. In adolescent patients, a repeat cytology exam in 1 year is recommended. In adults, colposcopy is performed.

- c. High-grade squamous intraepithelial lesion (HSIL) has a high likelihood of high-grade dysplasia on biopsy and invasive cancer will sometimes be detected. Patients with HSIL, regardless of age, are evaluated with colposcopy
- d. Glandular abnormalities refer to disease in the endocervical canal. These lesions are difficult to see and may therefore be detected later. Skip lesions occur in 10%-15% of cases, indicating the importance of evaluating the entire canal with curettage or similar sampling methods. All three glandular lesions reported have a high likelihood of high-grade dysplasia and a moderate likelihood of associated invasive cancer. Colposcopy and endocervical gland sampling with curettage with possible endometrial sampling is required. Cells in this category will be reported as
 - i. Atypical glands, not otherwise specified (AGC-NOS)
 - ii. Atypical glands, favor neoplasia
 - iii. Adenocarcinoma *in situ* (AIS)
2. Adolescents and young adult women, defined as being 24 years of age and younger, have a very high prevalence of HPV infection and a very low likelihood of cervical cancer. Because the disease will often regress in this age range, management guidelines have become progressively more conservative
3. The colposcope is a binocular microscope (Figure 39–3) that allows close inspection of the squamo-columnar junction (SCJ) on the cervix where the majority of squamous cervical cancers arise. High-grade lesions have a characteristic appearance including white light reflection after staining with acetic acid in areas of dysplasia (aceto-white change), abnormal vascular patterns (punctuation, mosaic, and atypical vessels), and altered contours. Small biopsies are obtained with colposcopic guidance using cervical biopsy forceps designed for this task. Treatment decisions are based on biopsy results. (Figure 39–4).
4. Biopsy proven low-grade cervical intraepithelial neoplasia (CIN-1) has a high likelihood of spontaneous regression with a median time of 2 years and very little likelihood of progressing to cancer. Management is conservative in order to minimize treatment morbidity that has been shown to adversely affect fertility. Persistence of disease longer than 2 years may either be treated or surveillance may be continued
5. Biopsy-proven high-grade cervical intraepithelial neoplasia (CIN 2-3) has a much higher risk of progressing

▲ **Figure 39-3.** Colposcopy. **A:** Zeiss colposcope. (From *Current Diagnosis & Treatment Obstetrics and Gynecology*, New York: McGraw-Hill, 2006.) **B:** Mosaic vascular pattern with atypical vessels (arrows). (From Schorge JO, Williams JW: *Williams Gynecology*, New York: McGraw-Hill, 2008.)

to invasive disease if left untreated. Treatment options are discussed in the section on Surgery for Benign Cervical Disease

6. HPV mediated disease may also affect the vagina and vulva. Colposcopic examination and directed biopsies allow triage of lesions into low-grade and high-grade lesions that are managed either by surveillance or removal, respectively
7. A new consensus system of nomenclature for squamous neoplasia of the anogenital tract was published in 2012. In this system, neoplasms of the cervix, vagina, and vulva are now classified as low-grade or high-grade squamous intraepithelial neoplasms (LSIL and HSIL, respectively). This two-tiered classification system was designed to reflect the understanding of the biology of these lesions, and recognizes that LSIL rarely progresses, while HSIL has a significant risk of progression to cancer

SURGERY FOR BENIGN VULVAR DISEASE

There are a large number of possible masses and benign neoplasms of the vulva. The clinical approach is to rule out potential malignancy and to treat symptomatic lesions. Biopsy or excision of small masses is usually performed in

Management of the abnormal Pap test in adult women

▲ **Figure 39–4.** Colposcopy triage. Satisfactory colposcopy is defined as complete visualization of the squamocolumnar epithelium, which comprises the cervical region most likely to develop invasive disease. ECC refers to endocervical curettage to obtain tissue from the endocervix above the area that may be inspected with the colposcope. Colposcopically directed biopsies are taken. Low-grade dysplasia usually resolves and the preferred treatment is observation with periodic retesting for high-risk HPV DNA on 12-month intervals. Any high-grade CIN in women 25 years and older must be treated. Persistent low-grade cervical intraepithelial neoplasia (CIN) may be treated or surveillance may be continued. New guidelines treat adolescent and young adult patients differently. See text for details.

the office setting under a local anesthetic with either a punch biopsy instrument or scalpel. Punch biopsy sites are usually left open, while elliptical excisions are closed with fine, interrupted, absorbable sutures. The differential diagnosis for benign lesions is as follows:

1. Solid lesions

a. Leiomyoma

Natural History: Uncommon on vulva. Benign smooth muscle tumor that arises from deep connective tissues. Occurs at any age, predominating

in fourth and fifth decades. May become very large. Rarely undergoes malignant degeneration
Appearance: Slowly growing, firm, usually mobile subcutaneous nodule

Diagnosis: Excisional biopsy

Treatment: Local complete excision

b. Lipoma

Natural History: Uncommon on vulva. Benign tumor of histologically normal appearing adipose cells. Large lesions may ulcerate. Usually asymptomatic.

Rarely associated with family Lipoma syndrome, an autosomal dominant disease. Rarely undergoes malignant degeneration

Appearance: Soft, rounded, slowly growing sessile or pedunculated mass ranging widely in size

Diagnosis: Excisional biopsy if symptomatic

Treatment: Local excision if symptomatic

c. Syringoma

Natural History: Benign tumor of eccrine ductal origin within fibrous stroma. Occurs mostly after puberty

Appearance: Multiple, 1-2 mm, flesh-colored or yellow papules on lateral labia major

Diagnosis: Biopsy

Treatment: Local excision

d. Trichoepithelioma

Natural History: Rare benign tumor on vulva, derived from hair follicle without hair development

Appearance: Single or multiple small pink or flesh colored nodules that can mimic basal cell carcinoma

Diagnosis: Biopsy

Treatment: Local excision

e. Granular cell tumor

Natural History: Rare benign tumor of nerve sheath. Occurs in adults and children. Usually asymptomatic and solitary in 85%

Appearance: Slow growing subcutaneous nodule, usually on labia majora, clitoris, or mons pubis

Diagnosis: Biopsy

Treatment: Wide local excision

f. Neurofibroma

Natural History: Rare on vulva. Benign tumor of nerve sheath. Half occur in patients with von Recklinghausen disease, an autosomal dominant heritable disease affecting skin, nervous system, bone, and endocrine glands. Rare before puberty. Rarely undergoes malignant degeneration

Appearance: Solid, cutaneous nodules usually less than 3 cm, but reported as large as 25 cm.

Diagnosis: Clinical appearance of von Recklinghausen disease or biopsy.

Treatment: In asymptomatic patients with von Recklinghausen disease, no treatment for a vulvar lesion is needed. For symptomatic patients, local excision

g. Schwannoma

Natural History: Rare. Benign tumor of neuroectodermal nerve sheath

Appearance: Usually solitary

Diagnosis: Biopsy

Treatment: Local excision

2. Glandular lesions

a. Papillary hidradenoma

Natural History: Benign tumor of apocrine sweat glands. Contains both glandular and myoepithelial elements. Occurs after puberty. Usually asymptomatic. Virtually always in Caucasian women

Appearance: Hemispherical in shape, measuring less than 2 cm in diameter. Usually located in labia majora or lateral labia minora

Diagnosis: Biopsy

Treatment: Local Excision

b. Nodular hidradenoma

Natural History: Benign tumor of eccrine sweat glands. Probably arises from embryonic rests. Clear cells on biopsy. Rare on vulva

Diagnosis: Biopsy

Treatment: Local Excision

c. Ectopic breast or nipple

Natural History: Rare. May occur on the vulva with or without underlying glands and lactation has been reported. Rarely undergoes malignant degeneration

Appearance: Amorphous swelling of the labia most often detected with pregnancy. Pigmented vestigial nipple may or may not be present

Diagnosis: Biopsy

Treatment: Local excision if symptomatic

d. Endometriosis

Natural History: Rare on vulva. Benign ectopic endometrial tissue. May cause cyclic pain and may ulcerate or bleed

Appearance: Nodule with blue or red-brown appearance. Cyclic tenderness

Diagnosis: Biopsy

Treatment: Local excision

3. Cysts

a. Bartholin cysts or masses

Natural History: Cysts are common, arising in 1%-2% of women. Cysts often occur after gland abscesses, although the duct may become occluded any time. Small cysts usually asymptomatic. Large or infected cysts are painful

Appearance: Spherical cyst or nodule in subcutaneous tissue of posterior labia majora

Diagnosis

i. Incise and drain abscesses

ii. Biopsy recurrent cysts or solid nodules

Treatment

i. Incise and drain abscesses using a small balloon-tip catheter (Word) catheter introduced through a stab incision in the medial aspect of the cyst cephalad to the hymen. The catheter should remain in place for 2 weeks to allow tract

- epithelialization. In the event of surrounding cellulitis, antibiotic therapy can be added
- ii. Marsupialize or resect recurrent cysts
 - iii. Resect solid nodules since these may be malignant
- b. Epithelial inclusion cyst (sebaceous cyst)

Natural History: Common. Usually on labia majora. Can occur at any age and may be solitary or multiple. Usually asymptomatic. Caused by trauma to skin or occlusion of pilosebaceous duct

Appearance: Single or multiple, round cysts usually ranging from 2-3 mm up to 1-2 cm in diameter. Often have yellow color

Diagnosis: Clinical appearance

Treatment: No treatment if asymptomatic. If symptomatic, local excision
 - c. Wolffian cyst (Mesonephric cyst)

Natural History: Uncommon. Benign, thin-walled cysts on lateral vagina at the introitus

Appearance: Round cysts with thin smooth walls on lateral vagina at the introitus (Diagnosis: Clinical appearance or biopsy)

Treatment: No treatment if asymptomatic. If symptomatic, local excision
 - d. Cyst of canal of Nuck (Mesothelial cyst)

Natural History: Uncommon. Benign cyst

Appearance: Smooth cysts usually located in anterior labia majora or inguinal canal. Thought to be due to peritoneal inclusions. May become large. Differential diagnosis includes inguinal hernia

Diagnosis: Clinical appearance or excisional biopsy

Treatment: No treatment if asymptomatic. If symptomatic, local excision
4. Vascular lesions
 - a. Angiokeratoma

Natural History: Very common. A clinically insignificant variant of hemangioma that occurs almost exclusively on vulva (and scrotum in men). Occurs during reproductive years. Contains dilated vessels and may have hyperkeratotic overlying epithelium. May resemble Kaposi sarcoma or angiosarcoma. Some forms associated with inborn errors of glycosphingolipid metabolism

Appearance: Red to purple to brown-black 2-5 mm papules usually in large numbers anywhere on the vulva

Diagnosis: Clinical appearance. Occurrence of multifocal lesions in childhood may indicate inborn errors of glycosphingolipid metabolism

Treatment: None, if asymptomatic. Symptomatic lesions treated with laser ablation, electrodesiccation, or local excision
 - b. Capillary hemangioma

Natural History: Capillary hemangioma (strawberry hemangioma) occurs in infants and young children. Usually regresses spontaneously over time. May ulcerate or bleed

Appearance: Well demarcated, red, slightly raised lesion

Diagnosis: Clinical appearance

Treatment: None if asymptomatic
 - c. Cavernous hemangioma

Natural History: Rare on vulva. Dilated vessels that may be associated with underlying pelvic hemangioma. Usually regresses spontaneously over time. May ulcerate or bleed

Appearance: Dilated vessels

Diagnosis: Clinical appearance

Treatment: None if asymptomatic
 5. Nevi and pigmented skin lesions
 - a. Vitiligo

Natural History: Inherited disorder with loss of melanocytes. Asymptomatic

Appearance: Depigmented skin in well-circumscribed macular pattern

Diagnosis: Clinical appearance

Treatment: None
 - b. Fibroepithelial polyp (skin tag, acrochordon)

Natural History: Very common. Single or multiple. Hormonal factors are implicated in development and lesions are more common in obese or diabetic patients (Fisher, Nucci). Also common in axilla

Appearance: Multiple soft skin colored or pigmented lesions. Usually painless unless inflamed or torsed

Diagnosis: Gross recognition. Biopsy or excision if symptomatic

Treatment: Excise, electrodesiccate or freeze with liquid nitrogen if symptomatic
 - c. Seborrheic keratosis

Natural History: Common on body but uncommon on vulva. Usually occur after age 30. Probably autosomal dominant inheritance (Fitzpatrick). Multiple lesions occurring over a short period of time may indicate internal malignancy (Leser-Trelat syndrome)

Appearance: Lesions appear “stuck on” and are brown to black in color. Most are asymptomatic but can be pruritic. Occur on hair bearing skin

Diagnosis: Gross appearance, biopsy or excision

Treatment: If asymptomatic, no treatment. If symptomatic, excise, electrodesiccate, curette, or freeze with liquid nitrogen

d. Lentigo simplex

Natural History: Most common hyperpigmentation lesion on vulva. Occurs on skin and mucous membranes

Appearance: Usually small, less than 4 mm, flat, uniformly pigmented. Often resemble junctional nevi

Diagnosis: Clinical appearance. Biopsy only if clinical morphology worrisome. Remember ABCDE criteria: Asymmetry, Border irregularity, Color variegations, Diameter larger than 6 mm, Enlargement or Elevation

Treatment: None required

e. Vulvar melanosis

Natural History: Hyperpigmented macules or freckles are benign and asymptomatic. They are usually acquired, beginning between ages 30 and 40

Appearance: Asymptomatic brown to black irregular macular patches on vulva

Diagnosis: Clinical appearance. Biopsy only if clinical morphology worrisome. Remember ABCDE criteria: Asymmetry, Border irregularity, Color variegations, Diameter larger than 6 mm, Enlargement or Elevation

f. Treatment: None required

Acquired melanocytic nevocellular nevus

Natural History: Common, especially in Caucasians. Tend to develop in childhood and early adulthood, followed by gradual involution by age 60. Lesions are usually asymptomatic

Classification (Fisher)

- i. Junctional nevus: melanocytes at the dermal-epidermal junction above the basement membrane. First stage of nevus evolution. Least common type on vulva
- ii. Compound nevus: melanocytes in both the dermis and above the basement membrane. Second stage of nevus evolution
- iii. Intradermal nevus: melanocytes exclusively in the dermis below the basement membrane. Final stage of evolution after which many nevi involute
- iv. Other types include halo nevus, blue nevus

Appearance:

- i. Junctional nevus: Pigmented macule with smooth border and uniform tan, brown or dark brown pigmentation
- ii. Compound nevus: Papule with dome shape or macule. Dark brown or black color. May have hairs
- iii. Intradermal nevus: Papule with dome shape or macule. Skin colored, tan or light brown

Diagnosis: Clinical appearance. Biopsy if clinical morphology worrisome. Remember ABCDE

criteria: Asymmetry, Border irregularity, Color variegations, Diameter larger than 6 mm, Enlargement or Elevation

Treatment: None required if asymptomatic and if ABCD criteria are benign. All others: local excision

g. Dysplastic nevus

Natural History:

- i. Rare on the vulva
- ii. Lesions arise later in childhood than nevi in general and continue to develop throughout life
- iii. Sun exposure contributes to development of these lesions on other areas of the body. Several genetic loci have been implicated for development of melanoma
- iv. Risk of melanoma doubles with one dysplastic nevus and increases 12-fold if 10 or more dysplastic nevi are present
- v. Dysplastic nevi are sometimes associated with a hereditary propensity for melanoma

Appearance

- i. On biopsy, atypical cells are superficial and the deeper cells are without atypia. Pagetoid spread of cells is noted in lower third of epithelium
- ii. Tend to be larger in size than nevi (> 10 mm vs < 5 mm, respectively)
- iii. Dysplastic nevi are asymmetrical, with variegation of color

Diagnosis: Wood lamp accentuates pigmentation and margins are more easily delineated. Remember ABCDE criteria: Asymmetry, Border irregularity, Color variegations, Diameter larger than 6 mm, Enlargement or Elevation. Excisional biopsy

Treatment: Excisional biopsy. Careful longitudinal skin surveillance exams

SURGERY FOR MALIGNANT VULVAR DISEASE

Vulvar cancer accounts for about 5% of gynecologic malignancies. At least 90% of vulvar cancers are of squamous cell type. Etiology of vulvar carcinoma is grouped into the HPV-associated basaloid-warty histological group and the non-HPV-associated keratinizing squamous cancers. The age distribution is bimodal with younger women more likely to develop HPV-associated disease and older women more likely to develop keratinizing squamous cell carcinoma. The latter group is often associated with lichen sclerosis of the vulva. Vulvar intraepithelial neoplasia (VIN) is a preinvasive form of HPV-associated neoplasia and is often associated with persistent pruritus. Uncommon histological types of vulvar cancer include melanoma (6%), Bartholin gland adenocarcinoma (4%), basal cell carcinoma (< 2%), extramammary Paget disease of the vulva (< 1%), and rare sarcomas, found

arising primarily in the soft tissues, or metastases from other tumor sites.

Lesions arise in the labia majora in about 50% of cases and about 25% of cases occur on the labia minora. Clitoral lesions and Bartholin gland adenocarcinomas are less common. The natural history of vulvar carcinoma includes spread to inguinal lymph nodes. Lesion depth and diameter are of prognostic value for assessing risk of metastasis, and to a lesser degree histological type, and presence of lymphatic involvement. Lesions of ≤ 1 mm depth have less than 1% risk of nodal metastasis, and define a category of microinvasive disease that may be treated more conservatively by omitting the inguinal node dissection. Lymph node status is the most significant predictor of survival.

In patients with HPV-mediated disease, multifocal involvement of the vagina and cervix predisposes to a significantly higher risk of cancer at these sites. Smoking is a cofactor for the development of HPV-mediated disease. Smoking cessation may reduce risk of persistent or progressive disease. Women with extramammary Paget disease, in *in situ* apocrine adenocarcinoma related to breast tissue developed along the milk-line *in utero*, there is a significant risk of a second, underlying adenocarcinoma elsewhere. Sites that require evaluation include colon, especially for perianal lesions, Bartholin gland, cervix, endometrium, ovary, and breast.

Cancer of the vulva is staged by International Federation of Gynecology and Obstetrics (FIGO) criteria, which is a surgical staging system. Melanoma is staged using AJCC staging rules.

► Appearance

VIN occurs in women 15-20 years before the average age of invasive disease. Incidence has risen strongly and the average age at time of incidence has fallen from 52.7 years in 1961 to 35 years in 1992. One-third of lesions are solitary, and two-thirds are multifocal. Lesions are widely variable in size and may be slightly raised or papillary. Color variation ranges from white, red, or brownish patches on the skin or mucosa. Ulcerated lesions or underlying subcutaneous induration may indicate invasion. Larger lesions have a higher probability of lymph node involvement, but metastatic disease in the lymph nodes may not be palpable. Local spread may involve the urethra, vagina, anus, and rarely the symphysis pubis or other pelvic bones.

► Diagnosis

Biopsies are necessary to establish the correct diagnosis. The differential diagnosis is large and includes benign lesions discussed earlier in addition infections that mimic neoplasms and also vulvar dystrophies. Granulomatous infections such as lymphogranuloma venereum and granuloma inguinale of the vulva may be clinically suspicious, and biopsy of the involved may need to be supplemented with

cultures for documentation of infection. These infections are rare unless a patient has traveled internationally. VIN is best diagnosed by colposcopic examination techniques including use of magnification and staining the epithelium with 5% acetic acid. Lesions usually appear acetowhite.

► Treatment

Focal VIN may be treated by wide excision or CO₂ laser photoblation. Excision is preferred for lesions in the hair-bearing skin and laser is generally less prone to cause scarring in the mucosal surfaces. Laser ablation is contraindicated if there is any suspicion of invasion. A skinning vulvectomy with split-thickness skin grafting is effective for widely multifocal disease. Extramammary Paget disease requires wide but superficial excision as the tumor cells often spread far wider than is visible to the surgeon. Local recurrences are common, but invasion is rare.

Vulvar cancer is staged using the international system developed by the FIGO (Table 39-1). Microinvasive lesions

Table 39-1. FIGO staging for vulva r cancer.

Stage	Revised 2009
I	Tumor confined to vulva
IA	Lesion ≤ 2 cm in size, and stromal invasion of ≤ 1 mm, nodes negative
IB	Lesion > 2 cm in size, or stromal invasion of > 1 mm, nodes negative
II	Tumor of any size extending to adjacent perineal structures: (anus, lower 1/3 of urethra, lower 1/3 of vagina); nodes negative
III	Tumor of any size with or without extension to adjacent perineal structures: (anus, lower 1/3 of urethra, lower 1/3 of vagina); inguinofemoral nodes positive
IIIA(i)	With 1 lymph node metastasis of ≥ 5 mm
IIIA(ii)	1-2 lymph node metastases of < 5 mm
IIIB(i)	With 2 or more lymph node metastases of ≥ 5 mm
IIIB(ii)	3 or more lymph node metastases of < 5 mm
IIIC	Positive nodes with extracapsular spread
IVA(i)	Invades upper urethra or vagina; bladder or rectal mucosa; or fixed to pelvic bone
IVA(ii)	Fixed or ulcerated inguinofemoral nodes
IVB	Any distant mets including pelvic nodes

Depth of invasion measured from epithelial-stromal junction of the adjacent most superficial dermal papilla to the deepest point of invasion. This system applies for all tumor types other than melanoma. Melanoma should be staged using the AJCC melanoma staging system. Staging assessment may require cystoscopy, sigmoidoscopy, and chest x-ray for locally advanced lesions. (Reproduced, with permission, from Pecorelli S: Revised FIGO staging for carcinoma of the vulva, cervix, and endometrium. *Int J Gynecol Obstet.* 2009; May;105(2):103-104)

of less than or equal to 1 mm invasion are adequately treated by wide and deep local excision with 1 cm margins due to the low likelihood of nodal spread. Stage I lesions are generally treated with radical local excision with a 1-2 cm margin. For lesions greater than 1 mm in depth, sentinel node mapping of inguinal nodes is carried out to assess for spread of disease. Radiation therapy with concurrent chemosensitization is required for inoperable lesions and for patients with positive nodes or involved resection margins.

► Prognosis

Following radical resection with negative nodes and margins, a 5-year rate of 90% is anticipated. If nodes are involved, survival is linked to number of nodes involved, unilaterality versus bilaterality, and bulk of disease.

Levenback CF, Ali S, Coleman RL, et al: Lymphatic mapping and sentinel node biopsy in women with squamous cell carcinoma of the vulva: a gynecologic oncology group study. *J Clin Oncol* 2012;30:3786-3791.

SURGERY FOR BENIGN VAGINAL DISEASE

► Imperforate Hymen

Diagnosis of imperforate hymen is often delayed until puberty, when either a workup for primary amenorrhea has ensued or the patient presents with menstrual symptoms such as cramping, without associated menses. If the patient has obstructed flow of her menses, defined as hematocolpos, examination will reveal a bulging imperforate hymen. Confirmatory rectal exam will detect a bulging, cystic mass. In younger girls, the finding is more subtle due to the absence of swelling. Delay of diagnosis may result backpressure causing a cystically enlarged uterus (hematometra) and possible retrograde menstruation leading to endometriosis. In the presence of a tightly distended hematocolpos, compression of the bladder and ureters may result in urinary obstruction.

Imperforate hymen is treated with a hymenotomy, where the obstructed hymen is incised or resected with either a scalpel or laser.

► Longitudinal Vaginal Septum

Duplication of the vagina resulting in a septum may occur with or without similar defects in the uterus based on where the defect of Müllerian duct fusion occurred. The duplication may take the form of a partial longitudinal septum or complete duplication of the vagina. Patients will occasionally report bleeding despite placing a tampon during menses, indicating the possibility of a second passage for menstrual flow. Excision is performed transvaginally for symptomatic patients including those with dyspareunia, obstruction of labor or similar problems.

► Transverse Vaginal Septum

Occasionally, the vagina fails to communicate with the urogenital sinus at the introitus. This may result in formation of a transverse septum, most of which are partial. If the septum is imperforate, hematocolpos will develop following menarche. Marsupialization or excision of the septum restores vaginal patency.

► Vaginal Agenesis

Vaginal agenesis, or absence of the vagina, is associated with absence of the uterus in most cases. The lower vagina, derived from the urogenital sinus may be present, but Müllerian ductal structures comprising the upper two-thirds of the vagina and the uterus are absent or deficient. Diagnosis is usually made at time of evaluation for primary amenorrhea.

Vaginal agenesis is treated by reconstruction of a functional vagina. Treatment is usually deferred until the patient wishes to become sexually active. In a motivated patient, the vagina may be created by nonoperative dilation and elongation of the vulvar vestibule or vaginal introitus. This method, called the Frank nonoperative technique, requires up to 2 hours of dilating per day for 4-6 months. Success has been reported with vaginal dilators, vaginal molds, modified bicycle seat, and with intercourse alone. If there is failure to progress, or if the anatomy does not favor dilation alone, surgical construction using a skin graft (McIndoe procedure), interposed bowel, or myocutaneous flaps from the perineum are effective.

► Gartner Duct Cyst

Gartner duct cysts are derived from mesonephric (Wolffian) duct remnants and contain a serous fluid. They are usually located in the lateral walls of the upper vagina and are generally asymptomatic. These cysts are detected most often during a routine physical examination. Small asymptomatic cysts require no treatment. Gartner duct cysts may occasionally reach 5-6 cm diameter. Larger or symptomatic cysts should be excised.

SURGERY FOR MALIGNANT & PREMALIGNANT VAGINAL DISEASE

Vaginal intraepithelial neoplasia (VAIN) is the term used to describe the preinvasive neoplastic changes that arise in the vagina. VAIN is frequently present whenever carcinoma *in situ* or invasive carcinoma of the cervix or vulva is present, and it may develop in the vagina years after completion of treatment for cancers of these two sites. Carcinoma *in situ*, or VAIN 3, of the vagina is most often detected with a Pap test. Subsequent evaluation with colposcopy, staining with 5% acetic acid and directed biopsies provide an accurate assessment of grade and location of disease.

► Treatment

Low-grade dysplasia (VAIN 1) has a low probability of progression and may be managed with surveillance using the same principles as for management of low-grade cervical dysplasia. High-grade dysplasia (VAIN 2-3) should be treated by local excision of involved areas or with CO₂ laser photoablation. New terminology for these lesions was published in 2012. Low-grade lesions are now referred to as LSIL and high-grade lesions previously called VAIN 2, VAIN 3 and carcinoma *in situ*, are now referred to as HSIL. The irregular surface topography of the vagina caused by rugae makes successful visualization of lesions for treatment challenging. Recurrence rates for dysplasia are higher for vaginal dysplasia than for similarly treated cervical dysplasia, with a failure rate in the 25% range. Intravaginal placement of topical 5-fluorouracil is an off-label indication that has been reported in the literature, and failure rates are higher than for resection or ablation. Topical 5-fluorouracil has been reported to cause painful vaginal ulcers that heal poorly, limiting the utility of this treatment to carefully selected patients. Extensive involvement of the vagina may require subtotal or complete vaginectomy with skin grafting for maintenance of sexual function. For the elderly, sexually inactive patient, colpocleisis, where the vagina is resected and closed permanently is an option.

Invasive carcinoma of the vagina is rare, accounting for less than 2% of gynecologic malignancies. Most vaginal cancers involve extension from either cervical or vulvar cancers, both of which are more common than lesions arising in the vagina. By convention, if the cancer involves cervix or vulva in addition to the vagina, the tumor is categorized as either cervical or vulvar cancer, respectively. True vaginal cancer arises only in the vagina. About 85% of vaginal cancers are of squamous type. The next most common type is adenocarcinoma, usually with clear cell type. Rare primary tumors of the vagina include mixed mesodermal tumors, sarcoma botryoides (embryonal rhabdomyosarcoma), sarcoma, adenocarcinoma arising from Gartner duct or Müllerian duct remnants, embryonal carcinoma, and malignant melanoma.

The most common presenting symptoms of vaginal cancer include postmenopausal bleeding in about 65% of patients and persistent vaginal discharge in about 30%. Most tumors arise in the upper third of the vagina along the anterior and posterior surfaces. These sites are usually covered by the vaginal speculum and can easily be missed unless the physician observes all vaginal surfaces upon insertions and withdrawal of the speculum. Diagnosis is confirmed by biopsy.

Staging of carcinoma of the vagina is defined by FIGO and is clinical rather than surgical (Table 39-2). Squamous cancers are most commonly found in postmenopausal

Table 39-2. FIGO staging for vaginal cancer.

FIGO Stage	Description	TNM Class
Stage 0	Carcinoma <i>in situ</i> ; intraepithelial neoplasia grade 3	Tis N0 M0
Stage I	The carcinoma is limited to the vaginal wall	T1 N0 M0
Stage II	The carcinoma has involved the subvaginal tissue but has not extended to the pelvic wall	T2 N0 M0
Stage III	The carcinoma has extended to the pelvic wall	T1 N1 M0 T2 N1 M0 T3 N0 M0 T3 N1 M0
Stage IV	The carcinoma has extended beyond the true pelvis or has involved the mucosa of the bladder or rectum. Bullous edema as such does not permit a case to be allotted to stage IV	
IVA	Tumor invades bladder and/or rectal mucosa and/or direct extension beyond the true pelvis	T4 any N M0
IVB	Spread to distant organs	Any T Any N M1

Reproduced, with permission, from Benedet JL, Hacker NF, Ngan HYS (eds): FIGO staging classifications and clinical practice guidelines in the management of gynecologic cancers. FIGO Committee on Gynecologic Oncology. *Int J Gynaecol Obstet.* 2000 Aug;70(2):209-262.

patients, although they may occur even in adolescent patients. Clear cell adenocarcinoma of the vagina is more likely to occur in women below the age of 25, generally arising in vaginal adenosis. Diethylstilbestrol (DES) has been implicated in increasing the incidence of clear cell carcinoma from 1:50,000 in the unexposed population to 1:1000 in women exposed to DES *in utero*. Although DES is no longer produced or prescribed in this country, DES and similar substances have been detected in the environment and in some food supplies.

Treatment of vaginal cancer is most often a combination of radiation therapy and chemosensitization using treatment plans similar to cervical cancer. Radical surgery such as radical hysterectomy with vaginectomy is possible for selected, small, upper vaginal lesions, favoring lesions on the posterior wall due to the improved likelihood of attaining adequate margins. Surgery is preferred for young patients with clear cell carcinoma as long as negative margins can be attained. In over 50% of patients tumor has penetrated the vaginal wall at the time of the initial examination. Involvement of the bladder and rectum is common. Survival for stage I disease is about 70%, but falls to about 40% for stage II and stage III disease.

SURGERY FOR MALIGNANT CERVICAL DISEASE

Cervical cancer is the twelfth most common cancer of women in the United States, but remains the second most common cancer of women worldwide. Almost all cervical cancers arise because of persistent infection with high-risk human papillomavirus (HPV) types, most commonly types 16 and 18. Low-risk HPV types such as types 6 and 11 are usually associated with condyloma and rarely, if ever, are associated with cancer. Cervical cancer can be considered a sexually transmitted disease since most HPV infections are transmitted via sexual contact. Early sexual debut and multiple partners greatly increase the risk of exposure to high-risk HPV types. HPV infections are common and about 80% of the population will have detectable HPV antibodies indicating prior infection. In most infected individuals, the immune system will mount a successful response, with a median time to regression of infection of about 2 years. Persistent infection with a high-risk HPV type after age 30 increases the relative risk of cervical cancer more than 400-fold for HPV 16 over the population at large. Persistent infections and progression to cancer may be more likely in women who smoke or those with dietary deficiency of folate, and beta-carotene. Progression to cancer is usually gradual, allowing development of effective screening strategies with Pap tests and testing for high-risk HPV DNA in addition to effective triage with colposcopy. Low-grade lesions usually regress, making potentially destructive treatments that have an adverse effect on fertility unnecessary. In 2006, the FDA first approved a vaccine for primary prevention of HPV infection. The vaccine is targeted for adolescents prior to their sexual debut. Widespread vaccination may largely eradicate cervical cancer in the future, although the vaccines are selective only for the most common of high-risk HPV types raising the possibility of shifting prevalence of HPV types.

About 75% of cervical cancers are squamous type; the remainder consist of adenocarcinomas, mixed carcinomas (adenosquamous), and rare sarcomas (mixed mesodermal tumors, lymphosarcomas). The relative prevalence of cervical adenocarcinoma has risen in recent years and now accounts for about 25% of cases.

Most cervical cancers arise from a preinvasive dysplastic lesion through a process that generally lasts for years. Carcinoma *in situ* occurs most frequently in the fourth decade, whereas invasive carcinoma is encountered most often in perimenopausal women between ages 40 and 50. Once invasion occurs, spread is by direct extension to the

vagina and the parametrium in addition to lymphatic channels to the iliac and obturator nodes, with occasional direct spread to para-aortic nodes. Staging is clinical, since not all stages will require surgery. The staging system defined by FIGO is used internationally, and is included in Table 39-3. Probability of lymph node metastasis increases according to the extent of the primary lesion, being approximately 12% in stage I, 30% in stage II, and 45% in stage III. About 80% of patients with stage IV cancer have lymph node involvement.

Table 39-3. FIGO staging for cervical cancer.

FIGO Stage	Revised 2009
Stage I	Carcinoma confined to cervix (extension to corpus would be disregarded)
IA	Invasive carcinoma, diagnosed only by microscopy. All macroscopically visible lesions, even with superficial invasion, are Stage IB
IA-1	Measured stromal invasion ≤ 3 mm and < 7 mm in horizontal spread
IA-2	Measured stromal invasion > 3 mm and ≤ 5 mm with a horizontal spread of 7 mm or less
IB	Clearly visible lesion confined to the cervix or microscopic lesion greater than Stage IA
IB-1	Clinically visible lesion ≤ 4 cm in greatest dimension
IB-2	Clinically visible lesion > 4 cm in greatest dimension
Stage II	Tumor invades beyond uterus but not to pelvic wall or to the lower third of vagina
IIA	Tumor without parametrial invasion
IIA-1	Clinically visible lesion ≤ 4 cm in greatest dimension
IIA-2	Clinically visible lesion > 4 cm in greatest dimension
IIB	Tumor with obvious parametrial invasion
Stage III	Tumor extends to the pelvic wall and/or involves lower third of vagina and/or causes hydronephrosis or non-functioning kidney. Determination is based on rectal exam with no cancer-free space between tumor and pelvic wall
IIIA	Tumor involves lower third of the vagina, with no extension to pelvic wall
IIIB	Extends to pelvic wall or causes hydronephrosis or nonfunctioning kidney
Stage IV	Carcinoma extends beyond true pelvis or with biopsy proven spread to bladder or rectal mucosa. Bullous edema does not cause case to be allotted to Stage IV
IVA	Spread to adjacent organs
IVB	Spread to distant organs

► Dysplasia & Carcinoma *In Situ*

Successful screening has greatly reduced the incidence and mortality of cervical cancer and its precursors over the last 50 years. Current screening recommendations for lower genital tract cancers of the vulva, vagina, and cervix have been discussed previously in this chapter. When a neoplastic lesion is detected by screening, proper and timely triage is needed. High-grade squamous intraepithelial lesions are typically asymptomatic.

Colposcopic examination of the cervix is the gold standard for assessing dysplasia, carcinoma *in situ* and early invasive disease. Application of Lugol iodine can be a useful adjunct to the colposcopic exam. Normal mature squamous epithelium of the cervix and vagina contains glycogen and stains a dark brown color, whereas dysplastic cells lack glycogen and stain a light yellow color.

Colposcopically directed biopsy is performed for visible abnormalities including acetowhite change, abnormal vessels, ulceration, and papillary lesions. Biopsy confirmed CIN-1 is managed conservatively since most of these lesions regress spontaneously and there is very little risk of progression to cancer. Biopsy showing a high-grade dysplastic lesion including moderate dysplasia (CIN-2), severe dysplasia (CIN-3), and carcinoma *in situ* (CIN-3), are treated with either ablative therapy or resection using cryotherapy or electrocautery loop excision, respectively. Treatment is directed to either ablation or removal of the entire transformation zone, defined as the area bounded by the original and current squamocolumnar junction. These two treatment modalities are usually performed in the office setting and are well tolerated. There are some exceptions when treating adolescent and young adult patients under age 25, so the clinician must be familiar with current guidelines. Some dysplastic lesions may extend into the endocervical canal including squamous lesions and most glandular lesions. The preferred treatment for lesions extending out of colposcopic view into the endocervical canal is usually excision with a cold-knife cone biopsy in the operating room. Both electrocautery loop excision and cold-knife cone biopsy increase future risk of preterm delivery, mandating careful triage of only those individuals truly requiring an excisional therapy.

► Invasive Carcinoma

Early stromal defined as microinvasion, is usually asymptomatic. Larger lesions frequently cause postmenopausal bleeding (46%), intermenstrual bleeding (20%), or post-coital bleeding (10%). A watery or malodorous vaginal discharge may be the only symptom. Pain is a manifestation of advanced stage disease typically extending to the pelvic sidewall with entrapment of the sciatic nerve or femoral nerve. Inspection of the cervix typically reveals an ulcerated or papillary lesion of the cervix that bleeds on contact. The

cytologic examination almost always demonstrates exfoliated malignant cells, although the false-negative rate for Pap tests approach 50% for invasive lesions due to obscuration of malignant cells by inflammation and necrotic debris.

► Differential Diagnosis

Chronic cervicitis may appear similar to cancer of the cervix. Polyps of the cervix are often benign, but malignancy can only be ruled out with biopsy. Nabothian cysts are benign, common, and can appear bizarre to the untrained eye, but are readily distinguished from cancer by biopsy.

► Natural History

Spread of cervical cancer into the parametrium may cause obstruction of the ureter, resulting in hydronephrosis, hydro-nephrosis, and uremia. Bilateral obstruction of the ureters leads to failure of kidney function and death. Involvement of the iliac and obturator lymph nodes may lead to lymphatic obstruction resulting in lymphedema. Pelvic sidewall nerves, especially the sciatic nerve, may become compressed, causing sciatica or pain in the low back, hip, and leg. Tumor invasion into the bladder or rectum sometime causes vesicovaginal or rectovaginal fistula, especially following radiation therapy. Widespread metastases to lung, liver, brain, and bone may occur.

► Treatment

Treatment of cervical cancer is stratified by stage. Microinvasive disease, defined as FIGO stage IA-1, has less than a 1% chance of lymphatic metastasis and may be managed conservatively with cone biopsy for preservation of fertility or with simple hysterectomy when preservation of fertility is not desired or relevant. Radical hysterectomy with bilateral pelvic lymph node dissection is the preferred treatment for FIGO stage IA-2, IB, and IIA lesions. Radical hysterectomy results in resection of much wider margins than is performed with a simple hysterectomy, including removal of cardinal and uterosacral ligaments and the upper third of the vagina, in addition to pelvic, obturator and para-aortic nodes. Radical hysterectomy procedures may be performed either via laparotomy or laparoscopy. The radical hysterectomy is a completely different type of hysterectomy than the simple or total hysterectomy. Procedural details for the most commonly used hysterectomy types are described in Table 39-4.

Complications of radical surgery include hemorrhage, infection, thromboembolism, and less than 1% risk of ureterovaginal, vesicovaginal, or rectovaginal fistula. Early stage lesions may also be treated with radiation therapy and concurrent chemosensitization with cisplatin with equal likelihood of cure but higher potential morbidity.

Table 39–4. Types of hysterectomy.

Anatomic Structure	Comparison of Hysterectomy Types		
	Extrafascial Type 1	Modified Radical Type 2	Radical Type 3
Uterus	Removed	Removed	Removed
Ovaries	Optional removal	Optional removal	Optional removal
Cervix	Removed	Removed	Removed
Vaginal margin	None	1-2 cm margin	Upper 1/3 of vagina
Ureters	Not mobilized	Dissected through broad ligament	Dissected through broad ligament
Cardinal ligaments	Divided at uterine border	Divided where ureter transits the broad ligament	Divided at pelvic sidewall
Uterosacral ligaments	Divided at cervical border	Partially resected	Divided near sacral origin
Bladder	Mobilized to base of cervix	Mobilized to upper vagina	Mobilized to middle vagina
Rectum	Not mobilized	Mobilized below cervix	Mobilized below middle vagina

The recently developed radical trachelectomy with laparoscopic lymphadenectomy offers carefully selected individuals with stage IA-2 or stage IB-1 squamous lesions of ≤ 2 cm diameter a fertility sparing option. The cervix, upper vagina, and supporting ligaments are removed as with a radical hysterectomy, but the uterine corpus is preserved. In the posttrachelectomy pregnancies currently reported, there is a 10% likelihood of second trimester loss, but 72% of patients carry their gestation to 37 weeks or more.

Advanced-stage disease, including FIGO stage IIB and above, requires treatment with external radiation, brachytherapy implants and concurrent chemosensitization. At least five randomized trials have confirmed a survival advantage for cisplatin-based therapy given weekly during radiation therapy. Delayed complications of radiation therapy affect quality of life and include cystitis and proctitis, but are uncommon and usually. Severe radiation cystitis or proctitis may result in hemorrhage, fistula, or strictures, typically arising several years after treatment in about 1%-3% of patients. Radiation necrosis of the cervix and diffuse radiation pelvic fibrosis are rare complications. Radiating the reproductive tract destroys the function of the uterus, and unless the ovaries have been surgically transposed out of the pelvis, ovarian failure is unavoidable. Recurrent or persistent disease in the central pelvis following radiation therapy may potentially be cured with the ultraradical pelvic exenteration procedure.

► Prognosis

Survival is strongly linked to stage at time of diagnosis. Properly treated stage I disease averages 90% survival at

5 years, and approaches 96% in radical hysterectomy cases with negative margins and negative nodes. For stage II, 5-year survival is about 65%; dropping to about 45% for stage III and to less than 10% for stage IV.

SURGERY FOR PELVIC FLOOR DEFECTS

Cystocele, Rectocele, & Incontinence

An understanding of pelvic support defects requires a thorough knowledge of the anatomic relationship of the pelvic viscera and their supporting tissues. These conditions were originally thought to result from stretching and tearing of the muscles, nerves, and connective tissues of the pelvis during vaginal childbirth. The current understanding is that many pelvic floor defects arise from site-specific tears or breaks of pelvic connective tissue. Causes can include stretching, compression, or tearing during parturition; in addition to behaviors that increase intra-abdominal pressure such as chronic constipation, heavy lifting, obesity, and chronic cough. Smoking, poor nutrition and lack of pelvic floor exercise may exacerbate pelvic floor defects. The symptoms of pelvic floor defects may include: pelvic pressure

▲ **Figure 39-5.** Anatomy of pelvic support. (From Schorge JO, Williams JW: *Williams Gynecology*, New York: McGraw-Hill, 2008.)

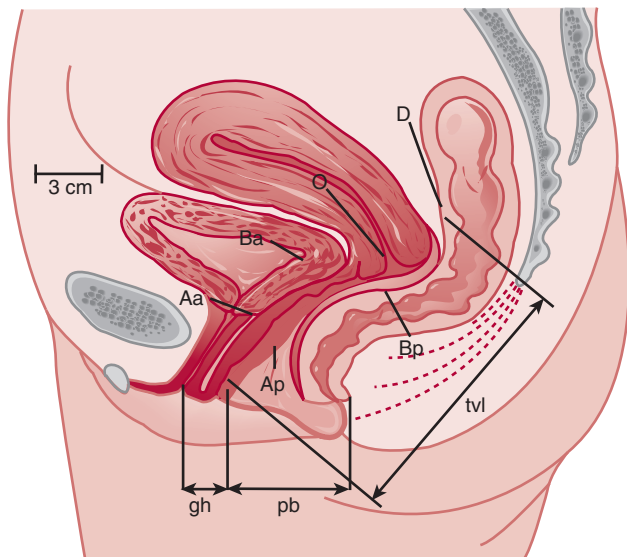

or a sensation of “falling out” of the pelvic organs, a mass protruding from the vagina (which may be a cystocele, rectocele, cervix, or all of these), stress incontinence, fecal incontinence, and other difficulties with defecation.

Complete examination generally requires evaluating the patient in the lithotomy and standing position, and by asking her to Valsalva or cough. Vaginal support is described with three different levels, illustrated in Figure 39-5. Level I includes the cervix and upper third of the vagina. Level I support is comprised superiorly by uterosacral ligaments, endopelvic fascia, and smooth muscle; laterally by support from the cardinal ligaments; and anteriorly from the pubocervical fascia. Level II defines mid-vaginal support and is comprised laterally by attachments to the arcus tendineus fascia pelvis, anteriorly by the pubocervical fascia, and posteriorly by Denonvillier fascia. Level III refers to support of the lower vagina and urethra. Level III support is provided anteriorly by attachment of the urogenital membrane to the symphysis pubis, laterally to the levator ani muscle and posteriorly to the perineal body. A pelvic organ prolapse quantification profile (POPQ) has been defined by the International Continence Society, the American Urogynecology Society, and the Society of Gynecologic Surgeons (Figure 39-6). Use

of the POPQ quantitates the extent and location of defects such that subsequent therapy is directed more specifically. Descent and bulging of the anterior vagina is usually a cystocele, a paravaginal defect, or an anterior enterocele. An anatomic defect in the posterior vagina is usually a rectocele or enterocele.

Additional testing that may be necessary for elucidation of the site-specific defect include assessment of urethral mobility with the so-called Q-tip test, cystourethroscopy, cystometrogram, anoscopy, colonoscopy, anal manometry, and transanal ultrasound. Chronic urinary tract infections must be ruled out prior to deciding upon surgical repair. For fecal incontinence, gastrointestinal disorders such as irritable bowel syndrome, infections such as *Clostridium difficile* or other causes of diarrhea, or malabsorption must be ruled out before proposing surgery.

Repair of pelvic floor defects is based on the principle of identification of the specific site of injury leading to site-specific repair. Pelvic support defects are often treated non-surgically. For example, postmenopausal woman with mild to moderate defects as determined by the POPQ score may experience improvement of symptoms after the administration of a topical estrogen, initiation of Kegel exercises, or

The Nine-Point POPQ and Staging Definitions

Point	Description	Range
Aa	Anterior wall 3 cm from hymen	-3 to +3
Ba	Most dependent part of the rest of the anterior wall	-3 to +TVL
C	Cervix or vaginal cuff	+/- TVL
D	Posterior fornix (if no prior total hysterectomy)	+/- TVL
Ap	Posterior wall 3 cm from hymen	-3 to +3
Bp	Most dependent part of the rest of the posterior wall	-3 to +TVL
GH	Genital hiatus (mid-urethra to PB)	No limit

▲ **Figure 39-6.** Pelvic organ prolapse quantification table. Six sites (points Aa, Ba, C, D, Bp, and Ap), genital hiatus (GH), perineal body (PB), and total vaginal length (TVL) are used for quantification of pelvic organ support. Each point is described with respect to position relative to the hymen in centimeters. Positive values represent distance outside the hymen, and negative numbers represent distance superior to the hymen. (Schwartz SI, Brunicaudi F: *Schwartz's Principles of Surgery: Self-Assessment and Board Review*, 8th ed. New York: McGraw-Hill, 2007.)

by fitting a pessary to support pelvic structures. Pessaries are inert material manufactured in many different sizes and shapes that can be fitted to the patient. When inserted in the vagina, a pessary mechanically supports pelvic structures resulting in temporary correction of the underlying symptoms. A pessary is a good option for patients choose not to undergo surgery or for those who cannot have surgery.

► Differential Diagnosis

Urethral diverticulæ may mimic cystocele and produce a bulge of the anterior vaginal wall. A discrete mass is usually palpable. Pressure or massage of the mass may result in turbid or purulent urethral drainage. Vaginal cysts such as Gartner duct or Skene duct cysts are occasionally mistaken for bladder support defects.

► Treatment

Categories of pelvic floor defects include anterior compartment, vault prolapse, uterine prolapse, enterocele, posterior compartment, urinary incontinence, and fecal incontinence.

Anterior Compartment

Anterior compartment defects, including cystocele, para-vaginal defects often are associated with concurrent urinary incontinence. **Stress incontinence** is involuntary loss of urine. Stress incontinence is associated with leakage caused by increases in intra-abdominal pressure including coughing, heavy lifting, or Valsalva maneuver in the absence of detrusor contraction. Stress incontinence is usually demonstrated during examination by asking the patient to cough. Stress incontinence should be distinguished from other common types of urinary incontinence including urge and overflow incontinence. With **urge incontinence**, the detrusor muscle contracts or spasms resulting in leakage with associated urgency. **Mixed incontinence** is defined as a combination of stress and urges incontinence. **Overflow incontinence** is often a continual slow leak of urine but may present with symptoms of any of the other types of incontinence. It can be ruled out by detecting large residual urine volume following voiding. Surgical correction of stress incontinence occasionally produces urge incontinence that may persist in 10%-15% of patients.

Normally, the proximal urethra is supported above the urogenital diaphragm and is subjected to the same intra-abdominal pressure changes as those applied to the bladder. In patients with anterior vaginal compartment defects, increased intra-abdominal pressure causes the hypermobile proximal urethra and bladder base to descend into the vagina. Pressure in the bladder thereby exceeds the sphincter pressure resulting in leakage of urine. Intrinsic sphincter deficiency is a second mechanism of stress incontinence. Risk factors include previous incontinence surgery, prior radiation therapy, and age over 50.

Site-directed repair of anterior compartment defects may include anterior colporrhaphy, or repair of paravaginal defect. Repair of stress urinary incontinence often involves retropubic colposuspension using either the Burch or Marshall-Marchetti-Krantz procedures. Success of these two procedures is approximately 85% at 5 years. Recurrent or difficult cases of stress urinary incontinence are often surgically treated with use of slings or grafts to augment support. Grafts may be created from endogenous fascia, usually harvested from the rectus fascia, or exogenous sources including allografts, xenografts, or synthetic mesh. Procedures utilizing the grafts may include sling procedures or the tension-free vaginal tape procedure (TVT), which has significantly reduced the morbidity of graft procedures compared to historical controls. For patients with intrinsic sphincter deficiency or for patients who are not candidates for more involved surgical procedures, a minimally invasive treatment involves injection of collagen at the urethrovaginal junction as a bulking agent to increase outlet resistance.

Prolapse

Prolapse, where the level I support involving upper vagina or uterus is deficient, results in symptomatic descent of the upper vaginal tissues and/or uterus. Prolapse may also be associated with anterior and posterior compartment defects.

Repair of vaginal prolapse is generally performed with a unilateral sacrospinous ligament suspension (SSL) procedure performed transvaginally or with an abdominal sacrocolpopexy procedure performed via laparotomy or laparoscopy. In the SSL procedure, the upper vagina is sutured to the uterosacral ligament. In the abdominal sacrocolpopexy procedure, a retroperitoneal mesh is sutured from the upper vagina to the anterior longitudinal sacral ligament. Treatment of uterine prolapse sometimes involves hysterectomy combined with SSL or with abdominal sacrocolpopexy procedures. Uterine preservation is permissible, combined with plication of uterosacral ligaments or the other procedures described above. Results of surgical correction of prolapse are not optimal since up to one-third of patients require reoperation for recurrent disease. Sacrocolpopexy outcomes appear to be more durable.

Enterocoele

Enterocoele is a hernia that develops between the vagina and the rectum. Diagnosis is confirmed by palpation on pelvic exam and can also be documented on transvaginal ultrasound. Surgical repair requires reapproximation of the fascial defect at the apex of the rectovaginal septum via laparotomy, laparoscopy, or by vaginal approach depending on other planned combined procedures such as hysterectomy.

Posterior Compartment

Posterior compartment defects, including rectocele and anal sphincter defects often are associated with concurrent fecal incontinence or difficulty with defecation. Fecal incontinence is involuntary loss of stool or flatus.

Etiology of fecal incontinence is associated with diarrhea; increased bowel motility; neurological disorders such as diabetes, spinal cord injury, or multiple sclerosis; and pelvic support defects including injury to the anal sphincter. Testing includes careful exam of level II and level III structures, anal sphincter tone, and voluntary anal sphincter contraction. Additional test that may be needed to elucidate the etiology of the lesion include anal manometry, transanal ultrasound, MRI, colonoscopy, defecography, and electromyography. Diarrheal illness and gastrointestinal disorders such as irritable bowel syndrome are treated prior to consideration of surgery.

Nonsurgical treatment may include use of medication to slow transit time, bulking agents, biofeedback, and electrical stimulation therapy.

Site-directed repair of posterior compartment defects may include posterior colporrhaphy, where posterior fascial defects are repaired primarily or with grafts, sphincteroplasty, or repair of rectal prolapse.

In patients for whom sexual activity is not an issue, closure (colpocleisis) or removal (colpectomy) of the vagina is an option.

Delancey JO: Why do women have stress urinary incontinence? *Neurourol Urodyn* 2010;29(Suppl 1):S13-S17.

Urinary Tract Fistula

Urinary tract fistulas to the vagina include vesicovaginal, ureterovaginal, and urethrovaginal types. Vesicovaginal fistula is the most common type. In the United States, most urinary tract fistulae occur following pelvic surgery with unrecognized injury or because of ischemia. Potential causes of ischemic change include effects of radiation therapy upon vasculature of pelvic organs. Less common in this country, but much more frequently in other parts of the world is ischemic injury following prolonged or obstructed labor. Fistulas may also occur as a result of tumor invasion, retained foreign bodies, and chronic inflammation.

Most urologic fistulae arise following gynecologic surgery rather than urologic or colorectal surgery. Total abdominal hysterectomy is the procedure most often complicated by the development of vesicovaginal fistula. A skillful surgeon using a technique of careful identification of anatomic structures can greatly minimize the risk of causing fistula formation. Injuries recognized at the time of primary surgery should be repaired immediately. Development of postoperative fistulae may require a waiting period to allow inflammation to subside before undertaking repair.

► Symptoms & Signs

Vaginal leakage of urine or constant urinary leakage are symptoms of a urologic fistula. If the fistula involves the distal urethra, the patient may experience vaginal leakage only at the time of voiding. Vesicovaginal and ureterovaginal fistulae almost always develop near the vaginal vault. A urethrovaginal fistula opens into the anterior vagina.

On speculum exam, urine will usually be seen pooling at the vaginal apex. Most fistulae in nonradiated patients are small and may not be readily seen with the naked eye. Confirmation of a suspected vesicovaginal fistula may be demonstrated by instilling dilute methylene blue dye or sterile milk into the bladder with a catheter while inspecting the vaginal vault. A small fistula may leak very little and is often better seen by placing a tampon in the vagina when methylene blue dye is instilled and then removing the tampon to inspect for blue staining after 15-20 minutes. If a vesicovaginal fistula is not detected, IV methylene blue or indigo carmine blue dye will be excreted through the ureters. This is best detected by placement of a tampon for about 30 minutes followed by inspection for staining.

Other useful diagnostic tests include cystoscopy, cystogram, and intravenous pyelogram to assess for the site of injury.

► Treatment

In nonradiated, noninfected tissue, many small fistulae will close spontaneously if the bladder is drained with an indwelling catheter. Larger fistulae or small fistulae that fail conservative management must be repaired surgically. Time of the order of 8-12 weeks must be allowed for resolution of edema and inflammatory reactions prior to undertaking repair. Premature repair has a high likelihood of being unsuccessful. Urinary tract infections should be treated and skin integrity should be protected with an occlusive barrier cream before surgical correction is attempted.

Repair of vesicovaginal fistulae involves a number of techniques including layered closure with the Latzko procedure via the vaginal approach, or via laparotomy with omental interposition. Principles of repair include meticulous and atraumatic technique using fine suture material;

approximation without tension; and bladder decompression postoperatively. Ureterovaginal fistulae are repaired with ureteroneocystostomy if the ureteral injury is in the lower pelvis and with ureteroureterostomy for injury sites higher in the pelvis. These are usually performed via laparotomy, but the laparoscopic approach is also used. Fistulae in radiated tissue cannot be repaired primarily due to chronic tissue ischemia. These fistulae require the introduction of a nonradiated blood supply provided by bulbocavernosus or gracilis myocutaneous flaps for successful repair or permanent diversion.

Rectovaginal Fistula

Rectovaginal fistulae may occur following obstetrical injury, pelvic surgery, cervical or rectal cancer, radiation therapy, inflammatory bowel disease, or diverticular disease. The patient will report vaginal passage of flatus or feces, or foul vaginal discharge, sometimes associated with bleeding. The fistula can often be demonstrated upon speculum examination, or by palpation on rectovaginal exam. Diagnostic studies such as barium enema or sigmoidoscopy may be useful for smaller lesions.

To reduce the risk of infection and breakdown of a planned fistula repair, the bowel should be prepared with a low-residue diet, antibiotics, and a cathartic bowel regimen preoperatively. A rectovaginal fistula in the lower third of the vagina should be repaired after the surrounding inflammation and edema have resolved, usually requiring a delay on the order of 12 weeks. Rectovaginal fistulae in the upper two thirds of the vagina are best treated with a preliminary diverting colostomy, followed by fistula repair and subsequent colostomy take down 2-3 months after the repair.

Fistulae caused by inflammatory bowel disease such as Crohn disease have a high likelihood of recurrence unless the disease is clearly in remission. Ileostomy and abdominoperineal resection are necessary in patients whose symptoms are unacceptable despite medical management. Fistulae associated with radiation therapy can rarely be repaired and those associated with cancer are not amenable to surgical repair. A diverting colostomy provides considerable relief of symptoms.

THE UPPER GENITAL TRACT

SURGERY FOR BENIGN UTERINE DISEASE

Congenital Uterine Anomalies

Congenital duplication defects of the uterus are rare, with a reported incidence of 0.4%-1% and are usually diagnosed following investigation for recurrent spontaneous abortions, premature labor, fetal malpresentation, retained placenta,

and postpartum hemorrhage. (Figure 39–1) Anomalies include septate uterus, comprised of a simple midline septum; bicornuate uterus, which is a duplication of the uterine horns; and uterus didelphys consisting of complete duplication of the corpus and cervix. These anomalies are often detected with physical examination, especially during or after pregnancies complicated by malpresentation, or preterm labor. Testing with MRI or hysterosalpingogram will usually confirm the diagnosis, and are combined with ultrasonography or laparoscopy if the diagnosis remains uncertain. Combined laparoscopy and hysteroscopy is useful for planning surgical correction.

Surgical correction of uterine anomalies is indicated for prevention of documented or anticipated pregnancy-related complications. A septate uterus is twice as likely to cause spontaneous abortion than a bicornuate uterus, with an overall loss rate of 88% reported for patients with a complete septum. The septate uterus is treated with a septoplasty, completed in most cases by hysteroscopic division or resection of the septum with up to an 86% success rate for subsequent pregnancy. Alternatively, the abdominal metroplasty is indicated for a large or thick septum or for the bicornuate uterus. A wedge of myometrium is resected allowing the two horns of the uterus to be reconstructed. This procedure results in measurable loss of uterine volume. Pregnancies occurring after abdominal metroplasty should be delivered by cesarean section as the risk of uterine rupture is increased.

Abnormal Uterine Bleeding

Abnormal uterine bleeding may occur at any age. It is not unusual for a female infant to have a small amount of self-limited vaginal bleeding attributable to the decline of circulating estrogen from maternal sources after delivery.

Abnormal uterine bleeding during the reproductive years is described according to the chronicity and amount of bleeding because this is often useful in elucidating the etiology. Hypermenorrhea, also referred to as menorrhagia, is defined as excessive or prolonged bleeding at the normal time of menstruation. Polymenorrhea is defined as bleeding that occurs more frequently than every 3 weeks, and metrorrhagia, defines intermenstrual bleeding that occurs in the interval between menses.

Hypermenorrhea may be due to such physical disease of the uterus including uterine leiomyoma, adenomyosis, and endometrial polyp. Dysfunctional uterine bleeding is abnormal uterine bleeding related to functional response of a normal uterus to extrauterine causes such as abnormal cycling of estrogen and progesterone in patients with anovulation, oligo-ovulation, or persistence of the corpus luteum. This condition is seen most often in adolescents and in perimenopausal women. Polymenorrhea is sometimes related to a shortened proliferative phase secondary to hypothyroidism. Causes of metrorrhagia include endometrial

polyps, submucous leiomyoma, coagulopathy, granulomatous infections such as tuberculosis, or cancer of the cervix or uterine corpus. Complications of pregnancy should not be overlooked as a cause of abnormal bleeding in women of reproductive age.

Postmenopausal bleeding is defined as any vaginal bleeding occurring a year or more after menopause and is of concern because it may be a symptom of endometrial cancer. When postmenopausal bleeding is fully evaluated including biopsy and hormone studies, the majority will be attributed to benign etiologies such as atrophic change, benign polyp, cervicitis, and physiologic withdrawal from exogenous hormones. Endometrial cancer is detected in about 15% of cases of postmenopausal bleeding, but is also linked to the age of the patient: a 50-year-old woman has about a 2% chance of cancer, while an 80-year-old woman with the same symptom has about a 60% chance of malignancy. Cervical cancer may also present with postmenopausal bleeding. The exogenous administration of estrogenic substances, including hormone replacement therapy, and use of estrogen analogs such as tamoxifen cause postmenopausal bleeding. Much less likely are estrogen-producing tumors of the ovary, coagulopathy, or environmental sources of estrogenic substances. Postmenopausal bleeding in any amount ranging from scant brown vaginal discharge to frank, profuse, bright red bleeding should prompt further workup. Cancer should be considered the likely cause until proven otherwise.

► Clinical Findings

Obtain a complete history and perform a careful pelvic examination including a Pap test. The exam will often reveal vaginal, cervical, uterine, or adnexal disease. A complete blood count and measurement of red cell indices will ascertain the degree of chronic blood loss. Additional blood studies including thyroid function testing and testing for coagulopathy may be necessary in some cases.

Abnormal bleeding in women over the age of 35 or with Pap test results showing atypical glandular cells of any type, or in women of any age with a Pap test showing atypical glandular cells, or women with risk factors for gynecologic cancer, endometrial biopsy is required to confirm a diagnosis. The biopsy should be timed at an appropriate time in the menstrual cycle, such as after the sixteenth day of the cycle if anovulatory bleeding is suspected, but may be performed at any time to evaluate for hyperplasia or carcinoma. Endometrial sampling with a disposable suction device can be accomplished in an office setting in most patients. Obese patients or patients with cervical stenosis may require dilatation and curettage in the operating room. Pregnancy should always be ruled out before performing a biopsy in a woman of reproductive age.

Hysteroscopy, involving insertion of a narrow diameter videoscope through the cervix while distending the uterine

cavity allows inspection of the endometrium and directed biopsy of suspicious features. Hysteroscopy is very useful for determination of the cause of bleeding and offers the opportunity for simultaneous treatment such as hysteroscopic resection of a polyp. Hysteroscopy can be accomplished in an office or outpatient surgical setting and is recommended when bleeding is recurrent or resistant to therapy or when structural abnormalities of the endometrium such as polyps or submucous leiomyomata are suspected.

Transvaginal ultrasound is useful to measure endometrial thickness and structural abnormalities of the uterus such as a polyp or leiomyoma. In the postmenopausal patient, an endometrial strip of less than or equal to 4 mm virtually excludes the likelihood of cancer. Biopsy is still preferable unless it is unable to be performed for technical reasons. The sonohysterogram, where saline is introduced into the endometrial cavity during ultrasound increases diagnostic accuracy for defects in the endometrial cavity.

► Treatment

Dilation and curettage is both diagnostic and therapeutic for many causes of uterine bleeding. Definitive treatment, however, will be targeted toward the etiology of the abnormal uterine bleeding.

Medical management of most nonneoplastic causes of abnormal uterine bleeding is generally prescribed before considering surgery because many symptoms will resolve or managed without surgical intervention. Chronic blood loss due to hypermenorrhea produced by leiomyoma or hyperplasia, can be reduced by the administration of a progestin. A gonadotropin-releasing hormone (GnRH) agonist will result in amenorrhea and is sometimes prescribed prior to planned surgery for leiomyomata. The antiprogestin mifepristone may significantly shrink leiomyomata, but a side effect includes increased risk of endometrial hyperplasia. Dysfunctional bleeding due to chronic anovulation is treated with cyclic progestin therapy, or oral contraceptives. For women who wish to conceive, ovulation induction with drugs such as with clomiphene are prescribed. Control of acute heavy bleeding may be achieved through the use of higher doses of combination oral contraceptives prescribed as one pill four times a day for 3 or 4 days, tapered to one pill a day over one week. Alternatively, intravenous conjugated estrogen, 25 mg every 4 hours, has been used also to control acute bleeding. Such a regimen must be followed by a progestin to prevent additional irregular bleeding at a later time. Following control of acute bleeding, maintenance therapy with an oral contraceptive is recommended. Another strategy for maintenance includes placement of an intrauterine device (IUD) containing levonorgestrel resulting in amenorrhea in about 25% of women and light menses in the remainder. In the absence of identified intrauterine pathology, hypermenorrhea associated with

ovulatory cycles can be ameliorated with nonsteroidal anti-inflammatory drugs.

Persistence of symptoms will generally require surgical intervention. Surgical treatment of bleeding caused by uterine leiomyoma is discussed later in this chapter. Severe or intractable dysfunctional uterine bleeding may require hysterectomy. Endometrial ablation by hysteroscopically directed electrosurgery, or use of proprietary endometrial ablation devices may avoid hysterectomy in the premenopausal patient with bleeding that cannot be managed medically. Ablation generally requires normal size and shape of the uterine cavity. Only about 20% of women report amenorrhea following endometrial ablation, and about one-third will undergo eventual hysterectomy. Placement of a levonorgestrel-containing IUD is nearly as effective as hysteroscopic endometrial ablation.

Postmenopausal bleeding due to atrophic changes may resolve with estrogen therapy, administered with progestin in either a cyclic or continuous fashion. Postmenopausal bleeding attributed to physiologic withdrawal bleeding from prescribed estrogen-based therapy is treated by discontinuing therapy or converting to a continuous regimen. Curettage for removal of benign endometrial polyps is often curative, although polyps may recur. Endometrial carcinoma is a relative contraindication to estrogen therapy and is treated surgically with possible postoperative adjuvant radiation or chemotherapy based upon stage and grade of the tumor. Well-differentiated endometrial adenocarcinoma in young women who desire to maintain fertility has been successfully treated using high-dose progestins in about three-fourths of cases.

Adenomyosis

Extension of endometrial glands and stroma into the myometrium is defined as adenomyosis. Symptomatic adenomyosis is most prevalent in the between age 35 and menopause. Symptoms include dysmenorrhea, hypermenorrhea, polymenorrhea, metrorrhagia, and dyspareunia. Concurrent endometriosis is common. Symptoms typically improve after menopause supports.

Upon pelvic examination, the uterus is slightly to moderately enlarged and is frequently tender to palpation, particularly in the secretory phase of the menstrual cycle. Preoperative confirmation of adenomyosis is challenging. Neither ultrasound nor endometrial biopsy is useful for making the diagnosis. The T2 weighted sequences on MRI is more effective, with sensitivity of 70% and specificity of 86%. Definitive diagnosis is confirmed after hysterectomy.

► Differential Diagnosis

Leiomyomata of the uterus are common and cause many symptoms similar to adenomyosis. Low-grade endometrial

stromal sarcoma is rare, but can be mistaken as adenomyosis. This is an indolent malignancy with a significant likelihood of local recurrence. Distant metastases to the ovary, peritoneal surfaces, and lung are occasionally seen. Tumors of this type should not be morcellated. Subsequent treatment may include pelvic radiation therapy and hormone therapy based on stage at time of diagnosis and presence of estrogen and progesterone receptors.

► Treatment

Total hysterectomy with or without bilateral salpingo-oophorectomy is the only clearly effective treatment. Hormonal approaches may be successful in treating symptoms, particularly if the patient is nearing menopause. Menopause causes symptoms to regress.

Leiomyomata

Uterine leiomyomata, or fibroids, are present in 20%-30% of women of reproductive age. The true prevalence is unknown because many fibroids are asymptomatic. Black women have a threefold higher incidence than white, Asian, and Hispanic women. Other risk factors include obesity, nulliparity, and early menarche or infertility. Myomas arise from monoclonal proliferation and are stimulated by estrogen, progesterone, and growth factors. Fibroids increase growth rate during pregnancy and regress after menopause. Fibroids are usually multifocal and vary hugely in size, ranging from a few millimeters to masses that fill the abdomen. Location of leiomyomata can be nearly anywhere within the uterus. Descriptive terms for location include intramural for fibroids arising within the myometrium, subserosal for lesions below the exterior surface of the uterus, and submucosal for fibroids below or adjacent to the endometrium. Other types of leiomyomata include pedunculated lesions connected with a narrow vascular stalk to the uterus, intraligamentous lesions within the broad ligament, and parasitic leiomyomata, detached from the uterus and deriving blood supply from adjacent organs.

► Clinical Findings

Symptoms are determined by location, number, and size of the lesions. Common symptoms include hypermenorrhea, prolonged menses, pelvic pressure, increased abdominal girth, urinary frequency, dyspareunia, low back pain, and constipation. Infertility may occur secondary to fibroids, particularly if the uterine cavity is enlarged or distorted by a submucous lesion. Adverse pregnancy outcomes such as abnormal placentation, malpresentation, abruption, and dysfunctional labor are recognized complications associated with fibroids. Degenerative changes may spontaneously occur, potentially causing significant pain that requires treatment. Submucous

leiomyomata are more likely to cause hypermenorrhea, polymenorrhea, and metrorrhagia.

Palpation of the uterus during bimanual examination detects a lobular and enlarged structure with a characteristic rubbery consistency. Soft and tender lesions are characteristic of degenerating fibroids. Larger lesions may be felt on abdominal examination.

Anemia may result from acute or chronic abnormal uterine bleeding. Endometrial biopsy should be performed in women with abnormal uterine bleeding to rule out endometrial cancer. Pelvic ultrasound is the most useful study for diagnosis. Sonohysterogram or hysteroscopy are useful for confirmation of submucous leiomyomata. MRI is expensive and should be utilized selectively for evaluation of an atypical lesions that could represent sarcoma or for of lesions prior to a myomectomy. Hydronephrosis may be apparent on imaging studies, arising as a result of external compression of the by the mass.

► Differential Diagnosis

Uterine leiomyosarcoma is a rare but aggressive neoplasm. Among women undergoing surgery for fibroids, only 0.23% is found to harbor sarcoma. The rapidly growing leiomyoma, defined as 6 cm growth in 1 year, will be malignant in less than 0.1% of cases. In a postmenopausal woman with an enlarging uterine mass, sarcoma is more likely. Most sarcomas are not detected prior to surgery, although a high T1/high T2 pattern on MRI has been reported to be predictive of sarcoma. On cut section, leiomyomata are well-circumscribed, solid tumors with a pseudocapsule and an off-white, whorled appearance. If a lesion lacks an apparent capsule, appears necrotic, is soft or friable, then a frozen section should be submitted. These findings are likely to represent a sarcoma.

Other potential diagnoses to consider include solid ovarian tumors. Enlargement of the uterus may arise due to adenomyosis or could represent an undiagnosed pregnancy. A pregnancy test should be considered.

► Treatment

Asymptomatic fibroids require no therapy. Women with hypermenorrhea or polymenorrhea often benefit from a trial of cyclic or continuous oral contraceptives or progestins. GnRH agonists decrease myoma size and stop menstruation prior to surgery. However, long-term use of GnRH agonists causes osteoporosis. Treatment with the antiprogestin mifepristone may result in significant shrinkage of fibroids, but may cause endometrial hyperplasia. In premenopausal women, leiomyomata grow soon after medication is discontinued.

For women with symptoms unresponsive to medical management, several treatment options are available. Myomectomy is a procedure for removal of leiomyomata

with subsequent repair of resultant defects in the uterine wall in order to preserve the uterus. Myomectomy is usually offered to women who desire to retain their fertility. Some women who do not desire pregnancy also choose this option. Myomectomy is performed via laparotomy, laparoscopy, or hysteroscopy depending on the location, number, and size of the leiomyomata. Women who have completed childbearing and desire an alternative to hysterectomy may choose uterine artery embolization or guided focused ultrasound surgery, both of which are designed to decrease the size of lesions. Embolization involves diminishing blood flow to the uterus by occluding vessels to the lesion using angiography. Uterus and fibroids have been reported to decrease in size by one-third to one half. Bleeding and pelvic pressure improve in 80%-90% of women. Hysterectomy is definitive treatment for women with symptomatic myomas. Alternatives to total abdominal hysterectomy include vaginal hysterectomy, supracervical hysterectomy, and laparoscopic hysterectomy.

► Prognosis

Myomectomy results in improvement of symptoms in 80% of women. Ten percent of women undergoing myomectomy require additional surgery for recurrent lesions and 50% will develop recurrent leiomyomata.

SURGERY FOR MALIGNANT UTERINE DISEASE

Endometrial Cancer

Endometrial carcinoma is the most common gynecologic malignancy in the United States. It is primarily a disease of postmenopausal women. Tumors are grouped into type I and II categories based on their underlying etiology. The more common type I tumors arise due to prolonged estrogen stimulation of the endometrium. The estrogen is most commonly endogenously produced estrone arising by aromatase conversion of androstenedione in peripheral adipocytes. Obese women produce much more estrogen and are at much higher risk for developing this cancer. Exogenous estrogens prescribed without accompanying progestin in postmenopausal women greatly increases the risk of endometrial cancer as does treatment with other estrogen receptor agonists such as tamoxifen when prescribed for treatment or prevention of breast cancer. Other risk factors for development of endometrial cancer include diabetes, early menarche, late menopause, and low parity. Oral contraceptives are protective against this cancer. Also at risk are premenopausal women with chronic anovulation such as with polycystic ovary syndrome.

Complex hyperplasia with atypia is a precursor lesion for type I endometrial cancer. These tumors usually express estrogen and progesterone receptors. Type II endometrial

cancer consists of anaplastic or high-grade, papillary serous, clear cell, and squamous carcinomas. These tumors rarely express estrogen or progesterone receptors and are not thought to arise as a result of estrogen stimulation. Adverse prognostic factors include grade, histology, depth of myometrial invasion, cervical extension, tumor size, and extension beyond the uterus.

Endometrial cancer is staged surgically as shown in Table 39–5.

► Clinical Findings

Postmenopausal bleeding is the presenting symptom in about 90% of cases and should be considered to be cancer until proven otherwise. Common etiologies of postmenopausal bleeding include physiologic bleeding from hormone replacement therapy (27%), benign polyps (7%-23%), cervicitis (6%-14%), endometrial carcinoma (13%-16%), atrophy (10%),

Table 39–5. FIGO staging for endometrial cancer.

FIGO Stage	Revised 2009
Stage I	Tumor confined to corpus uteri
IA	No or less than 50% myometrial invasion
IB	Invasion equal or greater than 50% of myometrium
Stage II	Tumor invades cervical stroma but does not extend beyond uterus
Stage III	Local and/or regional spread. Positive cytology has to be reported separately without changing the stage
IIIA	Tumor invades serosa and/or adnexae
IIIB	Vaginal and/or parametrial involvement (direct or metastases)
IIIC	Metastases to pelvic and/or para-aortic lymph nodes
IIIC-1	Positive pelvic nodes
IIIC-2	Positive para-aortic nodes with or without positive pelvic nodes
Stage IVA	Tumor invades bladder or bowel mucosa
Stage IVB	Distant metastases, including intra-abdominal and/or inguinal lymph nodes
Grade 1	
Grade 2	
Grade 3	

Grade of tumor is related to the proportion of nonsquamous, solid growth pattern in the tumor. Grade 1 is comprised of ≤ 5% of nonsquamous solid growth pattern; grade 2 is 6-50% nonsquamous solid growth pattern; and grade 3 is > 50% nonsquamous solid growth pattern. (Reproduced, with permission, from Pecorelli S: Revised FIGO staging for carcinoma of the vulva, cervix, and endometrium. *Int J Gynecol Obstet.* 2009 May;105(2):103–4.)

cervical carcinoma (1%-4%). Despite workup, up to 20%-23% of cases will have no identified etiology. Cervical stenosis with pyometrium or hematometrium is highly suggestive of endometrial carcinoma. Pain is not a common symptom. Vaginal cytology is positive in 40%-80% of cases but is entirely unreliable as a diagnostic tool for endometrial cancer. Endometrial biopsy performed in the office using a disposable biopsy instrument is highly sensitive. If endometrial biopsy fails to provide a definitive diagnosis, dilatation and curettage of endocervix and endometrium, is definitive.

Type II endometrial carcinoma comprised of poorly differentiated, or adverse histological types, may disseminate relatively early in the course of the disease. Metastatic spread may occur to the vagina, regional pelvic and para-aortic lymph nodes, ovaries, lungs, brain, and bone. The most frequent site of recurrence following treatment for endometrial carcinoma is the vaginal vault.

► Prevention

Oral contraceptives have been shown to reduce the risk of endometrial cancer by up to 50% depending on duration of treatment. Progestin therapy will reduce the possibility of endometrial carcinoma in the anovulatory patient as well as in postmenopausal women receiving estrogen replacement therapy. Progestins in both OCP and hormone replacement regimens cause downregulation of estrogen receptors and atrophy of endometrium.

► Treatment

Endometrial cancer is staged surgically. The route of surgical approach for the staging procedure can be either via laparotomy or laparoscopy. Definitive therapy includes total hysterectomy, bilateral salpingo-oophorectomy, pelvic and para-aortic lymphadenectomy and pelvic washings for type I cancers. For type II lesions, omentectomy is usually added. Lymphadenectomy is sometimes omitted for patients with type I lesions with low-risk such as small, grade-1 cancers without myometrial invasion.

If the cervix is grossly involved, patients may receive preoperative radiation followed by total hysterectomy, bilateral salpingo-oophorectomy, pelvic and para-aortic lymphadenectomy and pelvic washings. Alternatively, a radical hysterectomy bilateral salpingo-oophorectomy, pelvic and para-aortic lymphadenectomy may be performed without preoperative radiation. The radical hysterectomy includes removal of the upper third of the vagina, cardinal, and uterosacral ligaments.

Adjuvant pelvic radiation therapy is administered to patients with cervical extension (stage II); deep myometrial invasion with a grade 3, type I lesion; or vaginal extension (stage IIIB). A randomized clinical trial comparing radiation to chemotherapy with cisplatin and doxorubicin showed a survival benefit for patients with positive nodes (stage IIIC) treated with chemotherapy. Metastatic and type II lesions

such as papillary serous carcinomas are very likely to recur after surgery regardless of stage. These tumors are usually treated with multimodal therapy using a combination of radiation and chemotherapy.

Metastatic or recurrent disease is usually treated with multimodal therapy using surgery, radiation and/or chemotherapy based on the location, size, and histology of lesions. Chemotherapy combinations usually include either a doublet of cisplatin with paclitaxel or doxorubicin or a triplet regimen combining all three drugs. Metastatic cancer of type I may be treated with progestin therapy.

► Prognosis

Survival at 5 years is about 70%-90% for stage I disease, depending on grade and myometrial invasion. Survival declines to about 60% in stage II. Anaplastic tumors, deep myometrial penetration, and absence of estrogen and progesterone receptors all worsen the prognosis.

Uterine Sarcoma

Uterine sarcomas fall into three histological groups including leiomyosarcoma, endometrial stromal sarcoma, and carcinosarcoma. These tumors are rare, accounting for about 3% of uterine neoplasms. Sarcomas of the uterus spread via hematogenous and lymphatic pathways in addition to direct extension. Lung and liver are frequent sites of metastases and recurrence.

In patients in whom the tumor is confined to the pelvic organs, treatment consists of total hysterectomy, bilateral salpingo-oophorectomy, pelvic and para-aortic lymphadenectomy, omentectomy and pelvic washings. There are no randomized trials documenting survival benefit for adjuvant therapy with either chemotherapy or radiation. However, individualized postoperative radiation and/or chemotherapy may be offered based on the poor prognosis of these tumors. Radiation reduces pelvic recurrences, but does not appear to improve overall survival.

The outlook for patients with uterine sarcoma is dependent on grade and stage of the tumor. Leiomyosarcomas with more than ten mitoses per ten high-power fields carry a poor prognosis, with recurrence within 5 years in about two-thirds of patients. About 40% of patients with carcinosarcoma survive. Isolated, late recurrence of leiomyosarcoma in the lung is treated by resection of the affected lobe with generally good salvage rates of about 50% at 2 years.

Gemcitabine and Taxotere is the combination with the highest likelihood of response for metastatic or recurrent leiomyosarcoma. High-dose progestin therapy is very effective for treatment of metastatic low-grade endometrial sarcoma. Carcinosarcoma is most effectively treated with combination of either cisplatin and ifosfamide or ifosfamide and paclitaxel.

Gestational Trophoblastic Disease

Gestational trophoblastic disease refers to tumors arising from placental tissue. They are unique among all neoplasms in that their genetic complement is provided by the father, thereby resulting in a tumor with genetic material and markers foreign to the patient. Gestational trophoblastic diseases may be divided into preinvasive and invasive types. The preinvasive types include complete and partial hydatidiform moles.

The frequency of hydatidiform mole is about 1:700 to 1:2000 pregnancies in the United States, Canada, and Western Europe and about 1:85 to 1:520 pregnancies in Asia. Hydatidiform mole is more common in women over 40. A prior history of gestational trophoblastic disease significantly increases the risk of recurrence with a future gestation.

The gross appearance of a hydatidiform mole is related to the hydropic villi in the absence of a fetal circulation. The histological appearance reveals varying degrees of trophoblastic proliferation. Hydatidiform moles can be classified as either complete or partial, based on cytogenetics and histopathology. These features are compared in Table 39–6. The majority of complete moles carry a 46XX karyotype, with chromosomes exclusively of paternal origin. Partial moles are typically triploid with 69XXX or 69XXY, where two or three sets of chromosomes are paternal in origin. Complete moles are not associated with a developing fetus, and partial moles may include a fetus that is typically small and with multiple anomalies.

Invasive gestational trophoblastic disease is categorized as invasive mole, choriocarcinoma, or placental site trophoblastic tumor. Invasive mole is diagnosed after 15% of complete moles and 3.5% of partial moles. Metastases occur following 4% of complete moles and 0.6% of partial moles. Choriocarcinoma occurs following 3%–7% of hydatidiform moles and 1:40,000 term pregnancies. Out of all choriocarcinoma cases, 50% are preceded by a mole, 25% by sponta-

neous abortion, and 25% by term pregnancy. Placental site trophoblast tumor (PSTT) is a very rare variant with only 55 cases reported in the literature by 1991.

Invasive mole is comprised of hyperplastic trophoblasts with villi invading myometrium. Choriocarcinoma involves sheets of syncytiotrophoblasts with no villi and demonstrates invasion into myometrium or other tissues. Necrosis and hemorrhage are common. PSTT is comprised of intermediate cytotrophoblasts.

Human chorionic gonadotropin (β -hCG) is a clinically useful tumor marker for all types of preinvasive and invasive gestational trophoblastic disease except PSTT, where human placental lactogen (hPL) may be elevated.

► Clinical Findings

The most common presenting symptom with hydatidiform mole is vaginal bleeding, occurring in 97% of complete moles and 73% of partial moles. On pelvic exam, about 50% of complete moles and 8% of partial moles will reveal uterine size greater than expected for a given estimated gestational age. Theca lutein cysts are physiologic ovarian cysts as a result of hyperstimulation by very high levels of β -hCG produced by 50% of complete moles. These cysts typically resolve once the β -hCG level regresses following appropriate treatment. Preeclampsia may develop in 27% of women with complete moles and virtually never with partial moles. Clinical hyperthyroidism can develop in about 7% of women with complete moles with very high β -hCG levels due to cross reactivity of this hormone with thyroid stimulating hormone. A rare but potentially fatal complication is trophoblastic embolization to the lung during or after evacuation of large complete moles.

Diagnosis is usually confirmed with either ultrasound or β -hCG values. Serum β -hCG levels are above 100,000 mIU/mL in 46% of women with complete moles and these values persist beyond the twelfth week gestation, neither of which should be observed in a normal pregnancy. Ultrasound will usually demonstrate multiple small sonolucencies due to the hydropic villi. In a partial mole, the fetus, if present, will usually be small and afflicted with multiple anomalies.

► Differential Diagnosis

Threatened abortion or missed abortion will often present with similar symptoms of bleeding and both are more likely than gestational trophoblastic disease. A multiple gestation must be considered because it may produce unusually high levels of β -hCG in addition to uterine size greater than the gestational date.

► Complications

Metastasis is most common with choriocarcinoma, but may occur with any of the invasive types of gestational

Table 39–6. Features of hydatidiform moles.

Characteristic	Complete Mole	Partial Mole
Karyotype	46XX (90%) 46XY (10%) All paternal chromosomes	Triploid (90%) 69XXX or 69XXY Diploid (10%) 46 paternal chromosomes
Fetus	Absent	Often present
Villous edema	Prominent and diffuse	Focal if at all
Fetal RBC	None	Usually present
Proliferation of trophoblast	Prominent	Mild to moderate
Likelihood of local invasion	15%	3.5%
Likelihood of metastasis	4%	0.6%

trophoblastic disease. The most common sites of spread include lung (80%), vagina (30%), pelvis (20%), brain or liver (10%), bowel or kidney or spleen (<5%). Unlike virtually any other tumor, metastatic disease is still potentially curable in many patients.

► Treatment

Once the diagnosis of a molar pregnancy has been established, the uterus should be evacuated by suction curettage. All specimens are submitted for histology and cytogenetics. Theca lutein cysts of the ovaries regress following treatment of the mole and should not be surgically excised.

Following evacuation of the uterus, weekly serum β -hCG levels should be monitored until normalized for 3 weeks; followed by monthly testing for 6-12 months depending on assessment of pretreatment risk factors. If the β -hCG value plateaus for 3 weeks or rises for 2 weeks, invasive gestational trophoblastic disease including either invasive mole or choriocarcinoma should be suspected. Effective contraception during the surveillance phase is important in order not to complicate interpretation of the β -hCG.

Patients with invasive or persistent gestational trophoblastic disease should be evaluated with a metastatic workup including pelvic examination, CT scan of the head, chest, abdomen, and pelvis, a complete blood count, and renal and

liver function tests. Lumbar puncture to detect occult central nervous system metastases is sometimes necessary.

Staging of gestational trophoblastic tumors is outlined in Table 39-7. Unlike most neoplasms, gestational trophoblastic disease is staged using a nonanatomic staging system based on prognostic factors. Current FIGO staging combines anatomic staging with the modified WHO prognostic scoring system. For anatomic stage I disease, risk is usually low and for anatomic stage IV disease, risk is usually high. Stage II and III disease is best stratified with the modified WHO prognostic scoring system. Stage is recorded as anatomic stage and FIGO modified WHO score, separated by colon.

Single-agent chemotherapy is the preferred treatment for patients with stage I or low-risk disease who wish to maintain reproductive options. If future childbearing is not an issue, patients with invasive mole may be treated with a hysterectomy and possible adjuvant chemotherapy. Preferred regimens for single-agent therapy include methotrexate or dactinomycin. Both of these regimens can be toxic and should be administered under the guidance of a gynecologic oncologist or medical oncologist. Intermediate and high-risk gestational trophoblastic disease should receive aggressive combination chemotherapy. The most effective regimen reported includes etoposide, methotrexate, dactinomycin, cyclophosphamide, and vincristine (EMACO). There is

Table 39-7. FIGO anatomic staging for gestational trophoblastic disease.

FIGO Staging	Description			
Stage I	Disease confined to the uterus			
Stage II	GTN extends outside of uterus, but is limited to genital structures including adnexa, vagina, broad ligament			
Stage III	GTN extends to lungs with or without genital tract involvement			
Stage IV	All other metastatic sites			
Modified WHO Prognostic Scoring System as adapted by FIGO				
Factor	Description		Score	
	0	1	2	4
Age (years)	< 40	≥ 40		
Antecedent pregnancy type	Mole	Abortion	Term	
Pregnancy to treatment interval (months)	< 4	4 - < 7	7 - 13	≥ 13
Pretreatment β -hCG (mIU/L)	< 10^3	$10^3 - 10^4$	$10^4 - 10^5$	$\geq 10^5$
Tumor size including uterus (cm)	–	3 - 5	≥ 5	–
Site of metastases	Lung	Spleen Kidney	GI	Brain Liver
Number of metastases	0	1 - 4	5 - 8	> 8
Previous failed chemo regimens			Single	≥ 2

Total: If score is ≥ 7 , then patient is high risk and requires intensive, multiagent chemotherapy. Current staging combines anatomic staging with the modified WHO prognostic scoring system. Stage is recorded as anatomic stage and FIGO modified WHO score, separated by colon. Example of format: Stage IV: 8.

occasionally a role for surgery or radiation for selected metastatic disease sites and intrathecal methotrexate is sometimes needed for treatment of central nervous system disease.

► Prognosis

The prognosis for cure of gestational trophoblastic tumors is excellent, including cases with pulmonary metastases, which are still considered low risk. Five-year survival of up to 85% is reported in cases with high-risk metastatic disease. The risk of recurrence of gestational trophoblastic disease in a future pregnancy has a relative risk of 20-40, but in absolute terms, this translates to a recurrence risk of less than 5%. During any subsequent pregnancy, ultrasound is recommended. The placenta should be examined after delivery, and β -hCG should be monitored until normalization.

SURGERY FOR BENIGN FALLOPIAN TUBE DISEASE

Infertility Attributed to Fallopian Tube Disease

Infertility is defined as failure to conceive after 1 year of normal coital activity without use of contraceptives. About 15% of couples are infertile within this definition. When the etiology of infertility is evaluated, approximately 40% will be attributable to male factor infertility including low sperm count, impaired motility, or abnormal morphology of sperm. Anatomic abnormality of the pelvic organs is the single most common cause of infertility in women, and tubal factor infertility is the most common cause of infertility.

Common causes for tubal factor infertility include acute and chronic salpingitis, endometriosis, and adhesions from previous appendicitis with rupture or surgery. Chlamydia and gonorrhea infections are the most common causes of tubal damage causing infertility. Desire to reverse previous tubal sterilization may also be a reason for tubal surgery. One-third of infertile couples have more than one problem.

► History

It is important to elicit any history of sexually transmitted disease, pelvic inflammatory disease, pelvic surgery, cyclic pain, or dyspareunia.

► Clinical Findings

The size and mobility of the uterus should be assessed. Adnexae should be palpated for masses consistent with endometrioma or hydrosalpinx, in particular. Cul de sac or uterosacral ligament nodularity and tenderness suggest endometriosis. Ultrasound may reveal the presence of isochoic masses suggesting endometriosis or a tubular mass consistent with hydrosalpinx. Hysterosalpingogram, a test

that involves fluoroscopic assessment of tubal patency by transcervical injection of the uterus with radiocontrast, may reveal an obstruction including its location. Use of a water-based dye is indicated for the first attempt, and if occlusion is noted, an oil contrast medium may be used subsequently. The oil based hysterosalpingogram is reported to have therapeutic benefit.

Laparoscopy is warranted if the evaluation for anatomic abnormalities is inconclusive. Therapeutic interventions including lysis of adhesions or ablation of endometrial implants may be efficacious. If laparoscopy is performed following a normal hysterosalpingogram 24% will have mild endometriosis and 6% of patients will have adhesions.

► Treatment

Tuboplasty procedures may be performed to restore tubal patency. However, in vitro fertilization has become a much more popular intervention in recent years for treatment of infertility attributed to tubal occlusion or when multiple infertility factors affect the couple. Hydrosalpinx is usually treated by salpingectomy in order to optimize subsequent in vitro fertilization. Other factors of prognostic significance include age of the couple, and presence of other causes of infertility including ovulatory dysfunction or male factor infertility.

Heterotopic pregnancies and multiple gestation pregnancies are much more likely than the general population for patients undergoing in vitro fertilization.

► Prognosis

Age and severity of tubal disease are predictors of success. Women with mild adhesive disease and age less than 35 have the highest success rates, approaching 70%. For severe tubal disease, success is less than 15%. Ectopic pregnancy is twenty times more likely with a history of Fallopian tube surgery or preexisting scar resulting in a 10% incidence. IVF success rates vary by program and have generally been improving steadily in recent years. Decisions regarding planned tubal surgery versus IVF should take into account the relative costs and success rates.

Ectopic Pregnancy

Ectopic pregnancy is implantation of a viable pregnancy in a location other than within the endometrium lining the uterus. Risk factors for ectopic pregnancy include prior tubal surgery, previous ectopic pregnancy, history of pelvic inflammatory disease or Chlamydia infection, and pregnancy arising from assisted reproduction techniques. Smoking and history of infertility are also associated with increased risk of ectopic pregnancy. Over 95% of ectopic pregnancies occur in the Fallopian tube, generally within the ampullary portion. A less common location includes

interstitial pregnancy within the tubal lumen where it passes through the myometrium. Rare sites include cervix, ovary, omentum, pelvis, and abdomen. Heterotopic pregnancy refers to the rare occurrence of an intrauterine pregnancy with a synchronous ectopic pregnancy. The incidence of heterotopic pregnancy has increased from a spontaneous rate of 1:30,000 pregnancies to 0.1%-1% for pregnancies arising from assisted reproductive technology.

The incidence of ectopic pregnancy has been reported to occur in approximately 2% of pregnancies, although the true incidence is difficult to ascertain due to the potential for spontaneous resolution of some ectopic pregnancies resulting in unrecognized disease in addition to under reporting of early ectopic pregnancies treated medically rather than surgically. Pregnant women with pain or bleeding have a fourfold higher incidence of ectopic pregnancy. The primary potential morbidity of ectopic pregnancy is the potential rupture of the Fallopian tube or other implantation site resulting in hemorrhage. Failure to make a timely diagnosis can result in hemorrhagic shock and death.

► Symptoms & Signs

Patients will usually present with amenorrhea and a diagnosis of pregnancy. Subsequent irregular bleeding occurs in many but not all cases. In the early evolution of the ectopic pregnancy, patients may be asymptomatic. Presence of pain is also variable. Classic symptoms of a ruptured ectopic include severe abdominal pain, referred pain to the shoulder and hemodynamic instability. Upon pelvic examination an adnexal mass may or may not be present. The uterus is usually slightly enlarged and softened secondary to hormonal influence of the ectopic pregnancy.

► Diagnostic Studies

Trophoblastic cells of the blastocyst produce β -hCG that may be detected shortly after implantation. The rise of β -hCG is logarithmic, with a doubling time of about 48 hours. The β -hCG should rise at least 66% every 48 hours in 85% of normal pregnancies and will plateau in normal pregnancy late in the first trimester. Ectopic pregnancies show a slower rise of β -hCG in all but 15% of cases. An absolute β -hCG does not permit distinction between an ectopic and a nonviable intrauterine pregnancy.

Transvaginal ultrasound has almost 100% sensitivity for detection of intrauterine pregnancy as long as care is taken to discriminate between an actual pregnancy and the pseudo sac, defined as intrauterine fluid that can be mistaken for an intrauterine pregnancy. A true gestational sac is located eccentrically in the uterus and should demonstrate a fetal pole. The absence of an intrauterine pregnancy in the setting of a positive β -hCG is strongly suggestive of an ectopic pregnancy if the β -hCG value is above the discriminatory threshold of transvaginal ultrasound to detect a gestational

sac. The discriminatory threshold has been reported to occur with β -hCG values above 1500-3000 mIU/mL, although variables such as body mass index, quality of ultrasound equipment, and experience of the sonographer all impact on the threshold value. Diagnosis of the ectopic pregnancy by direct ultrasound localization of the pregnancy is much less accurate than detection of intrauterine implantation.

Other tests that are of value include obtaining a blood count to assess for anemia in addition to serum progesterone levels. Variability of progesterone values in normal pregnancy limits the utility of this test for diagnosis of ectopic pregnancy.

► Treatment

If the β -hCG shows an abnormal rate of rise, including plateau, slow rise, or declining values, then ultrasound is warranted. However, if the β -hCG value is below the discriminatory threshold, suction curettage is useful to distinguish between a nonviable intrauterine pregnancy and an ectopic gestation. The absence of chorionic villi in the curettage specimen in the presence of an elevated hCG is predictive of an ectopic pregnancy, though in early gestation the curettage may be falsely negative for villi.

Treatment of ectopic pregnancy is either surgical or medical depending on several variables. The surgical approach is definitive, but invasive and more costly than medical management. Medical management results in successful treatment for 90% of appropriately selected patients. Methotrexate is utilized for medical management. Appropriate indications for medical management require a hemodynamically stable patient who is compliant and has no medical contraindication to methotrexate. Relative contraindications include a gestational sac > 3.5 cm, presence of fetal cardiac motion, or a β -hCG value of > 15,000 mIU/mL. Administration of a single dose of methotrexate has reported efficacy of 84%. Use of multidose regimens increases the rate of success. Failure of the β -hCG value to fall by at least 15% within 4-7 days after treatment indicates that additional methotrexate or surgery is indicated. Patients who are Rh negative are given $\text{RH}_0(\text{D})$ immune globulin whether treated medically or surgically. Other developments in medical management include the use of other agents such as potassium chloride, prostaglandins, and mifepristone, but these have not been studied as well as methotrexate.

Surgical options for treatment of ectopic pregnancy are intended to remove the ectopic gestation and preserve functional Fallopian tube, if possible. If the patient is hemodynamically stable, the laparoscopic approach is usually preferred. If she is in shock or if the abdomen is distended with blood, emergent laparotomy is necessary. If the Fallopian tube is generally healthy, a salpingostomy is possible whereby the involved section of the Fallopian tube is removed through an incision in the antimesenteric

portion of the tube, while leaving the remainder of the tube intact. If the tube is more extensively damaged, complete or partial salpingectomy is recommended. If conservative approaches to preserve the Fallopian tube are utilized, the β -hCG value should be monitored postoperatively until normalization occurs.

Expectant management of a documented ectopic pregnancy may be an option in stable patients if the β -hCG value is less than 200 mIU/mL and declining. Patients must be counseled regarding the risks of rupture and hemorrhage, and emergency management must be readily available.

► Contraception

Contraception to prevent unwanted pregnancy may be attained using either reversible or permanent methods. Reversible methods include hormonal contraceptives via oral, transcutaneous or subcutaneous routes; injectable long acting progestins; IUD; and condoms, to name a few. Modern IUD contraceptives contain progestational hormones or copper, delivered in low doses to the uterine cavity where they inhibit sperm motility and block fertilization. They are inserted as an office procedure without requiring local anesthetic or cervical dilation in most cases. Both copper and progestin devices are highly effective and long lasting. Contemporary IUD contraceptives do not increase the risk of pelvic infection. Progestin-releasing IUD devices menstrual flow by about 50% and have been shown to be as effective for control of abnormal uterine bleeding, prevention of hyperplasia during estrogen replacement therapy, and treatment of hyperplasia.

Subdermal implant contraception uses low serum concentrations of contraceptive progestins found in birth control pills to thicken cervical mucus and inhibit ovulation. These actions result in failure rates comparable to those reported following sterilization and intrauterine contraception. Their duration of action is FDA approved for 3 years. As with intrauterine contraceptives, the principal side effect is change in menstrual bleeding; the majority of users experience a diminution in blood loss but an increase in number of days of bleeding, sometimes at unpredictable intervals.

Contraceptive implants require subdermal insertion with a disposable trocar with local anesthetic and are removed under local anesthetic through a small incision. These procedures take only a few minutes, and pain and infections are rare. Contemporary systems utilize a single-rod and are easier to use, have a shorter life, and are associated with somewhat more acceptable bleeding patterns than the now-discontinued multirod implants.

Unintended pregnancies result in about one million abortions per year in the United States. Uterine aspiration using either manual or electric vacuum pumps allows safe elective abortion in the first trimester, with a mortality rate of less than 1:200,000 procedures. Morbidity and mortality

of abortion rises substantially as the length of gestation increases.

Permanent sterilization options are available for both men and women. Prior to performing any permanent sterilization procedure, the physician must carefully counsel and determine whether a permanent method of contraception is appropriate for the patient. Reversal of permanent sterilization is costly and often ineffective. Permanent male sterilization via vasectomy is safe, effective with reported failure rates of 1.5 per 1000, and minimally invasive. For women, there are several permanent sterilization options. Most of the procedures for women are designed to occlude or remove the Fallopian tube via laparotomy or laparoscopy. These include Pomeroy, Irving, Uchida, and Madelener laparotomy operations in addition to laparoscopic procedures using unipolar or bipolar electrocautery of the Fallopian tubes, application of Silastic bands or proprietary clips (Filshie clips, Hulka clips). Mini laparotomy for Pomeroy-type tubal occlusion is often utilized for postpartum sterilization. There are now a limited number of proprietary methods of transcervical tubal occlusion based on intrauterine access to the tubal ostia using a hysteroscope.

The observed failure rate for tubal ligation procedures ranges from 0.7% to 3.6%, which is comparable to the failure rate of IUD and subdermal implants.

SURGERY FOR MALIGNANT FALLOPIAN TUBE DISEASE

Benign and malignant tumors of the Fallopian tubes are very rare. Adenocarcinoma of the Fallopian tube accounts for less than 1% of female reproductive tract cancers. Women with *BRCA1* and *2* mutations are at increased risk for Fallopian tube cancer concordant with their increased risk for ovarian cancer.

The most common presenting symptoms for cancer of the Fallopian tubes are postmenopausal vaginal bleeding or history of intermittent and profuse, watery vaginal discharge. The latter symptom is referred to as *hydrops tubae perfluens*. An adnexal mass is sometimes, but not always palpable. Tumor markers such as CA-125 are usually elevated, although early stage disease may result in elevation of the CA-125 in less than half of patients with Fallopian tube or ovarian cancers. The diagnosis of the Fallopian tube carcinoma is usually not made preoperatively.

The differential diagnosis for Fallopian tube cancer includes disorders that may result in enlargement or obstruction of the distal Fallopian tube. The most common example would be hydrosalpinx whereby obstruction of the Fallopian tube results in accumulation of fluid within the lumen and causes distension of the tube. Common causes of hydrosalpinx include prior infection or endometriosis. Another potential confounding diagnosis is the presence of paratubal cysts, which are simple cysts arising in the mesosalpinx or

loosely attached to the exterior of the tube. Paratubal cysts are nearly always benign and arise from Müllerian and Wolffian duct remnants.

Fallopian tube cancer is staged using the FIGO staging rules for ovarian cancer.

Treatment for Fallopian tube cancer is identical to treatment for ovarian cancer. Multimodal therapy including a primary surgery for staging and debulking of disease is followed by adjuvant chemotherapy based on the stage and grade of the disease. A more detailed discussion of the surgery and postoperative adjuvant therapy considerations is described in the ovarian cancer section of this chapter. If the disease is confined to the tube, the prognosis is good. Like ovarian cancer, most Fallopian tube cancers are of advanced stage at the time of diagnosis, and the subsequent survival is much lower.

SURGERY FOR BENIGN OVARIAN DISEASE

► Adnexal Masses

Adnexal masses are abnormal structures arising in the ovary, Fallopian tube, or broad ligament. Preoperative assessment can narrow the differential diagnosis, but definitive diagnosis usually requires surgical resection or biopsy.

The differential diagnosis of adnexal masses is complex (Table 39–8). Every structure native to the pelvis can potentially present as a detectable adnexal mass. The majority is benign, but the probability of malignancy increases with age. About 10% of persistent adnexal masses attributable to the ovary are malignant in premenopausal women rising to nearly 50% in postmenopausal women.

► Functional Cysts

Functional cysts are relatively common in reproductive age women, but are also reported in postmenopausal women. These cysts are usually larger than 3 cm in order to be diagnosed and may attain diameters of up to 10 cm. Histological examination reveals no pathologic features such as atypia, necrosis, or invasion. Follicular cysts produce estrogen until resolution of the cyst and the corpus luteum cyst produces progesterone until resolution. Because of the hormone production by these types of cysts, menses may be delayed or irregular, often leading to an incorrect clinical diagnosis of ectopic pregnancy. The least common type of functional cyst is the theca lutein cyst, which arises as a physiologic response to hyperstimulation by elevated β -hCG values produced by complete hydatidiform moles. Functional cysts usually regress spontaneously within 1–3 months, or in the case of theca lutein cysts, when the β -hCG value normalizes following treatment.

Correct identification of functional cysts prevents many unnecessary surgical procedures. The functional cyst is typically a smooth, unilateral cyst on pelvic examination. Transvaginal ultrasound will show a simple, sonolucent

Table 39–8. Differential diagnosis of adnexal masses.

Ovarian Etiology	Fallopian Tube Etiology
Functional ovarian cyst Corpus luteum cyst Follicular cyst Theca lutein cyst	Non-neoplastic Fallopian tube conditions
Endometrioma	Ectopic pregnancy Tubo-ovarian abscess/PID Hydrosalpinx Paraovarian or paratubal cyst
Polycystic ovaries	Malignant Fallopian tube neoplasms
Benign ovarian neoplasm	Uterine Etiology
Germ cell Mature cystic teratoma	Benign conditions
Epithelial Serous cystadenoma Mucinous cystadenoma	Pedunculated leiomyoma Uterine anomalies Undiagnosed pregnancy
Stromal Adenofibroma Fibroma Thecoma	Malignant neoplasms Endometrial carcinoma Uterine sarcoma
Malignant ovarian neoplasm	Nongynecologic Etiology
Germ cell Dysgerminoma Immature teratoma Endodermal sinus (yolk sac) Embryonal Choriocarcinoma	Diseases of appendix or colon
Epithelial Invasive Papillary serous Endometrioid Mucinous Clear cell Transitional cell	Diseases of bladder
Low malignant potential Serous Mucinous	Vascular anomalies
Stromal Sertoli-Leydig Granulosa cell, adult	Bony deformation
Granulosa cell, juvenile	

morphology and β -hCG is not elevated. Follow-up examination with ultrasound after 4–6 weeks will generally demonstrate resolution without treatment. About 85% of functional cysts smaller than 6 cm regress, but larger masses may be more likely to persist. Feedback inhibition on pituitary gonadotropin production by hormonal suppression with oral contraceptives may prevent development of additional functional cysts and are advocated by some clinicians to assist in the regression of existing cysts. Hormonal suppression is by no means required, however, since the majority of functional cysts will regress without intervention.

The majority of functional cysts remain asymptomatic, but they will occasionally rupture or undergo torsion resulting in acute colicky abdominal or flank pain. Torsion requires prompt surgical intervention, usually with laparoscopy, in order to restore the vascular supply to the ovary by untwisting the pedicle before significant ischemia or necrosis of the ovary can occur. If the functional cyst ruptures pain of varying levels may occur. In rare cases, bleeding from the ovary leads to hemodynamic instability requiring surgery. Hospitalization for observation for 24 hours, allowing serial examinations and blood counts is appropriate for patients with symptomatic cyst rupture.

► Persistent Adnexal Masses

Adnexal masses that persist are likely to be neoplasms. Benign masses can generally be removed effectively by the general gynecologic surgeon, while malignancies are more effectively treated by gynecologic oncologists with expertise for surgical staging, debulking, and administration of adjuvant therapies to optimize outcome. Triage of adnexal masses provides the best opportunity to serve the patient's interest by having the correct surgical team involved in care of the patient.

The most useful test for assessment of the newly diagnosed adnexal mass is transvaginal ultrasound. Ultrasound is particularly well suited for delineation of the morphologic features of adnexal masses. Medical literature abounds with description of morphology that correlates with benign and malignant neoplasms of the ovary. Figure 39–7 illustrates the morphologic features used to distinguish possible cancers from likely benign lesions. The reported sensitivity for identifying a malignant ovarian neoplasm is 90%–94%, but specificity is only about 60%. Specificity can be improved to about 85% without reducing sensitivity by evaluating Doppler waveforms in the tumor vessels. Vessels arising in malignant lesions have lower resistance to flow than in normal tissues: the ratio of diastolic to systolic flow is therefore higher than in normal tissue (Figure 39–8) and this can be quantitated by reporting the pulsatility index. This test is more specialized, costly and time consuming, limiting its effective use to selected lesions. MRI appears to have a promising role in the characterization of adnexal masses, but is much more costly than ultrasonography.

In addition to ultrasound, tumor markers can be very useful for triage of the palpable adnexal mass. The ideal tumor marker is elevated only in the presence of cancer and should correlate with the burden of disease. In reality, no marker is perfect. There are identified markers for ovarian malignancies arising from germ cell, epithelial and stromal origin. Optimal use of tumor markers involves ordering markers most likely to be clinically useful based on clinical presentation rather than to order all of them. Commonly used tumor markers are listed in Table 39–9. Many new markers will likely be validated in the next few years, including panels of multiple

markers using gene chip technology. For example, malignant germ cell neoplasms usually arise in women younger than 35, are almost always unilateral, and typically demonstrate solid morphology on ultrasound evaluation. In this setting, it would be appropriate to order tumor markers including alpha fetoprotein (AFP), β -hCG, and lactate dehydrogenase (LDH). Epithelial tumors are more often complex cystic and solid, bilateral lesions. In this circumstance CA-125, CA-19-9 and CEA are better markers. Interpretation of CA-125 is difficult in premenopausal women because benign diseases such as endometriosis, which is much more common than ovarian cancer, will cause false positive test results. In addition, many tumor markers are normally elevated in pregnancy, thereby complicating evaluation of masses diagnosed during pregnancy.

The American College of Obstetricians and Gynecologists has issued a committee opinion regarding triage of adnexal masses that recommends referral of individuals with high-risk characteristics to gynecologic oncology subspecialists. For postmenopausal women, referral is warranted for patients with a pelvic mass and at least one of the following: CA-125 above 35 U/mL, ascites, nodular or fixed mass, evidence of abdominal or distant metastasis, or family history of one or more first-degree relatives with ovarian or breast cancer. In premenopausal women, the recommendations are identical except the threshold for CA-125 is raised to > 200 U/mL, to account for diseases such as endometriosis in this age group. Motivation for referral is based upon data showing higher staging accuracy and improved outcome when subspecialists treat ovarian cancer patients.

Low-risk masses thought to be functional cysts are managed expectantly. A mass that persists, or demonstrates worrisome features on exam, imaging studies or tumor marker measurement should be resected. A basic principle of surgical resection for ovarian neoplasms is not to allow spill or rupture of cyst contents into the abdomen. It is never appropriate to needle aspirate an ovarian mass that may harbor malignancy because of the potential to spread disease intra-abdominally. The surgical procedure to be performed is either oophorectomy or ovarian cystectomy for high-risk and low-risk lesions, respectively. The route of surgical approach may be either with laparoscopy or laparotomy. The laparoscopic approach is better suited for cystic masses that are small enough to be placed in a specimen retrieval bag without spill or rupture. Large or solid masses or evidence of metastatic disease such as ascites or omental caking require laparotomy for removal. Ovarian conservation is chosen after a balanced assessment of relative risk for cardiac disease versus ovarian cancer. In women with benign appearing masses under 60, they can expect some cardioprotective benefit even after menopause.

A simple cystic mass of less than 5 cm with normal CA-125 is considered low risk, even in the postmenopausal woman. Conservative management is reasonable.

Benign Pattern	1. Simple cyst without internal echo	
	2. Simple cyst with scattered echoes	
	3. Polycystic echo	
	4. Sessile or polypoid smooth mural echoes	
	5. Central dense round echoes	
	6. Thin or thick multiple linear echoes	
	7. Thin or thick multiple linear echoes with dense part	
	8. Polycystic echoes with septum	
Malignant Pattern	9. Cystic echoes with papillary or indented mural part	
	10. Polycystic echoes with irregular thick septum and solid part	
	11. Solid pattern (solid part >50%) heterogeneous component with irregular cystic part	
	12. Completely solid with homogeneous component	

▲ **Figure 39-7.** Differential diagnosis of adnexal masses by ultrasound morphology. (From Kawai M et al: Transvaginal Doppler ultrasound with color flow imaging in the diagnosis of ovarian cancer. *Obstet Gynecol* 1992;79:163.)

▲ **Figure 39-8.** Doppler waveform and pulsatility index (PI) indicating the objective differences between perfusion in normal versus malignant tissue. If the ratio of $1/PI$ is greater 0.8, the likelihood of cancer is 96% ($p < 0.01$). The waveform on the right has high diastolic flow, and the pulsatility index is low, consistent with a cancer diagnosis. $PI = (\text{peak systolic flow} - \text{peak diastolic flow})/\text{mean flow}$. (From Kawai M et al: Transvaginal Doppler ultrasound with color flow imaging in the diagnosis of ovarian cancer. *Obstet Gynecol* 1992;79:163.)

SURGERY FOR MALIGNANT OVARIAN DISEASE

Ovarian cancer is stratified into three histological groups based on the cellular origin of the tumor. Epithelial tumors, germ cell tumors, and sex cord-stromal tumors comprise the primary lesions, and the fourth category is from disease arising elsewhere that metastasizes to ovary. Epithelial carcinoma accounts for about 85% of ovarian cancers, and about 5% arise from each of the remaining categories of germ cell, sex-cord stromal and metastatic disease from other sites. The peak incidence of epithelial ovarian cancer is in the fifth and sixth decades of life, while malignant germ cell tumors are more likely to occur under the age of 30. Stromal tumors have a bimodal distribution with peaks around ages 25 and 55 years of age. Malignant ovarian disease spreads

by primary extension in the peritoneal cavity, in addition to lymphatic and hematogenous spread.

Epithelial ovarian cancer etiology can be either sporadic or hereditary. The sporadic cases appear to be strongly related to number of lifetime ovulations or chronicity of gonadotropin stimulation. There are also data to suggest environmental impact with the observation that tubal ligation results in reduction of risk, and diets with high lipids relative to omega-3 fatty acids increase risk. About 10% of ovarian cancers are hereditary. Three pedigrees account for most hereditary cases, including ovary-site specific, breast-ovary, and hereditary nonpolyposis colorectal cancer (HNPCC). Genetic inheritance of a mutation in the *BRCA1* or *BRCA2* gene imparts up to a 40% or a 25% lifetime risk of developing ovarian cancer, respectively. Ethnic groups including Ashkenazi Jews and Icelandic peoples have increased incidence of founder mutations that increase risk. Other reproductive factors associated with an increased risk include infertility, including use of ovulation induction agents. A recent discovery is that many if not the majority of epithelial cancers may arise in the fallopian tubes and subsequently spread to the ovaries.

Epithelial tumors are divided into invasive and low malignant potential (borderline) types. The invasive type accounts for 80% of epithelial cancer and is usually detected in advanced stages. The low malignant tumors occur in women with an average age 10-15 years younger than for invasive disease and up to 80% are stage I at diagnosis. Destructive stromal invasion is absent in low malignant potential tumors, but they are considered to be malignant and have the potential to metastasize. Epithelial tumors are subcategorized by histology as serous, mucinous, endometrioid, clear cell, transitional cell, or undifferentiated types. Serous tumors are the most common, comprising about 50% of epithelial carcinomas. Endometrioid carcinomas are the second most frequent variety, accounting for 24% of ovarian cancers, and are sometimes associated with endometriosis. Clear cell tumors, accounting for less than 5% of epithelial tumors, are also associated with endometriosis and have a more virulent natural history. Mucinous tumors account for 15% of epithelial cancers, and may become very large. Epithelial ovarian cancer is commonly involves both ovaries.

Germ cell cancer types include dysgerminomas, immature teratoma, endodermal sinus tumor, mixed types, and rare nongestational choriocarcinoma. Germ cell cancers are almost always unilateral and are commonly detected while stage I. Germ cell cancers are three time more common in women of Asian or African descent. A separate entity is adult-type cancer arising in an otherwise benign mature cystic teratoma. This can occur in up to 1% of mature cystic teratomas and is most commonly a squamous carcinoma.

The most common sex-cord stromal tumors include Sertoli-Leydig, adult granulosa, and juvenile granulosa cell tumors. These are frequently hormonally active tumors. Sertoli-Leydig cell tumors occur most often in the third

Table 39-9. Tumor markers for ovarian cancer.

Tumor Histology	Commonly Used Serum Markers
Epithelial Tumors	CA-125, CA-19-9, CEA, HE-4, OVA1
Papillary serous	CA-125
Endometrioid	CA-125, HE-4
Mucinous	CA-19-9, CEA
Germ Cell Tumors	AFP, β -hCG, lactate dehydrogenase (LDH)
Dysgerminoma	LDH
Endodermal sinus	AFP
Immature teratoma	None
Mixed type	AFP, β -hCG, lactate dehydrogenase (LDH)
Choriocarcinoma	β -HCG
Sex-Cord Stromal Tumors	Testosterone, estradiol, inhibin A and B
Sertoli-Leydig	Testosterone
Granulosa cell	Estradiol, inhibin A and B

decade, and arise from Wolffian duct remnants. They are rare and usually produce testosterone, resulting in manifest defeminization (amenorrhea, atrophy of the breast) and virilization (deepening of the voice, hirsutism, clitoral hypertrophy). Adult granulosa cell tumors arise in the sixth decade and are estrogen-producing tumors in most instances. Because of the estrogen production, postmenopausal bleeding is common, and endometrial cancer may arise in up to 15%. Juvenile granulosa cell tumors are similar, but arise in younger patients. Like germ cell tumors, the sex-cord stromal tumors are unilateral in most cases and detection is typically at early stages.

Metastatic carcinoma from other primary sites occurs not infrequently. Common sites include the gastrointestinal tract (Krukenberg tumor), breast, pancreas, lymphoma, and kidney. These tumors are classically solid, and bilateral. Prognosis for these tumors is especially poor.

► Clinical Findings

Almost 90% of stage I patients have symptoms and only 5% are asymptomatic. The symptoms usually include gastrointestinal complaints that persist for an average of 12 days per month for 3 months. Less often, pelvic pain or metrorrhagia may be present. On examination, any mass should prompt further evaluation. An ovarian mass should be regarded as potentially malignant until proven otherwise. Smooth, mobile masses on exam indicate low risk and solid, irregular, or fixed pelvic masses are suggestive malignancy. Triage of the pelvic mass should include transvaginal pelvic ultrasound and selective tumor markers as described previously in the adnexal mass section of this chapter. It should be noted that CA-125 may be negative in half of early-stage ovarian cancers. If an ovarian malignancy is suspected preoperatively, referral to a gynecologic oncologist is recommended.

Occasionally, ovarian cancer is discovered during an operation for different indication or when triage has not been properly performed. If ascites, carcinomatosis, or papillary excrescences are noted, the tumor should be removed intact and submitted for frozen section. If cancer is diagnosed, a gynecologic or surgical oncologist should be consulted for surgical staging and debulking.

► Treatment

Ovarian cancer is staged surgically (Table 39–10). When a complex adnexal mass is to be removed the procedure should begin with obtaining washings for cytology, and the mass should subsequently be removed intact. Upon removal of the mass, a frozen section should be obtained for definitive diagnosis. If an ovarian malignancy is confirmed, complete staging requires assessment and biopsy of the pelvic and para-aortic nodes, omentum, and peritoneum. All peritoneal surfaces are inspected and any suspicious lesions are biopsied.

If no suspicious lesions are noted, a predetermined pattern of biopsies is taken from the pelvic sidewalls, cul de sac, bladder peritoneum, pericolic gutters and both hemidiaphragms. A decision must be made about possible resection of the uterus and contralateral ovary. If the patient is young and desires to retain her fertility, criteria to identify candidates for conservation of fertility should be applied. Factors that favor preservation of fertility include germ cell and sex-cord stromal tumors because they are usually unilateral, and subsequent chemotherapy, if needed, has curative potential. Low malignant potential tumors affecting one ovary or in select cases where extra-ovarian disease can be completely resected are also candidates. Patients with invasive epithelial tumors are poor candidates for conservative surgery because of the high likelihood of bilateral involvement and the primarily palliative role of chemotherapy for all but early stages of disease. If preservation of fertility is not appropriate, then hysterectomy and removal of the contralateral tube and ovary is completed.

When the disease spread into the pelvis or abdomen is documented, debulking of all resectable macroscopic disease is critically important. Numerous randomized clinical trials have demonstrated the concept of debulking and consistently show survival advantage for patients with maximal cytoreduction. Intraoperative decision making for debulking focuses effort on the biggest tumor, wherever it may be. If the largest lesion can be resected, attention is directed to the next largest lesion. This process continues until either all measurable disease is removed or a lesion that is unresectable is encountered. In order to resect the disease at each decision point of this algorithm, the surgeon may need to perform intestinal resection, splenectomy, modified posterior exenteration, culdotomy, diaphragm resection, and other upper abdominal procedures. In two prospective Gynecologic Oncology Group clinical trials survival for microscopically debulked ovarian cancer was 65% at 4 years, and fell to about 35% if less than 1 cm of macroscopic residual disease remained after surgery. If greater than 2 cm of residual disease remained, the 4-year survival was only 20%. Optimal debulking can be attained in up to 70% of patients who are operated on by subspecialists trained in ovarian cancer surgery.

Patients with stage IA grade 1 or grade 2 epithelial tumors have a very good prognosis and usually are not treated with additional chemotherapy. For more advanced stages of epithelial cancer, chemotherapy is very effective for inducing clinical remission but relapses are very common with an average progression interval between 2 and 3 years. The best chemotherapy combination for treating advanced stage epithelial cancer includes both taxane and platinum agents, administered either intravenously or intraperitoneally for at least six cycles. Intraperitoneal chemotherapy has been demonstrated to induce longer progression free intervals, but acute toxicity is much higher and only 40% of patients are able to complete planned therapy on this regimen. The

Table 39–10. FIGO staging for ovarian cancer.

FIGO Staging	Description	TNM Class
Stage I	Tumor limited to the ovaries	T1
IA	Limited to one ovary, no tumor on external surface, capsule intact; negative peritoneal cytology	T1a
IB	Limited to both ovaries, no tumor on external surface, capsule intact; negative peritoneal cytology	T1b
IC	IA or IB tumor, but with surface tumor, ruptured capsule, or positive ascites or peritoneal cytology	T1c
Stage II	Tumor extending to the pelvis	T2
IIA	Metastasis to the uterus or tubes	T2
IIB	Metastasis to other pelvic tissues	T2b
IIC	IIA or IIB tumor, both with surface tumor, ruptured capsule, or positive ascites or peritoneal cytology	T2c
Stage III	Tumor extending outside the pelvis and/or retroperitoneal or inguinal nodes. Extension to small bowel, omentum, or superficial liver	T3 and/or N1
IIIA	Histologically confirmed microscopic disease of abdominal peritoneal surfaces; lymph nodes negative	T3a
IIIB	Implants of abdominal or peritoneal surfaces not exceeding 2 cm in diameter; lymph nodes negative	T3b
IIIC	Implants of abdominal or peritoneal surfaces > 2 cm in diameter, or positive retroperitoneal or inguinal lymph nodes	T3c and/or N1
Stage IV	Distant metastasis beyond the peritoneal cavity	M1

Reproduced, with permission, from Benedet JL, Hacker NF, Ngan HYS, eds: FIGO staging classifications and clinical practice guidelines in the management of gynecologic cancers. FIGO Committee on Gynecologic Oncology. *Int J Gynaecol Obstet*. 2000 Aug;70(2):209–262.

CA-125 tumor marker is useful as a marker for assessing the effectiveness of therapy.

The best current regimen for malignant germ cell tumors is cisplatin, etoposide, and bleomycin, administered as a 3- or a 5-day treatment that is continued until at least one cycle after normalization of elevated tumor markers. Sex-cord stromal tumors are treated similarly.

► Prognosis

The prognosis for epithelial ovarian carcinoma is related primarily to stage and histological grade. Because most ovarian

cancers are of advanced stage at the time of initial diagnosis, the long-term survival rate for ovarian cancer is only 50%. Five-year survival rates for patients with stage III or stage IV disease are around 20%-35%. Prolonged disease-free intervals can be achieved by combining comprehensive surgical staging aggressive debulking and adjuvant chemotherapy.

► Prevention

Oral contraceptives reduce the risk of ovarian epithelial carcinoma. The magnitude of risk reduction is based on dose and duration of therapy. The protective effects are durable, lasting for a decade or more after discontinuation of the medication.

Any woman with a strong family history should be considered for genetic counseling and testing. For patients with a confirmed hereditary risk of ovarian cancer based on careful pedigree analysis or genetic testing will benefit from prophylactic removal of ovaries and Fallopian tubes. The current recommendation is for removal after completion of childbearing at age 35 or 10 years younger than the earliest incidence of disease in the family. Prophylactic removal of ovaries and tubes reduces the risk of ovarian cancer at least 95%, but a small number of individuals may still develop primary peritoneal carcinoma.

To date, no screening test for ovarian cancer has proven to be sufficiently sensitive or specific enough to have earned the recommendation of the US Preventive Services Task Force, ACOG, or the American Cancer Society. Prospective ultrasound screening studies and combined CA-125/ultrasound studies show a trend toward earlier stage at time of diagnosis on screened patients, resulting in prolongation of progression-free intervals, but not survival.

SURGERY FOR MULTIORGAN DISEASE

Chronic Pelvic Pain

Chronic pelvic pain is generally defined as 6-12 months of pain below the umbilicus producing a significant impact on quality of life. Evaluation and treatment of chronic pelvic pain accounts for up to 40% of all referrals to gynecologists, leading to up to 40% of all laparoscopies, and 12% of all hysterectomies.

► Diagnosis

The differential diagnosis chronic pelvic pain is complex. While many patients attribute their pain to a gynecologic

cause, the physician must consider nongynecologic diagnoses of the gastrointestinal, urinary, and musculoskeletal systems in addition to psychological and psychosomatic problems. The most common nongynecologic diagnoses include irritable bowel syndrome, inflammatory bowel disease, nephrolithiasis, interstitial cystitis, ventral or inguinal hernia, muscle strain, nerve injury, depression, and somatization. Of note, patients are more likely to have suffered sexual assault as an adult or child.

The gynecologic causes of chronic pelvic pain are classified as cyclic or continuous in nature. Sources of cyclic pain include primary dysmenorrhea, defined as painful menses without identifiable pelvic pathology; and secondary dysmenorrhea attributable to pathologic conditions such as endometriosis or adenomyosis. Mid-cycle ovulatory pain may occur that produces unilateral pain at mid-cycle that resolves after a day or two. Continuous pain sources include endometriosis and adenomyosis, and pelvic organ prolapse, both discussed earlier in this chapter, in addition to chronic salpingitis, and pelvic adhesions. Another cause of continuous pain is ovarian remnant syndrome, which occurs when residual ovarian tissue after oophorectomy becomes retroperitoneal location. Pain may occasionally be caused by degenerating fibroids or by mass effect from large fibroids.

► Clinical Findings

The pelvic examination requires careful communication with the patient to understand where and when her pain occurs. Identification of palpable abnormalities and localization of focal tenderness is important. If a pelvic mass is detected, it should be triaged as discussed previously in the adnexal mass section of this chapter. An abnormal pelvic examination has about an 80% predictive value for pelvic abnormalities noted at laparoscopy.

► Treatment

Nongynecologic causes of pain are treated according to the diagnosis. Gynecologic pain etiology is also treated according to the diagnosis. Reproductive-age women with cyclic pain are offered treatment consisting of nonsteroidal anti-inflammatory drugs and ovulation suppression, usually with oral contraceptives if appropriate for the age and medical risk factors of the patient. Continuous pain attributable to endometriosis or adenomyosis is treated similarly. Other causes of continuous pain include spasm or tension in pelvic floor musculature. Physical therapy and “reverse Kegel” exercises to relax the muscles often result in improvement. An antibiotic may be prescribed if a chronic infection is suspected, but care should be taken to treat documented infection and not to over prescribe antibiotics. Concurrent depression is common, usually arising as a secondary effect of the pain rather than as the primary etiology. Treatment

with antidepressant medication is often beneficial. The tricyclic antidepressant class is often more effective than serotonin reuptake inhibitors for this indication. Severe and refractory pain may require prescribing of narcotics to attain control. The physician must use careful judgment regarding initiation of narcotics in a chronic setting due to the potential for dependence and addiction. It is often useful to manage these patients with a narcotic contract between the patient and her physician to regulate drug use. Referral to a multidisciplinary pain service is often useful for difficult or refractory cases.

If the pain is refractory to medical management or if the physical examination is abnormal, then diagnostic laparoscopy is indicated. During the laparoscopic procedure, upper abdominal structures, pelvic organs and peritoneum, appendix, rectum, and sigmoid colon are carefully inspected. The most commonly identified pathology is endometriosis occurring in one-third of patients and adhesions in one third of cases. Most of the remaining cases will have no identified pathology. The presence of abnormalities may not explain the pain, and treatment of disease such as endometriosis may not resolve the pain.

The evidence for therapeutic benefit of laparoscopy for treatment of pelvic pain is tenuous, at best. Procedures that remove or ablate adhesions, endometriosis may or may not relieve pain. If pain is attributed to the uterus or cervix and cannot be controlled with lesser procedures or medical management, options include hysterectomy, or if fertility preservation is desired, interruption of the autonomic nerve tracts with a presacral neurectomy. Pain attributed to degenerating or large fibroids may be relieved either with uterine artery embolization procedures or surgical removal of the leiomyomata with either hysterectomy or myomectomy. Severe dysmenorrhea that is refractory to medical management may be significantly improved with endometrial ablation.

Published data indicate that laparoscopic treatment will produce a short-term reduction of pain in about 60%-80% of patients, but long-term benefits are not well documented. In patients who have completed their childbearing or who wish definitive treatment, hysterectomy has reported success rates of up to 95% if uterine pathology such as degenerating fibroids is present. If no pelvic pathology is noted, 50%-91% experience improvement. The success rate is poor if the patient has symptoms of depression. Patients with endometriosis should also be offered bilateral salpingo-oophorectomy to minimize pain from residual implants.

► Endometriosis

Endometriosis is defined as extrauterine, functional endometrial tissue. The most common sites include ovaries, uterosacral ligaments, and the cul-de-sac. Less commonly, Fallopian tubes, uterine serosa, sigmoid colon and rectum,

peritoneum, and small intestine or mesentery are involved. Ectopic endometrium is occasionally detected at distant sites including lung, lymph nodes, surgical incision sites, umbilicus, perineum, and breasts.

The etiology of endometriosis is thought to occur any of three potential mechanisms: (1) retrograde menstruation with implantation; (2) metaplasia of Müllerian duct remnants or coelomic epithelium; and (3) lymphatic or venous dissemination. Retrograde menstruation through the uterine tubes is common and yet rarely causes endometriosis. It is not known what factors contribute to implantation and growth of endometriosis. Uterine outflow obstruction from cervical stenosis or congenital anomalies such as imperforate hymen increases the likelihood of developing endometriosis.

Endometriosis may develop at any time after onset of menarche and will virtually regress after menopause. Prevalence of endometriosis is difficult to determine because many women with the disease are asymptomatic. The estimated prevalence of endometriosis is about 15%-20%. Endometriosis may cause scarring that impairs fertility. As a consequence, diagnosis of endometriosis during a workup for infertility is higher, with up to 20%-47% of patients affected. Conversely, in women with proven fertility who elect tubal sterilization are found to have endometriosis on only 1%-5% of cases. The incidence of endometriosis is higher in women who choose to delay childbearing, or in women with a family history of the disease. There may be environmental toxins that predispose to endometriosis, such as dioxin. Pregnancy and hormonal contraceptive hormones are protective.

Carcinoma may arise in endometriosis at any site and is most commonly of endometrioid histology. Clear cell carcinoma is rare and more aggressive.

► Classification

An anatomic staging system for endometriosis has been developed by the American Society of Reproductive Medicine (Figure 39-9.) The Revised AFS classification system is accepted worldwide. The staging system is broadly predictive of outcome with treatment. The stage of endometriosis does not correlate well with pain symptoms. Alternate systems that recognize the varied presentation of endometriosis in addition to development of serum markers have been proposed.

► Symptoms & Signs

Endometriosis frequently causes pain. The pain often begins shortly before menses and continues during menstruation. The presence of pain and its severity is highly variable. Some patients with extensive disease are asymptomatic, while others with small peritoneal implants may be incapacitated. Unexplained infertility may be present in asymptomatic

endometriosis. Symptoms may occur at any time during reproductive years, but are most common in the third and fourth decades of life. Symptoms usually resolve with menopause unless the patient is prescribed a hormone replacement regimen. Patients may also complain of dyspareunia, tenesmus, back pain, or sciatica. Rare manifestations may include ureteral obstruction or bowel obstruction.

► Pelvic Examination

Bimanual pelvic examination including the rectovaginal examination should be performed. Common findings include pelvic tenderness, adnexal masses, and soft nodularity in the cul de sac or along the uterosacral ligaments. Adnexal masses attributable to endometriosis are often bilateral and are frequently immobile due to adhesions along the posterior broad ligament.

► Testing

Ultrasound description of isoechoic masses within the ovaries is highly suggestive of endometrioma. Serum concentrations of CA-125 are elevated above 35 U/mL in about one-third of patients with advanced disease, which complicates triage of adnexal masses that may be either benign (endometriosis) or malignant. Following surgical and medical treatment, measurement of the CA-125 trend is a useful marker of treatment efficacy and disease recurrence similar to how the marker is used for monitoring treatment of ovarian cancer.

Definitive diagnosis requires biopsy, usually obtained with a laparoscopic procedure. The biopsy diagnosis requires the presence of both glands and stroma. Location and extent of disease is noted at the time of surgery to complete disease staging. Characteristic peritoneal implants include the so called “powder-burn” marks of darkly colored endometrium, in addition to red, blue, and white lesions. Peritoneal disease may be flat or raised, including nodular or vesicular appearance. Laparotomy is occasionally necessary for large ovarian masses, or bowel and ureteral obstructions that may be present.

► Treatment

Treatment should be tailored to severity of symptoms, age of the patient, desire for fertility, and the stage of disease. The range of therapeutic options includes observation, medical management with hormones and analgesics, up to hysterectomy with bilateral salpingo-oophorectomy. A conservative approach is preferred for patients with minimal symptoms or minimal measurable disease on pelvic exam. Surveillance examinations should be regularly performed, with the interval determined by severity of symptoms, age of the patient, desire for fertility, and the stage of disease. If symptoms or physical finding worsen, the management plan may be changed accordingly.

**American Society for Reproductive Medicine
Revised Classification of Endometriosis**

Patient's Name _____ Date _____

Stage I (Minimal) - 1-5 Laparoscopy _____ Laparotomy _____ Photography _____
 Stage II (Mild) - 6-15 Recommended Treatment _____

Medical Treatment

The goal of medical therapy is to control disease by inducing a remission. There are no known medical therapies that result in a cure. Hormonal therapy is not administered for patients actively attempting to conceive. Upon treatment discontinuation, symptoms commonly recur. Long-term suppression with hormonal contraceptive regimens should be considered.

Progestins

Norethynodrel, norethindrone acetate, and medroxyprogesterone acetate are commonly used. Continuous progestins induce amenorrhea resulting in decreased symptoms in more than three quarters of patients. Progestin therapy causes downregulation of estrogen receptors in endometrial tissue, resulting in atrophic change in both endometriosis and endometrium. Breakthrough bleeding is not unusual. Side effects include weight gain secondary to appetite stimulation, fluid retention, headaches, and mood swings.

Oral contraceptives

Oral contraceptives with a low estrogen dose and a high potency progestin are preferred and may be administered either as cyclic or as continuous regimens without withdrawal intervals each month. Symptoms are relieved in up to 80% of patients. Oral contraceptive may be continued long term as a maintenance therapy in healthy women. Women over 35 who smoke or individuals with hypertension are at increased risk of thromboembolic complications. Side effects include headaches, fluid retention, breast tenderness, breakthrough bleeding, and occasional nausea.

GnRH analogs

GnRH analogs act by negative feedback inhibition on the pituitary resulting in prevention of FSH and LH secretion. The consequence of low gonadotropin levels is absence of follicle development and low estrogen production. This treatment strategy induces the medical equivalent of the postmenopausal state. Endometrial implants atrophy in the hypoestrogenic environment and about 80% of patients report clinical improvement. Side effects mimic menopause with vasomotor symptoms, vaginal dryness, and mood swings. Long-term treatment causes osteopenia and osteoporosis. To prevent bone loss, "add-back" therapy with either norethindrone acetate or combined hormone replacement therapy concurrent with GnRH analog may be prescribed and does not interfere with treatment of the endometriosis.

Surgical Treatment

Indications for surgery include treatment of current infertility, treatment to preserve future fertility, or control of symptoms. Medical therapy is unlikely to result in reduction of symptoms for bulky disease, and surgery is recommended for any endometrioma larger than 4 cm. Options for preservation of fertility in symptomatic women who have failed medical therapy include laparoscopic procedures for resection or ablation of implants, lysis of adhesions, or presacral neurectomy. When definitive therapy is necessary and preservation of fertility is not an issue, total hysterectomy and bilateral salpingo-oophorectomy is indicated. Endometriosis is dependent upon estrogen. Preservation of an ovary in this setting causes symptoms sufficient to prompt additional surgery in 20% of cases. Bowel implants can be locally resected by appropriately trained surgeons.

Postoperative estrogen replacement therapy usually does not lead to exacerbation of endometriosis. The use of estrogen-progestin combinations is generally not required.

Guidice LC: Clinical practice: endometriosis. *N Engl J Med* 2010;362(25):2389-2398.

MULTIPLE CHOICE QUESTIONS

- The differential diagnosis of a vulvar lesion includes all of the following, except
 - Bartholin abscess
 - Melanoma
 - Hidradenitis suppurativa
 - Luteal cyst
 - Epithelial inclusion cyst
- All of these are true about cervical cancer, except
 - Most is related to high-risk HPV types
 - About 75% are squamous type
 - Screening for premalignant lesions is effective because of slow progression through dysplastic precursors
 - Carcinoma occurs most frequently in women between the ages of 20 and 30 years
 - Vaccination is targeted to both protect individuals and to limit prevalence of infection
- Treatment of cervical carcinoma
 - Usually includes hysterectomy for microinvasive disease
 - Consists of radiation therapy and chemotherapy for advanced disease

- C. Cannot preserve fertility in women with microinvasive disease
 - D. Includes systemic therapy only for distant metastases
 - E. Often requires radiation therapy for bone metastases
4. Uterine leiomyomata
- A. Are present in 20%-30% of women of reproductive age
 - B. Are more common in white women than in blacks or Asians
 - C. Often appear after menopause if estrogen supplements are not used
 - D. Are usually multifocal, with a single tumor in the uterine wall
 - E. Can only be treated by hysterectomy
5. The differential diagnosis of adnexal masses includes
- A. Endometrioma
 - B. Appendiceal mass
 - C. Pedunculated leiomyoma
 - D. A, B, and C
 - E. A and C only

Orthopedic Surgery

Kelly Vanderhave, MD

40

INTRODUCTION

Improvements in implant design and materials have been responsible for significant advances in our ability to treat patients with complex orthopedic problems. Like all medical fields, orthopedic surgery has become a group of subspecialized fields in recent years.

TERMINOLOGY

Varus and **valgus** are descriptive terms frequently used for the characterization of angular musculoskeletal deformities. They refer to the direction of the apex of the deformity in relation to the midline of the body. When the apex points away from the midline, the deformity is termed varus; when the apex points toward the midline, the deformity is termed valgus. Knock-knees is an example of a valgus deformity, such that the apex is defined by the patient's knees pointing toward the body's midline. Conversely, "bow-legged" is an example of a varus deformity. These terms can also be applied to fractures such that the apex of the deformity is the fracture itself. **Comminution** describes a fracture that is significantly fragmented. A fracture is **displaced** when the main bony fragments are translated or separated from each other. Displacement can further be subcategorized into minimally, moderately, or completely displaced.

Open fractures define fractures with overlying wounds such that the fracture is exposed to the external environment. Open fractures can be obvious in significant trauma with substantial degloving of the soft-tissues, or they can be more subtle where only a small poke hole is visible with draining fracture hematoma. As a result, when patients are transferred from other hospitals or urgent care facilities, all splints should be removed, and the skin overlying all fractures must be carefully inspected for open injury. Open fractures are orthopedic emergencies and must be addressed with prompt surgical debridement and irrigation

to minimize the subsequent development of infection and associated fracture nonunions.

Joint dislocations also warrant immediate treatment. **Reduction** refers to the maneuver used to restore proper alignment of a joint or fracture. Vascular structures spanning the joint or fracture may be damaged at the time of injury. Alternatively, these structures may be compressed or kinked due to the resulting deformity. Arterial pulses should always be assessed distal to a musculoskeletal injury and carefully documented. Often absent pulses are restored with reduction of a joint or fracture. If reduction does not successfully return pulses, the vessels are likely torn; early repair and reconstruction is often required to restore distal circulation to the limb. Vascular injuries repaired prior to fracture or joint reduction and stabilization, may be in danger of subsequent failure due to bony instability. Orthopedists can quickly stabilize fractures and dislocations using external fixation, providing a stable scaffold on to which necessary vascular repairs can be made.

Joint or fracture reduction may be treated by **open** or **closed** techniques. A dislocation or fracture is described as **unstable** if there is a high likelihood of subsequent deformation after reduction is performed. Following reduction, unstable fractures or dislocations may be stabilized by closed or open means. Closed treatment may involve traction, casts, splints, or braces; open techniques involve surgical exposure of the fracture or joint and reduction followed by maintenance of the reduction with internal or external fixation devices. The surgical treatment of an unstable fracture or dislocation is therefore described as "Open reduction with internal or external fixation."

SPLINTING AND CASTING

Splinting and casting are noninvasive ways of stabilizing fractures and maintaining reductions. **Splints** are typically made of plaster and are not circumferential, while **casts** are

circumferential and can be made of either plaster or fiberglass. Splints are best used for a short period of time (days up to one or two weeks) in acute scenarios shortly after injury or after an operation when swelling is a concern to avoid compartment syndrome. Casts are sturdier, used to maintain bones in appropriate alignment for extended periods of time (weeks to a few months). For example, a distal radius fracture may be reduced and placed in a sugar-tong splint with follow-up in clinic. At clinic follow-up, if the reduction is adequate and swelling has subsided, the splint can be overwrapped in a cast or transitioned to a new cast for continued closed treatment. After ankle fractures are surgically fixed with open reduction and internal fixation, they are often placed in a short-leg splint with stirrups postoperatively, followed by transitioning to short-leg cast for 4-6 weeks to protect the operative repair. There are many types of splints and casts depending on the type of injury being treated. Examples of splints include the volar forearm, sugar-tong, long-arm posterior, double sugar-tong, coaptation, short leg posterior with or without stirrups, and long-leg posterior. Splints can be augmented with a thumb spica or foot plate depending on the injury. Examples of casts include short-arm, long-arm, with or without thumb spica, as well as short-leg, long-leg, spicas.

ORTHOPEDIC HISTORY TAKING AND PHYSICAL EXAMINATION

Key elements of the history taking include the demographics of the patient (age, sex, and race), comorbidities, hand dominance (if there is an upper extremity injury), mechanism of injury, allergies to medication, and smoking or drinking history.

Examination begins with visualization of the injured extremity noting deformity, swelling, and or bruising. Careful skin examination is crucial to rule out wounds and the presence of open fracture. Neurovascular examination should be performed documenting motor and sensory function as well as strength of pulses (palpable, 1+, 2+, or identifiable by Doppler). Finally, careful secondary exam should be performed on all other joints and extremities testing for tenderness to palpation as well as range of motion. Distracting pain from the primary injury can often prevent a patient from realizing they have an injury elsewhere. Secondary examinations should be performed multiple times during the treatment course of the patient. As the pain from the primary injury subsides, patients may begin to appreciate additional injuries.

ORTHOPEDIC EMERGENCIES

The following is list of conditions that require immediate orthopedic evaluation and treatment: compartment syndrome, open fractures, septic arthritis, and acute dislocations. Additionally, there are other injuries such as femoral neck fractures, that depending on the age of the patient and choice of treatment that require intervention as soon as

possible. Each of these conditions will be elaborated on in the upcoming chapters.

► Compartment Syndrome

Compartment syndrome is caused by increased pressure in a closed fascial space that initially leads to compromised perfusion followed by severe tissue damage. Nerves and muscles in the affected area can be significantly compromised in a matter of hours. Severe ischemia for 6-8 hours leads to muscle and nerve death leading to chronic debilitating dysfunction of the affected extremity. As a result, compartment syndrome is an orthopedic emergency requiring immediate evaluation and treatment. Compartment syndrome can occur after fracture, limb compression or crush, vigorous exercise, or burns.

Although, it most commonly occurs in the forearm and leg, it can occur in the foot, thigh, and arm. Compartment syndrome typically presents as a painful, swollen, tense extremity. Pain with passive range of motion of the digits and pain out of proportion are considered to be the most reliable early indicators of compartment syndrome. Clinical signs of compartment syndrome include the 5 Ps: pain, poikilothermia, pallor, paresthesias, and finally pulselessness. A change in pulses is a very late sign occurring after significant damage has already occurred. Of note, compartment syndrome can occur at intracompartmental pressures well below arterial pressure. Therefore, compartment syndrome can occur in a pink limb with normal pulses.

Compartment syndrome is a clinical diagnosis; many authors advocate that if compartment syndrome is suspected immediate fasciotomy should be carried out. In scenarios where patients are obtunded, intubated, or otherwise unable to express having pain, compartment pressure can be evaluated using a commercially available self-contained pressure monitor. If a commercial pressure monitor is not available, large bore catheter can be inserted in the compartment under sterile technique. The catheter is connected to a pressure monitor via intravenous tubing filled with sterile saline solution. Absolute pressure more than 30 mm Hg in any compartment, or a pressure within 30 mm Hg of the diastolic blood pressure in hypotensive patients are indications for surgical compartment release.

Fasciotomy should be carried out with complete release of the skin and fascia of the involved compartments. Adjacent compartments in the same limb are typically released as well. Compartment pressures are rechecked after release to ensure adequate decompression. The wounds are left open and covered with sterile dressings or a vacuum-assisted closure (VAC), and are subsequently treated with delayed primary closure or skin grafting days later.

► Open Fractures

An open fracture is a defined as an osseous disruption with a break in the overlying skin and soft tissues resulting in

communication between the fracture, its hematoma, and the external environment. Any wound occurring on the same limb as a fracture must be carefully inspected to prove that it is not an open fracture. Open fractures have important soft tissue consequences: (1) contamination of the wound and fracture by the external environment, (2) crushing, stripping, and devascularization that results in soft tissue devitalization and subsequent increased infection susceptibility, (3) disruption of the soft tissue envelope may affect the type of fracture immobilization as well as adversely affect fracture healing due to the loss of osteoprogenitor cell contribution from overlying soft tissues, and finally (4) loss of function from damaged muscle, tendon, nerve, vascular, and ligamentous structures.

Open fractures are typically high energy injuries. One-third of patients with open fractures have multiple injuries. As a result, initial evaluation of the patient with an open fracture follows the ABCDEs: airway, breathing, circulation, disability, and exposure. Initial resuscitation is performed along with immediate treatment for any-potential life-threatening injuries. The head, chest, abdomen, pelvis, and spine are individually evaluated for injury. Injuries to the other extremities should be identified. Neurovascular exam for the injured limb should be carefully documented; the skin and soft tissues should be assessed as well. Wound hemorrhage should be managed with direct pressure rather than limb tourniquets or clamping which may disrupt perfusion to the rest of the limb. Exploration of the wound in the emergency department setting is not indicated if operative intervention is planned due to risk of further contamination and precipitation of additional hemorrhage. If surgical delay is anticipated, gentle irrigation with sterile normal saline may be undertaken. Only obvious foreign fragments that are easily accessible should be removed. Bone fragments should not be removed and disregarded, regardless of apparent nonviability. Sterile injection of joints can be performed to determine if there is communication with a nearby wound. The wound should be covered with a sterile normal saline soaked piece of gauze (iodine has fallen out of favor due to reports of tissue toxicity). Provisional reduction and splinting should be performed, follow by subsequent neurovascular examination to confirm no additional damage. Standard trauma survey includes radiographic evaluation of the spine, chest, abdomen, and pelvis. The injured extremity including the joint above and below, along with any other extremities suspected of injury should be evaluated with x-rays in anticipation of operative intervention.

Angiogram should be performed if vascular injury is suspected in the following scenarios: knee dislocation, cool, pale hand, or foot with poor distal capillary refill, high energy injury in an area of susceptible vessels (eg, Popliteal fossa), and documented ABI less than 0.9 in an extremity with an associated injury. Of note, evaluation of the contralateral limb may reveal underlying vascular disease as the cause of decreased ABI rather than acute injury.

Open fractures can be characterized using the Gustilo and Anderson classification: Grade I: clean skin opening is less than 1 cm, Grade II: Laceration is less than 1 cm but is less than 10 cm, soft tissue damage without significant fracture comminution or crush component; Grade IIIA: extensive soft tissue damage, Grade IIIB: extensive soft tissue injury with periosteal stripping or bone exposures requiring flap coverage, and Grade IIIC: concomitant vascular injury requiring repair.

Antibiotic treatment and tetanus prophylaxis should be addressed as soon as possible in the emergency department setting. Grade I and II fractures require treatment with a first-generation cephalosporin. Previously, grade III fractures mandated the addition of an aminoglycoside to cephalosporin; however, the most recent recommendations entail treatment with ceftriaxone. For farm injuries with gross contamination, add a penicillin in addition to ceftriaxone.

Operative intervention should be carried out for open fractures as soon as possible. Intervention less than 8 hours after injury has been reported to result in a lower incidence of infection and subsequent osteomyelitis. In the operating room, the wound should be extended proximally and distally to examine the zone of injury. Meticulous debridement of the soft tissues, including the skin, subcutaneous fat, and surrounding muscle should be carried out. Large skin flaps should be avoided as their development risks further devitalization. The fracture surfaces should be exposed and debrided. Fractures can be stabilized provisionally or definitively with external or internal fixation depending on the scenario and surgeon expertise. Pulsatile lavage irrigation should be carried out, followed by meticulous hemostasis. Fasciotomy should be considered as treatment for or prophylaxis against impending compartment syndrome. Historically, only the surgically extended portions of the wound were closed, followed by dressing the open wound with saline soaked gauze or VAC. Serial debridements should be performed every 24-48 hours until there is no evidence of remaining necrotic soft tissue and bone. Bone grafting and wound coverage using delayed primary closure, skin graft, rotational, or free muscle flaps can be performed at this time.

ORTHOPEDIC TRAUMA

FRACTURES & JOINT INJURIES

1. Fractures & Dislocations of the Spine

► Demographics

There are more than 10,000 new spinal cord injuries each year. The ratio of male to female patients sustaining vertebral fractures is 4:1. For patients with spinal cord injury the overall mortality rate is 17% during the initial hospital stay.

Unfortunately, delayed diagnosis happens frequently due to loss of consciousness secondary to trauma or intoxication with alcohol or drugs. As a result, suspicion for spinal cord injury should remain high in trauma patients who are unable to provide an accurate history.

► Anatomy

The spinal cord occupies between 35% and 50% of the spinal canal depending on the vertebral level. The remainder of the canal is filled with cerebrospinal fluid, dura mater, and epidural fat. The caudal termination of the spinal cord, located dorsal to the L1 vertebral body and L1-L2 intervertebral disk, is called the conus medullaris. The conus medullaris gives off motor and sensory nerve rootlets, also known as the “cauda equina” or horse’s tail.

The spinal column consists of four major components that contribute to its stability: (1) the vertebral bodies, (2) the posterior elements (pedicles, laminae, spinous process, and interlocking paired facets at each level), (3) the intervertebral disk; and (4) and attached ligamentous tissues (interspinous ligaments, facet capsules, and ligamentum flavum).

The atlas is the first cervical vertebra (C1). Although it does not have a vertebral body, it has two large lateral masses which serve as weight-bearing articulations between the skull and the vertebral column. The tectorial membrane and the alar ligaments are key contributors to normal craniocervical stability. The axis is the second cervical vertebra, whose body is the largest in the cervical spine. The transverse atlantal (aka cruciform) ligament is the primary stabilizer of the atlantoaxial joint, with the alar ligaments providing secondary stability. There are five additional cervical vertebra (C3-C7).

The thoracolumbar spine consists of 12 thoracic vertebrae and 5 lumbar vertebrae. The thoracic region is naturally kyphotic (apex of bow is posterior), while the lumbar region is lordotic (apex of bow is anterior). The thoracic spine is much stiffer than the lumbar spine in flexion-extension and lateral bending, due to the additional stability provided by the rib cage as well as thinner intervertebral disks. As a result, due to its transition zone status, the thoracolumbar junction (T11-L1) is more susceptible to injury.

The spinal column can also be conceptualized as three columns with regards to its stability: (1) the anterior column (the anterior half of the vertebral body, anterior half of the intervertebral disk, and anterior longitudinal ligament), (2) the middle column (the posterior half of the vertebral body, posterior half of the intervertebral disk, and posterior longitudinal ligament), and (3) the posterior column (the facet joints, lateral masses, intraspinal ligaments, supraspinous ligaments, and spinous processes). In general, a one-column injury is relatively stable, while a three-column injury is significantly unstable, with increased risk of injury to the spinal cord.

The spinal cord roots exit the spinal canal through the intervertebral foramina. In the cervical spine, the C1 root exits above the C1 vertebral body; the C2 root exits below the C1 vertebral body. This pattern continues for the other cervical nerve roots ending with the C8 root exiting below the C7 body. In the thoracic and lumbar spine, each root exits under the pedicle with the same number. For example, the L4 nerve root exits under the L4 pedicle.

► Clinical Evaluation

Clinical evaluation of the spine injury patient begins with the ABCDEs. All victims of trauma are suspected of having a spinal column injury until it proven otherwise. Initially, patients are placed in a c-collar and on a backboard until the patient’s spine can be assessed. A special backboard with head cutout should be used for children (6 years old or less) to prevent unintended neck flexion due to their proportionally larger head size and resulting prominent occiput.

The head-tilt-chin-lift maneuver should be avoided due to possible further disruption of the cervical spine. Airway and breathing are ensured by intubation and mechanical ventilation. Nasotracheal intubation is the safest method of airway control in the acute setting because it leads to less cervical spine motion compared with direct oral intubation.

Neurogenic shock with hypotension and bradycardia can occur in the setting of spinal cord injury. Initial resuscitation of the patient entails administration of isotonic fluids, as well as evaluating injuries to the head, chest, abdomen, pelvis, and extremities. The diastolic pressure should be kept above 70 mm Hg to maximize spinal cord blood flow. However, once the diagnosis of neurogenic shock is established, the blood pressure should be managed with vasopressors to prevent fluid overload.

If within 8 hours of injury, administer Methylprednisolone for complete or incomplete spinal cord injuries. An initial bolus of 30 mg/kg is administered over the first 15 minutes followed by 5.4 mg/kg/h over the following 24 hours (if steroids were started within 3 hours after injury) or 48 hours (if steroids were started within 3-8 hours after injury). Treatment with methylprednisolone has been shown to improve long-term motor recovery.

Sensory deficits caused by either cord or root level injuries can result in the rapid development of decubitus ulcers over insensate skin over high-pressure areas of the body (eg, the heels and ischium). As a result, timely assessment and removal of the patient from the spine board and onto an appropriate bed is critical.

Evaluating the spine includes logrolling the patient for visual inspection, palpation of the spinous processes for tenderness or diastasis, and performance of a rectal exam assessing resting tone, perianal sensation, and the bulbocavernosus reflex (squeeze of the glans penis or pull on urethral catheter results in contraction of the anal sphincter). Neurologic

examination should also be performed assessing motor strength and dermatomal sensation. The motor strength testing and motor nerve roots match up as follows: shoulder abduction (C5), elbow flexion and wrist extension (C6), elbow extension and wrist flexion (C7), wrist extension and finger flexion (C8), finger abduction (T1), hip flexion (L2), knee extension L3, ankle dorsiflexion (L4), long toe extensors (L5), and ankle plantar flexors (S1). Careful evaluation and documentation of the patient's neurologic status will allow the physician to determine the appropriate treatment plan and estimate the prognosis for functional recovery.

The cervical spine can be cleared clinically in patients if the following criteria are met: (1) no posterior midline tenderness, (2) full pain-free range of motion, (3) no focal neurologic deficit, (4) normal level of alertness, (5) no evidence of intoxication, and (6) no distracting injury. Radiographic evaluation is not required. The process of the clearing the thoracolumbar spine is similar; however, anteroposterior and lateral radiographs of the TLS spine should be routinely obtained for evaluation. If any of the above criteria are not met for clearing the cervical spine, due to its increased sensitivity compared to radiographs, CT scan with sagittal reconstructions of the cervical spine to rule-out injury has become the standard of care.

In addition to spinal trauma, other injuries should be assessed since they may influence the treatment of the patient. Suspicion of associated injuries is dependent on the mechanism and location of injury. Cervical Spine injuries can be associated with injuries to the vertebral artery. Flexion-distraction injuries (seat-belt injuries) of the thoracolumbar spine are associated with intra-abdominal injuries. Axial loading injury mechanisms that often result in burst fractures of the lumbar spine are also responsible for axial loading injury patterns in the lower lumbar spine and lower extremities. These include fractures of the pars interarticularis of the L5 vertebra, the tibial plafond, and the calcaneus.

It is important to note that any injury associated with progressive neurologic deficit warrants surgical intervention.

Neurologic injury can be described as complete (no sensation/motor caudal to the level of the spinal cord pathology) or incomplete (some neurologic function persists caudal to the level of injury). Four major patterns of incomplete spinal cord injury can occur: (1) **Brown-Séquard Syndrome** (hemicord injury with ipsilateral muscle paralysis, loss of proprioception, and light touch sensation), (2) **Central Cord Syndrome** (flaccid paralysis of the upper extremities and spastic paralysis of the lower extremities with sacral sparing), (3) **Anterior Cord Syndrome** (motor and pain/temperature loss controlled by the corticospinal and spinothalamic tracts with preserved light touch and proprioception controlled by the dorsal columns), (4) **Posterior Cord Syndrome** (rare, involves loss of deep pressure, deep pain, and proprioception with full voluntary

power, pain, and temperature sensation), and (5) **Conus Modularis Syndrome** (T12-L1 injuries resulting in loss of voluntary bowel and bladder control with preserved lumbar root function).

Nerve root lesions can occur at any level accompanying spinal cord injury. These lesions may be partial or complete, resulting in radicular pain, sensory dysfunction, weakness, hyporeflexia, or areflexia.

Cauda Equina syndrome is caused by multilevel lumbosacral root compression within the lumbar spinal canal. Clinical presentation can include saddle anesthesia, bilateral radicular pain, numbness, weakness, hyporeflexia or areflexia, and loss of voluntary bladder or bowel function.

► Classification of Neurologic Injury

The motor and sensory examination outlined by the American Spinal Injury Association (ASIA) is one system to assess the impact on the patient of spinal cord injury. This grading system allows the patient to be assessed through scales of impairment and functional independence, evaluating remaining sensory and motor function. A thorough neurologic examination should be performed and documented when the patient is initially seen and at frequent intervals thereafter both to ensure that there is no further neurologic deterioration and to document the resolution of spinal shock.

Spinal shock is defined as spinal cord dysfunction due to physiologic disruption, resulting in hypotonia, areflexia, and paralysis distal to the level of injury. Resolution usually occurs within 24 hours with the return of reflex arcs caudal to the level of injury; the bulbocavernosus reflex is usually the first one to come back.

If a patient has a complete neurologic deficit after spinal shock has resolved, the chance for recovery of neurologic function below the level of injury is extremely poor. In contrast, patients with root level injuries (at or below the cauda equina) will recover from functionally complete injuries if they have not been transected and if initial compression by bone fragments, malalignment, or disk material has been relieved.

► Determination of Sensory Levels

The sensory level is determined by the patient's ability to perceive pinprick (using a disposable needle or safety pin) and light touch (using a cotton ball). Testing of a key point in each of the 28 dermatomes on the right and left sides of the body as well as evaluation of perianal sensation is necessary. The variability in sensation for each individual stimulus is graded on a 3-point scale:

- 0 = Absent
- 1 = Impaired
- 2 = Normal
- NT = Not testable

In the cervical spine, the C3 and C4 nerve roots supply sensation to the entire upper neck and chest in a cape-like distribution from the tip of the acromion to just above the nipple line. The next adjacent sensory level is the T2 dermatome. The brachial plexus (C5-T1) supplies the upper extremities.

ASIA also recommends testing of pain and deep pressure sensation in the same dermatomes as well as evaluation of proprioception by testing the position sense of the both index fingers and both great toes.

► Determination of Motor Levels

The motor level is determined by manual testing of a key muscle in the ten paired myotomes from cephalad to caudal. The strength of each muscle is graded on a six-point scale:

- 0 = Complete paralysis
- 1 = Palpable or visible contraction
- 2 = Full range of motion of the joint powered by the muscle with gravity eliminated
- 3 = Full range of motion of the joint powered by the muscle against gravity
- 4 = Active movement with full range of motion against moderate resistance
- 5 = Normal strength

NT = Not testable

► ASIA Impairment Scale

The grading system is as follows: (1) Grade A (complete impairment; no motor or sensory function is preserved below the neurologic injury level), (2) Grade B (incomplete; sensory but not motor function is preserved below the neurologic level and extends through the sacral segment S4-S5), (3) Grade C (incomplete; motor function is preserved below the neurologic level with key muscles having a muscle grade < 3), (4) Grade D (incomplete; motor function is preserved below the neurologic level of injury; most key muscles below the neurologic level have a muscle grade > 3), and (5) Grade E (normal: motor and sensory function is normal).

► Imaging Studies

A. Cervical Spine

Plain radiographs can be used as the first imaging modality for the cervical spine, although CT scan of the cervical spine is becoming the initial test of choice due to its increased sensitivity and consistent ability to visualize the occipitocervical and cervicothoracic junctions. The standard series of radiographs includes an anteroposterior, lateral, and an open-mouth “odontoid” view. Eighty-five percent of all significant injuries to the cervical spine will be detected on the lateral view of the cervical spine. Radiographic markers of cervical spine instability include the following: compression fractures

with more than 25% loss of height, angular displacement more than 11 degrees between adjacent vertebrae, translation more than 3.5 mm, and intervertebral disk space separation more than 1.7 mm. If the standard lateral view does not adequately visualize the C7-T1 junction, further studies such as a swimmer’s view, oblique views, or CT of this area are necessary. Flexion-extension views of the cervical spine can be performed if instability is still suspected in a patient with otherwise normal radiographic findings. Performance of these radiographs should be delayed in a patient with neck pain, as muscle spasm can mask instability.

B. Thoracolumbar Spine

All patients with significant injury and pain in the spinal area require anteroposterior and lateral x-rays of symptomatic regions of the thoracic and lumbar spine. CT can be used to evaluate canal compromise, and for preoperative planning MRI is useful for assessing the degree of neural injury and prognosis.

► Complications

Patients with cervical spine injury may have impaired pulmonary function secondary to intercostal nerve paralysis. Mobilization of secretions by chest physical therapy and frequent suctioning are critical for preventing atelectasis and pulmonary infections. All patients with sensory deficits and paralysis are at high risk of developing pressure ulcers. Padding and suspension of high-risk pressure points (heels), frequent turning, and vigilant nursing care are necessary.

Patients with thoracolumbar spine fractures with or without spinal cord injury may have paralytic ileus secondary to sympathetic chain dysfunction. Oral intake should be limited to clear fluids initially, and gastric suction may be necessary if the degree or duration of ileus is significant.

The stress caused by the injury itself—in combination with systemic corticosteroid therapy—can increase the incidence of gastrointestinal ulceration and bleeding. High-dose corticosteroids can also contribute to the development of pancreatitis and infections.

Venous thromboembolic disease remains a significant problem in the management of patients with spinal injury. Pulmonary embolism is the most common cause of preventable death in hospitalized patients. Heparin can be used for DVT prophylaxis, until the patient’s mobility improves.

CERVICAL SPINE INJURIES

► Injuries to the Occiput-C1-C2 Complex

A. Occipital Condyle Fractures

Occipital condyle fractures can be classified as follows: (1) type I (impaction of condyle, stable), (2) type II (shear injury associated with basilar or skull fractures; potentially

unstable), (3) type III (condylar avulsion fracture, unstable). Treatment involves rigid cervical collar immobilization for 8 weeks for stable injuries and halo immobilization or surgical stabilization for unstable injuries.

B. Occipitoatlantal Dislocation

Also known as craniovertebral dislocation, this is almost always fatal. Postmortem studies show this injury to be the leading cause of death in motor vehicle accidents. Rare survivors usually have severe neurologic deficits. Immediate treatment includes halo vest application with strict avoidance of traction. Long-term stabilization is done surgically with occipitocervical fusion.

C. Atlas Fractures

Atlas fractures are rarely associated with neurologic injury. Instability due to transverse alar ligament insufficiency should be suspected with identification of bony avulsion or widening of the lateral masses on radiographic evaluation. These injuries can be classified as follows: (1) isolated bony apophysis fracture, (2) isolated posterior arch fracture, (3) isolated anterior arch fracture, (4) comminuted lateral mass fracture, and (5) burst fracture (fractures of the anterior and posterior ring). Stable fractures (posterior arch or nondisplaced fractures) may be treated with rigid cervical orthosis; unstable fractures require prolonged halo immobilization. Chronic instability or pain may be treated with C1-C2 fusion.

D. Transverse Ligament Rupture

This injury is rare, but usually fatal when it occurs. This injury is diagnosed by visualizing the avulsed lateral mass fragment, an atlantodens interval (ADI) more than 3 mm in adults, atlantoaxial offset more than 6.9 mm on an odontoid radiograph, or direct visualization of the rupture on MRI. Survivors are treated with halo or C1-C2 fusion.

E. Fractures of the Odontoid Process (Dens)

There is a significant association with other cervical spine fractures and a 5%-10% incidence of neurologic injury. The vascular supply to the odontoid arrives through the apex and the base of this bone with a watershed area in the neck. Odontoid fractures are classified as follows: (1) type I (oblique avulsion fracture of the apex), (2) type II (fracture at the junction of the body and the neck; high nonunion rate, which can lead to myelopathy), (3) type IIa (highly unstable comminuted injury extending from the waist of the odontoid to the vertebral body), and (4) type III (fracture extending in the cancellous body of C2 and possibly involving the lateral facets). Treatment entails cervical orthosis for type I fractures and halo immobilization for type III fractures. Treatment of type II fractures is controversial due to the high incidence of nonunion related to

poor vascularity; halo or surgical intervention is advocated depending on patient factors.

F. C2 Lateral Mass Fractures

These injuries are usually diagnosed via CT scan. Treatment varies from collar immobilization to late fusion for chronic pain.

G. Traumatic Spondylolisthesis of C2

Also known as the Hangman's fracture, this injury may be associated with cranial nerve, vertebral artery or craniofacial injuries. Type I injuries are nondisplaced fractures without angulation, less than 3 mm of translation, and the C2-C3 disk is intact. Type II injuries are displaced fractures of the pars. Type IIa is a displaced pars fracture with disruption of the C2-C3 disk. Type III is a dislocation of the C2-C3 facet joints in addition to the pars fracture. Type I injuries are treated with rigid cervical orthosis, type II injuries are treated with halo immobilization, type III injuries are usually treated initially with halo immobilization followed by surgical stabilization.

► Injuries to C3-C7

Injuries for the remaining vertebrae from C3-C7 include teardrop fractures of the anterior portion of the vertebral body due to compression flexion, vertical compression (burst fractures), anterior dislocations due to distractive flexion, vertebral arch and lamina fractures due to compressive extension, distractive extension injuries resulting in posterior dislocations, and lateral flexion injuries resulting in translational dislocations.

"Clay shoveler's fracture" is an avulsion fracture of the spinous processes of the lower cervical and upper thoracic vertebra.

"Sentinel fracture" is a fracture through the lamina on either side of the spinous process.

Treatment for each of these fractures includes the use of cervical orthoses, halo immobilization, traction, and surgery. Soft cervical orthosis does not provide any significant immobilization. It is used as needed for the patient's comfort. Rigid cervical orthoses do not provide complete immobilization; this treatment mainly limits range of motion in the flexion-extension plane. Cervicothoracic orthoses are effective in flexion-extension and rotational control, but do not limit lateral bending very effectively. Halo immobilization offers rigid immobilization in all planes as does surgical treatment. Traction can be used to reduce unilateral or bilateral facet dislocations with neurologic deficits or to stabilize and indirectly compress the canal in patients with neural deficits from burst-type fractures. Traction is contraindicated in type IIa spondylolisthesis injuries of C2 and distractive cervical spine injuries.

Choice of treatment depends on the type of injury and individual patient characteristics. In general, stable fractures can be managed with bracing, while unstable fractures require more rigid stabilization via halo application or surgical treatment.

► Halo Application

The halo apparatus includes the metal ring and halo vest. The halo ring should be applied approximately 1 cm above the ears. Anterior pin sites should be placed above the supra-orbital ridge, anterior to the temporalis muscle over the lateral 2/3 of the eyebrow to avoid the supraorbital nerve. Posterior sites are variable and are placed to maintain the horizontal orientation of the halo. Pin pressure should be 6-8 lbs in the adult. Pin care is essential. The halo vest relies on a tight fit that should be carefully maintained.

► Thoracolumbar Spinous Injuries

Anteroposterior and lateral radiographs of the Thoracolumbosacral spine are the standard initial evaluation. Abnormal interpedicular distance, height loss, and canal compromise should all be noted. Minor spine injuries include articular process fractures, transverse process fractures, spinous process fractures, and pars interarticularis fractures. Generally, these injuries can simply be observed. Six significant injury patterns requiring treatment are described: (1) wedge compression fracture, (2) stable burst fracture, (3) unstable burst fracture, (4) chance fracture, (5) Flexion-distraction injury, and (6) translational injuries.

A. Compression Fractures

Based off of the three column theory of instability, compression fractures are fractures that only affect the anterior column. Compression fractures can be anterior or lateral. In general these fractures are stable injuries and are rarely associated with neurologic injury. Fractures are considered unstable if there is more than 50% loss of vertebral body height, angulation more than 20-30 degrees, or multiple adjacent compression fractures. Four subtypes are described based off of endplate involvement: type A (fracture of both endplates), type B (fracture of superior endplate), type C (fracture of inferior endplate), and type D (both endplates are intact). Stable fractures are treated with Jewett brace or thoracolumbar spinal orthosis (TLSO). Unstable fractures can be treated with hyperextension casting or with surgery.

B. Burst Fractures

Burst fractures are fractures that involve the anterior and middle columns of the spinal cord. Radiographs may show loss of posterior vertebral body height and splaying of the pedicles on the anteroposterior view. It is important to note that no direct relationship exists between the amount

of canal compromise and the degree of neurologic injury. Treatment can entail the TLSO bracing or hyperextension in casting for stable fracture patterns without neurologic compromise. If the TLSO fails to restore appropriate alignment on radiographs, surgery should be considered. Early surgical intervention restoring sagittal and coronal alignment should also be considered for fractures with loss of vertebral height more than 50%, angulation more than 20-30 degrees, scoliosis more than 10 degrees, and concomitant neurologic deficit. Surgical treatment options include decompression via a posterior or anterior approach with or without instrumentation.

C. Flexion-Distraction Injuries

Also known as Chance fractures, involve all three columns of the spinal cord. These fractures are also known as “seat-belt type injuries” due to the most common mechanism by which they occur and often are associated with abdominal injuries. Radiographically, one may appreciate increased interspinous distance on the AP and lateral views. Four types of Chance fractures are recognized: (1) type A (one-level bony injury), (2) type B (one-level ligamentous injury), (3) type C (two-level injury through the bony middle column), (4) type D (two-level through the ligamentous middle column). Treatment for type A fractures may entail TLSO; however, one should consider surgical stabilization for the other three fractures given their innate lack of stability.

D. Fracture-Dislocations

Fracture-dislocations involve injury to all three columns with translational deformity. These injuries are often associated with neurologic injury and require surgical stabilization due to their unstable nature. There are three types of fracture-dislocations: (1) Flexion-rotation, (2) Shear, and (3) Flexion-distraction. Patients without neurologic injury do not require emergent surgery; however, patients whose fractures are stabilized within 72 hours of injury have a lower incidence of complications such as pneumonia and undergo a shorter hospital stay when compared to patients whose fractures are stabilized outside this time-frame.

E. Gunshot Wounds

Generally, fractures associated with low-velocity gunshot wounds are usually stable when a handgun is the weapon. These injuries are typically associated with a low infection rate and can be prophylactically treated with broad-spectrum antibiotics for 48 hours.

Any present neural injury, is usually secondary to “blast effect,” in which the energy of the bullet is absorbed and transferred to the soft tissues. As a result, decompression is usually not indicated. An exception to this rule is if the bullet fragment is found in the spinal canal between levels T12

and L5. Steroids after gunshot wounds to the spine are not recommended.

F. Spine Fractures or Dislocations With Neurologic Deficit

1. Incomplete neurologic deficit—If there is a neurologic deficit, surgical decompression is indicated. This can be done either through an anterior approach with bone graft and internal fixation, a posterior costotransversectomy approach, or a combined anterior and posterior approach. The operative plan is individualized to the particular patient. Patients with incomplete neurologic deficits and unstable fractures or fracture-dislocations have the same stability requirements as patients without neurologic deficits. They are best managed with open reduction, instrumentation, and spinal fusion. Neural canal compromise should be managed as in the preceding paragraph.

2. Complete neurologic deficit—No operative procedure has been devised that will achieve recovery in cases of complete neurologic deficit that has persisted beyond the stage of spinal shock. However, surgical stabilization is often necessary (1) because spinal instability may interfere with early mobilization and rehabilitation training and (2) because it may result in loss of function at a higher level by causing mechanical injury on the root or cord segment just above the level of injury.

FRACTURES & DISLOCATIONS OF THE PELVIS

Pelvic fractures are among the most serious injuries and account for 3% of all fractures. The mechanism is often high energy in nature; 60% result from vehicular trauma (eg, automobile, motorcycle, bicycle), 30% from falls, and 10% from crush injuries, athletic injuries, or penetrating trauma. Pelvic fractures are the third most commonly seen injury in fatalities due to motor vehicle accidents.

Life-threatening hemorrhage, deformity, neurologic injury, and genitourinary injury are all potential complications that must be identified and treated early in the setting of a pelvic fracture. Pelvic fractures pose a formidable clinical challenge. Hemodynamically unstable patients who present to the emergency department with pelvic fracture have a mortality rate of 40%-50%.

► Anatomy

An understanding of pelvic anatomy is essential for identifying fracture patterns and complications. The pelvis is made up of three bones: two innominate bones joined anteriorly at the symphysis and posteriorly at the paired sacroiliac joints. The innominate bones are further subdivided into the ilium, ischium, and pubis.

The acetabulum is the portion of the pelvic bone that articulates with the femoral head to form the hip joint. It

results from closure of the triradiate cartilage and is covered with hyaline cartilage. The innominate bone support of the acetabulum can be thought of as an inverted Y formed by two columns. The anterior column (iliopubic component) extends from the iliac crest to the pubic symphysis including the anterior wall of the acetabulum. The posterior column (ilioischiac component) extends from the superior gluteal notch to the ischial tuberosity including the posterior wall. The acetabular dome is the superior weight-bearing portion of the acetabulum at the junction of the anterior and posterior columns, including contributions from both.

The stability of the pelvis is dependent on its ligamentous attachments. A thick fibrocartilaginous disk joins the anterior aspects of the innominate bones to form the pubic symphysis. This joint acts as a supporting strut for the pelvis because the stability of the ring depends mostly upon the sacroiliac joints.

The posterior ligamentous structures supporting the sacroiliac joints can be divided into anterior and posterior complexes. The anterior sacroiliac joint ligaments are broad and flat and connect the iliac wing and the sacral ala. These ligaments primarily resist external rotation and torsional forces. The sacro-iliac ligaments provide most of the stability. Composed of the interosseous sacroiliac ligaments within the joint and the posterior sacroiliac ligaments spanning the sacrum between the posterior iliac spines, the posterior complex is considered to be the strongest ligament in the human body. The posterior sacroiliac complex resists shear forces between the sacrum and the ilium, clinically preventing displacement of the ilium onto the sacrum.

The pelvic floor contains two additional strong ligaments, the sacrospinous and the sacrotuberous ligaments. The sacrospinous ligament maintains rotational control while the sacrotuberous ligament is especially important in maintaining vertical stability of the pelvis. Additional stability is conferred by ligamentous attachments between the spine and the pelvis. The iliolumbar ligaments originate from L4 and L5 transverse processes and insert on to the posterior iliac crest. The lumbosacral ligaments originate from the transverse process of L5 and insert to the sacrum ala.

► Stability

Pelvic stability can be defined as the ability of the pelvic ring to withstand physiologic forces without abnormal deformation. Pathologically, the pelvic ring fails under one or more of three basic modes. External rotation strains the pubic symphysis and the sacrotuberous, sacrospinous, and anterior sacroiliac joint ligaments. After roughly 2.5 cm of diastasis, the pelvic floor ligaments and the anterior sacroiliac ligaments begin to fail, giving rise to gross rotatory instability. Because the posterior ligament complex is largely intact, superior or posterior displacement of the involved hemipelvis does not occur. Combined external and shear forces are

necessary to completely disrupt pelvic stability. Conversely, internal rotation places the pubic rami under compression and the posterior ligament complexes under tension. The rami often fail in their midportions with transverse fractures and sacral alar impaction. The pelvic floor ligaments remain intact, and gross posterior stability is maintained. Therefore, fractures involving torsional forces on the pelvis often have partial instability in the rotatory plane only, with maintenance of stability to other displacement.

Complete instability, however, occurs with disruption of both the anterior and the posterior ligamentous restraints. These injuries often present with widely displaced sacroiliac joints and multiaxial instability of the involved hemipelvis. Such fractures have components of superior and posterior displacement relative to the sacrum in addition to rotational displacement in the sagittal and horizontal planes.

► Clinical Evaluation

Physical examination includes palpation of the pelvic bony landmarks, compression maneuvers to assess stability, rectovaginal examination looking for bony spikes protruding through the mucosa representing an open fracture, and looking for blood at the urethral meatus, or a high-riding prostate on rectal exam which may indicate genitourinary injury. If bladder or urethral injury is suspected, retrograde urethrogram should be considered. The mortality rate of open pelvic fractures is as high as 50%—compared with 8%-15% for closed fractures. A secondary musculoskeletal survey examining each of the other four limbs including distal vascular status and a thorough neurologic examination should be performed as well.

► Radiographic Examination

The anteroposterior radiograph required in all patients with blunt trauma rapidly identifies the major pelvic injury. The AP pelvis radiograph can be looked at in a systematic way: the pubic rami, pubic symphysis (looking for widening >2.5 cm), the iliopectineal lines (represents limit of the anterior column of the acetabulum) ilioischial lines (represents limit of the posterior column of the acetabulum), the anterior lip of the acetabulum, the posterior lip of the acetabulum, the radiographic roof of the acetabulum, the pelvic wings, the sacro-iliac joints, femoral head position (rule-out concomitant hip dislocation), associated fracture of the femoral head or femoral neck, and finally the lumbar spine. Disruption of the iliopectineal line, ilioischial line, the anterior lip, posterior lip, or the radiographic roof may be indicative of acetabular fracture. Suspected acetabular fractures should be further evaluated with **Judet's views** (iliac oblique and obturator oblique). The **iliac oblique** (45-degree external rotation view) view better delineates the anterior column and posterior wall of the acetabulum, while the **obturator oblique** (45-degree internal rotation view) characterizes

the posterior column and anterior wall of the acetabulum in greater detail. Inlet and outlet radiographs are often required to supplement the anteroposterior film. The **inlet view** (patient supine, the tube directed 60 degrees caudal) can be used to evaluate for any anterior-posterior instability, while the **outlet view** (patient supine, tube directed 45 degrees cephalad) will best show any vertical displacement. CT scan is recommended for any suspected pelvis fracture; this modality is especially good for evaluation of the acetabulum and posterior pelvis, including the sacrum and sacro-iliac joints.

► Acute Management

Immediate care of the polytrauma patient with a pelvic fracture must address associated retroperitoneal hemorrhage, pelvic ring instability, and injuries to the genitourinary system and rectum as well as fractures open to the peritoneum. Cessation of blood loss, minimization of septic sequelae, and stabilization of the fracture, allowing early and safe patient mobilization, are the immediate treatment goals. Hemorrhage is the leading cause of death in patients with pelvic fracture, accounting for 60% of the deaths. Most of the blood loss is from the fracture site or injured retroperitoneal veins; only 20% of the deaths are associated with major arterial injury. An average blood replacement of 5.9 units has been reported.

General resuscitative principles are applied to stabilize the patient and provide adequate tissue perfusion. Once other sites of hemorrhage have been ruled out, active bleeding from a pelvic fracture may be controlled by wrapping a pelvic binder or sheet circumferentially around the pelvis. The sheet should enclose the bilateral anterior superior iliac spines and greater trochanters, and can be fixed in place by clipping the two ends with a hemostat. Wrapping the pelvis in this way stabilizes major fracture fragments and closes down the volume of the pelvis, dramatically reducing active blood loss. If this fails to control hemorrhage, angiography or arterial embolization is indicated. Definitive internal fixation is usually required after hemorrhage has been controlled and the patient has been stabilized.

Fracture-dislocations of the pelvis should be treated with immediate closed reduction of the hip. Stability should be assessed by ranging the hip through a full arc of motion. Unstable hips should be reduced and placed in skeletal traction. An Irreducible hip or new-onset sciatic nerve palsy after closed hip reduction requires immediate operative treatment.

► Classification & Treatment

Fractures of the pelvis may be classified according to the Young and Burgess system based off of mechanism of injury. AP compression (APC) injuries result from anteriorly applied force. APC-I characterizes less than 2.5 cm of

symphyseal diastasis; vertical fractures of one or both pubic rami occur, however, the sacroiliac ligaments are intact imparting rotational and vertical stability. In an APC-II injury disruption of the anterior sacro-iliac ligaments results in greater than 2.5 cm of symphyseal diastasis that is rotationally unstable, but vertically stable due to intact posterior sacroiliac ligaments. APC-III injury occurs with complete disruption of the symphysis, sacrotuberous, sacrospinous, anterior, and posterior sacroiliac ligaments resulting in a pelvis that is rotationally and vertically unstable. Lateral compression (LC) injury results from a laterally applied force to the pelvis that leads to shortening of the anterior sacroiliac, sacrospinous, and sacrotuberous ligaments with resulting transverse or oblique fractures of the pubic rami. LC-I injury describes transverse fractures of the pubic rami with sacral compression on the side of injury without rotational or vertical instability. LC-II injuries describe the addition of a crescent iliac wing fracture on the side of impact with variable disruption of the posterior ligamentous structures resulting in rotational instability. LC-III describes an LC-I or LC-II injury on the side of impact with continuation of the force producing an external rotation or open book (APC) type injury on the contralateral side. Vertical shear (VS) injury due vertical or longitudinal forces caused by falls onto an extended lower extremity, impacts from above, or motor vehicle accidents with a lower extremity impacted against the dashboard or floorboard, typically results in complete ligamentous disruption, rotational and vertical instability, with a high incidence of neurovascular injury, and hemorrhage. Combined mechanical (CM) describes a combination of injuries often due to crush mechanism.

Pelvic fractures may also be classified according to instability using the Tile classification: type A (rotationally and vertically stable), type B (rotationally unstable and vertically stable, or type C (rotationally and vertically unstable). Common radiographic signs of pelvic instability include (1) displacement of the posterior sacroiliac complex more than 5 mm in any plane; (2) the presence of a posterior fracture gap rather than an impaction; and (3) the presence of an avulsion fracture of the transverse process of the fifth lumbar vertebra or the sacro-ischial end of the sacrospinous ligaments.

Type A fractures involve the pelvic ring in only one location and are considered stable. Type A1 fractures are avulsion fractures that usually occur at muscle origins such as the anterosuperior iliac spine, anteroinferior iliac spine, and ischial apophysis. These fractures most often occur in adolescents, and conservative treatment is usually sufficient. Rarely, symptomatic nonunions develop and can be best treated surgically.

Type A2 fractures are isolated fractures of the iliac wing without involvement of the hip or sacroiliac joints and are usually a result of direct trauma. Even with significant displacement, bony healing is expected and treatment is

therefore symptomatic. Healing may be accompanied by ossification of the hematoma with exuberant new bone formation. Finally, type A3 fractures are isolated fractures of the obturator foramen and usually involve minimal displacement of the pubic or ischial rami. The posterior sacroiliac complex is intact, and the pelvis remains stable. Treatment is symptomatic, with early ambulation and weight bearing as tolerated.

Type B fractures involve breaks in the pelvic ring in two or more sites. This creates a pelvic fracture that is rotationally unstable but vertically stable. Type B1 fractures are open book fractures that occur from anteroposterior compression. Unless the anterior separation of the pubic symphysis is severe (> 6 cm), the posterior sacroiliac complex is usually intact and the pelvis is relatively stable to vertical forces. Significant associated injuries to the perineal and urogenital structures are often present and should always be looked for. For minimally displaced symphyseal injuries (< 2.5 cm), only symptomatic treatment is needed. However, if conservative treatment is pursued, serial radiographs are required after mobilization is begun to monitor for subsequent increased displacement that may require surgery. For more displaced fracture-dislocations, reduction is done by LC using the intact posterior sacroiliac complex as the hinge on which the “book is closed.” Reduction can be maintained with the use of an external fixator; however, internal fixation with a symphyseal plate is currently favored. “Closing the book” decreases the space available for hemorrhage, increases patient comfort.

Type B2 and B3 fractures involve a lateral force applied to the pelvis, causing inward displacement of the hemipelvis through the sacroiliac complex and ipsilateral (B2) or, more often, contralateral (B3) pubic rami fractures. The degree of involvement of the posterior sacroiliac ligament complex will determine the degree of instability. The hemipelvis is infolded, with overlapping of the pubic symphysis. Reduction can be accomplished with external fixation, with internal fixation, or with both. External fixation facilitates nursing care but is not strong enough for ambulation. Definitive care usually is accomplished with internal fixation of both the anterior and posterior aspects of the pelvic ring. Major hemorrhage is associated with these fracture types.

Type C fractures are both rotationally and vertically unstable. They often result from a VS injury such as a fall from a height. Anteriorly, the pubic symphysis or pubic rami may be disrupted. Posteriorly, the sacroiliac joint may be disrupted and dislocated, or there may be a fracture through the sacrum or adjacent iliac wing. The hemipelvis is completely unstable, and there may be associated massive hemorrhage and injury to the lumbosacral pelvis. External fixation is insufficient to maintain reduction, but it may help to control hemorrhage and ease nursing care in the acute stage. Internal fixation is usually required as definitive treatment.

SACRAL FRACTURES

Fractures of the sacrum can be described using the Denis classification according to the location of the fracture in relation to the sacral foramen: Denis I: lateral to the foramen, Denis II: through the foramen, and Denis III: medial to the foramen. The incidence of neurologic injury increases with higher classification.

FRACTURES OF THE ACETABULUM

Fractures of the acetabulum (Figure 40–1) occur through direct trauma on the trochanteric region or indirect axial loading through the lower limb. The position of the limb at the time of impact (rotation, flexion, abduction, or adduction) will determine the pattern of injury. Comminution is common.

► Classification

Letournel has classified acetabular fractures into ten different types: five simple patterns (one fracture line)-posterior wall, posterior column, anterior wall, anterior column, transverse and five complex patterns (the association of two or more simple patterns)-T-shaped, posterior column and posterior wall, transverse and posterior wall, anterior column/posterior hemi-transverse, and both column. This is the most widely used classification system as it allows the surgeon to choose the most appropriate surgical approach.

► Treatment

The goal of treatment is to achieve a spherical congruency between the femoral head and the weight-bearing acetabular dome and to maintain it until the bones are healed. As with

other pelvic fractures, acetabular fractures are frequently associated with abdominal, urogenital, and neurologic injuries, which should be systematically sought and treated. Significant bleeding is often present and should be stopped as soon as possible.

The stabilized patient with **protrusion** (the femoral head is impacted through the fracture of the acetabulum into the pelvis) or unstable fracture-dislocation should be put in longitudinal skeletal traction through a distal femoral or proximal tibial pin pulling axially in neutral position. Postreduction x-rays are obtained. Operative indications for acetabular fractures include displacement(> 2-3 mm), large posterior wall fragments, interposed intra-articular loose fragment, femoral head fractures, unstable reductions, and an irreducible fracture dislocation by closed methods. The choice of approach is of primary importance, and more than one approach will sometimes prove necessary. Acetabular surgery uses extensile approaches and sophisticated reduction and fixation techniques and is best performed by pelvic surgeons.

► Complications

Complications inherent to the injury include posttraumatic degenerative joint disease, heterotopic ossification, femoral head osteonecrosis, deep vein thrombosis, and other complications related to conservative treatment. Surgery is performed to prevent or delay osteoarthritis (OA), but it increases the possibility of complications such as infection, iatrogenic neurovascular injury, and increased heterotopic ossification. When the reduction is stable and fixation is solid, the patient can be mobilized after a few days with non-weight-bearing ambulation, and weight bearing may

▲ **Figure 40–1.** Forty-year-old man who fell from a height, sustaining a posterior hip dislocation and an acetabular fracture of the weight-bearing dome. **A.** Coronal CT reconstructions showing large fragment of the superior dome of the right acetabulum. **B.** Oblique radiograph demonstrating concentric reduction of the hip and restoration of the articular surface after open reduction and internal fixation.

begin as early as 6 weeks. Prophylactic anticoagulation and aggressive pulmonary toilet are key elements of postoperative care.

SHOULDER INJURIES

1. Clavicular Fractures

► Epidemiology, Mechanism, Anatomy, and Clinical Evaluation

Clavicle fractures are relatively common accounting for between 2% and 12% of all fractures. Clavicle fractures are characterized by location: medial, lateral, and middle third of the clavicle which is the most common type (80%). The most common mechanism of injury is fall on to the ipsilateral shoulder (87%); direct impact (7%) and falls onto an outstretched hand cause the rest. The clavicle is an S-shaped bone that serves as a strut bracing the shoulder in relation to the trunk, allowing the shoulder to function at maximum strength. The clavicle is stabilized by the acromioclavicular and coracoclavicular ligaments. The acromioclavicular ligaments prevent horizontal displacement while the coracoclavicular ligaments provide vertical stability. The middle one-third of the clavicle protects the brachial plexus, superior lung, subclavian and axillary arteries. As a result, it is critical to document a thorough neurovascular examination, and rule-out concomitant injuries such as brachial plexus palsy, vascular injury, and pneumothorax. It is also important to note the appearance of the skin as tenting may be an indication for surgery. Clavicle fractures are most often incidentally seen on the AP radiograph of the chest. Proximal third clavicle fractures can be further evaluated with computed tomography to differentiate between sternoclavicular dislocations from epiphyseal injury.

► Classification

Clavicle fractures are classified into three groups: Group I: middle third fracture, Group II: distal third, Group III: proximal third. Group II fractures are subclassified into three types according to the location of the coracoclavicular ligaments relative to the fracture. Type I fractures are interligamentous, either in between the conoid and trapezoid ligaments or between the coracoclavicular and acromioclavicular ligaments, with the ligaments still intact. Because ligaments are attached to both the proximal and distal fracture segments, the fracture is typically nondisplaced or minimally displaced. Group II, type II fractures occur medial to the coracoclavicular ligaments or in between the conoid and trapezoid ligaments with the conoid ligament torn, such that the proximal fracture segment is predisposed to significant displacement. Group II, type III is a distal-third fracture of the articular surface of the AC joint without ligamentous injury.

► Treatment

Clavicle fractures are typically treated conservatively with a sling or figure of eight brace for 4-6 weeks until healing is appreciated radiographically and clinically (area no longer tender with palpation). Sling is typically preferred due to lower incidence of skin problems and increased patient comfort. Some degree of shortening and deformity is expected with closed treatment. However, shoulder dysfunction is rare and there is no scar. Strict indications for surgery include open clavicle fractures, associated neurovascular injury, and skin tenting concerning for impending open fracture. Some authors advocate fixing significantly displaced (> 1-2 cm) middle-third clavicle fractures and Group II, type II distal clavicle fractures, due to predisposition to nonunion which may result in cosmetic deformity and shoulder dysfunction.

2. Acromioclavicular Dislocation

The AC joint is diarthroidal with fibrocartilage-covered articular surfaces between the medial acromion and the lateral end of the clavicle. The AC ligaments blend with fibers from the deltoid and trapezius to provide strength to the joint. As described previously, the AC ligaments provide horizontal stability while the coracoclavicular ligaments provide vertical stability. The mechanism for dislocation of the acromioclavicular joint is most commonly direct impact caused by a fall on the tip of the shoulder. Thorough neurovascular examination along with standard trauma series of the shoulder (AP, scapular-Y, and axillary views) completes the standard workup. Stress radiographs in which 10-15 lb weights are strapped to the wrists and an AP radiograph is taken of both shoulders comparing coracoclavicular distances, to differentiate between partial grade I to II injuries and grade III AC separations.

► Classification and Treatment

Type I is a strain of the acromioclavicular ligament. **Type II** injury involves rupture of the acromioclavicular ligament and strain of the coracoclavicular ligament complex, with slight superior displacement of the superior clavicle **type III** injury involves rupture of both the acromioclavicular and the coracoclavicular ligaments, which causes marked superior migration of the lateral end of the clavicle **types IV, V, and VI** injuries involve detachment of the deltoid and trapezius from the distal clavicle in addition to disruption of the AC and CC ligaments with marked posterior, superior, and inferior displacement of the clavicle, respectively.

► Treatment

Type I, II, and III AC joint injuries are typically managed nonoperatively with a sling for approximately 4 weeks

followed by gradual return to full activity. Most patients do not have significant dysfunction or any need to modify their activities. Surgical reconstruction may be indicated for types IV, V, and VI AC joint injuries. Type III injuries in young athletes or laborers who perform a lot of overhead work may be treated surgically.

3. Sternoclavicular Joint Dislocation

Dislocation of the sternoclavicular joint is rare. The mechanism of injury is usually a motor vehicle accident or sporting injury. Physical examination and anteroposterior and anteroposterior-cephalic tilt x-rays may demonstrate asymmetry. However, computed tomography is diagnostic test of choice as it can distinguish fractures of the medial clavicle from SC dislocation and can show minor subluxation. Anterior dislocation is more common, but posterior dislocation can cause injury to the esophagus, trachea, great vessels, subclavian artery, carotid artery, and pneumothorax. Dislocations of the sternoclavicular joint in children are often associated with physical fractures.

► Treatment

Most injuries to the sternoclavicular joint may be treated with a ice for the first 24 hours and immobilization with a sling, sling and swathe, or figure-of-eight bandage. Posterior dislocations may require emergent reduction if there is associated vascular compression or injury to the trachea, esophagus, or lungs. Closed reduction of posterior dislocations has been described using shoulder retraction and a towel clip. Rarely, open reduction may be necessary.

4. Scapular Fracture

Scapular fractures are classified by anatomic location: scapula body, neck, spine, acromion, coracoid, or glenoid. Scapular body fractures are often associated with other injuries such as subclavian vessel injury, aortic rupture, pneumothorax, rib fractures, brachial plexus injuries, and other soft tissue injuries associated with high-energy trauma. Fractures of the acromion and coracoid are rare. Glenoid fractures must be carefully evaluated for articular surface step-off and associated glenohumeral instability. These fractures may be caused by a blow on the shoulder or by a fall on the outstretched arm. Diagnosis with anteroposterior x-ray in the plane of the scapula and axillary x-ray may be supplemented by an axial view of the scapular body and transscapular Y-view. CT scan may also be helpful if surgery is being considered.

► Treatment

Most scapular fractures are treated nonoperatively in a sling for 4-6 weeks. Associated injuries may need to be

treated emergently and should not be overlooked. Surgical indications are controversial, but may include displaced intra-articular fractures involving more than 25% of the articular surface, scapular neck fractures more than 40 degree angulation or 1 cm of medial translation, scapula neck fractures with an associated displaced clavicle fracture, acromion fractures that cause subacromial impingement, and coracoid fractures that cause functional AC separation.

5. Dislocation of the Shoulder Joint

The shoulder (glenohumeral) joint is the most commonly dislocated joint in the body due to its freedom of motion and mobility in multiple planes. Diagnosis and management of this is presented in detail in the Sports Medicine section of this chapter.

6. Proximal Humerus Fracture

Fractures of the proximal humerus occur most commonly in elderly individuals with osteoporosis, after a fall initial assessment should seek to determine the cause of any related fall as well as the fracture pattern. Prodromal symptoms related to a syncopal episode, myocardial infarction, stroke, transient ischemic attack, or seizure are possible etiologies that should be investigated. Associated injuries include neurovascular injuries, dislocation, and rotator cuff tears. Axillary nerve function should be assessed testing sensation over lateral aspect of shoulder, overlying deltoid (motor testing is usually not possible, due to pain).

Diagnosis is established by standard shoulder trauma series (AP, lateral scapular Y, and axillary views). The axillary view is the best view for evaluating glenoid articular fractures and dislocations. If axillary view cannot be obtained due to pain, a Velpeau axillary view where the patient is left in a sling leaned obliquely backward 45 degrees over the cassette with the beam directed caudally is another option. Computed tomography can be used to further evaluate articular involvement, fracture displacement, impression fractures, and glenoid rim fractures.

► Classification and Treatment

Proximal humerus fractures can be classified according to the system developed by NEER. There are four major parts of the proximal humerus: humeral head, humeral shaft, greater, and lesser tuberosities. A part is defined as displaced if there is more than 1 cm of fracture displacement, or more than 45 degrees of angulation. Most proximal humerus fractures are minimally displaced (< 1 cm and < 45 degrees of angulation) and can be treated in a sling with early gentle range of motion exercises. Displaced fractures usually require surgery. Surgical options include closed

▲ **Figure 40-2.** Four-part proximal humerus fracture, impacted on inferior glenoid rim.

reduction and percutaneous fixation, open reduction and internal fixation, and prosthetic arthroplasty (Figures 40-2 and 40-3). Other indications for surgery include superior displacement of the greater tuberosity fragment of 5 mm or more which can lead to subacromial impingement, lesser tuberosity fractures that block internal rotation. Patients often lose some range of motion, but excellent pain relief and function can be attained. Long-term complications include shoulder stiffness and avascular necrosis of the humeral head (due to disruption of the arcuate branch off of the anterior circumflex humeral artery).

FRACTURES OF THE SHAFT OF THE HUMERUS

Most fractures of the shaft of the humerus result from direct trauma; indirect mechanism from fall on an outstretched arm is also a possibility. A careful neurovascular exam is required (radial nerve injury is most common). AP and lateral radiographs of the humerus, as well as shoulder and elbow series are mandatory to rule out the possibility of fracture or dislocation involving adjacent joints. Humerus fractures can be described descriptively: open versus closed, location (proximal, middle, and distal third), nondisplaced versus displaced, transverse, oblique, spiral, segmental or comminuted fracture, intrinsic condition of bone (osteopenic or not), and if there is any articular extension.

► Treatment

Most midshaft humeral fractures can be treated nonoperatively in a cast, splint, or brace. Alignment should be verified using AP and lateral x-rays with the patient standing. Twenty degrees of anterior angulation, 30 degrees of varus angulation, and up to 3 cm of bayonet apposition are acceptable for continued closed treatment. Other surgical indications include open fractures, concomitant vascular injury, pathologic fracture, “floating elbow” (concomitant

▲ **Figure 40-3.** Surgical reconstruction with hemiarthroplasty.

fracture of the forearm bones), segmental fracture, intra-articular extension, and bilateral humeral fractures. Radial nerve injury most commonly occurs with middle third fractures. Most radial nerve injuries are the result of stretching or contusion; function usually returns in 3-4 months. Delayed surgical exploration is warranted if there is no evidence of recovery on EMG or nerve conduction velocity studies at this time.

FRACTURES & DISLOCATIONS ABOUT THE ELBOW

► Anatomy & Biomechanics

The elbow is a modified hinge joint consisting of three separate articulations: ulnohumeral, radiohumeral, and proximal radioulnar. The elbow joint is intrinsically stable with bony and soft tissue contributions. The trochlea-olecranon fossa, coronoid fossa, radiocapitellar joint, biceps, triceps, and brachioradialis provide anterior-posterior stability during flexion and extension. On the medial side of the elbow the anterior bundle of the medial collateral ligament (MCL) is the primary stabilizer to valgus stress, while the lateral ulnar collateral ligament is the primary stabilizer on the opposite side of the elbow preventing posterolateral instability. Normal elbow range of motion entails 0-150 degrees of flexion, 85 degrees of supination, and 80 degrees of pronation. Functional range of motion requires 30-130 degrees

of flexion, 50 degrees of pronation, and supination. Elbow injury mandates careful examination of the entire upper extremity including shoulder and wrist, with thorough neurovascular examination. AP, lateral, and oblique radiographs are required to adequately visualize the elbow joint.

► Distal Humerus Fractures

The distal humerus can be conceptualized as medial and lateral columns, each roughly triangular in shape and composed of a condyle articulating with the bones of the forearm and an epicondyle (distal part of the humerus that flares just above the elbow joint at the level of the supracondylar ridge) connecting to the shaft of the humerus. These fractures can be classified descriptively: intercondylar (most common), supracondylar fractures (extension or flexion type), transcondylar, condylar, capitellum, trochlea, lateral epicondyle, medial epicondyle, or fractures of the supracondylar process. These fractures can also be classified using the AO system based on the concept of column integrity and articular involvement. Type A fractures are extra-articular (epicondylar, supracondylar, transcondylar) fractures. Type B fractures only involve a portion of the articular surface (unicondylar or intercondylar). Type C fractures involve the entire distal articular surface.

► Radiographic Evaluation

Standard AP, lateral, and oblique radiographs should be obtained. Traction radiographs or computed tomography may provide better fracture pattern visualization for preoperative planning. On the lateral radiograph, the anterior or posterior **“fat pad sign” representing displacement of the adipose layer over the joint capsule** may be the only indication of a nondisplaced distal humerus fracture. The AP radiograph should be carefully scrutinized for an intercondylar split. If an intercondylar split is present, the amount of rotation, in addition to displacement and fracture comminution should be noted.

► Management

The patient can be initially managed with a posterior long-arm splint with the elbow flexed at 90 degrees and the forearm neutral. Nonoperative treatment is indicated for nondisplaced or minimally displaced fractures. Surgery is indicated for displaced fractures, vascular injury, or open fracture.

SPECIFIC FRACTURE TYPES

► Supracondylar Fractures of the Humerus

Supracondylar fractures are much more common in children. There are two types: extension (distal fragment is displaced posteriorly) and flexion (distal fragment is displaced

anteriorly). Nondisplaced, minimally displaced, and severely comminuted fractures in the elderly with limited functional needs may be treated nonoperatively. Posterior splint immobilization is continued for 1-2 weeks after which gentle range of motion exercises are begun. The splint may be discontinued and weight bearing advanced after six weeks if signs of radiographic healing are appreciated. Surgical options include open reduction internal fixation with plates and screws. Total elbow replacement may be considered in elderly patients who were otherwise active with good preinjury function with severely comminuted fractures not amenable to ORIF.

► Transcondylar Fractures

Nonoperative treatment is indicated for nondisplaced or minimally displaced fractures or for debilitated elderly patients with poor function preinjury. Range of motion exercises should be initiated as soon as the patient is able to tolerate therapy. Surgical options include ORIF or total elbow arthroplasty.

► Intercondylar Fractures

Intercondylar fractures are the most common type of distal humerus fracture in adults. Fracture fragments are often displaced due to opposing muscle forces on the medial (flexor mass) and lateral (extensor mass) epicondyles, causing rotation of the articular surfaces (Figure 40-4). Fractures can be classified as type I (nondisplaced), type II (slight displacement with no rotation between the condylar fragments), type III (displacement with rotation), and type IV (comminution of the articular surface). Nonoperative treatment with two weeks of immobilization followed by range of motion exercises is indicated for nondisplaced fractures. Type IV fractures in the elderly with osteopenic bone can be treated with the “bag of bones” technique which entails very short-term immobilization with early range of motion. Open reduction internal fixation with dual plates is the preferred surgical treatment. Early range of motion is critical to prevent stiffness, unless fixation is tenuous. TEA is another option.

► Condylar Fractures

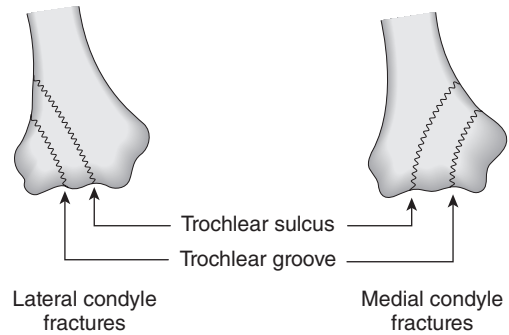

Medial or lateral condyle fractures are rare in adults (Figure 40-5). Type I (Milch classification) fractures do not traverse the lateral trochlear ridge. Involvement of the lateral trochlear ridge (type II) leads to medial-lateral instability. Nonoperative treatment, entailing a posterior splint with elbow flexed to 90 degrees and the forearm supinated for lateral condyle fractures or pronated for medial epicondyle fractures, may be pursued for nondisplaced or minimally displaced fractures. Open or displaced fractures can be treated surgically with screw fixation with or without collateral ligament repair as needed.

▲ **Figure 40-4.** Intercondylar fractures.
A. Type I undisplaced T-condylar fracture of the elbow.
B. Type II displaced but not rotated T-condylar fracture.
C. Type III displaced and rotated T-condylar fracture.
D. Type IV displaced rotated and comminuted T-condylar fracture.

► Capitellum Fractures

Capitellum fractures are rare, representing less than 1% of all elbow fractures. Due to lack of significant soft tissue attachments, these fractures may result in a free articular fragment that may displace anteriorly into the coronoid or radial fossa causing a block to elbow flexion. These fractures typically result from a fall on an outstretched arm with the force transmitted through the radial head to the capitellum. Occasionally, radial head fracture may also be present. Capitellum fractures can be classified as follows (Figure 40-6): type I “Hahn-Steinthal” large osseous fragment with or without trochlear involvement, type II “Kocher-Lorenz” fragment articular cartilage with minimal subchondral bone attached, and type III (significant comminution). Nonoperative treatment, reserved for nondisplaced fractures, consists of immobilization in a posterior splint followed by elbow range of motion exercises. Surgical treatment entails ORIF with screws or excision for type II fractures, severely comminuted type I fractures or chronic missed fractures with limited range of motion.

▲ **Figure 40-5.** Condyle fractures. Milch classification. The type II fracture involves the lateral lip of the trochlea—thus its inherent instability. (Reproduced, with permission, from Milch H: Fractures and fracture dislocation of the humeral condyles. *J Trauma*, 1964.)

► Trochlea Fractures

These fractures are extremely rare and associated with elbow dislocation. Nondisplaced fractures can be treated with posterior splint for three weeks, followed by elbow range of motion exercises. Displaced fractures are treated with ORIF; fragments not amenable to internal fixation can be excised.

► Epicondylar Fractures

Lateral epicondyle fractures can be treated with symptomatic immobilization with early range of motion. Nondisplaced or minimally displaced medial epicondyle fractures can be treated with immobilization in posterior splint with the forearm pronated, wrist and elbow flexed for 10-14 days. ORIF is indicated for displaced fractures, especially in the presence of ulnar nerve symptoms, valgus stress instability, wrist flexor weakness, and symptomatic nonunion.

► Supracondylar Process Fractures

The supracondylar process is osseous or cartilaginous projection arising from the anteromedial surface of the humerus. The ligament of Struthers which connects the supracondylar process to the medial epicondyle is a fibrous arch through which the median nerve and brachial artery passes. Most of these fractures are amenable to closed treatment with symptomatic posterior splint immobilization followed by early range of motion. Median nerve or brachial artery compression are indications for surgical exploration and release.

► Elbow Dislocation

Elbow dislocation most commonly results from a fall on an outstretched hand. A careful neurovascular examination

▲ **Figure 40-6.** Fractures of the capitellum. The type I fracture involves a large portion of bone, often the entire structure. Type II is a shear fracture, often with minimal subchondral bone, and may displace posteriorly (A). A type III fracture is a comminuted fracture with varying amounts of displacement of the fracture fragments (B).

along with AP and lateral radiographs of the elbow are required. Simple elbow dislocation (no associated fracture) are classified according to the direction of displacement of the ulna relative to the humerus: posterior (most common type), posterolateral, posteromedial, lateral, medial, and anterior (Figure 40-7). Acute elbow dislocations should undergo closed reduction with patient under sedation and adequate anesthesia as soon as possible. For posterior dislocation, the reduction maneuver entails longitudinal traction with elbow flexion. Postreduction range of motion exam, neurovascular

exam, and radiographs should be performed, followed by placement in a posterior splint with 90 degrees of flexion. A block to full range of motion may indicate an incarcerated fracture fragment or inadequate reduction. If reduction does not restore arterial flow, angiography, and immediate operative intervention are warranted. Postreduction films should be carefully evaluated for concentric reduction and associated fractures (medial or lateral epicondyle, radial head, coronoid process). Elbow dislocation with radial head and coronoid process fractures is known as the “terrible triad”,

▲ **Figure 40-7.** Elbow dislocations. An elbow dislocation is defined by the direction of the forearm bones. (Reproduced, with permission, from Browner B et al: *Skeletal Trauma*. Saunders, 1992.)

due to associated instability. Surgical intervention is indicated when the elbow cannot be held concentrically reduced position, redislocates, or if the dislocation is deemed unstable (if the elbow dislocates prior to reaching 30 degrees of flexion from a fully flexed position). Recovery of motion and strength may take 3-6 months. The most common complication is stiffness, associated with prolonged immobilization. Recently, the trend has been to immobilize elbows for one week postinjury, and then start range of motion exercises. If symptomatic heterotopic ossification is present, excision can be pursued 6 months or longer after injury.

FRACTURES OF THE PROXIMAL ULNA

▶ Olecranon Fractures

The olecranon is the most proximal palpable portion of the ulna. The subcutaneous position of the olecranon causes it to be especially susceptible to direct trauma. Posteriorly, the triceps tendon envelops the articular capsule before it inserts on to the olecranon. As a result, displaced fractures of the olecranon represent a functional disruption of the triceps mechanism, resulting in loss of active elbow extension. Anteriorly, the olecranon forms the greater sigmoid (semilunar) notch of the ulna, which articulates with the trochlea. The most proximal anterior portion of the ulna is the coronoid process, which lends stability to the elbow joint.

Olecranon fractures may result from a direct blow (fall on to the tip of the elbow) resulting in a comminuted olecranon fracture, or fall onto an outstretched arm accompanied by a strong, sudden triceps contraction resulting in a transverse or oblique fracture. Careful neurovascular exam followed by AP and lateral radiographs should be part of the initial evaluation. A true lateral radiograph should be carefully scrutinized for the extent of the fracture, any displacement of the radial head (the radial head should point toward the capitellum in all views; if this is not the case subluxation or dislocation is present), degree of comminution and articular surface involvement. Olecranon fractures are classified based on fracture pattern (transverse, transverse-impacted, oblique, comminuted, oblique-distal, or fracture dislocation) or according to the Mayo classification: type I (nondisplaced or minimally displaced), type II (displacement without elbow instability), type III (fracture with features of elbow instability). The goals of treatment are to restore articular congruity, restoration, and preservation of the elbow extensor mechanism and range of motion.

Nondisplaced fractures or displaced fractures in the elderly with poor preinjury function can be managed with closed treatment in a long-arm splint or cast with the elbow flexed from 45-90 degrees. Careful follow-up with radiographs should be done at weekly intervals for at least 2 weeks. In general, there is sufficient stability at 3 weeks to allow early motion from full extension to 90 degrees of

flexion, with progression of flexion at 6 weeks. Of note some authors are advocating earlier range of motion at one week out from injury to prevent stiffness.

Indications for surgery include any disruption of the extensor mechanism (any displaced fracture) or articular incongruity. Multiple surgical options are available, including intramedullary fixation, tension band wiring, plate and screws, and excision. Postoperatively the patient should be placed in a posterior splint with early range of motion.

The most frequent complication of these fractures is prominent implants that subsequently require removal after healing has occurred. Elbow stiffness and loss of fixation have also been reported.

▶ Coronoid Fractures

The coronoid process is the anterior beak-shaped portion of the ulna, forming the buttress anteriorly of the greater sigmoid notch. The anterior portion of the MCL attaches here, as well as a portion of the anterior capsule, contributing to elbow stability.

Isolated fractures of the coronoid are uncommon and are more frequently associated with posterior elbow dislocations or other fractures about the elbow. The mechanism of injury is usually forced posterior displacement of the proximal ulna as with a dislocation or hyperextension force of the elbow. Oblique radiographs may aid evaluation of these fractures as they are sometimes difficult to see on lateral and anteroposterior views.

These fractures have been classified by Regan and Morrey based on the size of the fracture fragment (Figure 40-8): type I (coronoid process tip avulsion), type II (single or comminuted fragment involving 50% or less of the coronoid process), type III (a single or comminuted fragment involving > 50% of the process). Type I fractures can be treated with immobilization in flexion for 3 weeks (or less if the fragment

▲ **Figure 40-8.** Coronoid fractures. The coronoid fracture has been classified into three types by Regan and Morrey. (Reproduced, with permission, from Browner B et al: *Skeletal Trauma*. Saunders, 1992.)

and elbow are stable). Associated fractures should be treated as appropriate in each case with the goal of fracture stability for early range of motion. Isolated coronoid fractures without elbow instability can be treated in the same way as type I fractures. Unstable type II fractures and type III fractures usually require operative intervention.

FRACTURES OF THE PROXIMAL RADIUS

► Radial Head Fractures

Radial head fractures typically result from a fall on an outstretched arm causing an axial load collision between the radial head and capitellum. Patients typically present with limited elbow and forearm motion, along with pain with passive range of motion of the forearm. The forearm and wrist should be examined for any tenderness which may indicate the presence of an Essex-Lopresti type injury (radial head fracture dislocation with associated interosseous ligament and distal radioulnar joint disruption). After documentation of neurovascular status, anteroposterior, lateral, and radial head view radiographs should be evaluated for fracture. Nondisplaced fractures should be suspected if a fat pad sign is present without obvious fracture. If Essex-Lopresti injury is suspected, additional radiographs of the forearm and wrist are indicated as well.

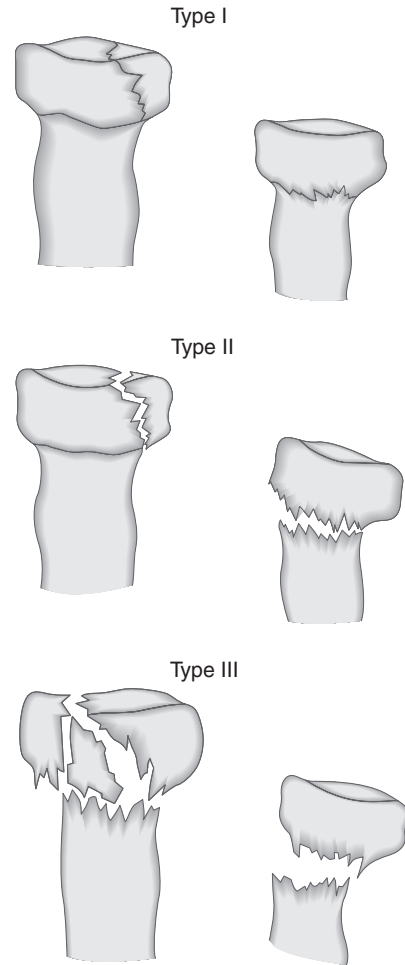

The Mason classification system is used to describe these fractures (Figure 40-9): type I (nondisplaced fractures), type II (marginal fractures with displacement), type III (comminuted fractures involving the entire radial head), and type IV (fracture associated with elbow dislocation).

Assessment of range of motion and stability to valgus stress is critical and can be performed after aspiration of the hemarthrosis and injection of lidocaine. This can be done through direct lateral needle insertion at the “soft spot” between the olecranon, radial head, and capitellum. Any mechanical block to motion should be carefully documented, as this can affect treatment decision-making.

Most isolated radial head fractures are treated with a brief period of immobilization in a sling followed by early range of motion 24-48 hours after the injury. Surgery is indicated for mechanical block to range of motion and type three fractures. A relative indication for surgery is displacement of a large fragment (> 2 mm); however, this is controversial. Surgical treatment options include ORIF, fragment excision with or without prosthetic replacement. Type IV injuries should be treated with closed reduction, followed by additional treatment based off of the above outlined criteria.

FRACTURES OF THE FOREARM

Forearm fractures are more common in men than women, secondary to a higher incidence of motor vehicle collisions, athletic injury, altercations, and falls from height experienced by men. The forearm acts as a ring: a fracture that

▲ **Figure 40-9.** Radial head fractures. The modified Mason classification system for radial head fractures. (Reproduced, with permission, from Browner B et al: *Skeletal Trauma*. Saunders, 1992.)

significantly shortens the radius or ulna will cause disruption of the proximal radio-ulnar joint or distal radio-ulnar joint. The ulna acts as an axis around which the laterally bowed radius rotates during supination and pronation. The interosseous membrane occupies the space between the radius and ulna; it provides a significant contribution to forearm stability.

Clinical assessment includes careful neurovascular exam (median, radial, and ulnar nerves) and assessment of any open wounds (even superficial wounds) can expose an ulna fracture to the outside world due to its subcutaneous position. Practitioners should have a high index of suspicion for compartment syndrome, if pain out of proportion, tense compartments, or pain on passive stretch is present.

Both-bone forearm fractures or fracture of one bone with concomitant injury to the elbow or wrist joint are more common than a fracture to either bone in isolation. As a result, it is crucial to obtain anteroposterior and lateral radiographs of the forearm that include both the wrist and elbow joints. The radial head must be aligned with the capitellum on all views to rule-out subluxation or dislocation.

Forearm fractures can be classified from a descriptive standpoint (closed vs. open, location, comminuted, segmental, multifragmented, displacement, angulated, and rotational alignment).

FRACTURES OF THE SHAFT OF THE RADIUS

▶ Isolated Radial Shaft Fractures

Radial shaft fractures can result from direct trauma or indirect trauma such as a fall on an outstretched hand. Although, isolated fractures of the proximal two-thirds of the radius are possible, a fracture of the distal one-third should raise high suspicion for concomitant injury to the distal radioulnar joint (DRUJ). Nondisplaced fractures can be managed closed in a long-arm cast. Any displacement, loss of radial bow, or concomitant injury to the DRUJ is surgical indications. Fractures of the radius are typically fixed with open reduction internal fixation with 3.5 mm DCP plates.

This is a fracture of the shaft of the radius (most commonly the distal third) in conjunction with a distal radioulnar joint injury. Wrist pain on physical examination should arouse suspicion. The diagnosis should be confirmed radiographically. DRUJ disruption is suggested by the following radiographic findings: fracture at the base of the ulnar styloid, widening of the distal radioulnar joint space on the anteroposterior radiograph, subluxation of the ulna, and radial shortening greater than 5 mm relative to the distal ulna.

In adults, these injuries should always be treated surgically with open reduction and internal fixation, along with intraoperative evaluation of the DRUJ. After fixing the radius, if the joint is stable through full pronation and supination, only short-term immobilization in a splint is required to protect the incision. If the joint can be reduced but is unstable with rotation, additional surgical treatment is necessary. If there is a repairable ulnar styloid fracture, then open reduction with internal fixation of this piece will result in a stable DRUJ. If there is no ulnar styloid fracture but the distal radioulnar joint is reducible but unstable with rotation, then two 0.0625-inch Kirschner wires are used to pin the distal ulna to the radius in a reduced position (usually supination). With both open reduction with internal fixation of the ulnar styloid and the use of transfixing pins, the forearm should be immobilized in full supination in an above-elbow cast or brace for 4-6 weeks. The transfixing pins are removed prior to allowing forearm range of motion. Rarely, the distal radioulnar joint cannot be reduced. In this instance, a dorsal approach to the joint is used to extract

interposed tissues (extensor carpi ulnaris is most common) blocking reduction.

FRACTURES OF THE SHAFT OF THE ULNA

▶ Isolated Ulnar Shaft Fractures (Nightstick Fractures)

Ulna night stick fractures usually results from a direct blow to the ulna along its subcutaneous border. Careful neurovascular examination and radiographs of the forearm including the wrist and elbow are essential. Radiographs should be carefully scrutinized for elbow dislocation; the radial head should point to the capitellum in all views or a Monteggia variant may be present. Nondisplaced or minimally displaced fractures may be treated acutely in a sugar tong splint. When swelling has subsided (after 7-10 days), the patient's arm can be transitioned to a long-arm cast or functional brace. Displaced fractures (> 10 degrees of angulation or > 50% displacement of the shaft) are best treated surgically with open reduction internal fixation.

▶ Monteggia's Fracture

Monteggia's fracture is a fracture of the proximal ulna with a radial head dislocation. Thorough neurovascular exam is necessary; injuries to the radial nerve or posterior interosseous nerve have been described. The Bado classification is based of the direction of the radial head dislocation: type I (anterior), type II (posterior), type III (lateral or anterolateral), and type IV (anterior dislocation with a fracture of the radius and ulna) (Figure 40-10).

Closed reduction and casting of Monteggia fractures should only be attempted in children. These injuries are typically treated with open reduction internal fixation with plates and screws. Of note failure of the ulna to reduce may indicate annular ligament interposition. If open reduction of the radial head is necessary, consideration should be given toward repairing the annular ligament. Postoperatively, if the repair is considered stable, the patient can be placed in a posterior splint for 7-10 days, followed by beginning range of motion exercises.

▶ Both-Bone Forearm Fractures

Fractures of both radius and ulna are usually the result of high energy mechanisms (motor vehicle accidents or fall from a height). The fractures are most often displaced. Careful examination to rule out neurovascular injury and compartment syndrome should be performed. Radiographs of the entire forearm including the elbow and wrist are necessary.

Treatment for both-bone forearm fractures in adults consists of open reduction and internal fixation with compression plating using 3.5-mm dynamic plates. The goal of plate fixation is to restore: the normal ulnar and radial length, rotational alignment, and radial bow (which have

▲ **Figure 40-10.** Monteggia's fractures. The classification of Monteggia lesions by Bado. **A.** Type I: anterior angulation of the ulnar fracture and anterior dislocation of the radial head. **B.** Type II: posterior angulation of the ulnar fracture and anterior dislocation of the radial head. **C.** Type III: fracture of the proximal ulna metaphysis and lateral dislocation of the radial head. **D.** Type IV: anterior dislocation of the radial head and fracture of the radial and ulnar shafts. (Reproduced, with permission, from Browner B et al: *Skeletal Trauma*. Saunders, 1992.)

been shown to be essential for rotation of the arm). With solid fixation, active range of motion of the forearm and elbow can be started at 10-14 days. Open fractures can also be treated successfully with these methods. However, if there is excessive soft tissue damage or wound contamination, the use of an external fixator may be a preferable option.

Complications of this fracture include nonunion, malunion, infection, neurovascular injury, compartment syndrome, synostosis, and loss of motion.

INJURIES OF THE WRIST REGION

► Anatomy

The distal radius has three articulations: the sigmoid notch which articulates with the ulna, and facets for the scaphoid and lunate bones. The base of the ulna styloid serves as an insertion point for the triangular fibrocartilage complex (TFCC) which is the primary stabilizer of the DRUJ. Normally, 80%

of the axial load is supported by the distal radius and 20% by the ulna and TFCC. There are six dorsal compartments of the wrist that contain wrist and digital extensor tendons. On the volar surface, the pronator quadratus lies across the distal radius and ulna. Just anterior to the pronator quadratus are the contents of the carpal canal, containing nine digital flexor tendons and the median nerve. Anterior to the transverse carpal ligament lie the flexor carpi radialis, flexor carpi ulnaris, and palmaris longus muscles. Guyon's canal contains the ulnar nerve and artery. It is bounded by the volar retinacular ligament and flexor retinacular ligament, the hook of the hamate radially, and the pisiform ulnarly.

Extrinsic ligaments connect the radius to the carpus and the carpus to the metacarpals. The proximal row of carpal bones consisting of the scaphoid, lunate, triquetrum, and pisiform bones, are attached to the distal radius via two sets of radiocarpal ligaments (volar and distal). The volar radiocarpal ligaments (radioscaphocapitate, radioschapolunate,

radiolunate, and radiolunotriquetral) are stronger and confer more stability to the radiocarpal articulation when compared to the dorsal radiocarpal ligaments. The radiocarpal joint is the primary joint for wrist motion (70 degrees of flexion/extension, 20 and 40 degrees of radial and ulnar deviation, respectively).

Intrinsic ligaments connect carpal bone to carpal bone (eg, scapholunate, etc). The distal carpal row, consisting of the trapezium, trapezoid, capitate, and hamate, is connected to each other and the base of the metacarpals with strong extrinsic ligaments. As a result, the distal carpal row is relatively immobile. The lunate is the key to carpal stability; injury to the scapholunate or lunotriquetral ligaments leads to unstable motion of the lunate and generalized carpal instability. Disruption of the scapholunate ligament or scaphoid fracture can lead to excessive dorsiflexion of the lunate and triquetrum (dorsal intercalated segmental instability). Injury to the lunotriquetral ligament leads to volar flexion of the lunate (volar intercalated segmental instability). The space of Poirer (ligament-free area between the capitate and lunate) is a potential area of weakness.

Normal anatomic relationships include radial inclination of 23 degrees, 11 mm of radial length, 11-12 degrees of palmar tilt, a 0 degree capitulunate angle (straight line drawn from the shaft of the third metacarpal, through the capitate and lunate with the wrist in a neutral position), a 47 degree scapholunate angle, and less than 2 mm of scapholunate space.

The vascular supply to the wrist consists of the radial, ulnar, and anterior interosseous arteries intertwining to form a network of arterial arches on the volar and dorsal surfaces of the carpal bones. The radial artery gives off branches that supply the scaphoid volarly (supplies distal scaphoid) and dorsally (supplies proximal scaphoid). The lunate typically receives blood supply from dorsal and volar surface branches.

1. Distal Radius Fracture

► Epidemiology

More than 450,000 distal radius fractures occur annually in the United States, representing one-sixth of all fractures treated in emergency departments. The incidence of distal radius fractures increases with old age and osteopenia.

► Mechanism

The most common mechanism for a distal radius fracture is fall on to an outstretched dorsiflexed hand. High-energy mechanisms such as motor vehicle collisions and falls from height can result in highly displaced or significantly comminuted fractures in younger patients.

► Clinical Evaluation

Patients typically present with a swollen, ecchymotic, tender wrist. Deformity of the wrist is variable with dorsal

displacement of the distal segment (Colles fracture) being more common than volar (Smith-type fracture). The ipsilateral elbow and shoulder should be carefully evaluated for concomitant injury. Careful neurovascular examination is paramount including the motor and sensory median, ulnar, and radial nerve distributions (Motor: a-ok, finger spread, and thumbs up signs; Sensory: volar aspect of the thumb, index, middle fingers, volar aspect of the small finger, and dorsal aspect of the thumb). Particular attention should be given to median nerve function as carpal tunnel syndrome is a relatively common complication (13%-23%) due to traction injury, fracture fragment trauma, hematoma, or increased compartment pressure.

► Radiographic Evaluation

Posteroanterior and lateral views of the wrist should be obtained. Elbow and shoulder symptoms should also be evaluated radiographically. Contralateral wrist views may be used for comparison ulnar variance and the DRUJ. Computed tomography scan can be useful for further characterization of intra-articular involvement and preoperative planning. Normal radiographic relationships include the following averages: 23 degrees of radial inclination, 11 mm of radial length, and 11 degrees of palmar or volar tilt.

► Classification

Distal radius fractures can be characterized descriptively—open versus closed, displacement, angulation, comminution, and loss of radial length. The Frykman classification organizes these fractures based on the degree of articular involvement as well as concomitant fracture of the distal ulna (Figure 40–11). Higher classification fractures have worse prognoses.

AO/ASIF CLASSIFICATION OF DISTAL RADIUS FRACTURES

Type A: Extra-articular fractures

1. Isolated distal ulnar fracture
2. Simple radius fracture
3. Radial fracture with metaphyseal impaction

Type B: Intra-articular complex fracture

1. Radial styloid fracture
2. Dorsal rim fracture
3. Volar rim fracture

Type C: Intra-articular complex fracture

1. Metaphyseal fracture with radiocarpal congruity preserved
2. Articular displacement
3. Diaphyseal-metaphyseal involvement

▲ **Figure 40–11.** Frykman classification of distal radius fractures. Types I, III, V, and VII do not have an associated fracture of the distal ulna. Fractures III–VIII are intra-articular fractures. Higher classification fractures have worse prognoses. (Reproduced, with permission, from Green D, Hotchkiss R, Pederson W: *Green's Operative Hand Surgery*. Churchill Livingstone, 1993.)

► Treatment

Emergent operative management is indicated for open fractures. Acute surgical intervention should be considered for distal radius fractures complicated by carpal tunnel syndrome that is not relieved with closed reduction.

► Nonoperative Treatment

All distal radius fractures should undergo closed reduction, even if surgical intervention is expected. The benefits of fracture reduction include limiting postinjury swelling, pain relief, and median nerve decompression. Although casting may be considered for nondisplaced or minimally displaced fractures with minimal swelling, a sugar-tong splint is generally preferred encompassing the dorsal and volar aspects of the wrist, limiting subsequent forearm rotation and possible fracture displacement. One week post injury the patient may be transitioned to a long-arm cast. If closed treatment is planned, radiographic evaluation should be done on a weekly basis for the first two to three weeks to monitor for displacement. Acceptable radiographic parameters for continued closed treatment include: radial length within 2–3 mm of the contra-

lateral wrist, neutral palmar tilt (0 degrees), intra-articular step off less than 2 mm, and radial inclination less than 5-degree loss. Surgery is indicated if reduction with respect to the above stated parameters cannot be achieved or maintained.

► Closed Reduction Technique

Hematoma block, Bier block, or conscious sedation can be used to provide analgesia. Hematoma block offers the benefit of speed and does not require that the patient have been without oral intake for a significant amount of time. Conscious sedation offers the benefit of muscle relaxation facilitating reduction. Initially manual or fingertrap-assisted traction is applied facilitating reduction via ligamentotaxis. For dorsally tilted fractures, volar directed pressure is applied to the distal fracture segment. C-arm if available can be used to assess fracture reduction. Once reduction is adequate a well-molded long-arm (“sugar tong”) splint can be applied with the wrist in neutral and the metacarpophalangeal joints free.

► Techniques of Surgical Management

Many surgical options are available. Choice of operation is determined by several factors, including the fracture pattern, bone quality, and surgeon preference.

► Closed Reduction Percutaneous Pinning

Reduction is achieved via closed means, followed by fixation typically with 0.0625-inch Kirschner wires. Interfragmentary technique entails wires used to stabilize a fracture and prevent collapse after reduction is achieved. With intrafocal technique where these wires are driven into the fracture site, used to lever the pieces achieving reduction, and then driven through the opposite cortex to maintain reduction. Postoperatively patients are placed in a splint or cast. The wires are typically removed after 6 weeks once bone healing is appreciated radiographically.

► External Fixation

This technique uses ligamentotaxis to restore radial length and radial inclination, but it rarely restores palmar tilt. It is especially useful for treating very comminuted or intra-articular fractures where there are several small pieces. External fixation is also useful for treating open fractures with severe tissue compromise or as a temporizing measure when a patient has other critical medical issues that need immediate attention.

► Open Reduction and Internal Fixation

In recent years, volar plating has become much more popular compared to dorsal plating due to its advantages when treating distal radius fractures with significant dorsal comminution, as well as the extensor tendon complications associated with dorsal plating of the distal radius.

► Complications

Stiffness of the wrist and digits is common. Patients should be instructed to begin range of motion exercises for the digits immediately after the fracture is initially treated. Include median nerve dysfunction, malunion, nonunion, stiffness, posttraumatic arthritis, tendon rupture, finger, wrist, and elbow stiffness. Articular congruity post surgical fixation is critical for avoiding the development of posttraumatic arthritis.

► Isolated Radial Styloid Fracture

Also called a “chauffeur’s fracture,” “backfire fracture,” or “Hutchinson fracture” this is an avulsion fracture with extrinsic ligaments remaining attached to the styloid fragment. This injury is often associated with intercarpal ligamentous injuries such as scapholunate dislocation or perilunate dislocation. This injury often requires open reduction with internal fixation.

FRACTURES OF THE ULNAR STYLOID

Fractures of the ulnar styloid are commonly seen in conjunction with distal radius fractures and can also be seen in isolation. Fractures of the tip of the ulnar styloid are often too small to fix. However, large fragments (the entire styloid from its base) may be indicative of a TFCC disruption that can lead to DRUJ instability. As a result, these displaced fractures should be treated with open reduction and internal fixation.

DISTAL RADIOULNAR JOINT DISLOCATION

DRUJ dislocation is discussed earlier in the section describing the Galeazzi fracture. DRUJ dislocation can also occur with a simple distal radius fracture. Careful examination of radiographs and the distal radioulnar joint will keep the clinician from missing this injury in the face of a distal radius fracture.

FRACTURES & DISLOCATIONS OF THE CARPUS

Most carpal bone fractures occur in the proximal carpal row, with the scaphoid being the carpal bone most commonly fractured. Carpal bone fractures usually occur in younger people, often from high energy falls on an outstretched hand. Wrist radiographs can be difficult to interpret, and careful scrutiny is necessary so as not to miss these injuries. In addition to the standard anteroposterior, lateral, and oblique views of the wrist, special radiographic views such as a scaphoid view (anteroposterior radiograph with the wrist supinated 30 degrees and in ulnar deviation), clenched fist view (to evaluate for carpal instability), or carpal tunnel view can often be helpful. Computed tomography is also useful to identify fractures if radiographs are inconclusive; MRI is sensitive for detecting occult fractures, osteonecrosis of carpal bones, and soft injuries including disruption of the scapholunate ligament or TFCC.

1. Fracture of the Scaphoid

The scaphoid is the carpal bone most commonly fractured. Anatomically, the scaphoid is divided into proximal and distal poles, a tubercle, and a waist. The blood supply for the scaphoid comes largely from branches of the radial artery traveling from a distal to proximal location. As a result, fractures of the scaphoid at the waist or more proximal are particularly prone to nonunion or avascular necrosis.

Fractures of the scaphoid most commonly occur as a result of a fall on an outstretched hand. Patients typically present with pain on the radial side of their wrist and tenderness to palpation over the anatomic snuffbox. Physical examination maneuvers include the scaphoid lift test (reproduction of pain with dorsal-volar shifting of the scaphoid) and the Watson test (painful dorsal scaphoid displacement as the wrist is moved from ulnar to radial deviation with compression of the tuberosity). Radiographic evaluation includes a “scaphoid view,” in addition to the standard wrist series. Initial radiographs are nondiagnostic in up to 25% of cases. As a result, if clinical exam suggests a scaphoid fracture, it is appropriate to employ a trial of immobilization with repeat radiographs in 1-2 weeks. Additionally, technetium bone scan, MRI, or CT scan can be used to diagnose occult scaphoid fractures that continue to not be visualized on radiograph, despite persistent pain. Scaphoid fractures can be classified based on the pattern (horizontal oblique, transverse, vertical oblique), displacement (nondisplaced fractures with no step-off are considered stable, displaced fractures > 1 mm, scapholunate angulation > 60 degrees, radiolunate angulation > 15 degrees), and location (tuberosity, distal pole, waist, and proximal pole). Nondisplaced fractures should be treated in a long-arm thumb spica cast for 6 weeks. After 6 weeks, the patient’s wrist can be placed in a short-arm spica cast until the fracture is united. Expected time to union for distal third fractures is 6-8 weeks, 8-12 weeks for middle third fractures, and 12-24 weeks for proximal third fractures. Surgical indications include fracture displacement more than 1 mm, radiolunate angle more than 15 degrees, scapholunate angle more than 60 degrees, hump-back deformity, or nonunion. Complications of scaphoid fractures include fracture nonunion or avascular necrosis (Figure 40-12). Patients with long-standing scaphoid nonunions go on to develop early arthritis of the radioscaphoid joint secondary to altered mechanics of the wrist.

2. Fracture of the Lunate

The lunate is the carpal bone most likely to dislocate, but fractures are rare. Fractures usually result from a fall on an outstretched hand. Patients typically present with tenderness to palpation over the volar wrist overlying the distal radius and lunate with painful range of motion. Radiographs are usually not helpful due to overlapping densities of multiple bones; CT, MRI, or bone scan are usually required to

▲ **Figure 40-12.** Scaphoid fracture.
A. Scaphoid fracture nonunion. **B.** Open reduction and internal fixation of scaphoid nonunion.

make the diagnosis. Nondisplaced fractures can be treated in a short- or long-arm cast. Displaced or angulated fractures require surgical treatment. Osteonecrosis (Keinbock's disease), can complicate this injury leading to advanced collapse and radiocarpal degeneration. Several surgical treatments are available for this sequella.

3. Fracture of the Hamate

This fracture generally occurs from a direct blow to the area such as occurs when swinging a baseball bat or golf club that suddenly comes to an abrupt stop as it encounters a firm surface. Patients present with ulnar-sided hand pain over the hamate. Fracture will often not be seen on routine wrist and hand radiographs. A carpal tunnel view (20 degree supination oblique view of the wrist) should be obtained if this fracture is suspected. If the diagnosis is suspected clinically but the radiographs show no fracture, a CT scan may be helpful. Nondisplaced fractures may be treated in a short-arm cast for six weeks. Displaced fractures of the body can be treated with open reduction internal fixation with screws or wires.

4. Other Carpal Bone Fractures

Fractures can occur in any of the other carpal bones as well, but much less commonly. Triquetral avulsion or dorsal impaction fractures can occur from falls on the outstretched hand. Isolated fractures of the remaining carpal bones are rare and generally occur with high-energy trauma and other injuries.

5. Traumatic Carpal Instability

Severe injury to the wrist causing damage to the complex ligamentous structures may lead to carpal bone dissociation, carpal dislocations, and fracture dislocations. The lunate is often called the "carpal keystone"; its ligamentous

attachments to the radius and other carpal bones make a significant contribution to radiocarpal stability. A sequence of progressive perilunate instability starts with scapholunate disruption (stage I), then midcarpal or capitolunate disruption (stage II), lunotriquetral disruption (stage III), ending in disruption of the radiolunate joint leading to volar lunate dislocation (stage IV).

Scapholunate dissociation secondary to disruption of the scapholunate and the radioscapholunate ligament leads to altered kinematics of the wrist and early degenerative arthritis. Clinical findings include volar wrist tenderness/bruising, positive Watson test, pain with grasping, and decreased grip strength. Radiographically, widening of the scapholunate space more than 3 mm ("Terry Thomas" sign), or scapholunate angle more than 70 degrees on the lateral are indicative of scapholunate disruption. Closed reduction with an audible, palpable click followed by thumb spica immobilization for 8 weeks is the first line of treatment. Inability to obtain or maintain reduction is surgical indications.

Lunotriquetral dissociation occurs as a result of disruption of the radiolunotriquetral ligament. Patients typically present with swelling over the peritriquetral area and tenderness dorsally, typically 1-2 cm distal to the ulnar head. Radiographs may show disruption of the normal proximal carpal row contour; frank gapping of the lunotriquetral space is rarely seen. Treatment with a short arm cast for 6-8 weeks or closed reduction with pinning of the lunate to the triquetrum is warranted.

Carpal dislocations represent a continuum of perilunate ligamentous injury with frank lunate dislocation being the final stage. Patients present with severe wrist pain and swelling after trauma. Most dislocations can be diagnosed with adequate AP and lateral views of the wrist. With a perilunate dislocation, the lunate remains in its normal position, articulating with the distal radius, but is angled in a volar direction, and the rest of the carpus is dislocated. With lunate

dislocation, on the lateral radiograph the lunate will be volar to the rest of the carpus and not in alignment with the distal radius. Treatment of carpal dislocations is accomplished with closed reduction of the midcarpal joint via traction combined with direct manual pressure over the capitate and lunate. Irreducible dislocations or unstable injuries should be treated surgically with open reduction internal fixation.

Ulnocarpal dissociation may result from disruption of the TFCC, where the lunate and triquetrum assume a supinated and palmar flexed position, while the distal ulna subluxes dorsally. Radiographs may show ulnar styloid avulsion or dorsal displacement of the ulna; MRI may demonstrate TFCC tear. Treatment requires operative repair of the TFCC and/or ORIF of large displaced ulnar styloid fragments.

Even with the best care, carpal bone and ligament injuries can be devastating, with long-term sequelae of pain, stiffness, and early arthritis.

FRACTURES & DISLOCATIONS ABOUT THE HAND

Metacarpal and phalangeal fractures are relatively common comprising a significant portion of emergency department visits. The significant variation in mechanism of injury accounts for the large number of different types of fracture patterns seen in hand injuries. Axial load or “jamming” injuries often result in shearing articular fractures or metaphyseal compression fractures, sometimes with concomitant injury to the carpus, forearm, elbow, and shoulder due to force transmission. Injury mechanisms with a bending component result in diaphyseal fractures or joint dislocations. Individual digits or joints caught in clothing or equipment can result in spiral fractures or complex dislocations. Industrial settings with heavy objects predispose to crushing mechanisms of injury. The direction of fracture angulation depends on the deforming forces caused by attached muscle. The palmar and dorsal interosseous muscles arise from the metacarpal shafts, usually flexing the fracture causing apex-dorsal angulation. Proximal phalynx fractures typically angulate in the opposite direction, apex-volar. Middle phalynx fractures angulate variably, while distal phalynx fractures are usually comminuted tuft fractures resulting from crush injuries. Clinical evaluation includes documentation of the patient’s age, hand dominance, occupation, mechanism of injury, time of injury, exposure to contamination, and financial issues (workman’s compensation). Physical examination should document neurovascular status, and pay particular attention range of motion, angulation, and malrotation (best evaluated when the intervening joint is flexed to 90 degrees). Radiographic evaluation includes AP, lateral, and oblique radiographs of the hand and the specific injured digit. Fractures can be classified descriptively: open versus closed, location, fracture pattern (comminuted, transverse, spiral, vertical split, extra-articular versus intra-articular, stable versus unstable, and angulational or rotational deformity). Fractures of the small

bones of the hand heal more rapidly than fractures of larger bones, and prolonged immobilization can cause stiffness and loss of motion that can be difficult or impossible to regain. As a result, fractures of the metacarpals and phalanges should not be immobilized for more than 3 weeks except under rare circumstances, due to subsequent development of stiffness. The safe position for splinting or casting of the hand is with slight wrist extension, the MP joints flexed 60-90 degrees, and the PIP and DIP joints extended. This “intrinsic plus” position, puts the ligaments of the hand on maximum stretch, avoiding posttreatment stiffness.

1. Open Fractures, Fight Bite, and Animal Bites

These types of fractures require special consideration. Open fractures of phalanges or metacarpals can be classified according to the Swanson, Stabo and Anderson classification: type I (clean wound without significant contamination or delay in treatment), type II (contamination with gross dirt/debris, human or animal bite, lake/river injury, barnyard injury or in patients with significant systemic illness such as diabetes, hypertension, rheumatoid arthritis [RA], hepatitis, or asthma). Type I injuries can be treated with primary internal fixation and immediate wound closure. Although type II injuries can be treated with primary internal fixation (no increase in infection rate); these injuries should not be closed primarily. Delayed closure is preferred to decrease infection risk.

Any laceration overlying a joint in the hand, particularly the metacarpal-phalangeal (MCP) joint must be suspected as being caused by a human tooth. Also known as a “fight bite,” these injuries should be assumed to have been contaminated with oral flora and treated aggressively with broad spectrum antibiotics including anaerobic coverage. Animal bites require antibiotic treatment that covers *Pasteurella* and *Eikenella*.

2. Metacarpal Fractures

► Metacarpal Head Fractures

Fractures of the metacarpal can be subclassified as follows: epiphyseal fractures, collateral ligament avulsion fractures, oblique, vertical, and horizontal head fractures, comminuted fractures, and fractures with joint loss. Most of these fractures require anatomic reduction to reestablish joint congruity and avoid posttraumatic arthritis. Stable reductions of fractures may be splinted in the intrinsic plus position. If unstable, percutaneous pinning, ORIF, or external fixation are options.

► Metacarpal Neck Fractures

Metacarpal neck fractures are typically caused by direct trauma with volar comminution and dorsal apex angulation. The most common metacarpal neck fracture is the “boxer’s

fracture” of the fifth metacarpal, usually caused by the fist striking a stationary object. These fractures can typically be closed reduced successfully. The degree of acceptable deformity varies according to the metacarpal injured: less than 10 degrees for the second and third metacarpal, less than 30-40 degrees for the fourth and fifth metacarpals. Unstable fractures require surgical intervention with percutaneous pinning or open reduction internal fixation.

► Metacarpal Shaft Fractures

Nondisplaced or minimally displaced metacarpal shaft fractures can be reduced and splinted. Surgical indications include rotational deformity (all fingers should point toward the scaphoid when flexed), dorsal angulation more than 10 degrees for second and third metacarpals, and more than 40 degrees for fourth and fifth metacarpals.

► Metacarpal Base

Fractures of the base of the second, third, and fourth metacarpals are typically minimally displaced and treated with splinting and early range of motion. A reverse Bennett fracture is a fracture dislocation of the fifth metacarpal and hamate bones. This injury often requires ORIF.

Fractures of the thumb metacarpal base can be extra-articular or intra-articular. Extra-articular fractures are usually transverse or oblique, and amenable to closed reduction and casting. Unstable fractures may require percutaneous pinning. Intra-articular fractures come in two types: type I or **Bennett’s Fracture** where a single fracture line separates the majority of the metacarpal from the volar lip fragment and type II also known as **Rolondo’s fracture** which is a comminuted intra-articular fracture usually with a “Y” or “T” pattern including dorsal and palmar fragments. Both type I and type II fractures are treated with closed reduction and percutaneous pinning or ORIF.

3. Proximal and Middle Phalanx Fractures

Intra-articular fractures can be classified as condylar fractures or fracture-dislocations. There are three types of condylar fractures: unicondylar, bicondylar, or osteochondral. Each of these fractures require anatomic reduction; ORIF should be performed for more than 1 mm displacement. Comminuted intra-articular fractures not amenable to surgical treatment, can be treated closed with early protected mobilization.

Fracture dislocations come in two varieties: volar lip fracture or dorsal lip fracture. Volar lip fracture (dorsal fracture-dislocation) treatment is controversial; if less than 35% of the articular surface is involved the injury may be treated with buddy taping, however, for more than 35% some recommend ORIF or volar plate arthroplasty if the fracture is comminuted while others recommend extension block splint if the joint is not subluxed. Dorsal lip fracture

(volar fracture-dislocation) with less than 1 mm of displacement may be treated closed with splinting while more than 1 mm displacement requires operative intervention.

Extra-articular fractures of the phalanges should be initially treated with closed reduction with finger-trap traction and splinting. Unstable fractures should be treated surgically.

► Distal phalynx fractures

Intra-articular dorsal lip fractures may be complicated by an extensor tendon disruption resulting in a “mallet finger.” “Mallet finger” may also result from purely tendinous disruption, without fracture. For either scenario, treatment is controversial. Some recommend full-time extension splinting for 6-8 weeks, while others recommend surgical intervention. For professionals who work extensively with their hands, such as surgeons, full-time extension splinting is not practical. Closed reduction with percutaneous pinning is a good option.

Intra-articular volar lip fractures can be associated with a flexor digitorum profundus rupture resulting in a “jersey finger” often seen in football or rugby players, most commonly involving the ring finger. Treatment is typically surgical, especially if large displaced bony fragments are present.

Extra-articular fractures can be transverse, longitudinal, or comminuted (nail matrix injury very common). These fractures are usually treated with closed reduction and splinting that traverses the DIP joint, leaving the PIP joint free. Surgery is indicated for fractures with wide irreducible displacement, due to the increased risk of nonunion.

► Nailbed Injuries

Nailbed injuries are easily missed in the context of distal phalynx fractures. When untreated, these injuries result in nail growth disturbances. Subungual hematomas are often indicative of nail bed injury. The nail plate should be removed and the hematoma drained. Nailbed disruptions should be carefully sutured with 6-0 chromic catgut under magnification. The nailplate should be replaced to keep the nail fold open; alternatively a piece of aluminum foil or xeroform gauze can be used.

4. Dislocations of the Digits

Carpometacarpal dislocations are usually high energy injuries. Careful neurovascular examination is essential. These injuries usually require surgical intervention for maintenance of a stable reduction.

MCP joint dislocations are usually dorsal in direction, presenting with a hyperextended posture. Simple dislocations can be reduced by flexion of the joint without traction. Wrist flexion, causing the flexor tendons to relax, can be used to facilitate the reduction maneuver. Complex MCP dislocations with the volar plate interposed in the joint are irreducible. The pathognomonic radiograph finding is the

appearance of the sesamoid in the joint space. Complex dislocations require surgery. Traction during reduction of simple dislocations should be avoided as simple dislocations can be converted into complex ones. Volar dislocations are rare; however, because they are particularly unstable, they often require surgical intervention.

Thumb MCPs are unique due to the multiplanar motion of the thumb MCP joint. With a one-sided collateral ligament injury, the phalanx tends to sublux volarly rotating around the opposite intact ligament. The ulnar collateral ligament of the thumb MP joint is the most commonly injured ligament in the digits. If the injury is acute, it is called a “skier’s thumb,” whereas chronic injury from repetitive trauma is known as a “gamekeeper’s thumb.” Nonoperative treatment with reduction and thumb spica splinting or casting is usually sufficient. A “Stener” lesion occurs when the ulnar collateral ligament avulses, and comes to rest dorsal to the adductor aponeurosis. The ulnar collateral ligament is not able to return to its normal insertion, preventing healing. As a result, Stener lesions and irreducible MCP dislocations require surgical intervention.

Proximal interphalangeal (PIP) joint dislocations include dorsal dislocation, pure volar dislocation, and rotatory volar dislocation. Once reduced, rotatory volar dislocations, collateral ligament ruptures, and dorsal dislocations congruent in full extension on the lateral radiographs can all begin active range of motion exercises immediately with adjacent digit strapping. Dorsal dislocations that continue to sublux on lateral radiograph, can be treated with a few weeks of extension block splinting. Volar dislocations with central slip disruptions are treated with 4-6 weeks of PIP extension splinting, followed by an additional 2 weeks of night-time splinting. Irreducible dislocations or unstable reductions may require surgical intervention.

Distal interphalangeal (DIP) dislocations and thumb IP joint dislocations can present late. Injuries are considered chronic after 3 weeks. Acute reduced dislocations may begin immediate active range of motion. Unstable dislocations should be immobilized in 30 degrees of flexion for 3 weeks. Complete collateral ligament injury should be protected from lateral stress for at least 4 weeks. Recurrent stability can be treated with Kirschner wire fixation. Chronic dislocation may be treated with open reduction to resect scar tissue, allowing for a tension free reduction. Transverse open wounds in the volar skin crease are not infrequent. Open dislocations require debridement to prevent infection.

INJURIES OF THE HIP REGION

1. Hip Dislocations

► Epidemiology

Hip dislocations of the native hip are relatively rare, usually due to high energy injury such as a motor vehicle accident. Posterior hip dislocations (85%-90%) are more common

than anterior (remaining 10%-15%). Ten to twenty percent of posterior hip dislocations can be complicated by sciatic nerve injury. Anterior hip dislocations are associated with a greater incidence of femoral head injury. Up to 50% of patients with a hip dislocation will sustain a concomitant fracture elsewhere (most commonly of the ipsilateral femur or pelvis).

► Anatomy

The hip articulation is a ball-and-socket joint, formed by the femoral head and acetabulum. Forty percent of the femoral head is covered by the acetabulum. The labrum surrounding the acetabulum has the effect of deepening the hip joint, increasing its stability. The medial and lateral circumflex femoral arteries from the profunda femoral artery form an extracapsular vascular ring at the base of the femoral neck; ascending branches provide the primary blood supply to the femoral neck and head, along with a minor contribution from the ligamentum teres off of the obturator artery. The contribution of the medial and lateral circumflex arteries is often disrupted with hip dislocation, leading to long-term complications including avascular necrosis. The sciatic nerve exits the pelvis at the greater sciatic notch, traveling deep to the piriformis muscle, down the posterior aspect of the thigh.

► Clinical Evaluation

A full trauma survey is essential due to the high energy nature of this injury. Patients typically present with severe discomfort and inability to move the injured extremity. The classic appearance of a posterior hip dislocation is shortened extremity with the hip flexed, internally rotated and adducted (Figure 40-13). Patients with an anterior dislocation hold

▲ **Figure 40-13.** Posterior hip dislocation with concomitant fracture of the posterior wall and weight-bearing dome of the acetabulum.

their hip with marked external rotation, mild flexion, and abduction. Careful neurovascular examination is key. If the sciatic nerve is injured often the tibial nerve is preserved with the peroneal portion of the nerve showing the effects of injury. Radiographic evaluation includes an AP view of the pelvis as well as radiographs of the entire ipsilateral femur. Evaluate the femoral neck and acetabulum to rule-out concomitant fractures.

► Treatment

The hip should be reduced emergently due to the risk of osteonecrosis from associated vascular disruption. Regardless of the direction of the dislocation, the hip can be reduced with in-line longitudinal traction with the patient supine. The key to successful reduction is relaxation of the patient's muscles which is accomplished with adequate sedation (ideally via general anesthesia, or iv sedation if general anesthesia is not available) and fatiguing of the patient's muscles that occurs with time. Following closed reduction, the hip should be examined for stability by flexing the hip to 90 degrees in neutral position and applying a posteriorly directed force. If any subluxation is detected, the hip is deemed unstable, and will require surgery or traction. Postreduction radiographs should be obtained to confirm reduction. Careful comparison should be made with the contralateral side, to determine if the reduction is concentric. Even slight asymmetry or subluxation may indicate the presence of a concomitant fracture or incarcerated piece of bone in the joint. Additionally, postreduction CT should be performed to investigate the presence of other fractures or an incarcerated bony fragment. If closed reduction is unsuccessful, open reduction should be performed as soon as possible.

► Fractures of the Femoral Head

Fractures of the femoral head are extremely rare. Most are secondary to motor vehicle accidents and are associated with hip dislocations. Clinical evaluation included careful neurovascular exam, AP view of the pelvis as well as AP and lateral radiographs of the injured hip. Femoral head fractures can be classified according to the Pipkin classification: type I (hip dislocation with fracture of the femoral head inferior to the vovea capitis femoris), type II (hip dislocation with fracture of the femoral head superior to the fovea capitis femoris), type III (type I or type II injury with femoral neck fracture), and type IV (type I or type II injury with associated fracture of the acetabular rim). Type I fractures involve the non-weight-bearing surface of the femoral head. As a result, closed treatment can be pursued if reduction is adequate (<1 mm step-off). Type II fractures involve the weight-bearing surface. Thus, if the reduction is not anatomic as seen on CT, surgical treatment should be pursued. Type III and type IV injuries usually require

surgical treatment. Complications include osteonecrosis and posttraumatic arthritis.

► The Femoral Neck

Approximately 350,000 fractures of the femoral neck occur each year. This number is expected to double by the year 2050 due to the aging demographics of the American population. Fractures of the femoral neck occur most often in elderly patients with osteopenic bone after a fall. Femoral neck fractures in patients less than 50 years old are rare, usually due high energy trauma. Patients with displaced fractures usually present with inability to walk, severe pain, and an externally rotated and shortened extremity. Patients with nondisplaced fractures may present with mild, persistent hip pain (for several days or couple of weeks); these patients often will have been walking, as a result index of suspicion should be high. A careful secondary survey should be performed, as 10% of elderly patients have associated upper extremity injuries. Radiographic evaluation includes AP pelvis radiograph, AP and lateral radiographs of the hip; and internal rotation or traction view can further delineate the fracture pattern. If no fractures are detected in an elderly patient with persistent hip pain, one should consider MRI or bone scan to look for a nondisplaced or incomplete fracture.

Fractures of the femoral neck may be classified according to location (subcapital, transcervical, and basicervical), or based on stability of the fracture pattern. The Pauwel's classification describes increasing instability of the increasing fracture angle from the horizontal: type I (30 degrees), type II (50 degrees), and type III (70 degrees). The garden classification describes four patterns: type I (incomplete fracture/valgus impacted), type II (complete fracture, nondisplaced), type III (complete fracture, with partial displacement, the trabecular bone pattern of the femoral head does not line up with the acetabulum), and type IV (completely displaced fracture, the trabecular bone pattern of the head does line up with the acetabulum).

Some authors advocate nonoperative treatment with limited weight-bearing for type I or valgus impacted fractures. Others advocate internal fixation with multiple screws to prevent fracture displacement. Type II (nondisplaced) fractures are treated with internal fixation, regardless of the patient's age. Treatment of type III and type IV (displaced) fractures is more controversial. For patients less than 60 years old, with good bone quality and little fracture comminution open-reduction internal fixation is the usual choice. For patients more than 60 years old, with osteopenic bone and comminuted fractures arthroplasty is the treatment of choice. Unipolar hemi-arthroplasty is most commonly used. If the patient has evidence of preexisting acetabular arthritis, total hip-arthroplasty may be offered. Recent studies have suggested that in the elderly, previously active patient with intact mental status, total hip arthroplasty

may be the best treatment option for displaced femoral neck fracture. Although, bipolar arthroplasty theoretically reduces the risk of prosthetic arthritis compared with unipolar hemiarthroplasty; this has not been borne out in the literature. As a result, given the higher cost, most authors do not advocate the use of bipolar hemiarthroplasty.

2. Trochanteric Fractures

► Fracture of the Lesser Trochanter

Isolated fractures of the lesser trochanter are quite rare. This fracture occurs most commonly in the adolescent patient secondary to forceful iliopsoas contracture. In the elderly patient, this fracture may be secondary to metastatic disease.

► Fracture of the Greater Trochanter

Like isolated fractures of the lesser trochanter, isolated fracture of the greater trochanter is rare. The typical mechanism is direct blow due to fall in an elderly patient. Treatment is typically nonoperative. In a young, active patient with a widely displaced greater trochanter, surgery may be considered.

► Intertrochanteric Fractures

Intertrochanteric fractures describe fractures that occur in the region between the greater and lesser trochanters of the proximal femur. These fractures are extracapsular, occurring in cancellous bone with abundant blood supply. Unlike displaced femoral neck fractures, these fractures are not

predisposed to nonunion and osteonecrosis. These fractures are relatively common, accounting for nearly 50% of all fractures of the proximal femur (Figure 40–14). The typical presentation occurs in an elderly individual after a fall. Clinical evaluation includes neurovascular check, secondary survey, and appropriate x-rays (AP pelvis, AP, and lateral of injured hip). One may consider an internal rotation or traction view for improved delineation of the fracture. Consider MRI or Technetium bone scan in a patient with persistent hip pain despite negative radiographs; these two studies may be useful for delineating nondisplaced or incomplete fractures.

It is important to evaluate the location of fracture line (proximal to distal), obliquity of the fracture line, the degree of comminution (paying specific attention to the posteromedial cortex which determines stability) and magnitude of displacement. Basicervical neck fractures are located just proximal to or along the intertrochanteric line. These fractures are usually extracapsular; however, the proximity to the blood supply of the femoral neck can result in a higher incidence of osteonecrosis. Typically, intertrochanteric fractures have an oblique fracture line that extends from the lateral cortex proximally to the medial cortex distally; this “standard obliquity” fracture pattern is considered stable, amenable to standard surgical treatment. “Reverse obliquity” intertrochanteric fractures (oblique fracture line extending from the medial cortex proximally to the lateral cortex distally), are considered unstable. Significant posteromedial comminution indicates an unstable fracture. Finally, subtrochanteric extension of the fracture should be noted, as it may affect treatment choice.

▲ **Figure 40–14.** Comminuted intertrochanteric hip fracture. **A.** Anteroposterior radiograph. **B.** Anteroposterior radiograph after fixation with a compression hip screw and sideplate.

Nonoperative treatment is associated with a higher mortality rate when compared to operative treatment. As a result, it may be considered only for patients who carry high surgical risk or demented/nonambulatory patients with mild hip pain. Early bed to chair immobilization is crucial to avoid the risks and complications of prolonged recumbence (atelectasis, deep venous thrombosis, and ulcers).

Treatment is usually surgical, with the goal being early ambulation with full weight-bearing status. Dynamic hip screw (large screw and side plate) is the typical surgical implant of choice. Intramedullary hip screws are used for “unstable” fracture patterns including: reverse obliquity IT fractures, fractures with significant posteromedial comminution, and fractures with subtrochanteric extension. Finally, arthroplasty may be chosen in patients for whom previous ORIF has failed or as primary treatment for comminuted, unstable fractures.

► Subtrochanteric Fracture

The Subtrochanteric femur fracture is located between the lesser trochanter and a point 5-cm distal to the lesser trochanter. This stretch of bone is subjected high biomechanical stresses. The medial and posteromedial cortices are sites of high compressive forces, while the lateral cortex experiences high tensile forces. Additionally, this area of bone is composed mainly of cortical bone. Due to less vascularity when compared to cancellous bone, the potential for healing is diminished.

The mechanism of injury may be low energy such as a fall in an elderly person or high energy in patients involved in motor vehicle accidents, falls from heights, or gunshot wounds. Additionally, fractures in this region may be pathologic in nature due to bone metastases.

Clinical evaluation includes standard trauma evaluation for patients involved in high-energy injury mechanisms. Field-dressings or splints should be completely removed to examine for soft-tissue injury and rule-out open fracture. Neuro-vascular status should be documented. Secondary survey should be performed. Blood loss can be significant in the thigh compartments, representing a potential source for hypovolemia. Traction pin should be considered until definitive fixation can be performed, to limit further soft tissue damage and bleeding. Radiographic evaluation includes the AP pelvis, AP and Lateral views of the hip and femur down to the knee.

The fracture may be classified according to its distance from the lesser trochanter, fracture line characterization, number of bone fragments, and involvement of the piriformis fossa.

Open fractures should be treated with immediate surgical debridement and fracture stabilization. Surgical treatment can involve the use of an intramedullary nail or fixed-angle plates depending on the fracture pattern (Figure 40–15).

▲ **Figure 40–15.** Subtrochanteric femur fracture with fracture of the distal third of the ipsilateral femoral shaft treated with a reconstruction type intramedullary nail.

The fracture is typically healed by 3–4 months post-operatively months, but delayed union and nonunion are not uncommon. Hardware failure can occur in these cases, requiring repeat internal fixation and bone grafting.

FRACTURE OF THE SHAFT OF THE FEMUR

A femoral shaft fracture is a fracture of the femoral diaphysis that occurs between 5 cm distal to the lesser trochanter and 5 cm proximal to the adductor tubercle. Femoral shaft fractures typically occur in young men after high-energy trauma, such as motor vehicle accidents. This injury can occur in the elderly after a fall, although less common. Fractures that are inconsistent with the level of trauma should be suspected for pathologic fracture.

The vascular supply to the femoral shaft is derived mainly from the profunda femoral artery. Due to the large volume of the three fascial compartments of the thigh (anterior, medial, and posterior), significant blood loss and hemodynamic instability can occur. In one series, blood loss was greater than 1200 mL, with 40% of patients ultimately requiring blood transfusion.

Clinical evaluation includes careful neurovascular exam and secondary survey looking for concomitant injury to

other joints and extremities. Specific attention should be paid to the ipsilateral hip and knee joints. Knee ligament injuries are common and easily missed. Radiographic evaluation should include AP and lateral views of the femur as well as the ipsilateral hip and knee. AP pelvis should also be obtained. Ipsilateral femoral neck and intertrochanteric fractures have been reported in up to 10% of patients with femur fractures.

Femoral shaft fractures can be classified descriptively: open versus closed, location (proximal, middle, and distal one-third), pattern (spiral, oblique, and transverse), degree of comminution, angulation, rotational deformity, displacement, and amount of shortening. Winquist and Hansen described a classification based off amount of comminution: type I (minimal or no comminution), type II (cortices of both fragments at least 50% contact), type III 50%-100% cortical comminution, and type IV (circumferential comminution with no cortical contact).

In the acute setting, femoral shaft fractures can be stabilized with skeletal traction. Traction provides pain relief, and can help minimize soft tissue injury and blood loss. Ideally surgical stabilization should occur within 24 hours of injury (Figure 40-16). If surgery is delayed due to an unstable patient, traction has the added benefit of pulling the fracture

fragments out to length, making subsequent fracture reduction and operative treatment more manageable.

Open fractures constitute a surgical emergency. Fractures should be debrided and stabilized as soon as possible. The most frequently used surgical treatment for femoral shaft fractures is intramedullary (IM) nailing. Compared with plate fixation, IM nailing offers the following benefits: lower infection rate, less extensive exposure/dissection of the fracture promoting healing, less quadriceps scarring, and lower tensile and shear stresses on the implant. Other advantages include early functional use of the extremity (the surgeon may allow immediate weight-bearing depending on strength of surgical management), restoration of length and alignment, rapid and high union rate, and low refracture rates.

IM nailing can be performed in an antegrade or retrograde fashion. Indications for retrograde nailing include ipsilateral injuries (fracture of the femoral neck, pertrochanteric, patella, acetabulum, or tibia), bilateral femoral shaft fractures, morbidly obese patient, pregnant woman, ipsilateral knee amputation, or when speed of surgical treatment is essential (unstable patient). Contraindications to retrograde nailing include restricted knee motion (< 60 degrees), patella baja, presence of associated open traumatic wound increasing the risk of intra-articular knee sepsis. One

▲ **Figure 40-16.** Femoral shaft fracture. **A.** Anteroposterior x-ray showing fracture of the midshaft of the femur. **B.** Anteroposterior x-ray after closed reduction and intramedullary fixation using an antegrade titanium locked nail. **C.** Anteroposterior x-ray showing fixation of a midshaft femoral fracture and ipsilateral femoral neck fracture with a retrograde intramedullary nail.

major disadvantage to retrograde nailing is the postoperative incidence of anterior knee pain.

Other surgical options include plating and external fixation. External fixation may be used acutely as a temporary bridge in the severely injured, unstable patient. Plating may be indicated in patients whose femoral canals are not amenable to IM nailing (medullary canal too narrow, medullary canal obliterated due to infection, previous closed fracture management, etc).

Postoperatively early patient mobilization and knee range of motion is recommended. Weight-bearing status is dependent on multiple factors, including the strength of operative fixation, patient's other injuries, soft tissue status, and location of fracture. Later complications are those of prolonged recumbence, joint stiffness, malunion, nonunion, leg-length discrepancy, and infection.

INJURIES OF THE KNEE REGION

1. Fractures of the Distal Femur

Distal Femur fractures account for about 7% of all femur fractures. Incidence follows a bimodal age distribution with the first peak occurring in young adults as a result of high-energy trauma and the second peak occurring in the elderly after a fall. Distal femur fractures can be subclassified as supracondylar or condylar fractures.

The supracondylar region of the femur is the area between the femoral condyles and the junction of the metaphysis with the femoral shaft. The distal femur widens from the cylindrical shaft to form two curved condyles separated by an intercondylar groove. The medial condyle extends more distally and is more convex than the lateral condyle,

producing the normal valgus position of the distal femur. The proximal fracture fragment is typically pulled superiorly by the quadriceps and hamstrings, the distal fragment is typically displaced and angulated posteriorly due to the pull of the gastrocnemius muscle.

Neurovascular examination is key as the distal fragment may impinge on the popliteal fossa, causing a loss or marked decrease of pedal pulses. Immediate reduction is indicated. If reduction of the fracture fragment fails to restore pulses, immediate arteriogram, and vascular operative intervention is indicated. Secondary survey should be performed, with concomitant injury to the ipsilateral hip, knee, leg, and ankle ruled-out. If a distal femoral fracture is associated with an overlying laceration or wound, the ipsilateral knee should be injected with 50 mL of sterile normal saline to rule-out continuity with the wound.

Radiographic evaluation includes anteroposterior, lateral, and oblique radiographs of the distal femur as well as the entire length of the femur (Figure 40–17). Traction views and computed tomography may be helpful for preoperative planning. MRI may be used to evaluate injuries to the meniscus and ligaments of the knee. Arteriography should be considered in the setting of knee dislocation (up to 40% associated vascular disruption reported in the literature).

Distal femur fractures may be classified descriptively: open versus closed, location (supracondylar, intercondylar, and condylar), fracture pattern (spiral, oblique, and transverse), intra-articular versus extra-articular, degree of comminution, angulation, rotational deformity, displacement, and amount of shortening.

Nonoperative treatment may be pursued for stable non-displaced fractures. Treatment involves immobilization of

▲ **Figure 40–17.**

A. Anteroposterior radiograph demonstrating a comminuted supracondylar femur fracture with intra-articular extension. **B.** Lateral radiograph.

the extremity in a hinged knee brace with partial weight-bearing.

Displaced distal femur fractures are best treated surgically. If operative treatment is delayed more than 8 hours, a tibial traction pin should be considered. Plates and screws are the typical choice of implant. A variety of plates are available including the 95-degree condylar blade plate, nonlocking periarticular plates, and locking periarticular plates. Due to the advantage of increased stability, locking periarticular plates are becoming more popular.

► Dislocation of the Knee Joint

Traumatic knee dislocation is extremely rare. However, this injury can be limb threatening due to disruption of the vasculature. The knee is a “hinge” joint consisting of three articulations: patellofemoral, tibiofemoral, and tibiofibular. Normal range of motion of the knee is from 10 degrees of extension to 140 degrees of flexion. Significant soft tissue injury including disruption of three out of four major ligaments of the knee (anterior cruciate, posterior cruciate, medial collateral, and lateral collateral ligaments) is necessary for knee dislocation to occur. During knee dislocation the popliteal vascular bundle may be injured or tethered. Associated fractures of the tibial eminence, tibial tubercle, fibular head or neck, and capsular avulsions should be ruled-out. The mechanism is typically high energy.

If the knee remains dislocated at presentation, immediate reduction should be performed without waiting for radiographs. Postreduction neurovascular status should be carefully documented. Isolated ligament examination may be difficult to perform due to patient discomfort. Standard ligament examination includes Lachman’s testing for the ACL, posterior drawer for the PCL, and varus and valgus stress to assess the LCL and MCL, respectively. Due to the incidence of delayed ischemia resulting from vasospasm or thrombosis occurring hours or even days after reduction, serial neurovascular exams should continue to be performed.

If a limb remains ischemic (absent pulses) after reduction, emergent surgical exploration is indicated; do not wait for an arteriogram. If the limb continues to display abnormal vascular status (diminished pulses, decreased capillary refill or $ABI < 0.9$) then arteriogram is indicated. Normal vascular status should be followed closely with serial exams.

Radiographic evaluation includes AP, lateral, notch views of the knee as well as “sunrise” view of the patella. Arteriography is indicated as described above. MRI is used to evaluate the ligaments and menisci of the knee, as well as articular cartilage lesions.

Knee dislocations can be classified according to the displacement of the proximal tibia in relation to the distal femur (anterior, posterior, lateral, medial, and rotational).

Immediate closed reduction is achieved with axial traction followed by placement of a splint with the knee in

20-30 degrees of flexion. Of note, posterolateral dislocation usually requires open reduction. Surgery is indicated for unsuccessful closed reduction, residual soft tissue interposition, open injuries, and vascular injuries. External fixation may be necessary for grossly unstable knees and dislocations that required vascular repair. Prophylactic fasciotomy of the leg compartments should be considered at the time of vascular repair to eliminate the compartment syndrome caused by postischemic edema. Ligamentous repair is controversial; timing of surgery is dependent on the status of both the patient and the limb.

2. Fracture of the Patella

Patella fractures only represent 1% of all skeletal injuries, occurring most commonly in the 20- to 50-year-old age group. The patella is the largest sesamoid bone in the body, with the quadriceps tendon inserting at its superior pole and the patellar ligament originating from the inferior pole. The patella has seven articular facets; the lateral facet is the largest (accounting for 50% of the articular surface). The medial and lateral extensor retinacula are strong longitudinal expansions of the quadriceps that envelop the patella and insert on the tibia. If the retinacula are intact, active extension will be preserved despite patella fracture.

The function of the patella is to increase the lever arm and mechanical advantage of the quadriceps tendon. The blood supply originates from the geniculate arteries which form anastomoses circumferentially around the outer border of the patella. Fractures of the patella may result from direct trauma or more commonly from forceful quadriceps contraction while the knee is semi-flexed during a stumble or fall.

Open lacerations associated with patella fracture should be investigated with 50 mL of sterile saline solution instilled into the knee joint to rule-out communication and open fracture. Active knee extension should be assessed; decompression of hemarthrosis and intra-articular lidocaine injection may facilitate testing.

Radiographic examination anteroposterior, lateral, and sunrise views of the knee. Of note bipartite patella (8% of the population) may be confused with fracture. Bipartite patella usually occurs in the superolateral portion of the patella and has smooth margins. Interestingly, it is bilateral in 50% of patients; thus contralateral knee x-rays may facilitate diagnosis.

Patella fractures may be classified descriptively: open versus closed, degree of displacement, fracture pattern (stellate, comminuted, transverse, vertical, polar, or osteochondral).

Nondisplaced or minimally displaced (2 mm) with minimal articular disruption (1 mm or less) can be treated nonoperatively in a knee immobilizer for 4-6 weeks if the extensor mechanism remains intact.

Surgical treatment for displaced fractures includes tension band wires, cerclage wiring, screws, or combination

thereof. Retinacular disruption should also be repaired at the time of surgery. Postoperatively, the patient should be placed in a splint to protect the skin; knee motion should be instituted early 3-6 days postoperatively with progression to full weight bearing by 6 weeks. Severely comminuted or marginally repaired fractures may be immobilized longer. Partial patellectomy may be performed in the setting of large salvageable fragment with a smaller, comminuted polar fragment not amenable to stable surgical fixation. Total patellectomy is rarely indicated, reserved for extensive patella fractures with severe comminution.

► Dislocation of the Patella

Patella dislocation is more common in women as well as patients with connective tissue disorders (Ehlers-Danlos or Marfan's) due to increased soft tissue laxity. Dislocation of the patella can be acute (traumatic) or chronic (recurrent).

Patients with an unreduced patella dislocation will present with inability to flex the knee, hemarthrosis, and palpably displaced patella. Patients with reduced or chronic patella dislocation may demonstrate a positive "apprehension test," where laterally directed force applied to the patella with the knee in extension reproduces pain and sensation of impending patella dislocation.

Radiographic evaluation includes anteroposterior and lateral views of the knee along with sunrise views of bilateral patellae for comparison. Assessment of patella alta (high-riding patella) or patella baja should also be performed using the Insall-Salvati ratio (the ratio of the patellar ligament length compared to the length of the patella, normal = 1.0; a ratio of 1.2 indicates patella alta, while 0.8 indicates patella baja).

Patella fractures may be classified descriptively: reduced versus unreduced, congenital versus acquired, acute (traumatic) versus chronic (recurrent), as well as direction of dislocation (lateral, medial, intra-articular, superior; note: lateral is most common).

These injuries are typically treated closed with reduction and casting or bracing with the knee in extension. Operative intervention is generally reserved for recurrent dislocation.

► Tear of the Quadriceps Tendon

Quadriceps tendon tears occur most commonly in patients more than 40 years old. The tendon usually ruptures within 2 cm of the superior pole of the patella. Location of rupture is associated with the patient's age: for patients more than 40 years old, the tear usually occurs at the bone-tendon junction, however, for patients less than 40 years old, the tear is often midsubstance. Risk factors for quadriceps tendon rupture include anabolic steroid use, local steroid injection, diabetes mellitus, inflammatory arthropathy, and chronic renal failure. Typically patients present with a history of a sudden "pop" while stressing the extensor mechanism. Patients have pain at the site of injury, difficulty with weight-bearing, knee

joint effusion, tenderness at the upper pole of the patella, and a palpable defect proximal to the superior pole of the patella. Complete tears result in loss of active knee extension, partial tears can still have knee extension.

Radiographic examination includes anteroposterior, lateral, and sunrise views of the knee. Nonoperative treatment includes immobilization with the knee in extension for 4-6 weeks followed by progressive physical therapy. Complete ruptures should be surgically repaired. Choice of surgical technique varies depending on location of the tear: complete ruptures near bone require reapproximation of the tendon to bone using nonabsorbable sutures passed through bone tunnels. Midsubstance tears may undergo end-to-end repair.

► Tear of the Patellar Ligament

Patella tendon ruptures are less common than quadriceps tendon ruptures. This injury typically occurs in patients less than 40 years old. Rupture commonly occurs at the inferior pole of the patella; risk factors include RA, lupus, diabetes, renal failure, systemic corticosteroid treatment, local steroid injection, and chronic patella tendonitis. Patients typically provide a history of an "audible" pop after forceful quadriceps contraction. Physical examination may show a palpable defect, hemarthrosis, painful passive range of motion, and partial or complete loss of active extension. Radiographic examination includes AP and lateral x-rays of the knee. Nonoperative treatment is reserved for partial tears, with intact extensor mechanism. Early repair (within 2 weeks of surgery) is preferred to delayed repair (> 6 weeks from injury), which is technically more demanding due to quadriceps contraction and patellar migration, as well as adhesions.

FRACTURES OF THE PROXIMAL TIBIA

1. Fractures of the Tibial Plateau

Tibial plateau fractures account for 1% of all fractures. Isolated lateral tibial plateau fractures are most common; although isolated fractures of the medial tibial plateau and bicondylar fractures happen as well.

► Anatomy

The tibia is the primary weight-bearing bone in the leg, supporting 85% of the transmitted load. The tibial plateau consists of the articular surfaces of the medial and lateral tibial plateaus. The medial plateau is larger and concave in shape, while the lateral plateau extends higher and is convex in shape. Normally, the plateau has a 10-degree posteroinferior slope. The two plateaus are separated by the intercondylar eminence, which serves as the tibial attachment for the anterior and posterior cruciate ligaments. There are three bony prominences 2- to 3-cm distal to the tibial plateau that serve as important insertion sites for tendinous structures: the tibial tubercle is located anteriorly and serves as the insertion

for the patellar ligament, pes anserinus is located medially and serves as attachment for semi-tendinosus, sartorius, and gracilis muscles, and Gerdy's tubercle which is the insertion site for the iliotibial band is located laterally. The peroneal nerve travels around the neck of the fibular head splitting into the superficial peroneal nerve which travels down the lateral aspect of the leg anterior to the fibula and the deep peroneal nerve which dives deep and travels down through the anterior compartment. The trifurcation of the popliteal artery is located posteriorly between the adductor hiatus proximally and the soleus complex distally. These structures are all at risk with a tibial plateau fracture.

► Mechanism of Injury

Tibial plateau fractures are usually the result of axial loading coupled with varus or valgus force. There is a bimodal distribution where young people experience these fractures after motor vehicle collisions, while the elderly can after a simple fall.

► Clinical Evaluation

Neurovascular examination is necessary to documenting the function of the deep peroneal, superficial peroneal, medial, and lateral plantar nerves distally is crucial. Additionally, the documentation of the popliteal artery, dorsalis pedis, and posterior tibial artery is required as well. Associated injuries include meniscal tears as well as injuries to the collateral and cruciate ligaments. Although, initial swelling and pain may prevent examination of these ligaments. When the swelling has reduced, ligamentous testing should be carried out. Consider intra-articular injection of the knee in the acute setting, in order to carry out a ligamentous exam.

The skin should be carefully examined for any breaks to rule-out open fracture. Intra-articular injection of 50 mL of sterile normal saline can be performed to rule-out communication of the fracture and overlying skin lacerations.

► Radiographic Examination

AP and lateral x-rays of the knee are part of the standard evaluation (Figure 40–18). Additionally, 40 degree internal or external rotation oblique views can be used to better assess the lateral and medial tibial plateaus respectively. A 5-10 degree caudally tilted plateau view can be used to evaluate articular step-off. CT scan is best for assessing the articular surface and is often used for preoperative planning. Associated ligamentous injury may be indicated by avulsion of the fibular head (LCL injury) and Second sign (lateral capsular avulsion off of the lateral tibial plateau, indicating ACL disruption). MRI should be considered if ligamentous injury is suspected. Arteriography should be performed if vascular injury is suspected.

► Classification

Tibial plateau fractures are most commonly classified according to the Schatzker classification: type I (lateral plateau, split fracture), type II (lateral plateau, split depression fracture), type III (lateral plateau, depression fracture), type IV (medial plateau fracture), type V (bicondylar plateau fracture), and type VI (plateau fracture with extension into the metaphysis). Of note, types IV-VI are higher energy fractures. Type I split fractures usually occur in younger individuals and are often associated with injury to the MCL. Type III depression fractures usually occur in older individuals with osteoporotic bone.

► Treatment

Initial treatment for lower energy fractures usually entails placement in a knee immobilizer locked in full-extension, non-weight-bearing status with crutches. For higher energy fractures with significant displacement, placement in a posterior splint or external fixation should be considered.

▲ **Figure 40–18.** Schatzker II tibial plateau fracture. **A.** Anteroposterior radiograph. **B.** Radiograph after fixation with lateral plate and bone grafting.

Nondisplaced or minimally displaced fractures can be treated with protected weight-bearing and early knee range of motion in a hinged brace. Radiographs should be taken at regular intervals to ensure no further displacement. Progression to full weight bearing can occur at 8-12 weeks from injury, if no further displacement occurs and fracture healing is appreciated radiographically.

Surgical indications include displacement of the articular surface, open fractures, compartment syndrome, or associated vascular injury. A variety of operative methods are used including external fixation, and open reduction internal fixation with plates or screws depending on fracture type and surgeon preference.

The postoperative course usually entails non-weight-bearing with continuous passive motion and progressive active range of motion. Progression to full weight-bearing is usually allowed by 8-12 weeks after surgery.

FRACTURE OF THE SHAFTS OF THE TIBIA & FIBULA

Fractures of the tibia and fibula are the most common long bone fractures. Mechanism of injury can be low-energy due to twisting/rotation or high energy related to motor vehicle accidents. Isolated fractures of the tibia and/or fibula are rare; these fractures most often occur together.

► Anatomy

The tibia is a tubular bone with a triangular cross-section. The tibia has a subcutaneous anteromedial border and is otherwise enveloped by four tight fascial compartments

(anterior, lateral, posterior, and deep posterior). The fibula is responsible for 10%-15% of the weight-bearing load. The common peroneal nerve is located subcutaneously, traveling around the fibular neck, making it particularly vulnerable to direct blows or traction injuries at this level.

► Clinical Evaluation

Neurovascular status, including the deep peroneal, superficial peroneal, medial, and lateral plantar nerves, as well as the posterior tibial artery and dorsalis pedis artery should be documented carefully. Thorough skin examination should be performed to rule-out open fracture. Additionally, the examiner should have a high suspicion for compartment syndrome in the acute setting. Pain out of proportion, pain with passive stretch, tense compartments, numbness, tingling, and cool toes are all signs of compartment syndrome. For obtunded or intubated patients who cannot relate an accurate history or their symptoms (pain level, presence of numbness/tingling), a monitor can be used to measure pressures in each of the four compartments. Greater than 30 mm Hg or pressure within 30 mm Hg of the diastolic pressure, are accepted indications for fasciotomy.

► Radiographic Evaluation

Radiographic investigation begins with AP and lateral x-rays of the tibia and fibula (Figure 40-19). Additionally, x-rays of the joint above and below should also be performed to rule-out other injury. Radiographs should be examined carefully to determine the location and morphology of the fracture, the presence of any secondary fracture lines that

▲ **Figure 40-19.** Anteroposterior **A.** and lateral **B.** radiographs of a displaced midshaft tibia fracture.

could displace during operative management. CT scan and MRI are rarely necessary. Technetium bone scans and MRI can be used in patients with persistent pain to diagnose stress fractures in tibial shafts that were not visible on radiographs.

► Classification

Fractures of the tibia shaft can be classified descriptively: open versus closed, anatomic location (proximal, middle, or distal third), fragment number and position (comminution, butterfly fragments), configuration (transverse, spiral, oblique), angulation (varus/valgus, anterior/posterior), shortening, displacement (percentage of cortical contact), rotation, and associated injuries.

Open fractures are classified according to the Gustilo and Anderson classification, described at the beginning of this chapter.

► Treatment

Fracture reduction and closed treatment in a long-leg cast with the knee in 0-5 degrees of flexion may be attempted for isolated, closed, low-energy fractures with minimal displacement and comminution. Protected weight-bearing with crutches with advancement to full weight bearing after 2-4 weeks is usually tolerated. After 4-6 weeks the long-leg cast may be exchanged for a short-leg cast or fracture brace. Regular radiographic follow-up is crucial to ensure no further displacement of the fracture. Acceptable parameters for continued closed treatment include: less than 5 degrees of varus/valgus angulation, less than 10 degrees of anterior/posterior angulation, less than 10 degrees of rotational deformity (external rotation is tolerated better than internal rotation), less than 1cm shortening, and more than 50% cortical contact.

Fractures with significant displacement or comminution that requires operative intervention, can be treated acutely with a posterior long-leg splint or external fixation if significant shortening is noted. Definitive surgical treatment includes several options: intramedullary nailing, external fixation, plates, and screws. Intramedullary nailing is by far the most popular technique as it preserves the periosteal blood supply, optimizing conditions for fracture healing. Compartment syndrome should be treated emergently with four-compartment fasciotomies. Concomitant fractures of the fibula do not require surgical treatment once the tibia has been stabilized.

1. Fracture of the Shaft of the Fibula

Isolated fracture of the shaft of the fibula is uncommon though it can occur with a direct blow to the side of the lower leg. Particular attention should be given to clinical and radiographic examination of the ankle and knee to rule out ligamentous or other subtle bony injuries. If no other injury

is present, immobilization is for comfort only. Three weeks or a month in a walking cast or removable cast boot is usually sufficient, and complete healing can be expected.

INJURIES OF THE ANKLE REGION

1. Ankle Fracture

The incidence of ankle fractures has increased significantly since the 1960s. Most ankle fractures are isolated malleolar fractures; however, bimalleolar and trimalleolar fractures make up approximately one-third of the total. Open fractures are rare.

► Anatomy

The ankle is a hinge joint composed of the fibula, tibia, and talus articulations along with several important ligaments. Specifically, the distal tibial articular surface is often referred to the “plafond,” which combined with the medial and lateral malleoli, forms the mortise which is a constrained articulation with the talar dome.

The talar dome is trapezoidal in shape and almost entirely covered with articular cartilage. The anterior portion of the talus is wider than the posterior portion. The tibial plafond is also wider anteriorly in order to accommodate the shape of the talus, conferring intrinsic stability to the ankle joint.

The medial malleolus, which articulates with the medial facet of the talus, can be divided into the anterior colliculus and posterior colliculus which serve as attachments for the superficial and deep deltoid ligaments, respectively. The deltoid ligament provides ligamentous support to the medial aspect of the ankle. The superficial portion of the deltoid is composed of three ligaments: tibionavicular ligament (prevents inward displacement of the talar head), tibiocalcaneal ligament (prevents valgus displacement), and the superficial tibiotalar ligament.

The lateral malleolus is the distal portion of the fibula, articulating with the lateral aspect of the talus. The distal fibula is attached to the distal tibia via soft-tissue constraint known as the syndesmosis. The syndesmosis, which is made up of four ligaments (anterior inferior tibiofibular, posterior inferior tibiofibular, transverse tibiofibular, and interosseous ligaments), resists axial, rotational, and translational forces, making it critical for ankle stability. The fibular collateral ligament, composed of the anterior talo-fibular ligament (ATFL), posterior talo-fibular ligament, and calcaneofibular ligament provides additional stability to the lateral aspect of the ankle.

► Clinical Evaluation

Neurovascular status (deep peroneal, superficial peroneal, medial and lateral plantar nerves, posterior tibial artery, and dorsalis pedis artery) should all be documented. The skin should be examined for open injury and blistering. The entire length of the fibula, including the proximal portion

(head and neck) should be palpated, to rule-out additional fractures. The “squeeze test” performed approximately 5 cm to the intermalleolar axis can be used to assess for syndesmotom disruption.

► Radiographic Evaluation

Initial workup includes AP, Lateral and mortise (15-20 degrees of internal rotation) x-rays of the ankle. Radiographs of the full tibia and fibula including the knee joint should be obtained to identify additional injuries. The dome of the talus should be centered under the tibia in all three views. Tibiofibula overlap less than 10 mm, tibiofibula clear space more than 5 mm, and medial clear space between the medial malleolus and talus all indicate syndesmotom disruption. If initial mortise views do not indicate medial clear space widening, an external rotation or gravity stress can be applied to the ankle. If widening more than 4 mm is noted with this stress, then significant syndesmotom injury is likely. Additionally, talar shift is indicative of ligamentous disruption. CT scan, MRI, and bone scan can be used to further investigate ankle injuries.

► Classification

Ankle fractures can be classified according to the Lauge-Hansen system which focuses on four patterns of ankle injury that are the result of different mechanisms. The Supination-adduction (SA) fracture pattern usually results in medial displacement of the talus and a transverse or avulsion-type fracture of the fibula distal to the joint and/or a vertical medial malleolus fracture. The supination-external rotation (SER) injury is the most common, producing variable disruption of the ATFL, spiral fracture of the distal fibula, posterior malleolus fracture, and fracture of the medial malleolus or deltoid ligament disruption. The pronation-abduction (PA) or pronation-external rotation (PER) injuries result in variable injury or fracture to the medial malleolus, deltoid ligament, syndesmotom ligament, and distal fibula fractures.

Ankle fractures can also be classified according to the Weber classification based off of the level of fibula injury: Weber A (fracture of the fibula below the tibia plafond), Weber B (oblique or spiral fracture of the fibula occurring at or near the level of the syndesmosis), and Weber C (fracture of the fibula above the level of the syndesmosis). The two classification systems correlate as follows: Weber A (SA injury pattern), Weber B (SER), and Weber C (PA or PER).

Other fracture variants include: Maisonneuve fracture (ankle injury with fracture of the fibula proximal third) and various avulsion fractures due to disrupted ligaments.

► Treatment

The goal of treatment is anatomic restoration of the ankle joint with preservation of fibular length and rotation. Initial

treatment, includes closed reduction and placement in a well-padded posterior splint with stirrups. Postreduction radiographs should be obtained to ensure correct position of the talus under the tibia. The injured limb should be elevated to the level of the heart at all times.

Nondisplaced, stable fracture patterns (isolated malleolus fractures) without disruption of the syndesmosis can be treated closed—transitioned from the splint to a long-leg cast for 4-6 weeks with serial radiographic examination to ensure no subsequent displacement. After this time, the patient can be transferred to a short-leg cast. Weight-bearing is restricted until fracture healing is demonstrated.

Surgical treatment is indicated for displaced medial malleolus fractures, and lateral malleolus fractures with displacement more than 2 mm or any loss of fibular length. Isolated lateral malleolus fractures with minimal displacement and no loss of length should be investigated for syndesmotom injury. Medial sided tenderness or medial clear-space widening noted radiographically is indicative of additional injury resulting in what is likely an unstable ankle fracture; as a result, surgery is usually recommended.

Surgical treatment includes plates and/or screws. For bimalleolar and trimalleolar fractures, the fibula is initially fixed with a plate and screws. The medial malleolus fracture remains unreduced, it should be stabilized with screws or tension band construct. Indications for surgical fixation of the posterior malleolus fracture include: involvement of more than 25% of the articular surface, persistent more than 2-mm displacement, or persistent posterior subluxation of the talus. Bimalleolar equivalent fractures (fibula fractures with medial ligament injury or syndesmotom disruption) may require syndesmotom screws. Proximal fibula fractures with syndesmotom disruption can be stabilized with syndesmotom screws once correct fibula length and rotation are achieved via reduction maneuvers.

Postoperative course usually entails non-weight-bearing in a splint/cast/removable boot for 4-6 weeks until fracture healing is appreciated radiographically. Ankle range of motion exercises should be started early to prevent postoperative stiffness.

2. Ankle Sprain

Ankle sprain is common, usually the result of forced inversion or eversion of the foot. Pain is usually maximal over the anterolateral aspect or medial aspects of the joint depending on the mechanism of injury. Ankle sprain is a diagnosis of exclusion. If no fractures, dislocations, or widening (> 4 mm) is appreciated between either malleolus or the talus then ankle sprain is a reasonable diagnosis.

Ankle sprains are usually treated with “RICE” (rest, ice, compression with elastic ace wrap, and elevation), NSAIDs, and non-weight-bearing or protected weight-bearing with crutches for 3-5 days. Splinting or use of an air cast is

optional. Continued pain and/or swelling that have not improved require further workup.

3. Syndesmosis Injuries

► Introduction

Syndesmotic injuries account for approximately 1% of all ankle ligament injuries. Many of these injuries go on undiagnosed and can lead to chronic ankle pain and instability if not treated appropriately.

► Clinical Evaluation and Diagnosis

Patients often present late, several hours or even days after a twisting injury to ankle, with persistent swelling/pain/difficulty weight-bearing. The fibula should be palpated along its entire length, proximally and distally. Two clinical tests have been used to evaluate for isolated syndesmotic injury: (1) the squeeze test—if squeezing the fibula midcalf reproduces distal tibiofibular pain or (2) external rotation test—pt is seated with knee flexed to 90 degrees, examiner stabilizes the patient's leg and externally rotates the foot; if pain is reproduced at the syndesmosis than injury is likely.

► Radiographic Evaluation

Radiographic evaluation starts with anteroposterior, lateral, and mortise views of the ankle looking for widening of the medial clear space between the medial malleolus and the medial border of the talus or widening of the tibiofibular clear space (interval between the medial border of the fibula and the lateral border of the posterior tibial malleolus). If no injury is appreciated, external rotation stress view (mortise

view with an external rotation stress applied to the foot with the leg stabilized) should be performed.

► Classification

Syndesmotic injuries can be organized according to the Edwards and DeLee classification: type 1 (diastasis involving lateral subluxation without fracture), type 2 (lateral subluxation with plastic deformation of the fibula), type 3 (posterior subluxation/dislocation of the fibula), and type 4 (superior subluxation/dislocation of the talus).

► Treatment

Patients can be initially immobilized in a non-weight-bearing cast for 2-3 weeks, followed by use of an ankle-foot orthosis that eliminates external rotation of the foot for an additional 3 weeks. Operative intervention with syndesmotic screws from the fibula to the tibia is considered for patients with and irreducible diastasis. These patients are often kept non-weight bearing for 6 weeks with screw removal at 12-16 weeks.

4. Pilon Fractures

► Epidemiology

Tibial Plafond or “Pilon” fractures are fractures that involve the weight bearing surface of the distal tibia that articulates with the talus (Figure 40–20). Pilon fractures account for 7%-10% of all tibia fractures. Most occur in men aged 30-40 years old from high energy mechanisms such as motor vehicle collisions or falls from significant height. As a result, extra care should be taken to rule out concomitant injuries.

▲ **Figure 40–20.** Axial loading injury to the ankle joint with the foot in dorsiflexion leading to a fracture of the tibial plafond. Anteroposterior **A**, and lateral **B**, radiographs.

Specifically, tibial plateau, calcaneus, pelvis, and vertebral fractures should be ruled-out.

► Mechanism of Injury

A fall from significant height results in an axial compression force directed through the talus into the tibial plafond, causing impaction and comminution of the articular surface. Shear injuries, such as can occur in a skiing accident, will result in a fracture with two or more large fragments and minimal comminution. Combined compression and shear result in fracture pattern that is somewhere in between.

► Clinical Evaluation

Examination of the patient includes documentation of a neurovascular exam and secondary survey to rule-out other injuries. Careful skin examination should be performed to exclude open fracture. Swelling is often rapid and considerable, potentially resulting in skin necrosis and blistering depending on fracture displacement. As a result, these fractures should be reduced provisionally and placed in a splint as soon as possible. The amount of swelling should be noted; some authors advocate waiting 7-10 days before taking patients to surgery for swelling to subside or until “skin wrinkling” is appreciated to avoid postoperative wound complications.

► Radiographic Evaluation

Initial radiographic evaluation includes anteroposterior, lateral, and mortise views of the ankle joint. CT with thin cuts, coronal, and sagittal reconstructions is useful for preoperative evaluation of the fracture pattern and articular surface. One should also consider radiographs of the contralateral side, which can be used for preoperative templating.

► Classification

The Ruedi and Algower classification is most commonly used: type 1 (nondisplaced fracture), type 2 (displaced fracture with minimal impaction and comminution), and type 3 (displaced fracture with significant comminution and/or metaphyseal impaction).

► Treatment

Choice of treatment is based off of multiple factors including the fracture pattern, as well as patient characteristics: age of patient, functional status, severity of injury to soft tissues, bone, cartilage, degree of comminution and/or osteoporosis, other injuries to the patient, and comfort level of the surgeon.

Nonoperative treatment, which involves long-leg cast for 6 weeks followed by bracing and range of motion exercises with progressive weight-bearing, is reserved for the nondisplaced fracture or severely debilitated patients.

Displaced fractures are usually treated surgically. Surgery may be delayed for 7-14 days to allow the soft tissues to calm down in an effort to avoid postoperative wound complications. “Skin wrinkling” may indicate that enough swelling has subsided for operative intervention to occur. Spanning external fixation should be considered initially to provide stabilization, partial fracture reduction, and restoration of length while waiting for final surgical management. Associated fibula fractures may undergo open reduction internal fixation at the time of fixator application.

The goals of operative fixation of pilon fractures include restoration of fibula length and stability, restoration of the tibial articular surface, buttressing of the distal tibia, and bone grafting metaphyseal defects as needed. Definitive surgical management may involve plates and screws, external fixation, or a combination thereof.

5. Achilles Tendon Rupture

► Epidemiology

Achilles tendon problems are often related to overuse injury. In the setting of trauma, acute rupture can occur. Delayed or missed diagnosis is common, caregivers should therefore have a high index of suspicion for this injury.

► Anatomy

The Achilles tendon is the largest tendon in the body. It has a paratenon with visceral and parietal layers, instead of a true synovial sheath, allowing approximately 1.5 cm of tendon glide. There are three sources for the tendon’s blood supply: (1) musculotendinous junction, (2) osseous insertion, (3) and multiple mesosternal vessels on the tendon’s anterior surface.

► Clinical Evaluation

Complete rupture often results in a palpable defect in the tendon that is not present with an incomplete injury. In the setting of complete rupture the Thompson test (plantar flexion with calf squeeze) is positive (no plantar flexion occurs) and the patient is unable to perform a single heel-raise.

► Treatment

Surgical treatment compared with non-operative management results in lower recurrent rupture rates, improved strength, and a higher percentage of patients returning to sports activities. However, there are significant complication rates associated with surgery including, wound infection, skin necrosis, and nerve injuries. As a result, surgery is usually reserved for the young, athletic patient looking to return to playing sports.

Nonoperative treatment usually entails 2 week immobilization in a plantar-flexed splint, followed by 6-8 weeks of

cast immobilization with progressive dorsiflexion to neutral and slow advancement of weight bearing. Cast removal is followed by the use of a heel-lift with eventual transition back to normal shoes. Progressive resistive exercises are started at 8-10 weeks from injury, with return to sports at 4-6 months. Maximal recovery can take up to one year; some residual weakness is often present.

Operative treatment can be done percutaneously or through a medial longitudinal approach. Postoperative management is similar to that which is used for closed treatment.

6. Peroneal Tendon Subluxation

Subluxation or frank dislocation of the peroneal tendon is rare, usually resulting from injury sustained during sports activities such as skiing. Clinical evaluation reveals lateral ankle swelling and tenderness posterior to the lateral malleolus. Radiographs may show a small fleck of bone off of the posterior aspect of the lateral malleolus indicating avulsion injury. MRI can be used for evaluation if diagnosis remains unclear. Treatment involves reduction of the tendon and placement in a well-molded cast with foot in slight plantar flexion and mild inversion. If dislocation of the tendon continues, operative intervention may be considered.

INJURIES OF THE FOOT

1. The Talus

► Anatomy

Sixty percent of the talus is covered by articular cartilage including the superior surface which is the weight-bearing portion. The cartilage extends medially and laterally in a plantar direction allowing articulation with the medial and lateral malleoli. The inferior surface of the talar body articulates with the calcaneus. The anterior aspect of the talus is wider than the posterior aspect, conferring inherent stability to the ankle joint. The neck of the talus extends from the body proximally and posteriorly, deviates medially, to join the talar head anteriorly and distally. The talar neck is most vulnerable to fracture. The head of the talus meets with the navicular bone anteriorly, the spring ligament inferiorly, the sustentaculum tali posteroinferiorly, and the deltoid ligament medially. The lateral process of the talus meets the posterior calcaneal facet inferiorly and the lateral malleolus superolaterally. The posterior process of the talus has a medial and lateral tubercle separated by a groove for the flexor hallucis longus tendon. An os trigonum, which can be mistaken for fracture, is present just posterior to the lateral tubercle in up to 50% of normal feet. The blood supply to the talus is composed of arteries to the sinus tarsi (originating from the peroneal and dorsalis pedis artery), an artery of the tarsal canal (posterior tibial artery), and the deltoid artery

(posterior tibial artery). The vascular supply reaches the talus through various fascial structures; when these structures are disrupted, for example, with dislocation, avascular necrosis of the talus can result.

► Fractures of the Talus

A. Epidemiology and Mechanism of Injury

Fractures of the talus represent approximately 2% of all lower extremity injuries. These injuries most commonly occur from high-energy mechanisms such as falls from significant height or motor vehicle accidents resulting in hyperdorsiflexion causing the talar neck to impact the anterior portion of the tibia.

B. Clinical Presentation and Radiographic Examination

Patients typically present with foot pain and diffuse swelling of the hindfoot. Associated fractures of the ankle and foot are common.

Initial radiographs include anteroposterior, lateral, and mortise views of the ankle as well as anteroposterior, lateral, and oblique views of the foot. A Canale view with the ankle in maximum equines (plantar-flexion), pronated 15 degrees and the radiograph machine directed 15 degrees from the vertical, provides optimal visualization of the talar neck. Additionally, a CT scan should be considered for better fracture characterization and to assess for any articular involvement. Bone scan and/or MRI should be considered for patients with persistent hindfoot pain despite negative radiographs to look for occult fractures of the talar neck.

C. Classification

Fractures of the talus are classified initially based off their anatomic location: talar neck fractures, talar body fractures, talar head fractures, lateral process fractures, and posterior process fractures.

Fractures of the talar neck are further subclassified based off of the Hawkins classification: I (nondisplaced), II (with associated subtalar dislocation), III (with associated subtalar and tibiotalar dislocation), and IV (associated subtalar, tibiotalar, and talonavicular dislocations).

D. Treatment

Truly nondisplaced fractures with no signs of articular comminution on CT scan can be treated nonoperatively initially in a short-leg cast, non-weight-bearing for at least 6 weeks until radiographic signs of healing are noted, followed by progressive weight-bearing.

Displaced fractures should be treated with closed reduction and splint placement. Open or irreducible fractures

require immediate operative treatment. Surgery entails open reduction and internal fixation with plates and screws.

► Other Fractures of the Talus

Lateral process fractures of the talus are commonly seen in snow-boarders. These fractures are often misdiagnosed as ankle sprains upon initial presentation. If the fracture is displaced less than 2 mm, then it can be treated closed with a short-leg cast. Greater than 2 mm of displacement requires operative intervention.

Posterior process fractures of the talus can be difficult to diagnose due to the presence of the os trigonum. Nondisplaced or minimally displaced fractures of the posterior process can be treated with a non-weight-bearing short-leg cast. Displaced fractures require surgical treatment with open reduction and internal fixation.

Talar head fractures may be associated with fractures of the navicular bone or talonavicular disruption. Nondisplaced or minimally displaced fractures can be treated for six weeks in a partial weight bearing short-leg cast molded to preserve the longitudinal arch. After discontinuation of the cast, an arch support should be worn in the shoe to reduce stress on the talonavicular articulation for an additional 4-6 months. Displaced fractures are treated with ORIF and/or primary excision of small fragments.

► Complications

The most common complication is posttraumatic arthritis. Avascular necrosis occurs as well and correlates with initial fracture displacement: Hawkins I (0%-15%), Hawkins II (20%-50%), Hawkins III (20%-100%), and Hawkins IV (100%). Other complications include delayed union or non-union, malunion, and wound complications.

► Subtalar Dislocation

Subtalar dislocation is defined by the simultaneous dislocation of the distal articulations of the talocalcaneal and talonavicular joints. Inversion of the foot results in medial subtalar dislocation, while eversion causes lateral subtalar dislocation. The large majority of these dislocations are medial (approximately 85%). All subtalar dislocations should be reduced as soon as possible with knee flexion, accentuation of the deformity to unlock the calcaneus and longitudinal traction. Subtalar dislocations are often stable once closed reduction is achieved. CT scan should be performed postreduction to assess for other associated fractures or continued subluxation. Failed closed reduction may be due to interposed extensor digitorum brevis muscle in the case of a medial dislocation or posterior tibial tendon for lateral dislocation. Unsuccessful closed reduction requires operative intervention.

► Total Dislocation of the Talus

Total dislocation of the talus is rare and usually an open injury. In general, open reduction with internal fixation is required. Complications including infection, osteonecrosis, and posttraumatic arthritis are common.

2. The Calcaneus

► Fracture of the Calcaneus

A. Epidemiology

The calcaneus is the most frequently fractured tarsal bone, constituting approximately 2% of all fractures. The large majority of calcaneus fractures occur in men aged 21-45 years old.

B. Mechanism

Most intra-articular calcaneus fractures are the result of axial loading where the talus is driven into the calcaneus during a fall from significant height or motor vehicle accident. Extra-articular calcaneus fractures may be the result of twisting injuries. For diabetic patients there is an increased incidence of calcaneus tuberosity fractures resulting from Achilles avulsion injuries.

C. Clinical Presentation

Patients often present with significant heel pain, swelling, and ecchymosis. When open fractures occur, they most often occur on the medial side of the foot. Compartment syndrome should be carefully ruled out. Associated injuries to rule out include lumbar spine injuries and other lower extremity fractures. Of note bilateral calcaneus fractures occur approximately 10% of the time.

D. Radiographic Evaluation

Initial radiographs include a lateral radiograph of the hind-foot, AP of the foot, a Harris axial view, and standard ankle series. The lateral radiograph should be examined to determine the Bohler tuber joint angle (intersection of the line drawn from the anterior process to the highest point of the posterior facet and the line drawn from the superior aspect of the calcaneal tuberosity to the highest point of the posterior facet). The Bohler angle is usually 20-40 degrees. A decrease in this angle indicates significant depression of the weight bearing posterior facet. The AP radiograph should be examined for extension of the fracture into the calcaneocuboid joint. A Harris axial view can be taken with the foot maximally dorsiflexed and the radiograph beam directed 45 degrees cephalad to better visualize the articular surface. However, dorsiflexion may be difficult due to patient discomfort. CT scan with 3-5 mm cuts offers the best

▲ **Figure 40–21.** Axial CT section showing a fracture of the calcaneus caused by an axial loading mechanism.

characterization of the articular surface and as a result is most useful for preoperative planning (Figure 40–21).

E. Classification

Extra-articular fractures of the calcaneus include fractures of the anterior process, calcaneal tuberosity, medial process, sustentaculum tali, and body fractures outside of the articular surface. Anterior process and calcaneal tuberosity fractures are best seen on lateral radiographs. Fractures of the medial process, sustentacular, or body fractures are best investigated on axial views or CT scan. Intra-articular fractures can be classified according to the Sanders classification which is based off of the coronal cuts of CT scans showing the number and location of articular fracture fragments. The posterior facet of the calcaneus is divided into three fracture lines (A, B, and C) moving from lateral to medial. There can be a total of four pieces: lateral, central, medial, and sustentaculum tali. The classification is as follows: type I (all nondisplaced fractures regardless of number of fracture lines), type II (two-part fracture, with further subclassification based on the location of the fracture line IIA, IIB, IIC), type III (three-part fractures, subtypes IIIAB, IIIAC, IIIBC), and type IV (four part articular fractures).

F. Treatment

Treatment remains controversial—even with adequate reduction fractures of the calcaneus often result in chronic pain and functional disability. Nonoperative indications include

nondisplaced or minimally displaced extra-articular fractures, nondisplaced intra-articular fractures, anterior process fractures with less than 25% involvement of the calcaneocuboid articulation, fractures in patients with severe peripheral vascular occlusive disease or diabetes (due to frequent wound complications associated with surgery), fractures in patients with other severe medical comorbidities, and fractures associated with significant soft tissue compromise. Initial treatment involves placement in a bulky-Jones splint or dressing with avoidance of pressure on the heel. The splint is converted to a prefabricated boot locked in neutral to prevent equines contracture with elastic compression stocking to prevent dependent edema. Early subtalar and ankle joint range of motion is started; non-weight-bearing is instituted for approximately 10-12 weeks until radiographic healing is appreciated.

Operative indications included displaced intra-articular fractures, fractures of the anterior process with more than 25% involvement of the calcaneocuboid joint, displaced calcaneal tuberosity fractures, fracture-dislocations of the calcaneus, open fractures of the calcaneus, tuberosity fractures that are displaced resulting in prominence through the skin, incompetence of the gastrocnemius-soleus complex, and/or extend into the articular surface. Surgery should only be attempted 7-14 days after the injury allowing enough time for swelling to subside. Fracture fixation depends on the type of fracture. Anterior process fractures are typically fixed with small or minifragment screws. Calcaneal tuberosity fractures usually require lag screw fixation with or without cerclage wire. Intra-articular posterior facet fractures may be fixed with lag screws into the sustentaculum tali and a thin lateral plate providing a lateral buttress. Postoperatively the patient is kept non-weight-bearing for 8-12 weeks with early subtalar range of motion exercises.

3. Fractures of the Midfoot

► Epidemiology, Mechanism of Injury, and Anatomy

Fractures of the midfoot are relatively rare, most often resulting from direct impact during a motor vehicle accident or a combination of axial loading and torsion during fall from a significant height. The midfoot consists of five bones: navicular, cuboid, medial, middle, and lateral cuneiforms. The midtarsal joint consists of the calcaneocuboid and talonavicular articulations which act together with the subtalar joint during eversion and inversion of the foot. The cuboid extends distal to the three naviculocuneiform joints minimizing motion at this level.

► Clinical and Radiographic Evaluation

Patient presentation is variable ranging from a limp with mild swelling and dorsal foot tenderness to a grossly swollen, painful midfoot resulting in nonambulatory status. Initial

radiographs include AP, lateral, and oblique x-rays of the foot. Stress views and weight-bearing x-rays can provide additional detail including detection of any ligamentous instability. CT scan is best for characterizing fracture-dislocations or discovering injuries that are otherwise undetected on x-ray. MRI may be used to evaluate ligamentous injury.

► Navicular Bone

The navicular is the keystone bone of the foot's medial longitudinal arch, transmitting motion from the subtalar joint to the forefoot. The talonavicular articular surface is concave and has a significant arc of motion. The distal articular surface has three separate facets for the three cuneiforms. Not much motion occurs at these joints. The navicular tuberosity is the medial prominence located on the inferior aspect of the navicular bone provides an attachment point for the posterior tibial tendon. Anatomic variants include the shape of the tuberosity and the presence of an accessory navicular bone (up to 15% of the time and bilateral 70-90% of the time).

Patients typically present with painful foot and dorsomedial swelling and tenderness. Radiographic Evaluation can include medial and lateral oblique x-rays of the midfoot in addition to the standard foot series, to assess the lateral pole of the navicular as well as the medial tuberosity.

► Classification

There are three basic types of navicular fractures with a subclassification of the body type fractures. Avulsion-type fractures can involve the talonavicular or naviculocuneiform ligaments. Tuberosity fractures usually involved disruption of the tibialis posterior tendon insertion without damage to the joint surface. Type I body fractures divide the navicular into dorsal and plantar pieces. Type II body fractures split the navicular into medial and lateral pieces. Type III body fractures are comminuted and often have significant displacement of the medial and lateral poles.

► Treatment

Nondisplaced fractures without instability may be treated closed in a cast or boot non-weight-bearing for 6-8 weeks. Disruption of the articular surface more than 2 mm requires operative intervention. Small fragments may be excised if symptomatic. Larger fragments (> 25% of the articular surface) require ORIF with lag screw fixation. If more than 40% of the talonavicular joint cannot be reconstructed, acute talonavicular fusion should be considered. Isolated dislocation or subluxation of the navicular bone without fracture requires surgical stabilization.

► Cuboid Bone

The Cuboid Bone is part of the "lateral column" of the foot articulating with the calcaneus proximally, the navicular

and lateral cuneiform medially, and the fourth and fifth metatarsal distally. The peroneus longus travels through a groove on the plantar surface of the cuboid on its way to its insertion at the base of the first metatarsal. Injury to the cuboid bone is usually seen in conjunction with injury to the talonavicular or Lisfranc joints. Patients typically present with dorsolateral foot pain and swelling. In addition to foot series, stress radiographs, and CT scan should be considered. MRI can be used to evaluate for stress fractures that are otherwise not seen on radiograph. Cuboid fractures without articular disruption or any loss of length can be treated closed, non-weight-bearing in a boot for 6-8 weeks. If more than 2 mm disruption of the articular surface is appreciated or the cuboid is compressed, then ORIF should be pursued. Calcaneocuboid fusion should be considered for fractures with residual articular displacement.

► Tarsometatarsal (Lisfranc) Joint

Injury to the Lisfranc Joint is relatively rare. However, given that up to 20% of the time this injury goes undiagnosed initially, suspicion should remain high especially in the poly-trauma patient with foot swelling or pain.

In the AP plane the base of the second metatarsal is recessed between the medial and lateral cuneiforms, limiting translation. In the coronal plane, the middle three metatarsal bones have trapezoidal shaped bases that form a transverse arch preventing displacement in the plantar direction. The second metatarsal base is "keystone" responsible for the inherent stability of the tarsometatarsal joint. The Lisfranc ligament travels from the medial cuneiform to the base of the second metatarsal bone providing additional stability. Of note the dorsalis pedis artery travels in between the first and second metatarsal bones at the Lisfranc joint; as a result it is vulnerable to injury with disruption or manipulation of this joint.

There are three common mechanisms of injury: (1) twisting (forced abduction of the forefoot) such as is seen in equestrians who fall from a horse with their foot caught in the stirrup, (2) axial load, and (3) crush injury.

Clinical evaluation includes careful neurovascular documentation given the proximity of the dorsalis pedis artery to this joint. Additionally, compartment syndrome of the foot should be ruled out. Stress testing applying gentle forefoot abduction or pronation with the hindfoot stabilized may be performed.

Radiographic evaluation includes anteroposterior, lateral, and oblique views of the foot. Normally, the medial border of the second metatarsal should be collinear with the medial border of the middle cuneiform on the AP view; additionally the medial border of the fourth metatarsal should line up with the medial border of the cuboid bone. Dorsal displacement of the metatarsals on the lateral view is also indicative of ligamentous injury. Weight-bearing views

should be performed as well looking for any displacement. CT scan can provide greater detail. Associated injuries to the cuneiforms, cuboid, and/or metatarsals are common and should be ruled out.

If no instability (displacement) is appreciated on standard and stress radiographs a diagnosis of midfoot sprain may be considered with initial non-weight-bearing treatment and progressive weight-bearing as comfort allows. Repeat x-rays should be obtained once swelling has subsided. For any displacement of the tarsometatarsal joint more than 2 mm, surgery should be pursued with screws and k-wires.

► Fractures of the Forefoot

Fractures of the first metatarsal are rare due its larger size and increased strength compared to the other metatarsals. Isolated fractures of the first metatarsal without instability may be treated with weight bearing as tolerated in a short-leg cast or removable boot for 4-6 weeks. If displacement is detected of the first metatarsal through the joint or fracture site, operative intervention is required.

Fractures of the second, third, or fourth metatarsals are much more common. Most isolated fractures can be treated closed with hard-soled shoes and progressive weight-bearing. Operative indications include fractures with more than 10 degrees of deviation in a dorsal or plantar direction or 3-4 mm of translation in any plane.

Fifth metatarsal fractures usually result from direct trauma and are divided into two groups: proximal base fractures and distal spiral fractures. The proximal fifth metatarsal fractures are further sub-divided: Zone I (cancellous tuberosity, which is the insertion of the peroneal brevis), Zone II (distal to the tuberosity), and Zone III (distal to the proximal ligaments, without extension past the proximal 1.5 cm of the diaphyseal shaft). Zone I injuries are treated symptomatically with hard-soled shoe. The treatment of Zone II injuries, aka Jones fractures, is controversial due to healing difficulty. Some authors advocate weight-bearing as tolerated, others recommend non-weight-bearing in a short leg cast or surgical intervention. Zone 3 injuries may be treated non-weight-bearing in a cast or with surgery. Fractures distal to the proximal 1.5 cm of the diaphyseal shaft, are called "Dancer's fractures" and are treated symptomatically with a hard-soled shoe.

4. Metatarsophalangeal Joint

Injuries to the first MTP joint are relatively common especially in persons who participate in athletic activities such as ballet, football, or soccer. The MTP joint is composed of a cam-shaped metatarsal head articulating with the concave proximally articular surface of the proximal phalanx. The stability of the joint is provided by ligamentous constraints which include the medial and lateral collateral ligaments as well as the dorsal capsule and plantar plate which are

reinforced by the extensor hallucis longus and flexor hallucis longus tendons respectively. "Turf toe" which is a hyperextension injury of the first MTP joint, resulting in stretching of the plantar capsule and plate, may be treated with RICE, nonsteroidal anti-inflammatory drugs (NSAIDs), and protective taping with gradual return to activity. MTP dislocations are treated with closed reduction and short-leg cast with toe extension for 3-4 weeks. Dislocations with displaced avulsion fractures require surgical intervention with lag screws or tension-band technique.

Injuries to the lesser MTP joints are common as well. Simple dislocations or nondisplaced fractures are managed with gentle reduction and buddy taping. Intra-articular fractures may be treated with excision for small fragments or ORIF with Kirshner wires or screws.

5. Fractures & Dislocations of the Phalanges of the Toes

Phalangeal fractures are the most common injury to the forefoot. The proximal phalanx of the fifth toe is the most common phalanx injured. Like the fifth digit, the first digit is also particularly vulnerable to injury due their border positions in the foot. Mechanisms of injury usually entails direct blow such as from a dropped heavy object or axial load resulting from a stubbing injury. Fractures and/or dislocations are diagnosed with foot series radiographs (AP, lateral, oblique). MRI or bone scan may aid in the diagnosis of stress fractures that are not visible on x-ray. Nondisplaced fractures are treated with stiff-soled shoe and protected weight-bearing with advancement as tolerated. Buddy taping may be used as well. Fractures with clinical deformity require reduction. Operative intervention is only performed for those rare fractures with gross instability or persistent intra-articular deformity. Dislocated IP joints without fracture are usually amenable to closed reduction and buddy taping with progressive advancement of activity.

6. Fracture of the Sesamoids of the Great Toe

Fractures of the sesamoid bones is rare, occurring with hyperextension injuries in ballet dancers and runners. The medial sesamoid is more frequently fractured than the lateral sesamoid due to increased weight-bearing on the medial side of the foot. Fractures of the sesamoids must be distinguished from bipartite sesamoids which are relatively common, up to 30% of the general population (bilateral in 85% of cases). These fractures are initially treated closed with soft padding and short-leg walking cast for 4 weeks followed by shoe with metatarsal pad for additional 4-8 weeks. Sesamoidectomy is reserved for cases of failed conservative treatment.

PEDIATRIC ORTHOPEDICS

CHILDREN'S FRACTURES & DISLOCATIONS

Children's skeletal injuries differ from those of adults in several significant ways. An important difference is the presence of the growth plate or physis, giving immature bone its potential for longitudinal growth. Bones increase in diameter by appositional growth from the periosteum. Injuries to the physis may disrupt skeletal growth. Children's bones heal rapidly, and nonunion is exceedingly rare. The periosteum is thick and strong, surrounding the long bone like a sleeve and helps to minimize fracture displacement and promote healing.

When injury occurs in a young child, especially one under 3 years of age, a careful social history should be taken (see Chapter 45). State law in all jurisdictions requires that suspected cases of abuse be reported to local authorities.

Closed treatment is usually sufficient for children's fractures. Manipulation also known as closed reduction under sedation may be required for significant displaced fractures. Open fractures, fractures with articular surface displacement, and less commonly fractures that cannot be reduced by closed means require operative treatment.

Although children's fractures do heal rapidly and immobilization rarely causes joint stiffness in children, so casts can be left on until union is achieved.

The bone in growing children is mechanically different from that in adults; immature bone is more porous and fails in compression as well as in tension. An example is the so-called buckle or torus fracture that occurs at the metaphysis of the distal radius. This stable injury should be protected in plaster for 3 weeks to control symptoms and prevent further trauma to the weakened bone.

Immature bone is less brittle than that of adults, and children's bones may therefore bend but not fracture. This plastic deformation may produce significant deformity that requires manipulation to restore alignment.

Greenstick fractures are also a result of the plasticity of children's bones. Incomplete disruption of a long bone occurs such that the bone fractures on the tension side but the opposite cortex remains in continuity. The periosteum

remains intact on the concave side and typically the intact cortex resists any significant angulation at the fracture site.

1. Growth Plate Fractures

About 15% of children's fractures involve a growth plate—most commonly the distal radius, distal tibia or fibula (or both), and distal humerus.

► Classification

Classification of physeal injuries helps to distinguish patterns that may disturb growth and also provides some guidance for treatment. It should be recognized that even “benign” injuries to the growth plate of the distal femoral and tibia can have clinically significant consequences.

Physeal injuries are classified according to the Salter and Harris system (Figure 40–22).

A. Type I

Type I injuries have fracture lines that follow the growth plate, separating the epiphysis from metaphysis. Without displacement, radiographs may appear normal. This is often a clinical diagnosis with tenderness localized over the physis confirming that a growth plate injury has occurred. Healing occurs rapidly, usually within 2–3 weeks.

B. Type II

In type II injuries, the fracture line traverses the epiphysis and exits in the metaphysis. The metaphyseal fragment is often referred to as the Thurston–Holland sign and is diagnostic of a growth plate injury. Type II injuries are the most common physeal fractures. Satisfactory alignment can often be achieved with gentle closed reduction and casting. If pin fixation is required, smooth pins can be safely used across the physis. The risk of growth disturbance is highest for distal femoral and distal tibial fractures.

C. Type III

Type III physeal injuries are those in which the fracture line exits through the epiphysis at the articular surface.

▲ **Figure 40–22.** Salter–Harris classification of physal injuries occurring at the zone of provisional calcification of the growth plate.

Any displacement at the articular surface requires operative intervention.

D. Type IV

Salter-Harris-type IV fractures cross both the metaphysis and the epiphysis. Because it involves the articular surface, anatomic reduction is essential to minimize the complications of type IV growth plate fractures, including growth disturbance, malunion, and articular incongruity. Even with perfect reduction, growth may be affected, and the prognosis is guarded.

E. Type V

Type V growth plate injuries are due to severe axial loading. Some or all of the physis is so severely compressed that growth potential is destroyed. Initial radiographs may appear normal like with SH 1 injuries. A history of a significant mechanism with swelling and tenderness over the physis should suggest the possibility of such an injury. Subsequent follow-up radiographs are critical to watch for premature closure of the physis, and/or progressive angular deformity due to asymmetric injury to the growth plate.

► Treatment

A. Conservative Treatment

Most fractures involving the physis may be managed nonoperatively. Nondisplaced fractures are protected in a cast until healed. Typically 3–6 weeks is usually sufficient depending upon the child's age and the site of injury. Displaced type I and type II injuries should be treated with a single attempt at closed reduction followed by immobilization as above. Because of the significant remodeling potential, acceptance of some deformity is better than repeated vigorous attempts at reduction which causes additional damage to the physis. Attempts at reduction should be avoided if more than seven days have passed since the injury.

B. Operative Treatment

Displaced type III and type IV injuries usually require open reduction and internal fixation. Fixation is ideally placed within the metaphysis or epiphysis. If it is necessary to cross the physis, only smooth pin fixation is recommended. Cast immobilization may be required to supplement fixation.

► Prognosis

All injuries that involve physes should be followed at least 12–18 months to confirm that growth has not been disrupted. The parents should be warned at the time of the injury of the possibility of altered growth. Physeal arrest may result in angular deformity and/or limb length inequality. When a physeal bar is suspected, CT scan or MRI can be

used to localize the area, and estimate its size. If the bony bar is less than 50% of the physis and the child has at least two years of growth remaining, resection of the bar can be considered. Alternatively, the portion of the physis that remains open can be intentionally closed down to limit angular deformity. Limb length inequalities will occur if there is a complete physeal arrest. If the difference is less than 2 cm, no treatment is typically required. Differences of 2–5 cm are most frequently managed with an epiphysiodesis on the contralateral limb. Limb lengthening techniques can be considered with limb length inequalities exceed 5 cm.

2. Upper Extremity Fractures & Dislocations

► Proximal Humeral Fractures

Separation of the unossified proximal humeral epiphysis has been described following difficult delivery of an infant. The child is unable to use the arm raising the concern for brachial plexus palsy. This “pseudoparalysis” resolves on the order of 7–10 days and radiographs demonstrate abundant callus, confirming the fracture. Older children most commonly sustain SH II fractures. Significant displacement and angulation is well tolerated and the child can be treated in a sling for 3 weeks. In the adolescent approaching maturity displaced fractures are treated with closed reduction and pin fixation. There is so much potential for remodeling in the proximal humerus that the best obtainable closed reduction is preferable to open surgery. Residual deformity, loss of motion, and functional problems are exceedingly rare following sustain proximal humerus fractures.

► Supracondylar Fractures of the Humerus

Supracondylar fractures are among the most common injury in children ages 4–8 years. The typical mechanism is a hyperextension injury to the elbow. Type I of undisplaced supracondylar fractures present with elbow pain, swelling, and tenderness at the site. Radiographs usually show a positive fat pad sign, indicating elbow hemarthrosis and a nondisplaced fracture of the distal humerus anteriorly. The fracture line may be subtle so comparison radiographs of the uninjured elbow may be helpful. Cast immobilization for 3–4 weeks is recommended. Type II fractures are those in which there is posterior angulation of the distal fragment, with an intact periosteal hinge. The anterior humeral line no longer bisects the capitellum on the lateral radiograph. Closed reduction and pinning is advised to restore this relationship. Type III fractures are completely displaced. These are serious injuries that threaten the neurovascular structures. The radial pulse and the function of the radial, ulnar, and median (including anterior interosseous) nerves should be checked immediately. If ischemia is present initially, prompt reduction of deformity is the next step toward restoration of normal perfusion. If pulses cannot be restored with reduction

then an angiogram and vascular consultation is urgent. When the loss of pulses occurs following attempts at reduction, vascular entrapment should be suspected and prompt surgical exploration of the brachial artery may be required.

Fracture reduction is secured with percutaneous pin fixation and splint immobilization for 4-6 weeks. Long-term problems include elbow stiffness, malunion, and growth arrest. Nerve injuries typically represent neuropraxias that resolve with observation over the subsequent 3-6 months.

Flexion type supracondylar fractures are rare, but when they do occur are typically managed with open reduction and pin fixation. The ulnar nerve is most at risk with these injuries.

► **Subluxation of the Radial Head (Nursemaid's Elbow)**

This common minor injury occurs in children under 4 years of age. It is caused by a sudden pull on the extended pronated arm, usually by an adult tugging on a reluctant toddler. The pronated radial head slips partially under the annular ligament and displaces into the radiocapitellar joint. The child suddenly stops using the arm, holding it in a flexed and pronated position. Radiographs show no abnormalities since positioning for elbow films will often reduce the subluxation. Reduction is achieved by firmly supinating the forearm and flexing the elbow while pressing down on the radial head. Often a "click" is felt when reduction is achieved. Soon after reduction the child becomes less apprehensive and gradually resumes use of the arm.

► **Other Fractures & Dislocations of the Elbow**

There are a few injuries unique to the pediatric elbow which warrant mention. Fractures of the distal humerus including displaced lateral condyle fractures and displaced medial epicondyle fractures require surgery to restore articular congruity. Radial neck fractures with angulation that inhibits forearm rotation require reduction and fixation. Displaced olecranon fractures, if not reduced by elbow extension, will also require internal fixation. Monteggia and Monteggia variant fractures represent a spectrum of injuries which include forearm fracture with radial head dislocation. Radiographs of the elbow are essential following any ulnar or radial shaft fractures to look for this injury.

► **Forearm Fractures**

Fractures of the shafts of both the radius and the ulna occur frequently in children. The most common problem is malunion with angular or rotational deformity which limits supination-pronation. Initial treatment is closed reduction. Because of the remodeling potential in the growing child, anatomic reduction is not essential. Side-by-side or

"bayonet" apposition is acceptable but angulation should be minimized. Radiographs are repeated weekly for 3 weeks to permit early remanipulation should the fracture displace. If displacement occurs repeat reduction and possibly internal fixation with intramedullary nails or plates may be required.

Galeazzi fracture combines dislocation of the distal radioulnar joint with fracture of the radial shaft. To avoid missing this injury radiographs of the wrist and the elbow are obtained to confirm that normal bony relationships are present.

3. Lower Extremity Fractures & Dislocations

► **Traumatic Hip Dislocation**

In children, traumatic dislocation is more common than fracture of the hip and has fewer complications. Prompt closed reduction under general anesthesia with good muscle relaxation is usually successful. Interposed soft tissue or bone fragments may necessitate open reduction. Following reduction, the hip should be protected for 4-6 weeks until soft tissue healing has occurred. With prompt reduction, avascular necrosis is rare but radiographs should be followed for 18 months.

► **Fractures of the Proximal Femur**

Proximal femur fractures are rare in children. This is fortunate, as displacement and injury to the growth plate and blood supply predispose to complications including avascular necrosis, physeal arrest, and nonunion. Fractures involving the proximal femur are typically the result of high energy trauma.

In children, most hip fractures involve the femoral neck. If there is no displacement, spica cast immobilization maintains alignment during healing, but close radiographic monitoring is required for prompt identification of any displacement. Displaced fractures of the femoral neck should be treated with anatomic reduction and screw fixation preferably placed short of the physis. Satisfactory results are achieved in half or less of cases, with avascular necrosis, varus malunion, and physeal arrest among the most common complications. Intertrochanteric and subtrochanteric fractures can generally be managed with open reduction and internal fixation. Late problems (eg, angular deformity and unequal limb lengths) are rare but do occur.

► **Femoral Shaft Fractures**

Femoral shaft fractures are fairly common childhood injuries. They often result from significant trauma, so that other injuries may also be present. Radiographs of the hip are required to ensure that fracture or dislocation is not present. The knee should also be x-rayed. Infants are treated with Pavlik harness. Children ages 1-6 are most commonly treated with closed reduction and spica casting for 4-6 weeks. Titanium elastic nails have become the mainstay of treatment

for the older child. Standard antegrade femoral nails are reserved only for skeletally mature adolescents because of the risk of avascular necrosis when the physes remain open.

► Fractures of the Tibia & Fibula

Fractures of the tibia and fibula are not unusual in childhood. An occult undisplaced spiral fracture may cause the toddler to refuse to weight bear (“toddler’s fracture”). These fractures heal rapidly in a long-leg cast. Nerve and vessel damage may be present, especially with displaced fractures of the proximal metaphysis. Fractures of the tibial spine and tibial tubercle are unique to children. If displaced, these fractures require open reduction and fixation. Stiffness about the knee is common and fracture healing must be balanced with restoration of joint motion to avoid long-term problems.

► Fractures of the Distal Fibula Physis and Transitional Fractures

Fractures of the distal fibular occur frequently in children. This injury is the equivalent of an ankle sprain in the skeletally mature individual. Physical examination localizes tenderness to the distal fibular growth plate, and radiographs will typically be interpreted as normal. Treatment is symptomatic, with resolution of symptoms expected in 3-4 weeks.

Children are at risk for so called transitional fractures of the distal tibia. These occur most commonly in kids ages 10-14 when a portion of the growth plate is closed, but some portion still remains open. A Tillaux fracture is a fracture involving the anterolateral distal tibial epiphysis. Any displacement warrants open reduction and screw fixation. Triplane fractures of the distal tibia are identified as SH III injuries on the AP radiograph and SH II injuries on the lateral radiograph. Again, anatomic reduction and fixation is critical.

GAIT DISORDERS & LIMB DEFORMITY

Abnormalities of the lower extremities in children may be noticed by parents as the child learns to walk. The two most common areas of concern include rotational malalignment and angular deformity at the knees.

1. Intoeing

A normal foot progression angle with walking is 10 degrees external rotation. There are three common causes of the “foot turning in” in children. Metatarsus adductus represents adduction of the forefoot. This deformity is typically present at birth and passively correctable. Mild cases will resolve with stretching. If it persists beyond early childhood, surgical correction is an option.

Tibial torsion is an internal rotation deformity of the tibia. On physical exam the ankle axis (a line connecting the tips of the medial and lateral malleoli) is internally rotated

relative to the tibial tubercle. This developmental variant is common in children 1-3 years of age and almost always corrects spontaneously with growth. Special shoes and orthotic devices have not been shown to change the natural history and are no longer recommended. Rarely spontaneous correction does not occur (by age 6) and tibial derotational osteotomy can be considered.

Femoral anteversion is another common finding in children who walk with their feet turned in. Parents will report that the child is a “W” sitter. Observation reveals that the whole limb is internally rotated, so that the patella as well as the foot points medially. On clinical determination internal rotation at the hip approaches 90 degrees. Femoral anteversion can correct spontaneously up until the age of 12. If functional limitations are noted, a femoral derotational osteotomy can be considered.

2. Angular Deformity of the Lower Extremities (Knock-Knees & Bowlegs)

Varus or “bow legs” denotes deviation of the knees away from midline. Valgus or “knock knees” denotes deviation of the knees toward midline. Children may develop bowlegs from about 12-18 months to 3 years. The majority of children will show spontaneous resolution and occasionally progression to slight valgus between ages 3 and 4 years. In young children, angular deformity of the knees requires radiographs evaluation after the age of 2 years if it is asymmetric, associated with abnormally short stature or progressing. The differential diagnosis included infantile blounts and rickets. If metabolic bone disease is suspected, serum calcium, phosphate, and alkaline phosphatase should be measured. Operative treatment may be considered in if deformity persists after the age of 3.

► Pathologic Genu Varum

It is important to distinguish physiologic tibia vara from pathologic conditions associated with varus including rickets, Blount’s disease and skeletal dysplasias. Blount’s disease (tibia vara) has both infantile and adolescent forms. Radiographs in infantile blounts typically show metaphyseal beaking and changes in the medial proximal tibial physis. The metaphyseal-diaphyseal angle (> 11 degrees) of the tibia helps to differentiate between physiologic bowing and infantile tibia vara. Progressive tibia vara should be treated with corrective osteotomy of the proximal tibia and fibula. Overcorrection into valgus alignment is recommended because recurrence is common. Adolescents blounts is most common in obese patients. Excessive stress on the medial tibial physis is thought to inhibit normal growth leading to bowing. When the growth plates remain open, growth can be modulated using staples or plates to temporarily tether the lateral growth plate and allow for

gradual correction. After skeletal maturity, proximal tibial osteotomy is recommended to restore normal mechanical alignment.

SYSTEMIC DISORDERS AFFECTING BONES & JOINTS IN CHILDREN

1. Juvenile Rheumatoid Arthritis

RA is an autoimmune disorder whose exact cause remains elusive. There are three basic clinical forms of juvenile rheumatoid arthritis (JRA). Pauciarticular arthritis generally involves a single joint, most commonly the knee or the ankle but occasionally the hip or an upper extremity (mainly the elbow or the wrist). Clinical symptoms include the insidious onset of swelling and loss of motion at the affected joint. Systemic manifestations are absent. Iridocyclitis, or inflammation of the iris and ciliary body, is most common in this form and JRA and an ophthalmology evaluation is necessary.

Polyarthritis is characterized by multiple joint involvement and minimal evidence of systemic disease. Fingers and toes, the neck, and the temporomandibular joints are more likely to be involved. The course is persistent, with periods of exacerbation.

Systemic rheumatoid disease (Still's disease) usually presents with multiple (more than five) involved joints, fever, lymphadenopathy, hepatosplenomegaly, rash, subcutaneous nodules, and pericarditis. The course may be remitting or relentless, causing severe permanent disability. Inflamed joints develop synovial hypertrophy and pannus, which destroy articular cartilage. The associated hyperemia can stimulate the adjacent physes, with resulting overgrowth, or physeal arrest. Damage to underlying bone and ligament can produce severe deformity and joint subluxation. Musculoskeletal involvement may include the cervical spine, with spontaneous fusion of the apophysial joints and result in C1-2 instability.

When a single joint is inflamed, it is necessary to exclude Lyme disease in endemic areas, septic arthritis, and reactive synovitis. Polyarticular JRA must be differentiated from rheumatic fever and leukemia.

Medical management is the first line of treatment; anti-inflammatory agents and range of motion exercises as synovitis resolves and appropriate bracing to minimize stiffness and allow function. Synovial biopsy can be done percutaneously with arthroscopy to help confirm the diagnosis. Synovectomy is controversial but some believe that it may slow the progression of arthritis.

2. Brachial Plexus Palsy

Brachial plexus palsy has three general patterns of involvement: (1) Erb's palsy, involving C5 and C6 (upper trunk); (2) Klumpke's paralysis, involving C8 and T1 (lower trunk); and (3) whole plexus. The first step in treatment is recogni-

tion. Physical therapy to maintain range of motion is started immediately and continued as the child is followed for recovery of function. Recovery of the biceps (elbow flexion and forearm supination) by 3-6 months is generally a good prognostic sign. If no spontaneous improvement is seen, neurosurgical evaluation/intervention is recommended. If muscle imbalance persists at the shoulder, transfer of the latissimus dorsi and teres major muscles, so that they become external rotators, is an option. Humeral osteotomy is typically reserved for the older child with residual internal rotation contracture.

SCOLIOSIS & SPINAL DEFORMITY

The spine is in balance when the head is aligned with the pelvis in the coronal and sagittal planes. Scoliosis is spinal curvature of more than 10 degrees in the coronal or frontal plane. Scoliosis is a three-dimensional deformity with concurrent rotational component that creates a rib and/or lumbar prominence. Deformity may also exist in the sagittal plane. Normal kyphosis ranges from 20-40 degrees. Scheurmann's kyphosis is defined as vertebral body wedging at three consecutive levels and greater than 40 degrees of kyphosis in the sagittal plane.

The etiology of spinal deformity in children may be congenital, neuromuscular, traumatic, or idiopathic (of unknown cause). The cause of deformity is an important determinant of the natural history, treatment options, and the goals of management. Any family history of scoliosis should be elicited.

► Clinical Findings

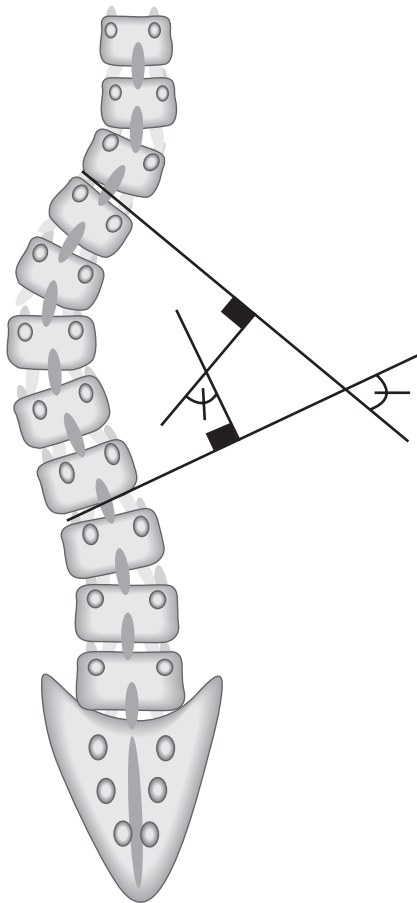

Spinal deformity may be recognized in the perinatal period or during infancy in children with congenital anomalies of the spine. Most commonly, deformity of the spine is detected during the preadolescent growth spurt, when the spine is growing most rapidly. Spinal deformity is most commonly detected by family members, sports physicals, and primary care physicians. Routine school screening using the Adams forward bending test has improved recognition. Scoliometer measurements of greater than 7 degrees are an indication for orthopedic evaluation.

Physical examination of the patient with spinal deformity includes both examination of the spine and a comprehensive examination. The location of the curve, deviation of the trunk from the midline (trunk shift), shoulder asymmetry, pelvic obliquity, and flexibility of the spine should be recorded. Clinical findings suggestive of intraspinal pathology, such as tethered cord or a syrinx include asymmetric abdominal reflexes, clonus, muscle weakness or contractures, and foot deformities. Patients with congenital scoliosis may have associated chest wall deformity and sacral dimples. Scoliosis due to connective tissue pathology may present with joint hypermobility.

► Imaging Studies

Spinal deformity occurs in three dimensions, and most imaging studies are limited by providing only a two-dimensional representation. Plain radiographs are useful for the detection of deformity and monitoring progression of deformity. The Cobb angle is used to measure deformity in the coronal and sagittal planes. An angular measurement is made between the end-vertebrae that are most tilted from the horizontal at either end of the curve (Figure 40–23). Other radiographic measures may include trunk shift relative to the pelvis and overall sagittal and coronal balance of the spine measuring a plumb-line between C7 and the sacrum.

MRI examination of the entire spine is an important imaging tool because of the association between intraspinal anomalies with certain types of spinal deformity. Congenital scoliosis may be associated with intraspinal abnormalities, including tethering of the cord, syringomyelia,

▲ **Figure 40–23.** Measurement of spinal deformity using the Cobb method.

diastematomyelia, diplomyelia, lipoma, teratoma, and neuroenteric cysts. MRI of the entire spine is indicated for patients with congenital scoliosis, patients with abnormal neurologic findings on physical examination, atypical curve patterns including left thoracic curves, as well as infantile and juvenile idiopathic scoliosis.

1. Idiopathic Scoliosis

Idiopathic scoliosis is the most common cause of spinal deformity in children and adolescents. The prevalence of adolescent idiopathic scoliosis is estimated at 2%-3% by age 16. Curves larger than 20 degrees are present in 0.3%-0.5% of adolescents. The ratio of affected males to females is equal in curves less than 15 degrees. However, for curves larger than 20 degrees, females are seven times more likely to be affected than males.

Nonoperative management of adolescent idiopathic scoliosis is intended to prevent progression of deformity during the growing years. Bracing is the only nonoperative treatment that has demonstrated efficacy in the management of progressive idiopathic scoliosis. Bracing is recommended for curves over 25-30 degrees in a child who remains skeletally immature. The efficacy of bracing is less predictable in larger curves.

► Treatment Options

Surgical management of adolescent idiopathic scoliosis is intended to prevent additional progression of deformity. Spinal fusion may be considered for curves greater than 45-50 degrees in patients when significant growth remains. The natural history studies of untreated idiopathic scoliosis suggest that curve size is a risk factor for curve progression once skeletally mature. Curves under 30 degrees at maturity are not thought to progress, curves 30-40 degrees progress 0.5 degrees/year and curves over 40 degrees progress 1 degree/year on average.

2. Neuromuscular Scoliosis

Neuromuscular scoliosis presumably develops from a lack of trunk control. The term encompasses a spectrum of disorders all of which result in some compromise of the patient's ability to control posture and trunk position. The severity of deformity is related to the severity of weakness or spasticity, the patient's age at presentation of neuromuscular pathology, and the rostral or caudal level of involvement within the spinal cord. A child with known neuromuscular disorder is monitored for progression of spinal deformity in concert with management of associated deformities involving the hips, feet, and upper extremities.

Neuromuscular scoliosis may present in patients with disorders involving upper motor neurons, lower motor neurons, or primary myopathies. Upper motor neuron disorders

may include cerebral palsy, spinocerebellar degeneration (Friedreich's ataxia, Charcot-Marie-Tooth disease, and Roussy-Levy disease), syringomyelia, spinal cord tumor, and spinal cord trauma. Lower motor neuron disorders include poliomyelitis, spinomuscular atrophy, myelodysplasia, dysautonomia, and trauma. Primary myopathies that may lead to neuromuscular deformity of the spine include muscular dystrophy, arthrogryposis, and congenital hypotonia.

Neuromuscular scoliosis characteristically presents with long, sweeping curves involving the thoracolumbar spine. This may result in imbalance of the trunk relative to the pelvis. Pelvic obliquity is common in neuromuscular scoliosis, resulting in poor sitting balance and skin breakdown. Pulmonary compromise may be an important feature of neuromuscular curves due to the combination of thoracic deformity with intercostal and accessory muscle weakness. The child with neuromuscular scoliosis often has comorbidities and functional considerations that are distinct from the patient with idiopathic or congenital scoliosis.

► Treatment Options

In the neuromuscular patient goals of treatment include sitting balance, prevention of sacral and ischial skin breakdown, and facilitating caregivers ability to assist with patient transfers and mobility.

Orthotics—including molded body jackets and thoracolumbar orthoses—may be useful in preserving sitting balance and preventing or delaying surgical stabilization. Indications for surgery include curve progression, poor sitting balance, and respiratory compromise. In the patient who is nonambulatory, fusion of the spinal column to the pelvis can be performed to correct pelvic obliquity.

3. Congenital Scoliosis

Congenital anomalies of the spine are caused by defects in the embryologic formation and segmentation of spinal elements. The formation of the spine begins during the third week of embryonic development. Abnormalities of either the notochord or the neural arch may lead to congenital anomalies of the spine. Congenital anomalies may include unilateral failure of formation (hemivertebrae and wedge vertebrae), failure of segmentation, rib fusions, and mixed or complex anomalies. These anomalies of the spine appear to be sporadic events and not hereditary. Because the cardiac and renal systems are developing simultaneously, these organ systems may also be affected. Routine cardiac evaluation and ultrasound of the renal system is recommended in patients with congenital scoliosis.

Progression of deformity in congenital scoliosis is dependent upon the type of vertebral anomaly, the position of the vertebral anomaly within the spine, and the growth potential for that segment of the spine.

► Treatment Options

Bracing has not been effective for congenital scoliosis and is not recommended. If progression of deformity is noted, surgical intervention is recommended. The goal of surgery in young patients is to prevent the development of a severe rigid deformity.

SEPTIC ARTHRITIS

► General Considerations

Infection is usually hematogenous and more frequent in infants exposed to invasive measures likely to cause bacteremia. The joint can be primarily involved, or secondary involvement may occur by spread of osteomyelitis from the proximal femur. Hip sepsis has also followed penetration of the joint during attempted blood aspiration from the femoral vein.

Staphylococcus aureus and *Streptococcus pyogenes* are the most common causative organisms.

► Clinical Findings

A. Symptoms and Signs

Refusal to bear weight, and pain with hip motion are early signs. Fever is unlikely in very young children, but sepsis may be suggested by generalized irritability and failure to thrive. Another focus of infection should increase suspicion. The hip is typically held flexed in slight abduction and external rotation. Attempts to move the hip are resisted and especially painful.

B. Laboratory Findings

The sedimentation rate and CRP are commonly elevated, but the white blood count may be normal. Leukocytes are abundant in the joint fluid and Gram-stained smears of fluid show microorganisms as well.

C. Imaging Studies

The early radiographic signs are subtle, with obliteration of soft tissue planes and a suggestion of capsular distention (Figure 40-24). Ultrasound imaging provides an early indication of a joint effusion and aspiration can be done under ultrasound guidance. Bone scan may initially be negative, especially in children under 6 months of age, but usually shows increased uptake around the involved joint before radiographic changes become evident. MRI may help identify associated osteomyelitis.

► Differential Diagnosis

Alternative diagnoses include fractures of the femur, acute osteomyelitis of the proximal femur, and iliopsoas abscess. Congenital hip dislocation is not painful and limited abduction with limb length inequality is noted. Transient

▲ **Figure 40–24.** Septic arthritis of the hip in a 2-year-old boy. **A.** Lateral radiograph shows signs of proximal femoral osteomyelitis. **B.** T2-weighted MRI showing large effusion in the hip joint and edema of the proximal femur.

synovitis typically presents with less severe symptoms, low-grade fevers, and responds to anti-inflammatory agents.

► Complications

Structural sequelae include pathologic dislocation and irreversible destruction of the femoral head and neck. Chronic persisting infection may also result.

► Treatment

Emergent surgical drainage is required. Side effects from a negative arthrotomy are so few that an aspiration is warranted if the diagnosis is uncertain. Gram-stained smears of intra-articular fluid guide the initial choice of parenteral antibiotic, which is modified if necessary according to the results of culture and sensitivity tests. Intravenous antibiotics are given until clinical improvement followed by oral antibiotics for 4 weeks.

► Course & Prognosis

If the diagnosis is made and surgical drainage performed in a timely fashion the long-term results are good. Delay and nonoperative treatment are predictably followed by the complications mentioned earlier in the chapter.

TRANSIENT SYNOVITIS OF THE HIP (TOXIC SYNOVITIS)

Transient synovitis is a common cause of a painful hip in young children. A respiratory illness often precedes the complaints of pain, which may be localized to the knee, thigh, or hip. The short duration of symptoms, absence of diagnostic radiographic signs, and nearly normal laboratory studies suggest a benign process. Children of any age may be affected, with the average age is 6 years. Perhaps the most important aspect of transient synovitis is recognition.

► Clinical Findings

A. Symptoms and Signs

When first evaluated, the child has rarely been symptomatic for more than a week. Pain in the lower extremity with activity (or even with rest) is the most common complaint. Limp and refusal to weight bear are also common. Passive range of motion of the hip must be checked and compared carefully with the opposite side. Normally, the child should be able to relax and motion should be free and easy without “guarding,” which is especially noticeable with rotation or at extremes of flexion or extension. Low-grade fever may be present, but the child does not appear ill.

B. Laboratory Findings

Although the white blood cell count and erythrocyte sedimentation rate may be somewhat elevated, they are usually normal. Hip aspiration, if performed to help clarify a confusing case, reveals clear synovial fluid with a low white cell count, no organisms on Gram-stained smears, and negative cultures for all types of organisms.

C. Imaging Studies

Radiographs are essential to rule out other diagnoses. X-rays are usually normal with transient synovitis of the hip. Hip ultrasound will show little or no effusion.

► Differential Diagnosis

Septic arthritis is the primary concern. Legg–Perthes disease (avascular necrosis), slipped capital femoral epiphysis, and, rarely, other forms of inflammatory joint disease such as RA or rheumatic fever must be considered.

► Treatment

Hospitalization for observation and serial clinical exams is often advised to ensure that an infection is not missed. The hip is placed at rest and anti-inflammatory agents are initiated. This almost always relieves symptoms promptly and also helps confirm the diagnosis. The child should then be reexamined to make certain that normal hip motion and comfort have been achieved. Anteroposterior and lateral x-rays are repeated in 2-3 months to ensure that avascular necrosis has not developed. Occasionally, signs of systemic reaction are more pronounced or the child continues to guard the hip longer than usual. In such cases, needle aspiration confirmed by arthrogram should be performed to rule out infection.

► Prognosis

Recurrent symptoms may develop after release from the hospital and resumption of activity but usually resolve with more rest.

DEVELOPMENTAL DYSPLASIA/DISLOCATION OF THE HIP

ESSENTIALS OF DIAGNOSIS

- Mechanical instability of the hip.
- Limitation of abduction.
- Limb length inequality if unilateral.
- Abnormal gait once walking begins.

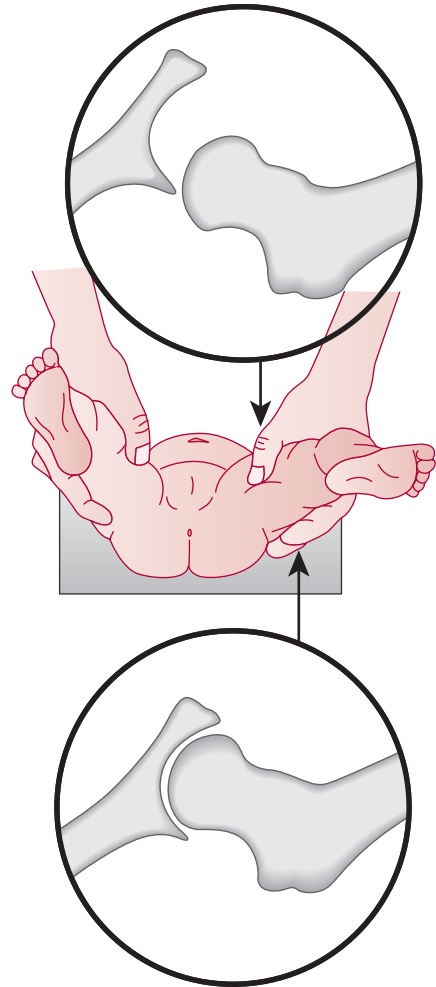

► General Considerations

Developmental hip dysplasia (DDH) may be detected at birth or develop early in life. The incidence of dislocation is 1 in 1000 infants. Both hips may be involved. DDH is more common in first born, females and with breech positioning. It is rarely painful or disabling to the child but results in significant symptoms in adults if left untreated. The hip may be dislocated by reducible, reduced but dislocatable or dislocated and not reducible.

► Clinical Findings

A. Symptoms and Signs

The physical signs of DDH are the key to diagnosis. They may be subtle, however, and can be missed by the most experienced examiner. This emphasizes the need for repeated evaluation of the hips during routine “well baby” checks.

▲ **Figure 40-25. Upper window:** Subluxation provocation test. Holding the thighs of the relaxed infant as illustrated, the examiner stabilizes the pelvis with one hand while gently but firmly trying to displace the opposite femoral head posteriorly out of the acetabulum. Adduction of the thigh aids this maneuver. If mechanical instability of the femoral head is present, a “jerk” will be felt, indicating that the hip is subluxable. **Lower window:** In Ortolani’s test, abduction and lifting with the fingers produces a corresponding jerk when the dislocated femoral head slides back into the acetabulum.

1. Dislocatable hip (Barlow positive)—The examiner attempts to displace the infant’s femoral head posterolaterally from the acetabulum by means of a provocation test (Figure 40-25). In a positive test, the femoral head is felt to displace out of the acetabulum. Mechanical instability—not a “click”—is the essential finding.

▲ **Figure 40-26.** **A.** X-ray of congenital dislocation of the right hip. **B.** Analysis of hip radiographs presupposes adequately exposed films of a properly positioned patient. Hilgenreiner's horizontal line is drawn through both triradiate cartilages (H), and Perkins's vertical line is drawn through the outer margin of each acetabulum (P). If the hip is located, the proximal femoral epiphysis will lie in the inferomedial quadrant formed by the two intersecting lines. Proximal or lateral displacement indicates dislocation. Abnormal acetabular development is suggested by lack of obvious concavity and by an acetabular index (θ) greater than 30 degrees.

2. Dislocated but reducible hip (Ortolani positive)—

Ortolani described relocation of a dislocated femoral head when the examiner abducts the flexed hip and lifts the greater trochanter anteriorly. The soft tissues surrounding the joint may not be lax enough to permit reduction. A fixed hip dislocation will result in limited abduction, apparent shortening of the affected side, and asymmetric thigh creases (if the dislocation is unilateral). As the child begins to walk, an abnormal gait becomes apparent. If dislocation is bilateral, the diagnosis is more challenging; the gait is “waddling,” and lumbar lordosis is prominent.

B. Imaging Studies

Until the cartilaginous acetabulum and femoral head become substantially ossified, x-rays may fail to indicate the true condition of the hip joint. Obvious abnormalities must be considered significant, but apparently normal radiographs do not exclude hip dysplasia until a well-ossified femoral head is adequately contained by the acetabulum. Femoral head ossification is usually present by 6 months of age but is may be delayed in DDH. Figure 40-26 shows several of the many radiographic relationships that are important for evaluation of the hip joint in infants. In older children, the femoral head should be adjacent to the radiolucent triradiate cartilage that forms the medial wall of the acetabulum. Displacement of the femoral head confirms dislocation. A shallow acetabulum that poorly covers the femoral head is termed dysplastic. Ultrasonography is the best technique for assessing the infant's hip prior to ossification of the femoral head.

► Differential Diagnosis

Proximal femoral focal deficiency and congenital coxa vara are rare conditions that produce shortening or instability in the hip region. Pathologic dislocation can occur rapidly in infected hips; the femoral head is displaced from a radiographically normal acetabulum. Hip dislocation may be caused by muscle imbalance in children with cerebral palsy or myelomeningocele.

► Complications

Complications include inability to gain or maintain a stable reduction, avascular necrosis of the femoral head following operative or nonoperative treatment, and limitation of motion.

► Treatment

A. Dislocatable hip

Neonates with confirmed dislocatable and reducible hips should be treated by means of abduction splinting (Pavlik harness) until stability is confirmed. It is important to flex the hips and abduct them no more than 60 degrees to avoid interfering with the blood supply and injury to the femoral nerve.

B. Dislocated hip

1. Birth to 18 months—In this age group, closed reduction is usually possible. Reduction can be maintained with

a spica cast. If closed reduction is not possible or cannot be maintained, open reduction is required. Arthrography and computed tomography are used to confirm reduction.

2. Eighteen months to 4 years—Open reduction is more likely to be required in this group. If adequate reduction is obtained, satisfactory results are more likely. Acetabular remodeling is best until age 4.

3. Older children and adults—Treatment of newly diagnosed congenital hip dysplasia in this age group is difficult. Acetabular remodeling through growth is minimal. Achievement of a concentric reduction does not ensure a stable pain-free hip. Salvage osteotomies of the innominate bone have been described for improving acetabular coverage of the femoral head. Pain and limitation of motion will eventually necessitate total hip arthroplasty for many of these individuals.

SLIPPED CAPITAL FEMORAL EPIPHYSIS (SCFE)

During the period of rapid skeletal growth in early adolescence, the normal relationship of the femoral head with the femoral neck may become disturbed by a shearing displacement through the growth plate—known as slipped capital femoral epiphysis. The head remains within the acetabulum, while the femoral neck shifts anteriorly and laterally. This displacement may occur in response to minor trauma, or it can be gradual, as indicated by reactive bone formation and remodeling of the femoral neck adjacent to the growth plate. An acute SCFE may be superimposed upon a gradual “chronic” one. Involvement is bilateral in at least 25% of cases. SCFE are considered stable if the child can bear weight, and unstable if weight bearing is not tolerated. The risk of avascular necrosis is reported to be near 50% for unstable SCFE. This condition can lead to severe deformity and may cause early degenerative joint disease.

► Clinical Findings

A. Symptoms and Signs

The patient typically reports pain in the knee or thigh and limps. Hip motion is limited especially flexion and internal rotation, with obligatory external rotation found on exam.

B. Imaging Studies

Radiographs are diagnostic in all but the most minimal slips (Figure 40–27). The epiphysis is not centered on the neck but rather relatively displaced posterior and medial. Since posterior displacement is often more marked, the displacement is more evident on the lateral view. Bony callus, or widening of the metaphysis adjacent to the growth plate, indicates a chronic slip. A significant SCFE produces a bony prominence on the anterolateral femoral neck, restricting hip motion.

▲ **Figure 40–27.** Left slipped capital femoral epiphysis. Note that a line extended along the lateral side of the femoral neck misses the capital epiphysis. On the normal right side, this line enters the femoral head, which should overlap the neck on both anteroposterior and lateral views.

► Treatment

Surgical stabilization of the proximal femoral epiphysis is advised. In situ pinning of the epiphysis without reduction is then performed. The surgeon should make sure that screw does not enter the joint space. Gradual mobilization with protected weight bearing follows. The goal of in site pinning is to prevent further slip and gain closure of the physis. The opposite side must be watched until the physis closes as well. If severe deformity prevents hip motion, a subtrochanteric osteotomy or excision of the bony prominence on the femoral neck may be considered.

PERTHES (LEGG–CALVE–PERTHES) DISEASE

Pertthes disease is an uncommon hip affliction that occurs in about one in 2000 children, generally between the ages of 4 and 10. Boys are affected five times as often as girls, but girls tend to have more severe involvement. About 10%-15% of patients have bilateral disease. The etiology is unknown but the hallmark is avascular necrosis of the proximal femoral epiphysis. Few patients achieve normal hip development. Others acquire permanent deformity of the femoral head, with limited motion and degenerative joint disease becoming symptomatic in middle age.

► Determinants of Final Outcome

A. Stages of Illness

The disease involves four stages: sclerosis, fragmentation, reossification, and remodeling. The earliest clinical signs are pain in the thigh and limping. Radiographs show an apparent increase in density of the capital epiphysis.

Later a subchondral crescent-shaped radiolucent fracture may occur, and the metaphysis may widen. The epiphysis becomes irregular and flattened during fragmentation. Gradually, reossification occurs and symptoms subside. The ultimate shape will depend upon the remodeling of the proximal femur with growth. A spherical head correlates well with good long-term results.

B. Age of Patient

Younger patients have a better prognosis. Boys generally have less severe involvement than girls.

C. Severity of Involvement

The lateral pillar classification divides patients with Legg–Perthes disease into three groups—according to the extent of involvement of the lateral pillar of the epiphysis relative to the central portion of the head; group A has minimal involvement the epiphysis involved, group B with 50% decrease in height of the lateral pillar, and group C, with involvement of the entire head.

D. The “Head at Risk”

Catterall proposed certain clinical and radiographic criteria for determining whether the femoral head might deform in the course of the disease. The clinical criteria are (1) obesity, (2) decreasing range of motion of the involved hip, and (3) adduction contracture. The radiographic criteria are (1) lateral subluxation of the femoral head, (2) Gage’s sign (widening of the lateral part of the growth plate, so that the superior portion of the femoral neck appears convex), (3) calcification lateral to the epiphysis in the cartilaginous femoral head, (4) diffuse metaphyseal reaction, and (5) a horizontal growth plate.

► Clinical Findings

A. Symptoms and Signs

Insidious development of limp and sometimes pain in the groin, anterior thigh, or knee eventually bring the patient to a physician. An occasional case presents as acute synovitis. Examination shows antalgic gait, decreased hip motion (especially abduction and internal rotation), and sometimes flexion-adduction contracture. Passive motion is guarded rather than free.

B. Laboratory Findings

Bone scan may help with early diagnosis and assessment of the extent of head involvement.

C. Imaging Studies

Well-exposed radiographs in both anteroposterior and frog-leg lateral views are essential. Findings will depend upon the

stage and severity of disease, as discussed above, but initial films usually show increased density and deformity of the femoral head epiphysis, which may be flattened or fragmented (Figure 40–28).

► Differential Diagnosis

The early inflammatory stage of Legg–Perthes disease can be confused with toxic synovitis and septic arthritis. The epiphysal abnormalities are similar to those seen in epiphysal dysplasias, hypothyroidism, and avascular necrosis from other causes, notably sickle cell anemia, Gaucher’s disease, and chronic use of corticosteroid drugs.

► Treatment

Treatment requires categorization according to the stage of disease, the extent of head involvement, and the condition of the hip joint at the time of presentation. The mobility of the involved joint must be determined and then followed as an important indicator of need for intervention and prognosis.

A. Observation

Children under the age of 6 without “at risk” signs typically do well with symptomatic treatment including activity restriction, stretching, and anti-inflammatory agents. In older children, if the femoral head remains contained in the acetabulum and motion is maintained observation is recommended.

Surgical Treatment

On occasion surgery is necessary to reorient the acetabulum or the proximal femur to achieve containment. Both innominate osteotomy and varus proximal femoral osteotomy have been successful.

▲ **Figure 40–28.** X-ray of Legg–Perthes disease, with significant deformity of right femoral head.

► Prognosis

Prolonged follow-up is necessary to determine the outcome. Long-term results are best correlated with the shape of the femoral head at the completion of skeletal growth.

FOOT DEFORMITIES IN CHILDREN

Positional deformities of the foot are described with the following specific terms. Equinus refers to plantar flexion. Calcaneus is the opposite position, or dorsiflexion. The forefoot alone may be in adduction, known as metatarsus adductus. The hindfoot deformity may be varus or valgus.

The goal of treatment of any foot deformity is a pain-free, flexible, plantigrade foot during normal gait.

1. Clubfoot

Talipes equinovarus, or clubfoot, is the most common foot deformity affecting approximately one in 1000 children. It occurs twice as often in boys and is bilateral half the time. There is a familial tendency, with a 5% chance that a sibling will also be affected. It can be idiopathic, or associated with an underlying syndrome.

► Clinical Findings

A. Symptoms and Signs

In clubfoot, there is varus of the hindfoot, adduction of the forefoot, and equinovarus deformity. The exact etiology remains uncertain. The joints principally involved are both the subtalar and talonavicular joints. The adjacent ankle and midtarsal joints are affected to a lesser degree. The overlying soft tissues are contracted. Successful treatment requires serial casting with correction of the deformities, cavus-adduction-varus-equinus, in that order as described by Ponseti. Surgical intervention is rarely required for clubfeet if treated early with casting.

► Treatment

Initial treatment is always nonoperative and should be started as soon as possible, preferably the day the infant is born.

A. Manipulation

Gentle manipulation into a corrected position should be done in order to stretch the contracted soft tissues—specifically, to align the calcaneus and navicular relative to the talus. Gentleness is required to avoid tissue trauma and to prevent overcorrection of the forefoot relative to persisting tarsal deformity.

B. Casting

After manipulation, a plaster cast is applied and molded to maintain the corrected position. Manipulation and cast

application are repeated weekly, typically for 6 weeks. Often a percutaneous tendoachilles lengthening is needed for residual equinus.

Casting is followed by application of Denis Browne bar with reverse last shoes worn at first full time and then at night and during nap times for two years. During this time, routine follow-up is required to monitor for recurrence.

C. Surgical Treatment

The traditional surgery involved a posteromedial release of the ankle and subtalar joints with realignment of the talonavicular and talocalcaneal joints. Surgery is rarely recommended for clubfoot.

2. Metatarsus Adductus

Metatarsus adductus is a common forefoot deformity that is often quite flexible. If passively correctable, there is an 85% chance of spontaneous correction by age 3 years. Easy passive correction also suggests that treatment is unnecessary. If the forefoot cannot readily be returned to a normal position, manipulation, and casting can be recommended. Only a very rare severe deformity will require surgical release or osteotomy and fusion of the tarsometatarsal joints.

3. Flatfoot

The normal newborn foot appears flat because subcutaneous fat fills the longitudinal arch. This fat deposit recedes over the first 4 years of life to reveal the typical adult appearance of a medial arch under the midfoot, which does not touch the floor with weight bearing. An inadequate bony arch, which permits the medial portion of the midfoot to bear weight, is the essential feature of true flatfoot. This deformity is further classified as rigid or flexible.

Rigid flatfoot is identified by the absence of normal mobility of the hindfoot. Rigid flatfoot presenting later in childhood is usually due to coalition of the tarsal bones. Associated episodic foot pain and spasm of the peroneal muscles are typical. Depending on the child's age and symptoms and the site of coalition, resection may be advisable or nonoperative treatment may suffice.

In flexible flatfoot, weight bearing obliterates the medial arch and also produces obvious valgus alignment of the calcaneus. Standing on tiptoes or sitting with the feet hanging free will restore the arch. Some patients with flexible flatfoot develop foot pain with weight bearing.

Treatment of asymptomatic flexible flatfoot in children is controversial. Parents distressed by the foot's appearance or by abnormal shoe wear often request treatment, but there is little evidence that treatment prevents future symptoms, and the majority of children with flexible flatfoot have no symptoms in adulthood.

The child with painful flexible flatfoot deformity deserves treatment. Exercises to stretch tight gastro-soleus muscle groups or to strengthen intrinsic plantar muscles are usually advised, and external support for the mediolongitudinal arch can be provided if necessary. If nonoperative treatment fails to control symptoms or if deformity precludes use of normal footwear, surgery may be considered.

SPORTS MEDICINE

PAIN SYNDROMES OF THE SHOULDER

1. Rotator Cuff Tendinitis and Subacromial Bursitis

► General Considerations

Inflammation within the glenohumeral joint is the most frequent cause of shoulder pain and limitation of motion. The patient is typically middle-aged. Repetitive overhead activity from occupation or sports is a common cause. The most common site of inflammation at onset is the insertion of the rotator cuff tendons, particularly the supraspinatus tendon. The location of the supraspinatus tendon between the greater tuberosity of the humeral head and the overhanging acromion process renders it particularly vulnerable to mechanical compression. The subacromial space is another common site of inflammation with subdeltoid soreness frequently radiating along the lateral humerus to the deltoid insertion.

► Clinical Findings

Night pain is common. Active abduction becomes especially painful when the inflamed rotator cuff and overlying bursa are compressed beneath the acromion. The range of active abduction may be extended if the patient is instructed to rotate the arms so that the palms face upward. This rotates the greater tuberosity posteriorly, so that the attached rotator cuff tendons pass behind the acromion, resulting in diminished pain with continued abduction.

► Treatment

The initial treatment of rotator cuff tendinitis and subacromial bursitis is with anti-inflammatory agents (naproxen, ibuprofen), and physical therapy to preserve motion. Slings and shoulder immobilization should not be used for more than a few days, since capsular adhesions and prolonged stiffness may result. Gentle passive range-of-motion exercises should be started as soon as tolerated, followed by active pendulum exercises. Active exercise is gradually increased while passive range of motion is continued.

If pain does not respond to oral anti-inflammatory agents, relief may be obtained by injection into the subacromial bursa.

2. Biceps Tendinitis

ESSENTIALS OF DIAGNOSIS

- Localized tenderness over the bicipital groove.
- Pain during supination of the forearm against resistance.

► General Considerations

A common inflammatory process producing shoulder pain involves the biceps tendon in the bicipital groove. Biceps tendonitis usually affects individuals whose occupation involves repetitive biceps flexion against resistance or whose recreational activities include forceful throwing of a ball. Pain is prominent over the anterior aspect of the arm and is aggravated by shoulder motion. Symptoms are worse at night and improve with rest. Deltoid muscle spasm may be present and may limit both active and passive motion.

► Clinical Findings

Biceps tendinitis can be distinguished from rotator cuff tendinitis by localization of tenderness to the bicipital groove. Forearm supination against resistance with the elbow flexed at the patient's side elicits extreme tenderness in the region of the bicipital groove when the tendon is palpated near the shoulder. Instability of the tendon in the groove is occasionally manifested by a snapping sensation as the arm is abducted and externally rotated. Subluxation of the tendons can be provoked by Yergason's maneuver, in which the patient actively flexes the elbow against resistance while the physician rotates the humerus externally. An unstable tendon will "pop" out of the groove.

► Treatment

Treatment of bicipital tendinitis includes cessation of offending activities and short-term immobilization of the shoulder in a sling and a trial of nonsteroidal anti-inflammatory agents. Surgery is occasionally required to stabilize a subluxating tendon. When discomfort has subsided, progressive mobilization is begun with exercises similar to those described in the section on rotator cuff tendinitis.

3. Adhesive Capsulitis (Frozen Shoulder)

ESSENTIALS OF DIAGNOSIS

- Diffuse shoulder pain
- Restricted shoulder joint motion

► General Considerations

A common cause of shoulder pain in middle-aged and elderly patients is adhesive capsulitis, or the so-called frozen shoulder. This disorder may complicate other inflammatory shoulder ailments, particularly in individuals immobilized for prolonged periods. It may also occur without any identifiable inciting trauma and has been associated with cardiovascular disease, diabetes, RA, and degenerative cervical spine disease. Though the exact pathogenesis is unknown, the end result is a chronically inflamed, contracted capsule densely adherent to the humeral head, the acromion, and the underlying biceps and rotator cuff tendons. Normal bursae are obliterated by scarring.

► Clinical Findings

A. Symptoms and Signs

The onset of symptoms is usually gradual and heralded by complaints of diffuse tenderness with disproportionately severe restriction of active and passive motion. Motion is not improved by lidocaine or corticosteroid injection.

B. Imaging Studies

Arthrography reveals a contracted joint capsule and no bursal filling. X-rays may reveal osteopenia of the humeral head.

► Treatment

The natural history of adhesive capsulitis is occasionally spontaneous resolution. Subsidence of pain and return of nearly full motion can be obtained, though the process may persist for 6 months to several years. Efforts to speed return of function have included intensive physical therapy and anti-inflammatory agents. Rarely, surgical intervention is required to release the capsule, and this can be done arthroscopically. Clearly, the best treatment of this condition is prevention. Prolonged disuse or immobilization of a painful shoulder must be avoided. Early mobilization is stressed, with initiation of gentle range of motion exercises and guidance by the physician and the physical therapist.

4. Dislocation of the Shoulder Joint

The shoulder (glenohumeral) joint is the most commonly dislocated joint in the body because it is less constrained than other joints and motion is possible in multiple planes. The constraints that prevent instability include the labrum, negative pressure of the joint, and glenohumeral ligaments. The rotator cuff also provides dynamic stability by compressing the humeral head against the glenoid. These static and dynamic stabilizers create a delicate balance between motion and stability.

Dislocations are usually related to overhead trauma when the arm is in abduction, extension, and external rotation.

Most traumatic dislocations are anterior, but posterior dislocations can occur. Shoulder instability is classified by several factors including traumatic versus atraumatic, initial versus recurrent, acute versus chronic, the direction of dislocation, and voluntary versus involuntary.

► Anterior Dislocations of the Shoulder Joint

Anterior dislocations can be diagnosed by history and physical examination. The arm is held in a position of slight abduction and external rotation. The anterior shoulder area appears full, and there is a vacant sulcus in the posterior shoulder area. Anteroposterior x-ray in the plane of the scapula and axillary x-ray are necessary to determine the direction of the dislocation and the presence of fracture. Humeral head impression fractures (Hill Sachs lesion) and glenoid rim fractures are easily missed if the radiographs are inadequate. Dislocation may also be complicated by injury to the brachial plexus (most commonly the axillary nerve) and rotator cuff tear. The examiner should check for sensory changes over the deltoid to assess the axillary nerve.

► Posterior Dislocation of the Shoulder Joint

Posterior dislocation is characterized by fullness beneath the spine of the scapula, flattening of the anterior shoulder, prominence of the coracoid, and restriction of motion in external rotation. The reported incidence of missed diagnosis is as high as 60%. The injury occurs either from direct or indirect force to the anterior shoulder, so that the humeral head is pushed out posteriorly. Common causes of posterior dislocation of the shoulder are seizures or electrical shock. Anteroposterior x-rays of the chest may look deceptively normal with posterior dislocation, but an axillary view and an anteroposterior x-ray in the scapular plane will show the true position of the head in relation to the glenoid. This dislocation may also be reduced by longitudinal and gentle transverse traction. The reduction may be held in a sling for 3-4 weeks with some external rotation if necessary.

► Multidirectional Instability

Patients with congenital or acquired laxity may develop symptomatic shoulder instability in multiple directions. These patients should be initially treated with rehabilitation and strengthening monitored by a physical therapist. Most of these patients recover stability with muscular strengthening of the rotator cuff and scapular stabilizing muscles.

► Voluntary Dislocators

Patients who voluntarily dislocate their shoulders have a high recurrence rate after surgical procedures. Therefore, surgery is usually avoided in this population.

► Treatment

The treatment of shoulder dislocations consists of closed reduction after careful examination and documentation of neurovascular status and good quality x-rays. Many methods of closed reduction have been described, including gentle traction in the prone position and traction-countertraction with a sheet. All methods of reduction rely on adequate analgesia and relaxation. Forceful reductions should be avoided because they may cause brachial plexus injury, vascular injury, or fracture. Postreduction x-rays document a concentric reduction and rule out any associated fracture. Once reduced, the arm is placed in a sling for 3-4 weeks before protected motion exercises are initiated.

Surgical reconstruction is indicated for anterior traumatic instability that is recurrent. The incidence of recurrent instability approaches 80%-90% for active young athletes. Therefore, the indication for surgery depends on age and activity level as well as the number of traumatic dislocations and associated fracture or soft tissue injury. After operative repair, the shoulder is usually immobilized in a shoulder immobilizer for 3-6 weeks before active motion is begun. Open and arthroscopic surgical repairs of the labrum for anterior dislocation are successful in preventing further episodes of dislocation in most patients.

5. Rotator Cuff Tears

Rotator cuff tears and rotator cuff impingement are common sources of shoulder pain. Four rotator cuff muscles (supraspinatus, infraspinatus, teres minor, and subscapularis) function to move the arm and stabilize the shoulder joint. There is a full spectrum of injury ranging from tendonitis to impingement and rotator cuff tears. The most severe condition is a massive, chronic rotator cuff tear that subsequently leads to proximal migration of the humeral head and arthritic changes of the humeral head known as rotator cuff arthropathy.

Patients with “rotator cuff syndrome” usually present with pain and weakness related to attempted overhead activities and active movements with the arm away from the body. Physical examination demonstrates impingement pain with certain overhead movements and rotator cuff weakness. Diagnosis is made by history and physical examination. Ultrasound and MRI are useful tests to evaluate rotator cuff tears and associated intra-articular pathology (Figure 40–29).

► Treatment

The treatment of shoulder pain related to rotator cuff pathology (inflammation, degeneration, and tear) depends on other patient variables such as age, activity level, hand dominance

▲ **Figure 40–29.** T2-weighted MRI showing a massive rotator cuff tear.

as well as the chronicity and level of pain and dysfunction. Tears may result from single event trauma (a fall on the outstretched hand), repetitive trauma (baseball pitchers), or degeneration of the rotator cuff in older patients.

Most cases of shoulder pain related to the rotator cuff tendonitis are initially treated nonoperatively. Activity modification, NSAIDs, and physical therapy can be beneficial. Some patients require a subacromial injection to control inflammation and pain. Rotator cuff tears can be treated with surgical repair. Acute traumatic rotator cuff tears should be repaired acutely in order to prevent rotator cuff atrophy and retraction. Acromioplasty and distal clavicle excision are performed at the same time if coracoacromial arch impingement contributes to the rotator cuff tear.

6. Glenohumeral Arthritis

Arthritis of the glenohumeral joint may be caused by OA, inflammatory disease, previous trauma, previous surgery, or arthritis of recurrent instability. Patients have pain with activities as in arthritis in other joints. They may also complain of stiffness, which is usually progressive over time. Physical examination discloses limited motion. Examination by proper shoulder x-rays shows the characteristic joint space narrowing and humeral head osteophytes.

Before operative treatment is elected, a thorough course of conservative measures is indicated. Surgery becomes an option for patients with significant pain and limitation of activity because of their arthritis. Shoulder arthroplasty (hemiarthroplasty, total shoulder replacement) can provide pain relief; however, motion is rarely restored to normal. Contraindications to total arthroplasty are active or latent septic arthritis, paralysis of the shoulder musculature, and neuropathic joints.

PAIN SYNDROMES OF THE ELBOW

1. Tennis Elbow (Humeral Epicondylitis)

ESSENTIALS OF DIAGNOSIS

- ▶ Tenderness over the lateral humeral epicondyle
- ▶ Pain at the elbow with resisted extension of the wrist

▶ General Considerations

Though far more common in nonathletes, humeral epicondylitis is commonly termed tennis elbow. This overuse syndrome is uncommon before age 18 years and most frequent in the fourth and fifth decades. Tennis elbow is commonly seen in nonathletes performing activities that require frequent rotary motion of the forearm, such as gardening, use of screwdrivers or wrenches, turning of doorknobs, and even operation of vehicles without power-assisted steering.

▶ Clinical Findings

Tennis elbow is characterized by tenderness and pain at the humeral epicondyle provoked by extension of the wrist. The origin of the inflamed common extensor muscle is the source of discomfort. The pain is readily reproduced with resisted extension of the wrist with the elbow extended.

Though the pathogenesis of tennis elbow is unknown, symptoms are usually attributed to inflammation of the origin of the common extensor muscle and, in some cases, to a tear in the origin of the extensor carpi radialis brevis. The tears are thought to be the result of repeated stress on degenerated tendon fibers. Elbow motion remains normal.

▶ Differential Diagnosis

Differential diagnosis includes radial nerve irritation at the elbow, which may often be delineated by electromyography (EMG).

▶ Treatment

A. Medical Treatment

Most patients with tennis elbow respond favorably to a brief period of rest and anti-inflammatory agents followed by a program of exercises to strengthen the forearm muscles. Subtendinous injection of soluble corticosteroids with lidocaine may be required in more severe cases. Repeated injections may further weaken tendons and should be avoided.

A nonelastic forearm band may be prescribed and worn near the elbow during occupational or recreational activities that aggravate the condition. The band is thought to be effective either because it limits full contraction of the tender

muscles or because it slightly alters the position of the extensor tendons.

B. Surgical Treatment

Rarely, patients with severe or refractory symptoms may require operative treatment. Most surgeons repair the origin of the torn wrist extensor tendon after excision of granulation tissue and any rough subjacent bone. Lengthening of the short wrist extensor results in loss of strength.

2. Olecranon Bursitis

ESSENTIALS OF DIAGNOSIS

- ▶ Tenderness and swelling over the olecranon
- ▶ Limited elbow flexion

▶ General Considerations

Olecranon bursitis is a common cause of periarticular elbow pain. Like epicondylitis, this condition is often related to occupational activities, in this case prolonged periods of leaning on the elbow.

▶ Clinical Findings

A. Symptoms and Signs

The subcutaneous olecranon bursa becomes distended, sometimes to dramatic proportions. The skin of the extensor surface of the forearm may be edematous and pitted. Traumatic bursitis is often only mildly painful despite marked swelling.

▶ Treatment

Treatment of idiopathic or traumatic olecranon bursitis consists of protecting the bursa from further pressure or irritation. Compression dressings may be necessary if symptoms are prolonged. Recurrence is not uncommon. Excision of the bursa may be required for rare persistent cases. The bursa must be totally excised and the overlying skin sutured to the olecranon periosteum to ensure obliteration of the space.

INJURIES TO THE LIGAMENTS, MENISCI, & CARTILAGE OF THE KNEE JOINT

Internal derangement of the knee joint mechanism is usually caused by trauma but can also result from overuse. Injuries to the ligaments, cartilage, and meniscus commonly occur as combined lesions.

X-rays are often normal in suspected ligament or cartilage injury. MRI is valuable imaging modality. MRI assists with preoperative confirmation of a clinical diagnosis.

Once a diagnosis is obtained, arthroscopy is a valuable diagnostic and therapeutic tool for the knee joint. The arthroscope is introduced into the knee joint through a small stab incision allows examination of structures inside. Meniscus tears, ligament reconstruction and chondral injury can all be addressed arthroscopically.

► Injury to the Menisci

Injury to the medial meniscus is the most frequent internal derangement of the knee joint. Clinical findings include swelling, pain, and varying degrees of restriction of flexion or extension. True locking (inability to fully extend the knee) is highly suggestive of meniscal tear. A marginal tear permits displacement of the medial fragment into the intercondylar region (bucket handle tear) and prevents either complete extension or complete flexion. Motion may cause pain over the anteromedial or posteromedial joint line. Tenderness can often be elicited at the joint line. Weakness and atrophy of the quadriceps femoris may be present. Injury to the lateral meniscus is less common. Pain and tenderness may be present over the lateral joint line.

Initial treatment may be conservative. Swelling and pain can be relieved by aspiration. Isometric quadriceps exercises should be performed frequently throughout the day with the knee in maximum extension, and the emphasis should be placed on restoring range of motion. Physical therapy and nonsteroidal anti-inflammatory drugs are helpful.

Arthroscopy with either meniscal debridement for central tears or meniscus repair for peripheral tears is recommended. Isometric quadriceps exercises and range of motion exercises are resumed and are gradually increased. As soon as the patient is able to perform these exercises comfortably, graded resistance maneuvers should be started. Exercises should be continued until motion and strength is equal to the other healthy knee.

► Injury to the Ligaments

Ligaments in general prevent displacement or angulation beyond its normal arc of motion.

A. Medial Collateral Ligament

The MCL is the primary restraint to valgus. Forced abduction of the leg at the knee causes injury varying from strain to complete rupture. The MCL is attached to the medial meniscus at the joint line.

A history of a twisting injury or direct blow at the knee with valgus strain can usually be obtained. Pain is present over the medial aspect of the knee joint. In severe injury, joint effusion may be present. Tenderness can be elicited at the site of the lesion. When only an isolated ligamentous tear is present, x-ray examination may not be helpful unless it is made while valgus stress is applied.

Treatment of an incomplete tear consists of protection from further injury while healing progresses in a brace that allows motion but protects the knee from valgus injury. It may be helpful to bend the brace into varus to take load off of the ligament.

Tear of the MCL is frequently associated with other lesions, such as tear of the medial meniscus and rupture of the anterior cruciate ligament.

B. Lateral Collateral Ligament

Tear of the lateral collateral ligament is often associated with injury to surrounding structures including the popliteus muscle tendon or the iliotibial band. Avulsion of the apex of the fibular head may occur, and the peroneal nerve may be injured.

Pain and tenderness are present over the lateral aspect of the knee joint, and hemarthrosis may be present. X-rays may show bone avulsion from the fibular head.

The treatment of partial tear is similar to that described for partial tear of the MCL. If complete tear is detected healing is rare without surgical intervention, and exploration and reconstruction is required.

C. Anterior Cruciate Ligament

The function of the anterior cruciate ligament is prevention of anterior displacement of the tibia relative to the femur. Injury to the anterior cruciate ligament is often associated with injury to the menisci or the MCL. The cruciate ligament may be avulsed with part of the tibial tubercle in children (Figure 40–30), but it usually ruptures within the substance of its fibers in adults.

▲ **Figure 40–30.** Lateral T1-weighted MRI image showing an acute rupture of the anterior cruciate ligament (arrow).

The characteristic clinical sign of tear of the anterior cruciate ligament is a positive lachman: the knee is flexed to 30 degrees and pulled forward, and excessive anterior excursion of the proximal tibia (in comparison with the opposite normal knee) is noted. MRI is helpful for identifying associated meniscal or chondral injury. Reconstruction is usually required for young active patients who wish to participate in sports that call for sudden cutting or twisting movements. Reconstruction is delayed until full range of motion is obtained. With avulsion, displaced tibial bone is present, and attachment of the fragment in anatomic position by arthroscopy is necessary.

D. Posterior Cruciate Ligament

Tear of the posterior ligament may occur within its substance or by avulsion of a fragment of bone at its tibial attachment. Tear of the posterior cruciate ligament can be diagnosed by the posterior “drawer” sign: The knee is flexed at a right angle, and the upper tibia is pushed backward; if excessive posterior excursion of the proximal tibia can be noted, tear of the posterior ligament is likely. MRI is very accurate for diagnosis of these injuries.

Bony avulsion of the PCL should be addressed surgically with reattachment. Isolated PCL tears can be treated nonoperatively. Treatment is directed primarily at the associated injuries and maintenance of competency of the quadriceps strength.

► Cartilage Injury

Damage to the cartilage is common with trauma to the knee and should be differentiated from OA. Developments in cartilage transplantation, including autograft and allograft reconstruction, have improved the prognosis for these injuries. Arthroscopy and MRI are required for accurate diagnosis (Figure 40–31). Cartilage can also be biopsied from the knee, cultured, and then emplaned at a later date.

► Ligamentous Reconstruction of the Knee

Knee joint instability may be (1) single plane (medial, lateral, posterior, or anterior), (2) rotatory, or (3) a combinations of the two.

Reconstructive procedures to replace the function of the anterior and posterior cruciate ligament include use of a portion of autograft or allograft tendon to recreate the native ligament. Indications for major reconstruction of knee ligaments depend on the patient’s age and activity level and the status of the articular cartilage within the knee.

PAIN SYNDROMES OF THE HIP

1. Bursitis & Tendonitis of the Hip

Bursitis and tendonitis are frequent causes of pain around the hip area. These conditions most commonly affect

▲ **Figure 40–31.** Intraoperative photograph showing a full-thickness cartilage injury.

middle-aged and elderly patients. Patients with a history of prior hip surgery, such as hip replacement or fixation of a hip fracture, may be especially prone to these conditions.

► Clinical Findings

A. Symptoms and Signs

A common complaint is the inability to sleep or rest on the affected side. The painful area is localized over the prominence of the greater trochanter, and the pain is reproduced by firm palpation. Hip bursitis may be associated with tendonitis of the hip abductors that insert onto the greater trochanter. Pain due to tendonitis may be reproduced with active hip abduction against resistance.

It is important to differentiate extra-articular sources of hip pain such as bursitis and tendonitis from intra-articular sources such as OA. Intra-articular pathology is suggested by pain localized to the groin, limited internal rotation, and reproduction of the patient’s pain at the extremes of rotation.

B. Imaging Studies

Plain radiographs are extremely useful in the evaluation of hip joint disorders.

► Treatment

Trochanteric bursitis often responds to rest, oral anti-inflammatory medications, and stretching. Corticosteroid injection is highly effective in refractory cases. Rapid relief of symptoms confirms injection of the proper area.

2. The Snapping Hip

The painful snapping hip is most commonly caused by the iliotibial band snapping over the prominence of the greater

trochanter. Less commonly, the iliopsoas tendon may be the cause of pain as it snaps over the hip joint capsule.

Snapping due to the iliotibial band can be reproduced with passive flexion of the hip starting from an adducted position. Snapping of the iliopsoas tendon may be reproduced with passive extension and internal rotation of the hip starting from a flexed and externally rotated position. Fluoroscopy after injection of the iliopsoas bursa with contrast can help to confirm this diagnosis.

Treatment usually consists of stretching and strengthening exercises. In rare circumstances, surgical release may be indicated for refractory cases.

JOINTS

ARTHRITIS

► General Considerations

Arthritis is an umbrella term for different inflammatory and noninflammatory disorders affecting synovial joints. Patients with advanced arthritis will experience pain, loss of motion, and joint deformity resulting in significant disability. Three major types of arthritis will be discussed in the following chapter: rheumatoid arthritis, spondyloarthritis, and osteoarthritis.

1. Rheumatoid Arthritis

► General Considerations

RA is a chronic inflammatory, autoimmune disease that attacks the synovial joints, causing a symmetric, erosive, deforming polyarthritis. RA is more common in women than in men affecting approximately 75 out of every 100,000 people. RA in many cases results in partial or total disability and is associated with a shortened life expectancy.

► Clinical Evaluation

Patients typically complain of joint pain, swelling, tenderness, and early morning stiffness that last greater than 1 hour and improve with activity. The joints most commonly involved include the MCP, PIP, and metatarsophalangeal (MTP). The cervical spine is often involved as well. In later stages of RA, tendon subluxation, tendon rupture, and joint destruction occur.

Currently, the most specific laboratory finding for RA is the presence of anticyclic citrullinated peptide antibodies. Approximately, two-thirds of RA patients will display these antibodies. Rheumatoid factor is a more sensitive but less specific laboratory finding, present in approximately ninety percent of patients with RA. Other common laboratory findings include presence of antinuclear antibody with homogenous pattern, elevated erythrocyte sedimentation

rate (ESR), elevated C-reactive protein (CRP), decreased hematocrit, and increased platelet count.

Radiographs typically show bony erosions and osteopenia. Joint space narrowing, bone resorption, deformity, dislocation, and fragmentation occur as the disease process progresses. “Protrusio acetabuli” (medial migration of the femoral head through the acetabulum into the pelvis is sometimes seen on x-ray.

► Etiology

Currently, tumor necrosis factor alpha (TNF-alpha) and interleukin-1b (IL-1b) are considered to be the major pro-inflammatory cytokines responsible for the pathogenesis of RA. When these two cytokines are secreted, they stimulate synovial cells to proliferate and produce collagenase which leads to cartilage degradation, bone resorption and inhibition of proteoglycan synthesis. Additionally, these two cytokines induce other inflammatory cytokines and matrix metalloproteinases which further contribute to and sustain the inflammatory cascade.

► Treatment

In the past, treatment of RA was purely for symptom relief, consisting of splinting and rest of inflamed joints with oral NSAIDs. However, with the advent of disease-modifying antirheumatic drugs (DMARDs) and anticytokine medications the actual progression of the disease has been curtailed in patients.

Currently, three TNF-alpha antagonists are approved for the treatment of RA in the United States: infliximab, etanercept, and adalimumab. When one of these three drugs are used in combination with methotrexate, patients experience better functional outcomes and less joint structural damage over the course of time when compared to patients who are treated with only one medication. Due to the increased risk of serious infection, especially tuberculosis reactivation, patients should be screened for TB prior to starting one of the TNF-alpha antagonists. Additionally, patients with demyelinating disease should not take one of these agents.

Glucocorticoids have also been used to treat active RA for several years. The immediate anti-inflammatory effects of glucocorticoids are well-known. However, glucocorticoids have severe long-term side effects that make their continued use undesirable. At this time, treatment with low-dose prednisolone for the first six months of treatment in combination with a DMARD (eg, methotrexate) is an acceptable management plan. However, after six months, the prednisolone should be discontinued in favor of other therapy.

Other treatment medications for RA include anakinra (IL-1 receptor antagonist), abatacept (T-cell modulator), rituximab (B-cell modulator), doxycycline (matrix metalloproteinase modulator), and statins (anti-inflammatory).

These medications may be considered when therapy with TNF-alpha antagonists is contraindicated.

For patients with severe arthritic change, joint-replacement surgery can provide excellent pain relief and improved function. Joints that can be replaced include the hip, knee, shoulder, elbow, and metacarpophalangeal joints. Additionally, fusion may be considered for diseased joints of the hand and wrist which are not amenable to replacement.

2. Seronegative Spondyloarthritis

► General Considerations

Spondyloarthritis encompasses a group of inflammatory arthritides characterized by spinal and peripheral joint oligoarthritis and enthesitis (fibrosis and calcification at the point of attachment between muscle and bone). This family of diseases includes ankylosing spondylitis (AS), psoriatic arthritis, enteropathic arthritis (associated with inflammatory bowel disease), reactive arthritis, and undifferentiated spondyloarthropathy.

3. Ankylosing Spondylitis

AS is a chronic inflammatory disease of the axial skeleton characterized by back pain, prolonged morning stiffness, and progressive loss of motion of the axial spine. There can also be sacroiliac involvement, arthritis of the hips, and peripheral arthritis. This disease typically affects young adults, with peak onset usually between 20 and 30 years of age. Males are more commonly affected than females. Over time, there is increased flexion of the neck, increased thoracic kyphosis, and loss of lumbar lordosis leading to a stooped posture. Radiographs will show squaring of the vertebral bodies early on. With disease progression, bridging syndesmophytes, ankylosis of the facet joints, calcification of the anterior longitudinal ligament, and atlantoaxial (C1-C2) subluxation may be noted.

Laboratory values have little role in the diagnosis of AS. ESR and CRP are often elevated. HLA-B27 is the only genetic locus definitively linked to AS; however, it is not specific.

Treatment with NSAIDs is very effective with significant improvement in back pain. Recently, TNF-alpha antagonists (infliximab, etanercept, and adalimumab) have been effective in the treatment of AS in clinical trials. As in patients with RA, tuberculosis screening should take place prior to the initiation of TNF-alpha treatment.

4. Psoriatic Arthritis

Psoriatic arthritis is chronic inflammatory disease characterized by skin lesions and arthritis of the peripheral joints. One-third of patients have arthritis of the spine as well. Patients may experience nail pitting and onycholysis (painless separation of the nail from the nail bed).

Psoriatic arthritis is commonly treated with NSAIDs. DMARDs such as methotrexate are also used with success. Like RA and AS, recent success has been demonstrated with the use of anti-TNF alpha agents.

5. Enteropathic Arthritis, Reactive Arthritis, and Undifferentiated Spondyloarthropathy

Enteropathic arthritis is the spondyloarthropathy associated with ulcerative colitis and/or Crohn's disease. Typically, the spondyloarthropathy in these patients progresses independently of the bowel pathology. Patients with reactive arthritis develop axial disease after exposure to an infectious agent such as Salmonella, Shigella, or Chlamydia. Undifferentiated spondyloarthropathy characterizes spinal disease without an adequate number of symptoms or signs to designate a specific type of arthritis. Treatment for these types of arthritides includes TNF-alpha inhibitors and NSAIDs.

6. Osteoarthritis

OA is a common age-related pathology characterized by damage to hyaline articular cartilage, synovitis, thickening of the joint capsule and bony remodeling. In contrast to RA, patients with OA will complain of joint pain worse with activity and short-acting stiffness after inactivity. Female sex, prior joint injuries, family history, and obesity are additional risk factors for the development of OA. Radiographs will often show joint space narrowing, sclerosis, and osteophytes.

Initial treatment includes NSAIDs or acetaminophen for pain relief and physical therapy to strengthen and improve the flexibility of muscles around the pathologic joint. A significant drawback to chronic NSAID treatment is the development of gastrointestinal toxicity including ulceration. Cox-2 inhibitors, such as celebrex, were introduced as anti-inflammatory alternatives without the same gastrointestinal side effects. However, due to concerns over possible increase in serious cardiovascular events, some Cox-2 inhibitors (rofecoxib and valdecoxib) were withdrawn from the market. At this time, there are Cox-2 inhibitors (celecoxib, etoricoxib, and lumircoxib), that have been shown to have similar efficacy for treatment of OA compared to nonspecific NSAIDs with fewer gastrointestinal side effects and without significant increase in the rate of serious cardiac events.

Exercise and weight loss are two additional interventions that are critical for the management of OA. Obesity is strongly associated with the development of OA. For the average person, their knees feel 3-6 times their body weight during activities such as walking and running. Moderate weight loss will reduce the pain and inflammation associated with OA, as well as slow the progression of this disease. Also improving the strength and flexibility of muscles around

joints through exercise will lead to better functional outcome and pain ratings.

Other treatment options include intra-articular injection of glucocorticoids and hyaluronans. These injections appear to improve pain in the short term, without many significant side effects. However, these treatments do not provide significant long-term relief for most patients, nor do they alter disease progression.

Glucosamine and chondroitin sulfate result in improved pain and function for some patients and no effect for other patients. Given that side effects are minimal, treatment with these two products is reasonable for those who have an improvement in their symptoms.

For severe cases of OA, surgery including total joint replacement may be considered depending on the state of the disease and patient characteristics.

7. Hip Disorders and Reconstruction

► General Considerations

In the United States 200,000 total hip replacements (THR) are performed annually for hip arthritis. The incidence of THR will continue to increase as the population ages. The causes of hip arthritis include childhood disorders such as developmental dysplasia, Legg–Calve–Perthes disease, slipped capital femoral epiphysis, as well as inflammatory arthritis, osteonecrosis, trauma, and infection. Although arthritis is the most common cause of hip dysfunction, there are other causes as well, for example, femoroacetabular impingement and “snapping hip syndrome.” Also patients will often complain of “hip pain” when their pain is actually lower back pain or pain over the greater trochanter or lateral thigh. As a result, thorough history, physical examination, and radiographic studies are crucial for differentiating among these different entities and making the correct diagnosis.

► Clinical Evaluation

True Intra-articular hip pathology typically presents as pain localized to the groin, exacerbated by internal rotation. Patients will often complain of difficulty with ambulation, climbing stairs, putting on shoes, and sexual intercourse.

Physical examination should include neurovascular documentation, hip range of motion, evaluation of the spine, and palpation for points of tenderness. Tenderness at the greater trochanter may be indicative of bursitis, which is often successfully treated with corticosteroid and lidocaine injection. True hip joint pathology should not result in pain that is reproducible with palpation.

Flexion contractures, asymmetric hip abductor weakness (Trendelenburg sign), and labral impingement signs (pain with flexion, adduction, and internal rotation or “FAI”) should also be tested for. Leg-length discrepancy should be noted as well.

It is important to recognize that although, groin pain, and exacerbation of pain with internal rotation or the FAI maneuver is indicative of pathology specific for the hip joint, the exact cause of the patient’s symptoms (arthritis, avascular necrosis, and impingement) still requires further delineation with additional physical examination maneuvers and radiographic testing.

Younger patients with hip pain may specifically complain of a “snapping” or “catching” sensation. Also known as the “snapping hip,” this may be caused by the iliotal band (IT band) snapping across the greater trochanter or the iliopsoas tendon snapping across the iliopectineal prominence. The IT band is likely the source if pain or snapping is reproduced with adduction and rotation of the hip while the patient is standing. The iliopsoas tendon is tested with the patient supine, moving the hip from a flexed and internally rotated position to an extended and externally rotated position.

Standard radiographs of the hip include AP view of the pelvis, AP, and frog-lateral of the pathologic hip. It is important to note any deformity of the femoral head, acetabulum, joint space, as well as any signs that may be specific to a particular disease process. For example, patients with developmental hip dysplasia often display a shallow socket with decreased anterior and lateral acetabular coverage on radiographs. A false-profile view (true lateral view of the acetabulum) may be performed to evaluate the degree of acetabular dysplasia present.

When plain radiographs fail to reveal a diagnosis, additional diagnostic imaging including MRI, CT, or bone scan may be performed looking for osteonecrosis, stress fractures, neoplasms, labral, or hyaline cartilage pathology.

If the clinical picture remains unclear or is complicated by concomitant spine pathology, intra-articular diagnostic injection of the hip joint with anesthetic may be performed.

► Femoroacetabular Impingement

Femoroacetabular impingement describes abnormal tracking between the femoral head and neck and the acetabulum through a normal range of hip motion resulting in pain and/or bony deformity. There are two types of femoroacetabular impingement: cam-type and pincer type. Cam-type impingement describes a femoral neck with prominent anterior bone that impinges on a normal acetabulum and labrum resulting in damage to one or both. Pincer-type impingement results from an anterior acetabular osteophyte that abuts the anterior femoral neck during hip flexion.

Femoroacetabular impingement can be treated with resection of the offending osteophytes or prominent bone, and debridement or repair of damaged labrum. These procedures can be performed through hip arthroscopy or an open approach.

► Avascular Necrosis of the Hip

Osteonecrosis of the femoral head can occur in young patients. Risk factors include steroid use, alcoholism, trauma, marrow-replacing diseases (such as Gaucher's disease), high-dose radiation treatment, and hypercoagulable states (sickle-cell disease, hypofibrinolysis, thrombophilia, protein S and C deficiencies). The disease course consists of decreased blood flow to the femoral head, resulting in osteonecrosis, subchondral fracture, and eventually collapse.

Standard AP and lateral radiographs of the hip often reveal the diagnosis. Of note subchondral fracture of the hip is most clearly seen on the lateral radiograph. If radiographs are nondiagnostic for a patient for whom osteonecrosis is suspected, MRI is the next step. The lateral and anterior aspects of the femoral head are most commonly affected.

Avascular necrosis of the hip may be classified according to the Ficat grading system: type I (no radiographic signs of AVN), type II (changes of the femoral head subchondral bone without collapse), type III (subchondral fracture with collapse), and type IV (collapse of the femoral head with changes on the acetabular side).

Unfortunately, without intervention, progression of osteonecrosis to collapse will occur in most patients. Patients with preclinical or asymptomatic osteonecrosis can be observed without surgical intervention. Symptomatic precollapse osteonecrosis may be treated with core decompression with or without bone graft, vascularized fibula grafting, or oral bisphosphonates. At this time, there is a paucity of data to definitively support one treatment over another.

Although, some studies have demonstrated success with treating postcollapse osteonecrosis with vascularized fibula grafts or rotational osteotomies, arthroplasty is the more reliable method of treatment. Treatment with unipolar and bipolar arthroplasty is initially successful, but often results in conversion to total hip arthroplasty due to eventual loss of acetabular cartilage and recurrent pain. Young patients who receive total hip arthroplasty with conventional polyethylene components experience a high rate of osteolysis and subsequent need for revision surgery. Currently, clinical trials are being performed to evaluate the use of alternative bearing surfaces and hip resurfacing surgery in this challenging patient population.

► Surgical Treatment Options for Hip Pathology

Surgical options for the hip include hip arthroscopy, osteotomies, resection, arthrodesis, and arthroplasty. Choice of treatment depends on the type of hip pathology being treated, patient characteristics, and the experience level of the surgeon.

A. Hip Arthroscopy

Hip arthroscopy typically involves the placement of two portals with the help of fluoroscopy. The arthroscope is inserted through one portal to visualize the hip joint and any pathology. The second portal serves as a “working portal” through which instruments such as debridors, shavers, or pincers are inserted to treat the pathology in question. This technique can be used to treat intra-articular and extra-articular hip pathology. Treatment of intra-articular pathology usually requires the aid of limb traction. Intra-articular indications include debridement of labral tears, loose body removal, chondral lesion debridement, osteophyte resection, biopsy, synovectomy. Extra-articular pathology such as the snapping hip may be treated with lengthening or releasing the iliopsoas and/or IT band. Complications of hip arthroscopy including pudendal and sciatic nerve palsies are becoming less frequent with improved patient positioning and surgical technique. More long term studies are needed to assess the efficacy of this technique.

B. Osteotomy

Osteotomy of the adult hip involves the use of saws or osteotomes to make bone cuts on the femur or pelvis. The resulting pieces of bone are realigned and fixed with plates and/or screws to correct deformity. Osteotomy is used to treat dysplasia, residual deformity from slipped capital femoral epiphyses, cerebral palsy with hip instability, and avascular necrosis. Choice of femoral or acetabular osteotomy is dependent on the pathology present and patient characteristics.

C. Resection Arthroplasty

Resection arthroplasty, aka “Girdlestone” procedure, involves complete resection of the femoral head without replacement. This procedure is a salvage surgery reserved for severe hip infection resistant to antibiotic treatment, failed total hip arthroplasty with unreconstructible bone defects, previous high-dose pelvic radiation exposure that would limit healing of a complex reconstructive procedure or patients with severe medical co-morbidities and limited functional needs who may not tolerate a longer procedure. Patients treated with resection arthroplasty will have a significant limb-length discrepancy that will likely require the use of a shoe-lift and/or other walking aides.

D. Arthrodesis

Arthrodesis of the hip may be indicated for patients with acquired (eg, trauma or infection) or developmental (such as dysplasia) hip abnormalities. The optimal position for arthrodesis is 5-10 degrees of external rotation, 20-30 degrees of flexion, and neutral adduction. Although pain

relief and function can be excellent, this procedure results in increased energy expenditure and late onset OA of the lumbar spine and knee due to increased joint stresses resulting from changes in the patient's gait.

E. Hip Arthroplasty

Hip arthroplasty involves the replacement of the femoral head and/or the acetabulum with manufactured components. Hemiarthroplasty may be performed replacing the femoral head without treatment of the acetabulum. Total hip arthroplasty entails replacement of the femoral head and placement of an acetabular component.

Hemiarthroplasty typically entails replacement of native the femoral head with a metal femoral head and neck. Indications include hip fracture in the elderly patient, avascular necrosis of the femoral head, and arthritis of the femoral head without acetabular disease. Hemiarthroplasty may be unipolar (one point of articulation between the metal femoral head and native acetabulum) or bipolar (two points of articulation: first point between the femoral head and acetabulum and the second point between the femoral neck and femoral head). Due to development of acetabular disease, many hemiarthroplasties are often converted to total hip arthroplasties with placement of an acetabular component. Although, bipolar hemi-arthroplasties offers the theoretical advantage of improved range of motion and decreased acetabular wear compared to unipolar arthroplasty due to the second point of articulation, these effects have not been demonstrated in clinical studies. Due to the significantly higher cost, most authors do not advocate the use of bipolar hemiarthroplasty over unipolar hemiarthroplasty.

Total Hip Arthroplasty involves replacement of the femoral head and placement of an acetabular component (Figure 40–32). Conventional polyethylene acetabular components with metal femoral heads have performed well at 15–20 year follow-up in older patient populations (greater than 60 years old). However in younger and or more active patients polyethylene wear and associated osteolysis (bone breakdown) represent the most common cause of long-term failure. Alternative bearing options such as ceramic-on-ceramic, metal-on-highly cross-linked polyethylene and metal-on-metal designs have been introduced to address these concerns.

Each of these bearing options has advantages and disadvantages. Ceramic-on-ceramic offers low wear rate without the production of metal ions; however, there is a reported 1%–3% “squeaking” rate and they can fracture resulting in catastrophic failure. Metal-on-metal produces metal ions that can significantly increase their concentration in the blood. To date, no increase in cancer rates or other side effects have been noted due to the metal ions. Metal-on-metal prostheses do not cause the squeaking side effects and are unlikely to fracture. High cross-linked polyethylene is

▲ **Figure 40–32.** Hybrid total hip replacement with porous coated acetabular shell and cemented femoral stem performed for osteoarthritis.

more forgiving with regards to the placement of the acetabular component. However, concerns regarding wear debris and subsequent osteolysis remain, although preliminary data suggests that the wear debris produced is significantly less than the regular cross-linked polyethylene.

F. Resurfacing Arthroplasty

Resurfacing arthroplasty is a type of total hip replacement that was first introduced in the 1970s. Resurfacing involves placement of an acetabular component in addition to replacing the surface (“resurfacing”) of the femoral head without resecting the entire femoral head or femoral neck. The resurfacing is typically done with a metal femoral component. This prosthesis interface initially did quite poorly, with high early failure rates related to wear debris, osteolysis, and subsequent prosthetic failure. Due to advances in metallurgy and other aspects of total joint technology, the resurfacing arthroplasty has produced short-term successful results and gained popularity in recent years. Resurfacing is ideal for younger patients without any cyst or other pathology of the

femoral neck. By preserving most of the femoral head and all of the neck, future total hip revision surgery if needed will be less difficult and demanding. Contraindications to this procedure include cyst or other pathology of the femoral neck, which can predispose to femoral neck fracture.

INFECTIONS ASSOCIATED WITH JOINT REPLACEMENTS

Infections that occur after total joint replacement may be caused by organisms introduced at the time of surgery or late hematogenous contamination. Medical providers should always maintain a high index of suspicion for infection in the patients with previous arthroplasty surgery. New onset pain or loosening of the prosthesis noted on x-ray is infection related until proven otherwise. ESR, CRP, and joint aspiration are part of the standard workup. Choice of treatment depends on when the infection occurs, the virulence of organism involved, and the stability of the prosthetic components. If the infection occurs within three weeks of the initial surgery, some authors advocate performing a washout with liner exchange. If infection occurs at a later

time and/or loosening is noted radiographically, resection of the prosthesis is typically recommended with interval placement of an antibiotic cement spacer (methylmethacrylate with impregnated antibiotic) and IV antibiotic treatment for at least 6 weeks. Once the infection has cleared, reimplantation of a new prosthesis may be considered. For chronically infected prostheses, fusion or resection arthroplasty may be considered.

TOTAL KNEE REPLACEMENT

Reconstructive surgical options for the arthritic knee (Figure 40–33) include high tibial osteotomy (HTO), unicompartmental knee arthroplasty (UKA), and total knee arthroplasty (TKA). Indications for reconstructive surgery of the knee include severe pain with or without deformity and radiographic evidence of arthritis for which conservative treatment (physical therapy, NSAIDs, corticosteroid joint injections) has failed. Choice of surgical treatment depends on patient characteristics in addition to the condition of the knee.

▲ **Figure 40–33.** **A and B:** Patient with RA and severe joint destruction of the right knee. **C and D:** Patient was treated with a cemented right total knee replacement.

► Total Knee Arthroplasty

TKA involves replacement of bone from the distal femur and proximal tibia with a metal component on the femoral side and polyethylene (or a metal tray with a polyethylene insert) on the tibial side. There are several types of TKA designs that vary in the degree to which they constrain knee motion. Choice of implant depends on the ligamentous stability of the knee and surgeon preference. A fully constrained prosthesis which only allows flexion and extension is typically used in knees with severe deformity and/or significant ligamentous instability. The literature reflects a significant success rate for TKA, with patients reporting good-to-excellent outcomes 85%–90% of the time. Factors associated with poor outcome as perceived by the patients include obesity, female gender, age less than 60 years old, and previous history of depression.

► Unicompartmental Knee Arthroplasty

UKA may be considered in the elderly individual (> 60 years old), with isolated medial or lateral compartment arthritis. The advantages of UKA over TKA include preservation of knee kinematics, decreased operative morbidity, and quicker rehabilitation time. However, UKA is contraindicated in patients with an anterior cruciate ligament-deficient knee, range of motion less than 90 degrees or flexion contracture more than 15 degrees and patients with arthritic disease in more than one knee compartment.

► High Tibial Osteotomy

The HTO may be considered in the young, active patient with isolated medial compartment arthritis, for whom TKA is an imperfect long-term solution. Patients with isolated medial compartment arthritis typically have varus deformity of the knee. The HTO will produce a valgus correction of this deformity and unload the diseased articular surface on the medial side. The short-term results of this procedure include reduction of pain levels and deformity correction; however, they typically deteriorate over time resulting in the need for additional surgery.

GLENOHUMERAL ARTHRITIS AND SHOULDER RECONSTRUCTION

Successfully treating the arthritic shoulder requires an understanding of the patient's functional demands, as well as the severity and quality of the patient's symptoms. A careful history and physical examination, along with the appropriate diagnostic studies will allow the treating physical to formulate an appropriate treatment plan.

History-taking starts with determination of the patient's primary complaint—is it pain, weakness, or loss of motion? Patients with significant glenohumeral arthritis typically complain of anterior or superolateral shoulder pain that is

worse with activity. Weakness with loss of motion due to inactivity may be noted as well. Posterior pain or radicular-type symptoms (pain that radiates from the spine down the back of the shoulder) is concerning for disorder of the spinal cord and should initiate the appropriate workup. Prior treatment, including physical therapy, injections, and any surgical procedures should be asked about as well.

Physical examination should note neurovascular status and the presence of any muscle atrophy. Particular attention should be paid to the integrity of the rotator cuff muscles (supraspinatus, infraspinatus, teres minor, and subscapularis) and deltoid muscles. The shoulder physical examination is described in greater detail in the sports section of this chapter. Cervical range of motion is assessed as well, along with the Spurling maneuver (test for cervical radiculopathy).

Radiographic studies include AP and axillary views of the shoulder. Glenoid erosion resulting in decreased humeral head offset from the lateral border of the acromion may be noted. Patients with associated rotator cuff disease may have superior subluxation of the humeral head with associated decrease in the acromiohumeral distance.

Early stages of shoulder arthritis can be treated nonsurgically with NSAIDs, intra-articular steroid or hyaluronic acid injections, and a physical therapy program that focuses on maintaining range of motion and strengthening exercises.

Patients with mild arthritis that does not respond to conservative treatment measures may pursue arthroscopic surgery. Debridement of any chondral lesions and loose body removal may alleviate mechanical symptoms, while arthroscopic lavage removing inflammatory enzymes and proteins from the joint fluid often provides pain relief.

For patients with significant arthritis, shoulder arthroscopy may or may not provide relief. If successful, this surgery represents a temporary solution that may relieve symptoms for a short period of time. Shoulder reconstructive surgery including humeral hemiarthroplasty, glenoid resurfacing, total shoulder arthroplasty, reverse total shoulder arthroplasty, and gleno-humeral fusion are the treatment options to consider. It is important to note that the primary indication for shoulder replacement surgery is debilitating pain. These surgeries may or may not improve the patient's range of motion and/or strength.

Patients with shoulder arthritis and an intact rotator cuff may be treated with total shoulder arthroplasty (replacement of the glenoid and humerus with prosthetic components) or hemiarthroplasty (resurfacing of the humerus) alone. Two recent prospective studies comparing the two procedures suggest that pain relief may be better and rate of revision surgery (conversion to TSA due to glenoid arthritis) may be lower for TSA compared to hemiarthroplasty. For patients with a deficient rotator cuff tear and arthritis, hemiarthroplasty is the preferred option, as superior humeral migration due to a deficient cuff leads to loosening of the

glenoid component. Biologic resurfacing of the glenoid with interposition graft (anterior capsule, fascia lata autograft, allografts) may be performed as well to address any arthritic change of the glenoid.

Reverse total shoulder arthroplasty which involves a convex glenoid and concave humerus may be used in elderly (> 70 years old) low-demand patients with a deficient rotator cuff and intact deltoid. This prosthesis places the center of rotation in the scapular neck, thereby increasing the lever arm.

Historically, shoulder fusion could be considered for the young laborer with severe arthritis due to long-term failure of shoulder arthroplasty. With the advent of glenoid biologic resurfacing, shoulder fusion has become a less common surgical option reserved for deltoid deficient arthritic shoulders.

ORTHOPEDIC SPINE

SPINE

Neck and back pain are two of the most common chief complaints in any outpatient clinic. Although most instances of these types of pain are related to muscular strain, neck and back pain may also be related to pathology of the spine. It is important for all healthcare providers to be able to distinguish between these two entities. True pathology of the spine requires timely referral to a Spine surgeon for evaluation and treatment.

► History and Physical Examination

A chief complaint of neck or back pain should prompt a thorough history and musculoskeletal examination including both the upper and lower extremities. Specific questions to ask regarding the pain include onset, characterization, intensity, radiation, and timing. Pain that radiates down a patient's arm or legs may qualify as a radicular symptom and is indicative of spine root pathology. Additionally, the patient should be asked about night sweats, fevers, nighttime pain, and weight loss which are red flags for infection or cancer. The presence of numbness, tingling, motor weakness, loss of bowel, or bladder control is indicative of spine root pathology. Arm or leg pain that occurs during walking or activity and is relieved immediately with rest may be due to neurogenic claudication indicative of spinal stenosis. Patients with lumbar stenosis and resulting leg pain, often state that their leg pain improves going upstairs or leaning over the grocery cart at the grocery store (flexion of the lumbar spine opens up the canal relieving the stenosis).

Physical examination includes strength, sensation, and reflex testing, gait observation and documentation of vascular status. Strength of muscles is graded according to the five point scale described in the Spine trauma

section. Neurosensory examination should also be carried out evaluating the C5-T1 dermatomes for neck pain and the L2-S1 dermatomes for back pain. Reflex examination includes the documentation of the biceps, triceps, brachioradialis, patella, Achilles, and the presence or absence of a Babinski. Wide-based gait may be indicative of cervical spine pathology.

When neurologic testing is abnormal, distinction should be made between radicular (root pathology) and myelopathic (spinal cord pathology) symptoms/signs. Radicular symptoms include complaints of radiating pain from the spine down the arms or legs. Loss of bowel and/or bladder control and groin/peri-anal numbness is indicative of sacral rootlet pathology. Radicular signs on physical examination include a positive straight leg raise (SLR; pain shooting down the back of the leg extending below the knee with SLR), positive Spurling's test (radiating arm pain with neck extension and rotation toward the pathologic side), specific muscle weakness (eg, biceps weakness on the right side only), specific dermatome numbness, and specific decreased reflexes. Myelopathic signs include diffuse muscle weakness below a certain level, hyperreflexia, clonus, positive Babinski, L'hermitte's sign (sensation of shooting pain down arms or legs with neck motion) and Hoffman's sign (the patient's middle finger is flicked into extension by the examiner resulting in unintended thumb and finger flexion).

1. Cervical Strain

► Clinical Findings

A. Symptoms and Signs

Cervical strain is characterized by paraspinal (next to the midline) neck pain with or without radiation to the shoulder. Oftentimes patients will display limitation of neck motion as well. These symptoms typically appear after an episode of overexertion or prolonged tension or poor posture. Specific points of deep tenderness with reproducible pain with palpation known as "trigger points" may be present. Pain is often characterized as deep aching or boring in sensation. Muscular spasm within the trapezius, levator scapulae, and paraspinal muscles may be palpable as a firm "knot." The patient may also complain of headache or dizziness. An important differentiating point from true spine pathology is that physical examination should not reveal any neurologic deficit.

► Imaging Studies

Radiographic evaluation starts with AP and Lateral x-rays of the cervical spine. Flexion-extension views should be considered in patients with precedent neck trauma, signs of RA, or Down syndrome to examine for instability. X-rays may

reveal degenerative change such as osteophytes, ankylosis of joints, or signs of instability. However, radiographs are often normal.

► Differential Diagnosis

One should consider cervical spondylosis and herniated cervical disk as part of the differential diagnosis. A patient with herniated cervical disk may complain of radicular symptoms in a specific dermatomal distribution, muscle weakness, and diminished sensation or paresthesias corresponding to the pathologic disk level. Additionally, diminished reflexes may be noted as well. Pain arising from cervical spondylosis (degenerative change) is often indistinguishable from that due to cervical strain.

► Treatment

Acute cervical spine pain is initially treated with rest and immobilization. Bracing with a soft collar, analgesics, and muscle relaxants are used as needed. However, the collar should not be used for more than 1-2 weeks to avoid cervical muscle atrophy. Ice, heat, and other modalities such as ultrasound and massage may be helpful as well.

Neck pain related to cervical strain usually subsides within 1 week from onset. Once the pain has diminished, the patient should begin physical therapy exercises to strengthen cervical muscles, improve posture, and increase range of motion.

2. Whiplash Injury

► General Considerations

“Whip-lash” is an acceleration-deceleration injury that occurs most commonly when the patient is rear-ended in a motor vehicle accident. Acute hyperextension occurs causing injury to anterior soft tissue structures of the neck, including the anterior longitudinal ligament, the intervertebral disk, the strap muscles, longus colli, and sternocleidomastoid muscles. When the vehicle decelerates, the head recoils into flexion, causing injury to the facet capsules, posterior ligaments, and paraspinal musculature.

► Clinical Findings

A. Clinical Evaluation and Imaging Studies

The symptoms after whiplash injury are often variable. Neck pain and stiffness are common. Occipital headaches and retro-ocular pain are also frequently noted. Spasm may manifest as decreased neck motion. Neurologic examination is normal. Radiographs are usually normal.

► Treatment

Management of whiplash injuries is similar for cervical strain: analgesics, rest, and immobilization in a soft cervical

collar until the pain is controlled, followed by gradual mobilization. Physical therapy exercises are initiated when range of motion normalizes.

3. Degenerative Cervical Disk Disease (Cervical Spondylosis)

► General Considerations

The degenerative changes of the spine that typically occurs with aging are collectively termed spondylosis. Most degeneration visualized on radiographs is asymptomatic. As a result, disk degeneration is considered a part of the natural aging process.

Cervical spondylosis is characterized initially by tears in the posterior annulus followed by fragmentation of the disk. The weakest area of the annulus is the posterolateral region, which is the most common site of bulging of the disk. With time uncovertebral joints and ligamentum flavum can hypertrophy, which along with prominent spurs and degenerative disk, may encroach onto the neural foramen and spinal canal, impinging on nerve roots and/or the spinal cord. Additionally, ossification of the posterior longitudinal ligament, which is particularly predominant in the Japanese population, can cause multisegmental cervical compression and myelopathy.

► Clinical Findings

A. Symptoms and Signs

Clinical symptoms may or may not accompany the degenerative changes of cervical spondylosis. Neurologic compromise may result from nerve root compression (cervical spondylotic radiculopathy) or compression of the cord itself (cervical spondylotic myelopathy) (Figure 40–34). Patients with cervical radicular symptoms typically complain of pain that radiates from the neck down into the shoulders and/or arms. Spurling’s test, as described above, may be positive. Patients with myelopathic symptoms may complain of L’hermitte’s sign (lightning pain down the spine with neck flexion), and/or difficulty with fine motor movements (buttoning a shirt) and balance.

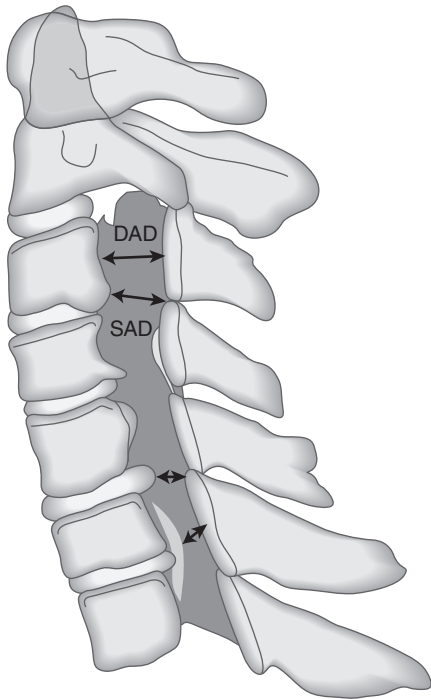

Physical examination of patients with cervical radiculopathy may show muscle weakness and diminished reflexes. Physical examination of patients with spondylotic myelopathy may be characterized by spasticity and clonus. An inverted radial reflex and a scapulohumeral reflex may also be seen. Positive Babinski and Hoffman signs may be present. Fine motion of the fingers may not be present, and intrinsic muscle wasting may be noted. The patient may have an abnormal gait characterized by wide-based, shuffling movements.

B. Imaging Studies

Radiographic findings of cervical spondylosis include narrowing of the disk space (Figure 40–35), osteophyte formation at the vertebral body margins, and arthritic degeneration of the facet joints. MRI is used to evaluate for nerve root or spinal cord impingement. EMG may be used as an adjunct study to confirm diagnosis by demonstrating generalized motor impairment resulting from motor neuron involvement.

► Differential Diagnosis

In addition to arthritis, radiculopathy or myelopathy may also be caused by tumors and vascular malformations of the spinal cord, syringomyelia, amyotrophic lateral sclerosis, subacute combined degeneration, and multiple sclerosis. MRI is the most useful study, in addition to thorough history and physical examination, to distinguish between these different diagnoses.

▲ **Figure 40–34.** The space available for the spinal cord in the subaxial cervical spine can be measured as the developmental anterior-posterior diameter (DAPD) in patients with developmental spinal stenosis and as the spondylytic anterior-posterior diameter (SAPD) in patients with cervical spondylosis.

▲ **Figure 40–35.** **A.** Lateral radiograph of a 50-year-old man with neck pain and myelopathy. **B.** Sagittal T2-weighted MRI showing spinal cord compression at C4-5 at the level of the spondylolisthesis.

► Treatment

A. Cervical Spondylotic Radiculopathy

Most patients with acute onset of cervical spondylotic radiculopathy have regression of symptoms over the course of 4-6 weeks. Progression to myelopathy is rare. Most patients achieve pain relief with rest, analgesics, and immobilization to relieve pain. Paresthesias and slight sensory changes may persist after neck and arm pain have subsided.

If pain continues, MRI of the cervical spine should be performed to investigate any areas of compression. If discrete herniation is present, surgical decompression with foraminotomy or discectomy with or without interbody fusion may be considered.

B. Cervical Spondylotic Myelopathy

Initial management of cervical spondylotic myelopathy involves the use of NSAIDs and cervical collar to minimize symptoms.

When symptoms are progressive, are not relieved by the use of a collar, or occur in younger patients, operative treatment may be necessary. Treatment depends upon the nature of the compression (disk, vertebral body, posterior osteophytes, hypertrophied ligamentum flavum, ossified posterior longitudinal ligament), the sagittal alignment of the cervical spine (kyphotic, neutral, or lordotic), and the number of levels involved. Compression confined to the intervertebral disks can be relieved by means of single-level or multiple-level anterior discectomies and fusion. When the disease is limited to two vertebral body levels or if there is a preexisting kyphosis greater than 15 degrees, anterior vertebrectomy, foraminotomy, and fusion with a strut graft

achieves decompression and stabilization of the degenerative segments. When the compression involves more than two vertebral body levels, the morbidity associated with the anterior approach increases significantly. As a result, a posterior decompression via multilevel laminectomy with or without fusion is recommended (Figure 40–36).

► Course & Prognosis

Most cases of cervical spondylotic radiculopathy resolve in 4–6 weeks with conservative management. With regards to cervical spondylotic myelopathy, the results of surgical management are better when symptoms are mild and of shorter

▲ **Figure 40–36.** **A.** Lateral postoperative radiograph of a patient who had multisegmental cervical stenosis and myelopathy treated with canal expansive cervical laminoplasty from C3 to C7. **B.** Postoperative axial MRI image showing significant canal expansion after the procedure.

duration. However, complete postoperative resolution of symptoms is rare even in these cases. Of note, the natural evolution of spondylotic myelopathy will often result in at least partial spontaneous remission. Chronic myelopathy and multiple-level involvement are associated with poorer surgical results.

PAIN SYNDROMES OF THE BACK

1. Low Back Pain

► General Considerations

In the United States, 400,000 workers are disabled by back pain each year. It has been estimated that 80% of the population suffers low back pain at some point during their lifetime. Due to its high prevalence all physicians should be able to differentiate between the multiple different etiologies of back pain.

► Clinical Findings

A. Symptoms and Signs

The most common cause of low back pain is mechanical strain. Patients complain of pain related to overexertion. Oftentimes patients in this group will demonstrate poor conditioning, abdominal muscle tone and posture.

Pain is often described as a deep-seated ache in the lumbosacral region. The pain is dull and somewhat diffuse, with or without radiation to the buttocks and hips. The pain is worsened by bending and relieved by inactivity. Palpation may reveal tenderness in the paraspinous area, with “trigger points” or “knots.” Spasm of the paraspinous muscles is a common finding.

Neurovascular exam including strength, sensation and reflexes are usually within normal limits. SLR test is normal. The SLR test is performed with the patient supine on examining table; the examiner lifts patient’s leg which is extended at the hip and knee, passively stretching the sciatic nerve with transmission of tension to the lumbosacral roots. Reproduction of pain down the legs is a positive test, indicating nerve root irritation.

B. Imaging Studies

Radiographic examination may reveal degenerative changes such as lumbar disk space narrowing and osteophytes or may be normal. X-rays should routinely be obtained. In persons over age 50, the presence of metastases should be evaluated. In patients under age 20, symptomatic congenital or developmental anomalies should be ruled-out.

► Treatment

Management of lumbar strain includes anti-inflammatory medication and rest during the acute phase. Lumbosacral

corsets may be considered for mechanical support. Abdominal conditioning and spinal muscle strengthening exercises are prescribed after the pain subsides. Typical exercises include bent-knee sit-ups and hamstring and spinal muscle stretching. Preventative measures should be presented to the patient, especially the correct manner of lifting objects while bending at the legs rather than at the spine.

► **Course & Prognosis**

The usual course of lumbar strain is spontaneous remission with time. Relapses of pain are common, often precipitated by heavy-duty activity. Patients with constant pain should be investigated for depression and or workman's compensation related issues, which may be contributing factors. Patients who fail to respond to conservative treatment should be investigated for neurologic compression via MRI. If no pathology is found, patients should be encouraged to return to normal activity as soon as possible. Prolonged reliance upon analgesics (especially opioids) should be discouraged.

2. Lumbar Disk Syndrome

► **General Considerations**

Patients may present with back pain and unilateral or bilateral leg symptoms. The back pain may be due to degeneration of the annulus fibrosis (outer layer of the disk) which contains many pain fibers. Degeneration of the annulus fibrosis may lead to herniation of the nucleus pulposis (central portion of disk) into the spinal canal impinging on neural elements, leading to leg symptoms. The postero-lateral portion of the lumbar disk is the weakest and as a result the most common location for herniation. These types of disk herniations are termed "paracentral" because they occur just lateral to the midline. Central disk herniations, which occur at the midline, occur less commonly.

The dural sac below L1 (conus modularis) contains only nerve rootlets (cauda equina). In the lumbar spine each nerve root emerges below its respective vertebra, just under the inferomedial border of its respective pedicle, and enters the neural foramen just above the intervertebral disk of that level. As a result, a paracentral disk herniation may compress the traversing root to the lower adjacent level. For example, an L4-5 paracentral disk herniation will compress the traversing L5 nerve root. In contrast, a far lateral disk herniation occurs near the exit zone of its respective neural foramen and therefore is most likely to compress the exiting root at that level, that is, a far-lateral disk herniation at L4-L5 will impinge upon the L4 nerve root. Due to their transition point status between the lumbar and sacral spine, the L4-5 and L5-S1 disk levels correspond to the region of maximal mechanical stress in the lumbar spine. As a result disk herniations are most likely at these two levels, and L5 and S1 nerve root pathology is most common.

► **Clinical Findings**

A. Symptoms and Signs

Back pain with sciatica (pain radiating down the posterior leg) is the most common presentation. The pain may be dermatome specific. The onset of leg pain is usually insidious, but pain may begin acutely when sudden disk herniation follows injury. Pain may be piercing, burning, or electrical in nature, accentuated by prolonged sitting or standing and relieved at least partially by rest.

Compression of nerve roots may produce objective sensory changes, with paresthesias and loss of sensation in the affected dermatome. With continued root compression, motor weakness may develop. Motor weakness corresponds to the specific myotomes innervated by the compressed nerve root. Muscle atrophy may accompany sensory and motor changes. Straight leg test may be positive.

► **Radiographic Evaluation**

Radiographs may show degenerative change including osteophytes and loss of disk height. MRI or myelogram are very sensitive and should reveal disk herniation if present. Care should be taken to specifically evaluate the location of the disk herniation including the disk level and the relationship of the herniation to the midline (central, para-central, or far-lateral).

► **Treatment**

Treatment of acute lumbar disk disease is controversial. If symptoms are produced by bulging rather than by extrusion of the herniated disk, conservative measures such as bed rest, analgesics, and anti-inflammatory medications often result in complete resolution of symptoms.

If symptoms continue or if neurologic symptoms progress or fail to respond to conservative measures, laminotomy and removal of the herniated disk may be required. Surgery is most successful in patients whose symptoms correlate with objective diagnostic study findings, that is, the patient with L4-5 para-central disk herniation and L5 nerve root symptoms (EHL weakness, pain/paresthesias in the L5 dermatomal distribution). Discectomy can be performed via standard microdiscectomy techniques or through a "minimally invasive" endoscopic approach.

3. Lumbar Stenosis

In the presence of severe disk space degeneration and spondylosis, a generalized narrowing of the lumbar spinal canal (spinal stenosis) without specific disk herniation can also occur. The etiology of lumbar spinal stenosis is multifactorial including: facet joint hypertrophy, disk degeneration and loss of disk height, and hypertrophy and buckling of the ligamentum flavum.

Spinal stenosis usually affects people in their fifties and sixties. Symptoms include generalized backache and stiffness. Narrowing of the lateral recess can occur causing unilateral nerve root symptoms, resulting in leg symptoms such as sciatica as well. Neurogenic claudication (back pain with radiating leg pain that is worse with activity and immediately relieved by rest) is a common complaint. This can be differentiated from vascular claudication by the immediacy of relief with rest (for vascular claudication, pain relief occurs only after minutes of rest).

For patients with spinal stenosis, extension leads to further narrowing of the canal exacerbating symptoms, while flexion of the spine provides symptom relief. Patients will often relate that it is easier to walk up stairs than down stairs (people have a tendency to lean forward or flex their spine when walking up stairs and lean backward or extend their spine when walking down stairs) and that walking hunched over a grocery cart helps their symptoms. On physical exam, diminished or asymmetric reflexes, specific motor weakness (extensor hallucis longus is most common), and decreased sensation in a specific dermatome may be noted.

► Imaging Studies

X-ray examination may reveal degenerative changes, such as disk space narrowing and osteophytosis, or the results may be entirely normal. A myelogram or MRI will confirm the diagnosis.

► Treatment

In the patient with persistent neurogenic claudication that fails to respond to conservative measures, foraminotomy or decompressive laminectomy is very effective in relieving symptoms and improving function. If spinal instability (degenerative spondylolisthesis) is also present, the spine should also be stabilized and fused over the affected levels.

4. Other Lower Back Conditions

In addition to the etiologies of back pain discussed above, one must also consider infection or tumor as possibilities. Additionally, conditions unrelated to the spine such as abdominal aortic aneurysm, pancreatitis, or pyelonephritis may also cause back pain and should be ruled-out when suspicion is present.

The most common extradural tumors in the adult spine are metastatic, most often from breast carcinoma in women and prostate cancer in men. Multiple myeloma also frequently involves the spine and often causes pain via lytic lesions that weaken bone and lead to pathologic fractures. Intradural spinal tumors (neurofibromas, meningiomas, and ependymomas) are much less common than metastases in adults. A history of primary tumors elsewhere, back pain worse at night, night sweats, fevers, or persistent bilateral

leg pain without back pain should arouse suspicion for cancer. Metastases of bone are often detected on routine x-ray studies. MRI should be ordered when radiographs are nondiagnostic.

Discitis and vertebral osteomyelitis can cause back pain in the absence of significant neurologic symptoms. Vertebral osteomyelitis can arise from a number of sources, including direct inoculation from iatrogenic procedures (injections, diagnostic studies), contiguous spread from a local infection, and hematogenous seeding (from infected vascular sites or urinary tract infection).

Once the infection is established in the metaphysis, it can subsequently rupture through the end plate into the adjoining disk and infect the adjacent vertebral body. The disk material is relatively avascular and is rapidly destroyed by bacterial enzymes. Osteomyelitis of the spine can extend into the spinal canal leading to epidural abscess or bacterial meningitis or the surrounding soft tissues resulting in local abscess. Destruction of the vertebral body and intervertebral disk can lead to instability and collapse. In addition, retropulsion of infected bone and granulation tissue into the spinal canal can cause neural compression or vascular occlusion. If a spinal infection is suspected, the pathogenic organism must be identified with biopsy or aspiration before appropriate treatment with antibiotics (with or without surgical debridement) can be instituted. An MRI with gadolinium is the best test for delineating the location of the infection as well as investigating for the presence of an epidural abscess (Figure 40–37).

5. Acute Cauda Equina Syndrome

Rarely, acute posterior midline disk prolapse at the L2-3 level may cause compression of many nerve roots in the cauda equina. This is known as acute cauda equina syndrome. Symptoms include intense leg pain in one or both extremities, muscle weakness, urinary retention, and decreased rectal tone with subsequent loss of bowel/bladder control. An MRI of the lumbar spine will reveal the site of compression, which must be treated by emergent decompression.

6. Mechanical Back Pain

► General Considerations

People with long-standing lumbar disk disease may develop numerous degenerative changes in the involved segments. Collapse of the disk results in abnormal motion anteriorly between the vertebral bodies and posteriorly between the intervertebral facets, leading to osteophytosis.

► Clinical Findings

Symptoms arise from inflammation surrounding the abnormal facets and generally include diffuse aching that may or

▲ **Figure 40-37.** Sagittal MRI images of a patient with low back pain due to L5-S1 discitis, vertebral osteomyelitis, and a small anterior epidural abscess. **A.** T1-weighted image. **B.** T1-weighted image with gadolinium vascular contrast. **C.** T2-weighted image.

may not radiate into the buttock or posterior thigh. Patients may also complain of postural discomfort and “locking” of the low back during stooping or attempts to straighten the back after forward bending.

► Diagnosis and Treatment

Radiographs may show osteophytes and narrowing of the disk spaces suggestive of degenerative change. Patients demonstrating symptoms suggestive of facet syndrome should be initially treated conservatively with rest and anti-inflammatory agents. Fluoroscopically guided injection of the lumbar facets with corticosteroids and lidocaine may be diagnostic and therapeutic. For patients who fail conservative therapy, lumbar fusion by anterior or posterior techniques may be considered to eliminate abnormal motion. However, the results of these surgeries have been inconsistent.

ORTHOPEDIC ONCOLOGY

INTRODUCTION

Bony lesions may be primary (of mesenchymal origin) or secondary (metastases, myeloma, and lymphoma). Bony metastases and myeloma are significantly more common than primary bone tumors, particularly in older patients. Primary bony lesions can be grouped into three types: malignant tumors (sarcomas), benign tumors, and reactive or miscellaneous lesions. Sarcomas tend to spread hematogenously, most commonly to the lungs. Benign bone tumors vary widely, and may be small and inconsequential or large and destructive.

PRESENTATION

Regardless of the type of lesion, most patients present with musculoskeletal pain, typically deep and dull in character. This may initially be intermittent and activity-related, but over time often becomes constant. Patients with a suspected bony lesion require careful physical examination. In the elderly, bony metastasis should be a significant concern, and should prompt evaluation for a distant primary tumor. Standard AP and lateral views of the area of concern should be obtained. If concerned for malignancy, a chest x-ray should be obtained. CT scan and MRI are useful adjuncts for characterizing bony lesions.

RADIOGRAPHIC FEATURES OF BONY LESIONS

Plain radiographs can significantly narrow the differential diagnosis for bony lesions. Specific attention must be paid to the anatomical site of the lesion, the zone of transition between lesion and normal bone, and internal characteristics of the lesion. Benign lesions tend to be slow-growing. While benign lesions can destroy cortical bone, a transitional rim of reactive periosteal bone is typically formed around the neoplasm. High-grade malignant lesions tend to grow rapidly, and host bone has little ability to wall off the lesion with a rim of periosteal bone. Correspondingly, aggressive lesions often have a poorly demarcated transitional zone. High-grade lesions frequently destroy cortical bone and can spread to adjacent soft tissue. Note should also be made of calcification or ossification within the lesion. Calcification appears more haphazard and frequently more dense than ossification, and often denotes a cartilaginous tumor. Ossification indicates

production of mineralized matrix giving the appearance of organization or structure, and is more common in tumors of bony origin.

BIOPSY AND SURGICAL TREATMENT

Biopsy is generally performed only after the lesion has been well-characterized by physical and radiographic examination. If a lesion is found to be malignant, the entire biopsy tract must be removed at the time of tumor resection. As such, the biopsy site and tract should violate as few intrafascial compartments to prevent seeding adjacent compartments with tumor and limit the extent of necessary resection. Transverse incisions should be avoided. Frozen sections should be sent to confirm an adequate sample of the lesion has been obtained; samples should also be sent for culture as infection can masquerade as an aggressive-appearing lesion.

Surgical treatment is directed toward removing the entire lesion and preventing local recurrence. In general, more extensive resection confers a lower risk of local recurrence. Four types of tumor resection have been described:

1. **Intralesional** Dissection proceeds through the tumor itself (eg, curettage)
2. **Marginal** Resection through the reactive zone of the tumor, which contains inflammatory cells, fibrous tissue, and possible satellite metastases
3. **Wide** Entire tumor is removed with a surrounding cuff of normal tissue
4. **Radical** Removal of tumor and its entire surrounding fascial compartment

STAGING

Staging for malignant musculoskeletal lesions is based on the histologic grade of the lesion, its location (intra vs. extracompartmental), and the presence of distant metastases. Grade (G) assesses the histologic characteristics of the tumor. G₁ lesions appear less aggressive and have a lower risk of distant metastasis. Increasing grade in G₂ and G₃ lesions denotes more aggressive cytologic features and increases the risk of distant metastasis. Tumor size (T) includes lesions within their capsule (T₀), extending through the capsule but within the compartment of origin (T₁), and beyond the compartment of origin (T₃). Metastasis (M) includes no metastases (M₀), and the presence of metastases (M₁).

CHEMOTHERAPY AND RADIATION

A detailed discussion of chemotherapeutic and radiation regimens for various musculoskeletal neoplasms is beyond the limits of this text. Modern chemotherapeutic regimens offer significant benefits in disease-free survival for osteogenic sarcoma and Ewing's sarcoma. Neoadjuvant

(preoperative) chemotherapy is becoming more popular in treating these cancers. Radiation is effective in local treatment of Ewing's sarcoma, osteosarcoma, lymphoma, myeloma, and metastatic bone disease.

METASTATIC BONE LESIONS

Metastases from remote primary tumors represent the majority bone tumors seen in adults. Of these, most are derived from carcinomas from the breast, prostate, lung, kidney, thyroid, pancreas, and stomach. While breast and prostate cancer metastases commonly result from a known primary cancer, bony metastasis of unknown origin frequently stems from lung or renal cancer. The presence of a lytic bone lesion in an adult older than 40 without a diagnosis of a primary cancer should prompt the following investigation, which successfully identifies the primary tumor in 85% of cases:

- Plain radiographs of the affected limb, chest x-ray, CT scan of the chest, abdomen, and pelvis.
- Technetium bone scan to detect multiple lesions.
- Skeletal survey (if myeloma is suspected).
- Complete blood count, serum chemistry, liver function tests, erythrocyte sedimentation rate, and serum or urine immunoelectrophoresis.

Metastases are most commonly observed in the pelvis, ribs, vertebral bodies, and proximal limbs. These lesions typically have a lytic appearance on plain radiographs, although breast and prostate metastases can be sclerotic or mixed with lytic and sclerotic features. Metastases from renal cell carcinoma tend to be extremely vascular, and angioembolization is an important consideration prior to biopsy or definitive surgical treatment. Of note, bone destruction is not caused by the malignant cells but rather through induction of local osteoclasts by the metastasis. As a result, bisphosphonate therapy has come into common use in cancer patients.

Multiple myeloma is a common malignant tumors affecting bone. It is a plasma cell disorder most commonly affecting patients between 50 and 80. Patients most often present with bone pain or pathologic fracture. Vertebral and large bone involvement is most common. Radiographs commonly demonstrate multiple punched-out, lytic bone lesions. Patients with multiple myeloma should undergo a skeletal survey to evaluate for other lytic lesions as bone scan is frequently uninformative.

Surgical intervention for metastatic bone lesions is centered around reducing pain and maintaining functionality. Internal fixation is performed prophylactically if an impending fracture is observed. Risk factors for pathologic fracture include greater than 50% destruction of diaphyseal cortices, greater than 50%-75% metaphyseal destruction, destruction of the subtrochanteric region of the femur, and persistent pain following radiation therapy.

COMMON PRIMARY MALIGNANT BONE TUMORS

► Osteosarcoma

Osteogenic sarcoma is the most common primary malignant tumor of bone. It is more common in men, and most commonly occurs in children and young adults about the knee (Figure 40–38). Other common locations include the proximal humerus and proximal femur. Histology demonstrates osteoid production with malignant stromal cells. Most lesions are high-grade and penetrate the cortex, forming an extramedullary soft tissue mass. Plain films show a destructive lesion demonstrating some bone formation. Modern chemotherapy regimens have significantly increased survival and feasibility of limb-sparing approaches. Treatment consists of neoadjuvant chemotherapy followed by resection and maintenance chemotherapy. Less common subtypes of osteosarcoma include telangiectatic, parosteal, and periosteal.

► Chondrosarcoma

Chondrosarcoma results from malignant cartilaginous cells with peak incidence in the fifth and sixth decades. It commonly occurs in the knee, shoulder, pelvis, and spine. Plain films demonstrate cortical thickening and stippling consistent with cartilage deposition. Determining malignancy in cartilaginous cells based solely on histologic examination is difficult; clinical history and imaging are essential for correct diagnosis. Chondrosarcomas tend to be Grade 1 or 2 and less aggressive than osteosarcoma. Surgical resection with wide margins is the treatment of choice. Dedifferentiated chondrosarcoma is a subtype containing highly aggressive spindle-shaped cells. Prognosis is poor, and treatment consists of wide-margin resection and chemotherapy.

► Ewing's Sarcoma

Ewing's sarcoma is a small, blue cell tumor with a characteristic t(11:22) chromosomal translocation. It commonly occurs in children older than five years and in young adults. Children younger than five years with a small blue cell tumor should have leukemia and metastatic neuroblastoma excluded before the diagnosis of Ewing's is made. Likewise, metastatic carcinoma must be excluded in adults. Pain and fever are common presenting complaints, with many patients having elevated inflammatory markers and a leukocytosis (which can be confused with osteomyelitis). The pelvis, knee, proximal humerus, and femur diaphysis are the most common locations. Plain films demonstrate a destructive, frequently diaphyseal lesion. The classic "onion-skin" appearance of multiple layers of reactive periosteum is uncommon; more commonly the appearance is lytic with variable amounts of

▲ **Figure 40–38.** Osteosarcoma with Codman's triangle, a new area of subperiosteal bone formed when a tumor raises the periosteum away from the bone.

reactive bone. Treatment including chemotherapy, radiation, and surgical intervention can produce long-term survival approaching 70%.

► Lymphoma of Bone

Lymphoma of bone can occur as a solitary focus, scattered through bone and soft tissue, or as a metastasis to bone. It

can affect patients at nearly any point in life. Pain and a large soft-tissue mass are common. The knee, pelvis, hip, shoulder, and vertebrae are commonly affected. Bony destruction with a variable degree of reactive bone is characteristic on plain film. Treatment centers around chemo- and radiotherapy. Surgical intervention is indicated for impending or pathologic fracture fixation.

COMMON BENIGN BONE LESIONS

► Osteoid Osteoma

Osteoid osteoma is a benign bone lesion typically producing pain in patients from 5 to 30 years of age. Progressive pain, particularly at night, is characteristic. The lesion is commonly found in the proximal femur, spine, and tibial diaphysis. Plain films typically show a radiolucent nidus with a sclerotic, reactive rim. Bone scans are always positive. Often, pain is well-relieved with NSAIDs, and 50% of lesions will “burn out” with conservative management. For persistent pain, percutaneous radiofrequency ablation of the nidus is highly effective.

► Enchondroma

Enchondromas are benign cartilaginous tumors commonly found in the metaphyses of long bones and the hand, where pathologic fractures can be common. Plain films demonstrate a lytic lesion with a stippled appearance. Most enchondromas can be observed and followed with serial radiographs at 3 months and 1 year after presentation. Treatment, if necessary, consists of curettage and bone grafting. Malignant transformation to chondrosarcoma is exceedingly rare, except in two cases: Ollier’s disease is characterized by multiple enchondromas, and confers a 30% risk of chondrosarcoma. Maffucci’s syndrome includes multiple enchondromas with associated soft tissue angio-mas. Both diseases also confer increased risk of visceral malignancy.

► Osteochondroma

Osteochondroma is a benign surface lesion of bone characterized by a cartilaginous cap connected to the medullary cavity of the underlying bone. It can be pedunculated or sessile. If asymptomatic, observation is sufficient. If painful, resection is appropriate. Multiple hereditary exostosis is an autosomal dominant condition in which patients have multiple osteochondromas. Although malignant transformation in isolated lesions is rare, multiple hereditary exostosis confers a higher risk (approximately 10%).

► Giant Cell Tumor of Bone

Although benign, giant cell tumors can be locally aggressive. GCT is more common in females, and typically occurs in

▲ **Figure 40–39.** Giant cell tumor of proximal humerus.

the epiphysis of long bones after the physis has closed. The knee, vertebra, distal radius, and sacrum are common sites. Plain films demonstrate a metaphyseal lytic lesion extending to the epiphysis (Figure 40–39). Treatment consists of cortical windowing, aggressive curettage, chemical cauterization with phenol, and bone grafting. If inoperable, radiation can be employed. Rarely, primary giant cell tumor can be malignant or can undergo secondary malignant degeneration (most often following radiation exposure).

► Aneurysmal Bone Cyst

Aneurysmal bone cysts (ABC) are benign, but can be associated with other tumors, including GCT, chondroblastoma, and fibrous dysplasia. It can also be found within a malignant tumor. Seventy-five percent of patients are less than 20 years old. History consists of pain and swelling over months to years. Plain films demonstrate an expansile lesion with a thin rim of cortical bone. ABC is characterized by a blood-filled interior without an endothelial lining. Occasional thin septae of bone may be present. Treatment is curettage with bone grafting, and recurrence commonly occurs if physes are open.

► Unicameral Bone Cyst

Unicameral bone cysts are characterized by cystic expansion and cortical thinning. They are most commonly observed in the proximal humerus, proximal femur, and distal tibia. Patients commonly present with pain or pathologic fracture. Radiographs demonstrate a mildly expansile lytic-centered lesion with thin surrounding cortices and trabeculae

(Figure 40–40). Active lesions border the physis, while latent lesions have interposed normal bone. First line treatment consists of aspiration and cytologic examination of the fluid followed by methylprednisolone injection. Curettage and bone grafting are used if this proves ineffective.

▲ **Figure 40–40.** Unicameral bone cyst with fracture.

► Fibrous Dysplasia

Fibrous dysplasia is a developmental disorder of bone. It can be solitary (monostotic) or present in multiple locations (polyostotic). McCune–Albright syndrome is diagnosed when the polyostotic form is associated with café-au-lait spots and endocrine abnormalities. While nearly any bone can be involved, the proximal femur is the most common location. Plain films demonstrate a lucent lesion surrounded by a well-defined sclerotic rim; the lesions can range from purely lytic to having a ground-glass appearance. Most patients do not require surgical treatment; however, curettage, bone grafting, and internal fixation are appropriate in areas of high stress or pathologic fracture.

► Osteomyelitis

Osteomyelitis can mimic bone tumors. Patients frequently present with bone pain, fevers, and chills. Constitutional symptoms, however, are not always present. Acute infections are typically lytic with periosteal elevation; chronic lesions can have a mixed lytic/sclerotic appearance. MRI can demonstrate changes in bone not easily seen on plain films early in the course of infection. In acute osteomyelitis, surgical treatment is initiated when there is an abscess present, patients have failed to respond to nonoperative management, and when soft tissues need debridement to prevent further destruction.

Chronic osteomyelitis can arise from incompletely treated acute osteomyelitis, IV drug abusers, or in immunocompromised hosts. The disease course commonly follows a relapsing/remitting course with acute exacerbations in pain interspersed with periods of relative quiescence. Intravenous antibiotic therapy should be guided by deep cultures from the infected site. Surgical therapy consists of removal of all infected bone and soft tissue, and removal of hardware (if present), followed by culture-directed IV antibiotic therapy.

▼ FOOT AND ANKLE

PAIN SYNDROMES OF THE FOOT

1. Interdigital Neuritis

► Introduction

Interdigital neuritis is a common cause for pain in the foot. Originally described by Thomas Morton, the irritation of the interdigital nerve was believed to be due to compression between the metatarsal heads. However, it is now known that this is not the case given the location of the interdigital nerve lying plantar to the intermetatarsal ligament and metatarsal heads. Instead it is now believed that interdigital neuritis is due to compression and tethering of a stretched nerve across the transverse metatarsal ligament.

► History and Physical Examination

Patients typically present with pain associated with burning or tingling on the plantar aspect of the foot near the webspace of the affected nerve. This syndrome occurs most commonly in middle-aged women. Shoe wear, particularly wearing shoes with a tight toe box or high heels, appears to significantly exacerbate symptoms due to increased pressure on the plantar aspect of the foot and increased stretching of the nerve with dorsiflexion of the toes. Pain can be relieved with removal of the offending shoe and massage. Pain in the interdigital space may be reproduced on physical examination with pressure applied just proximal to the metatarsal heads by squeezing the forefoot between the examiner's thumb and index finger.

► Diagnosis

The differential diagnosis includes synovitis, bursitis, and metatarsalgia. In metatarsalgia, the pain is located directly under the involved metatarsal bone and often is accompanied with callous formation. The pain caused by synovitis is usually located immediately distal to the metatarsal head. Bursitis may present with swelling in the web space, which is not a typical finding associated with interdigital neuritis.

Interdigital neuritis is typically diagnosed with history and physical examination as described above. Injection of the affected digital webspace with 1 mL of lidocaine with successful relief of symptoms can provide diagnosis confirmation.

► Treatment

Treatment begins with nonsurgical management: avoidance of shoes with high heels or a tight toe box, use of a firm crepe sole which prevents hyperextension or dorsiflexion of the toes, and a metatarsal pad which provides relief of pressure on the plantar aspect of the foot. Steroid injection may improve symptoms; however, the effect is usually short-lived. If conservative measures fail surgery with release of the transverse metatarsal ligament and/or neurectomy may be pursued.

2. Metatarsalgia

Metatarsalgia is a disorder defined by pain located below the metatarsal heads that is worse with weight-bearing. Mechanical factors such as laxity of the transverse intermetatarsal ligament appear to be the root cause. Plantar callosities, most commonly under the second metatarsal head, may also be present. Treatment starts with orthotics, such as felt or rubber pads below the metatarsal heads to relieve pressure. Surgery may be considered if conservative measures fail.

3. Hallux Valgus

► General Considerations

Hallux valgus is defined by subluxation of the first MTP joint, which results in first metatarsal head medial prominence and lateral deviation of the proximal phalanx on the first metatarsal.

► Etiology

Anatomic factors including varus alignment of the first metatarsocuneiform joint may predispose to hallux valgus. Women's shoes with a small toe box may also cause bunching of the toes, predisposing to the valgus deformity of the first MTP joint.

► Clinical Evaluation and Physical Examination

When evaluating hallux valgus, the patient's main complaint should be defined carefully as this may affect choice of treatment options. Chief complaints may be related to cosmesis, metatarsalgia, second-toe deformity, problems with shoe-fit, or simply pain. Additionally, the patient's occupational and recreational activities should be investigated as well. Professional dancers or high-performance athletes are not good candidates for certain surgeries.

Initially, the foot should be inspected for any deformity. Hallux valgus is present when there is medial prominence of the first metatarsal head, also known as a "bunion." Limitation of dorsiflexion, pronation deformity of the big toe, synovial thickening, dorsal osteophytes, and medial deviation of the second MTP joint may be present as well. Neurovascular status of the foot should be documented.

► Radiographic Evaluation

Initially weight-bearing AP, lateral and oblique radiographs of the foot should be obtained. The halux valgus angle (the angle between the proximal phalynx and the first metatarsal, normal is less than 15 degrees), the intermetatarsal angle (the angle between the first and second metatarsals, normal < 9 degrees) and the distal metatarsal angle (angle between the distal metatarsal articular surface and the long axis of the first metatarsal), normal is less than 10 degrees of lateral deviation) should be measured and recorded. Incongruence of the MTP joint (lateral deviation of the proximal phalynx from the metatarsal head) should be noted as well.

► Treatment

Initially conservative treatment should be pursued with a wide, soft shoe with adequate toe box and insole padding. If conservative therapy fails a number of surgical treatment options are available depending on the severity of the deformity, joint congruence, presence of arthritis, and other patient factors.

4. Hallux Varus

Hallux varus is subluxation of the medial proximal phalynx on the first metatarsal. Etiologies include trauma and iatrogenic (overcorrection via surgery for hallux valgus). Hallux varus may be defined as supple (correctable with physical manipulation) or rigid (fixed, not correctable via manipulation). If the deformity is supple, then tendon transfer with extensor hallucis longus or extensor hallucis brevis should be considered. If the deformity is rigid, then arthrodesis or fusion of the first MTP joint is the best surgical treatment.

5. Hallux Rigidus

Hallux rigidus entails significant arthrosis of the first MTP joint resulting in significant pain and restriction of dorsiflexion. There may be increased bulk of the joint as well, resulting in difficulty wearing shoes. Marginal osteophytes may be present dorsally and laterally.

Forced dorsiflexion performed by the examiner often reproduces the patient's pain. Grind test should also be performed by holding the first metatarsal steady and applying an axial load with circumduction of the proximal phalynx. Significant pain with this maneuver indicates a positive grind test which equates to significant loss of the plantar located cartilage. Additionally the dorsal medial cutaneous nerve may be sensitive as well.

Radiographic evaluation includes weight-bearing AP, lateral, and oblique views of the foot. The extent of joint narrowing should be noted. Hallux rigidus may be classified as follows based on radiographs: grade I (preserved joint space), grade II (<50% joint space narrowing), and grade III (>50% loss of joint space).

Initially, conservative management using a shoe with a large toe box to accommodate increased bulk of the first MTP joint and rigid rocker sole to minimize joint motion should be tried. If conservative measures fail, surgery may be considered.

Surgical treatment entails cheilectomy (removal of the osteophyte) or arthrodesis (fusion of the first MTP joint). Cheilectomy is indicated for grade I, grade II, and grade III pathology with a negative grind test. If cheilectomy fails to provide significant pain relief, arthrodesis may be performed. For grade III lesions on radiographs and a positive grind test (indicating lack of plantar cartilage) arthrodesis should be pursued. Although various arthroplasty (joint replacement procedures) are now available, the short-to-midterm results of these procedures are not as successful as cheilectomy and/or arthrodesis.

6. Plantar Fasciitis

Plantar fasciitis is a degenerative process involving the plantar fascia origin. The typical patient with this disorder is the overweight 40-70 year old with significant plantar heel pain

and localized tenderness at the plantar medial tuberosity of the calcaneus. An osteophyte (heel spur) may be visible on radiographs. Treatment entails stretching and massage of the plantar fascia and Achilles tendon, cushioned heel inserts, night splints, and/or a walking cast. If conservative measures fail, surgery with release of the medial third of the plantar fascia may be considered.

7. The Diabetic Foot

The pathology associated with the diabetic foot is complicated by neuropathy and angiopathy with varying degrees of severity. Diabetic ulceration and neuropathic arthropathy (aka Charcot Foot) can result. Management of these two pathologic disorders is dependent on a number of factors.

► Diabetic Ulceration

Due to neuropathy, patients with diabetes have decreased sensation around their feet. As a result, injuries to the superficial layer of skin are not perceived, and progression to ulceration can occur. These patients should be initially evaluated with transcutaneous oxygen pressures and ankle-to-brachial indices (ABIs) to determine healing potential. An ABI ratio > 0.6 and transcutaneous oxygen measurements more than 40 mm Hg are usually indicative of adequate vascularity and necessary healing potential. Additionally, the character of the ulcer itself affects treatment choice. Localized, superficial ulcers that do not extend to tendon, bone, or ligament can be debrided at the bedside followed by placement in an offloading shoe or cast with serial physical examinations. Ulcers that extend to deeper tissues and/or bone may require debridement in the operating room and antibiotic therapy. Additionally, nutrition should be optimized to encourage healing. If appropriate blood flow is present, these ulcers will typically heal. If healing does not occur or gangrene is appreciated due to poor vascularity, amputation may be considered.

► Neuropathic Arthropathy (Charcot Foot)

Neuropathic arthropathy is characterized by osteopenia, joint subluxation or dislocation and bony fragmentation that may progress to malunion at later stages. White blood cell-labeled scintigraphy with MRI can be used to differentiate this condition from osteomyelitis. Initial treatment includes non-weight-bearing of the affected lower extremity with or without cast placement. Operative intervention is considered only in special cases.

MULTIPLE CHOICE QUESTIONS

- Open fractures, defined as a break in the bone with violation of the skin and soft tissues requires the following management:
 - Splinting
 - Bedside irrigation and splinting
 - Formal irrigation and debridement in the operating room with stabilization of fracture and antibiotics
 - VAC dressing
 - Plastic surgery consultation
- A 37-year-old man is involved in a motor cycle accident at a high rate of speed. Upon arrival to the emergency room he reports that he has no feeling below the waist and cannot move his legs. The bulbocavernosus reflex is intact. According to the American Spinal Injury Association, he would be considered:
 - Asia A
 - Asia B
 - Asia C
 - Asia D
 - Asia E
- A 57-year-old woman is involved in a motor vehicle collision. She is transferred to the Emergency Department where radiographs confirm a closed pelvic fracture with symphyseal widening. She becomes acutely hypotensive in the resuscitation bay. The next important step in her treatment is:
 - Immediate transfusion
 - Exploratory laparotomy
 - Move blood pressure cuff to the leg
 - Apply sheet or pelvic binder around the patient
 - Obtain more x-rays
- A 23-year-old man presents to the Emergency Room with an acute injury to his left knee sustained playing football. He is unable to weight bear and on exam demonstrates anterior dislocation of the tibia. The next steps in management include:
 - Emergent reduction, splinting, vascular studies, and neurologic exam
 - Knee immobilizer and outpatient follow-up
 - Urgent MRI
 - Transport to operating room for open reduction of the knee
 - Reduction and casting
- A 3-year-old child fell from the monkey bars sustaining an acute injury to her left elbow. She demonstrates good strength with the exception of the anterior interosseous nerve. Radiographs confirm a displaced supracondylar humerus fracture. Parents are informed:
 - Splint will be applied and patient can return for outpatient follow-up.
 - Patient will require closed reduction and pinning of the elbow in the operating room. The AIN will require exploration and repair.
 - Patient will require closed reduction and pinning of the elbow in the operating room. The AIN will recover in most cases with observation over the next 3-6 months.
 - Patient can be observed for recovery of nerve overnight in the emergency room.
 - AIN is rarely injured with this type of fracture.

Plastic & Reconstructive Surgery

Henry C. Vasconez, MD

Jason Buseman, MD

Plastic surgery, although considered a technique-oriented and multiregional specialty, is in essence a problem-solving field. The training of a plastic surgeon allows him or her to see surgical problems in a different light and select from a variety of options to solve these surgical problems. Plastic surgeons have received broad training, and many have completed residencies in other fields such as general surgery, otolaryngology, orthopedics, urology, or neurosurgery. Other modalities of training have more recently integrated these and other surgical subspecialties into a more comprehensive training program.

The basic principles of plastic surgery are careful analysis of the surgical problem, careful planning of procedures, precise technique, and atraumatic handling of tissues. Alteration, coverage, and transfer of skin and associated tissues are the most common procedures performed. Plastic surgery may deal with the closure of surgical wounds—particularly recalcitrant wounds such as those occurring postirradiation or poorly healing wounds in immunocompromised patients. Plastic surgery also deals with the removal of skin tumors, repair of soft tissue injuries including burns, correction of acquired or congenital deformities, or enhancement of undesirable cosmetic features. Craniofacial and hand surgery, also within the realm of plastic surgery, may require additional surgical training.

In the past quarter century, increased knowledge of anatomy and the development of many new techniques have brought about important changes in plastic surgery. It is now known that in many areas the blood supply of the skin is derived principally from vessels arising from underlying muscles and larger perforating blood vessels rather than solely from vessels of the subcutaneous tissue, as was formerly thought. One-stage transfer of large areas of skin, fascia, and muscle tissue can be accomplished if the axial pedicle of the underlying fascia or muscle is included in the transfer. With the use of microsurgical techniques, musculocutaneous units or combinations of bone, fascia, muscle, and

skin can be successfully transferred and vessels and nerves less than 1 mm in size can be repaired. These so-called free-flap transplantations are a major advance in the treatment of defects that were previously untreatable or required lengthy or multistaged procedures. More sophisticated knowledge of the blood supply to the skin has introduced the concept of perforator flaps whereby one perforating vessel is identified that may supply a large segment of overlying skin and subcutaneous tissue. Similarly, the concept of neurocutaneous flaps has given rise to the design of additional flap territories such as the sural flap in the lower leg and the sensate radial flap in the forearm.

The plastic surgeon, as a member of the craniofacial surgical team, is able to dramatically improve the appearance and function of children with severe congenital deformities. Children of normal intelligence who previously had been social outcasts are now able to lead relatively normal lives. Improved understanding of facial growth and abnormal development and diagnostic techniques such as the CT scan, MRI, and 3D computer-assisted imaging enable the reconstructive surgeon to develop a complex strategy for remodeling the deformed craniofacial skeleton. This may involve remodeling or repositioning of part or all of the cranial vault, the orbits, the midface, and the mandible. These complex and at times formidable reconstructions are performed by moving specific skeletal units and adding autogenous bone grafts. These structures are kept in place using miniplate fixation; the miniplates are made of titanium or resorbable material.

A notable advance in craniofacial surgery was the introduction of distraction osteogenesis, which borrows from the Ilizarov principle of distraction. A cortical cut is made in the bone, and a distraction apparatus is applied so that in measured amounts (usually 1 mm per day) the bone is either stretched to offset a length discrepancy or transported to bridge a gap. In craniofacial surgery, it is more commonly brought to bear to enlarge or cause overgrowth of areas such as an underdeveloped mandible.

Additional areas of involvement for the plastic surgeon entail allotransplantation, particularly with the increasing number of clinical limb allotransplants, which unfortunately still require immunosuppression. It is hoped that immunotolerance will someday become a reality, allowing transplantation of nonessential organs with a minimum of dangerous immunosuppression. Transplantation of the hand with excellent functional recovery in some cases has been performed successfully but still requires a great deal of immunosuppression. Face transplants have been performed with some initial success. The first facial transplant was performed in France and consisted of a partial segment of the face. The functional recovery to date has been remarkable. The problems of facial animation still need to be refined. Additionally, a number of ethical issues with regard to facial identity and immunosuppression require further resolution.

Tissue engineering of bone, cartilage, and nerve is an area of ongoing research for plastic surgeons. Although encouraging experimental results have been reported in anatomic areas difficult to reconstruct, such as the external ear, the nose, or the larynx, there are as yet few clinical applications.

Fetal surgery for cleft disorders and scar considerations, an area pioneered by a number of plastic surgeons, appears to be in a quiescent stage, particularly because the persistent real and potential risks to the fetus and mother may not be warranted for disorders that are not life threatening. Significant technical advances in the postnatal treatment of cleft lip and cleft palate have also lessened the enthusiasm for fetal surgery for these disorders.

I. GRAFTS & FLAPS

SKIN GRAFTS

A graft of skin detaches epidermis and varying amounts of dermis from its blood supply in the **donor area** and is placed in a new bed of blood supply from the base of the wound, or **recipient area**. The way a skin graft survives or “takes” is first by diffusion of nutrient elements from the graft bed, known as imbibition; then after a period of 2-5 days, the graft actually revascularizes from the bed, a process known as inosculation. Although the technique is relatively simple to perform and generally reliable, definite considerations about the donor area and adequacy of the recipient area are important. Skin grafting is a quick, effective way to cover a

▲ **Figure 41-1.** Depths of full-thickness and split-thickness grafts.

wound if vascularity is adequate, infection is not present, and hemostasis is assured. Color match, contour, durability of the graft, and donor morbidity must be considered.

TYPES OF SKIN GRAFTS

Skin grafts can be either split-thickness or full-thickness grafts (Figure 41-1). Each type has advantages and disadvantages and is indicated or contraindicated for different kinds of wounds (Table 41-1).

A. Split-Thickness Grafts

Thinner split-thickness grafts (0.01-0.015 inch) become vascularized more rapidly and survive transplantation more reliably. This is important in grafting on less than ideal recipient sites, such as contaminated wounds, burn surfaces, and poorly vascularized surfaces (eg, irradiated sites). A second advantage is that donor sites heal more rapidly and can be reused within a relatively short time (7-10 days) in critical cases such as major burns.

In general, however, the disadvantages of thin split-thickness grafts outweigh the advantages. Thin grafts exhibit the highest degree of postgraft contraction, offer the least amount of resistance to surface trauma, and are least like normal skin in texture, suppleness, pore pattern, hair growth, and other characteristics. Hence, they are usually aesthetically unacceptable.

Thicker split-thickness skin grafts (> 0.015 inch) contract less, are more resistant to surface trauma, and are more similar to normal skin than are thin split-thickness grafts. They are also aesthetically more acceptable but not as acceptable as full-thickness grafts.

The disadvantages of thick split-thickness grafts are relatively few but can be significant. They are less easily

Table 41–1. Advantages and disadvantages of various types of skin grafts.

Type of Graft	Advantages	Disadvantages
Thin split-thickness	Survive transplantation most easily. Donor sites heal most rapidly.	Fewest qualities of normal skin. Maximum contraction. Least resistance to trauma. Sensation poor. Aesthetically poor.
Thick split-thickness	More qualities of normal skin. Less contraction. More resistant to trauma. Sensation fair. Aesthetically more acceptable.	Survive transplantation less well. Donor site heals slowly.
Full thickness	Nearly all qualities of normal skin. Minimal contraction. Very resistant to trauma. Sensation good. Aesthetically good.	Survive transplantation least well. Donor site must be closed surgically. Donor sites are limited.

vascularized than thin grafts and thus result in fewer successful takes when used on less than ideal surfaces. Their donor sites are slower to heal (requiring 10–18 days) and heal with more scarring than donor sites for thin split-thickness grafts—a factor that may prevent reuse of the area.

Meshed grafts are usually thin or intermediate split-thickness grafts that have been rolled under a special cutting machine to create a mesh pattern. Although grafts with these perforations can be expanded from 1.5 to 9 times their original size, expansion to 1.5 times the unmeshed size is the most useful. Meshed grafts are advantageous because they can be placed on an irregular, possibly contaminated wound bed and will usually take. Also, complications of hemostasis are fewer because blood and serum exude through the mesh pattern. The disadvantage is poor appearance following healing (alligator hide look).

Donor sites for split-thickness grafts heal spontaneously by epithelialization. During this process, epithelial cells from the sweat glands, sebaceous glands, or hair follicles proliferate upward and spread across the wound surface. If these three structures are not present, epithelialization will not occur.

B. Full-Thickness Grafts

Full-thickness skin grafts include the epidermis and all the dermis. They are the most aesthetically desirable of the free grafts because they include the highest number of skin appendage elements, undergo the least amount of contraction, and have a greater ability to withstand trauma. There are several limiting factors in the use of full-thickness grafts. Since no epidermal elements remain to produce epithelialization in the donor site, it must be closed primarily, and a scar will result. The size and number of available donor sites is therefore limited. Furthermore, conditions at the recipient site must be optimal in order for transplantation to be successful.

Areas of thin skin are the best donor sites for full-thickness grafts (eg, the eyelids and the skin of the postauricular, supraclavicular, antecubital, inguinal, and genital areas). Submammary and subgluteal skin is thicker but allows

camouflage of donor area scars. In grafts thicker than approximately 0.015 inch, the results of transplantation are less reliable, except on the face, where vascularity is usually superior.

C. Composite Grafts

A composite graft is also a free graft that must reestablish its blood supply in the recipient area. It consists of a unit with several tissue planes that may include skin, subcutaneous tissue, cartilage, or other tissue. Dermal fat grafts, hair transplant grafts, and skin and cartilage grafts from the ear fall into this category. Obviously, composite grafts must be small or at least relatively thin and will require recipient sites with excellent vascularity. These grafts are generally used in the face.

D. Cultured Epithelial and Dermal Grafts

Epithelial cells, grown or cultured in a special medium in vitro, will coalesce into thin sheets that can be used to cover full-thickness wounds. Although these cultured epithelial sheets were first used in the treatment of burns, the result was somewhat unsatisfactory because the coverage was very fragile and disfiguring. More recently, success has been obtained with artificial dermis, which when placed in an appropriate bed will revascularize and can then be covered by a very thin (0.05 cm) split-thickness skin graft, cultured or otherwise. This artificial dermis is increasingly being used in the treatment of burns. Modifications of this concept have also been applied to the care of chronic ulcers, particularly in the leg. The artificial dermis is made out of a collagen matrix and has very low or no antigenicity.

E. Biological Skin Substitutes

Research continues to develop bioengineered products that are becoming more common place in plastic surgery and general wound management. The source of these products varies (eg, human, porcine, etc) and can alter the products indications and overall ability to assist with wound management. Some of the more common products used are Integra and acellular dermal matrices (ADM), Integra is a bilayer

material consisting of interwoven bovine collagen and a glycosaminoglycan that mimics the dermal layer of skin. This has made it ideal for reconstruction cases where more than simple skin grafts will suffice, such as over a tendon. ADM is acellular cadaver skin that is chemically prepared. Although initially designed for burn reconstruction, it has been used in wound care and general reconstruction cases from head to toe.

► Obtaining Skin Grafts

Instruments used for obtaining skin grafts include razor blades, skin grafting knives (Blair, Ferris Smith, Humby, Goulian), manual drum dermatomes (Padgett, Reese), and electric or air-powered dermatomes (Brown, Padgett, Hall, Zimmer). The electric and air-powered dermatomes are the most widely used because of their reliability and ease of operation. A surgeon, even with only limited experience, can successfully obtain sheets of split-thickness skin grafts using the electric dermatomes.

► The Skin Graft Recipient Area

To ensure survival of the graft, there must be (1) adequate vascularity of the recipient bed, (2) complete contact between the graft and the bed, (3) adequate immobilization of the graft-bed unit, and (4) relatively few bacteria in the recipient area.

Because survival of the graft is dependent upon growth of capillary buds into the raw undersurface of the graft, vascularity of the recipient area is of prime importance. Avascular surfaces that will not generally accept free grafts are tissues with severe radiation damage, chronically scarred ulcer beds, bone or cartilage denuded of periosteum or perichondrium, and tendon or nerve without their paratenon or perineurium, respectively. For these surfaces, a bed capable of producing capillary buds must be provided; in some cases, excision of the deficient bed down to healthy tissue is possible. All unhealthy granulation tissue must be removed, because bacterial counts in granulation tissue are often very high. If bone is exposed, it can be decorticated down to healthy cancellous bone with the use of a chisel or power-driven burr, and a meshed split-thickness skin graft can be applied. If an adequate vascular bed cannot be provided or if the presence of essential structures such as tendons or nerves precludes further debridement, skin or muscle flaps are generally indicated for coverage.

Inadequate contact between the graft and the recipient bed can be caused by collection of blood, serum, or lymph fluid in the bed; formation of pus between the graft and the bed; or movement of the graft on the bed. The use of fibrin sealants (Artiss) has more recently been developed to assist with skin graft take. This is sprayed over the wound bed prior to placement of any skin graft. After 60-90 seconds, a fibrin clot develops that better holds the skin graft in place

and diminishes potential spaces between the wound bed and the skin graft, which can negatively affect skin graft survival.

After the graft has been applied directly to the prepared recipient surface, it may or may not be sutured in place and may or may not be dressed. Whenever the maximum aesthetic result is desired, the graft should be cut exactly to fit the recipient area and precisely sutured into position without any overlapping of edges. Very large or thick split-thickness grafts and full-thickness grafts will usually not survive without a pressure dressing. In areas such as the forehead, scalp, and extremities, adequate immobilization and pressure can be provided by circular dressings. Tie-over pressure stent dressings are advisable for areas of the face, where constant pressure cannot be provided by simple wraparound dressings; areas where movement cannot be avoided, such as the anterior neck, where swallowing causes constant motion; and areas of irregular contour, such as the axilla. The ends of the fixation sutures are left long and tied over a bolus of gauze fluffs, cotton, a sponge, or other suitable material (Figure 41-2).

Grafts applied to freshly prepared or relatively clean surfaces are generally sutured or stapled into place and dressed with pressure. The use of fibrin sealants has helped minimize the need for these usually uncomfortable bolster techniques. A single layer of damp or other nonadherent fine-mesh gauze is applied directly over the graft. Immediately over this are placed several thicknesses of flat gauze cut in the exact pattern of the graft. On top of these is placed a bulky dry dressing of gauze fluffs, cotton, a sponge, or other material. Pressure is then applied by wraparound dressings, adhesive

▲ Figure 41-2. Tie-over stent dressing.

tape, or a tie-over pressure stent dressing. An alternative dressing is to place a nonadherent fine-mesh gauze atop the graft followed by a negative-pressure dressing. The vacuum-assisted dressings may be useful for irregular contours, such as around digits and webspaces or joint surfaces, by maintaining wound-to-graft interface, immobilizing the grafted area, suctioning serosanguineous fluid, and possibly promoting neovascularization.

In many cases, it is permissible—and sometimes even preferable—to leave a skin graft site open with no dressing. This is particularly true in slightly infected wounds, where the grafts tend to float off in the purulent discharge produced by the wound. These wounds are best treated with meshed grafts so that liquid forming between the graft and the wound bed can exude and be removed without disturbing the graft. This treatment can also be used for noninfected wounds that produce an unusual amount of serous or lymphatic drainage, as occurs following radical groin dissections.

In severely ill patients, such as those with major burns, where time under anesthesia must be kept to a minimum, large sheets of meshed split-thickness skin grafts are rapidly applied but not sutured. Skin staples may be used to fix the graft rapidly. Grafts need not be dressed if the area is small, but if the area is large or circumferential, a dressing should be applied. Meshed grafts should generally be covered for 24-48 hours to prevent dryness, because their dermal barrier has been partly disrupted.

Skin graft dressings may be left undisturbed for 5-7 days after grafting if the grafted wound was free of infection, if complete hemostasis was obtained, if fluid collection is not expected, and if immobilization is adequate. If any one of these conditions is not met, the dressing should be changed within 24-48 hours and the graft inspected. If blood, serum, or purulent fluid collection is present, the collection should be evacuated—usually by making a small incision through the graft with a scalpel blade and applying pressure with cotton-tipped applicators. The pressure dressing is then reapplied and changed daily so that the graft can be examined and fluid expressed as it collects.

► The Skin Graft Donor Area

The ideal donor site would provide a graft identical to the skin surrounding the area to be grafted. Because skin varies greatly from one area to another as far as color, thickness, hair-bearing qualities, and texture are concerned, the ideal donor site (such as upper eyelid skin to replace skin loss from the opposite upper eyelid) is usually not found. However, there are definite principles that should be followed in choosing the donor area.

A. Color Match

In general, the best possible color match is obtained when the donor area is located close to the recipient area. Color

and texture match in facial grafts will be much better if the grafts are obtained from above the region of the clavicles. However, the amount of skin obtainable from the supraclavicular areas is limited. If larger grafts for the face are required, the immediate subclavicular regions of the thorax will provide a better color match than areas on the lower trunk or the buttocks and thighs. When these more distant regions are used, the grafts will usually be lighter in color than the facial skin in Caucasians. In people with dark skin, hyperpigmentation occurs, producing a graft that is much darker than the surrounding facial skin.

B. Thickness of the Graft and Donor Site Healing

Donor sites of split-thickness grafts heal by epithelialization from the epithelial elements remaining in the donor bed. The ability of the donor area to heal and the speed with which it does depends on the number of these elements present. Donor areas for very thin grafts will heal in 7-10 days, whereas donor areas for intermediate-thickness grafts may require 10-18 days and those for thick grafts 18-21 days or longer.

Because there is a normal anatomic variation in the thickness of skin, donor sites for thicker grafts must be chosen with the potential for healing in mind and should be limited to regions on the body where the skin is thick. Infants, debilitated adults, and elderly people have thinner skin than healthy younger adults. Grafts that would be split-thickness in the normal adult may be full thickness in these patients, resulting in a donor site that has been deprived of the epithelial elements necessary for healing.

C. Management of the Donor Site

The donor site itself can be considered a clean open wound that will heal spontaneously. After initial hemostasis, the wound will continue to ooze serum for 1-4 days, depending on the thickness of the skin taken. The serum should be collected and the wound kept clean so that healing can proceed at a maximal rate. The wound should be cared for as described above for clean open wounds in either of two ways.

One technique of donor site management is an open (dry) technique. The donor site is dressed with porous, sterile fine-mesh or nonadherent gauze. After 24 hours, the dry gauze is changed but the nonadherent gauze is left on the wound and exposed to the air, a heat lamp, or a blow dryer. A scab will form on the gauze and will peel off from the edges as epithelialization is completed underneath. This method has the advantage of simple maintenance once the wound is dry.

The second method that has become more popular is the closed (moist) technique. Studies have demonstrated that the rate of epithelialization is enhanced in a moist environment. In contrast to the dry technique, pain can be reduced or virtually eliminated. Moist-to-moist gauze dressings that require frequent wetting have been replaced by newer

synthetic materials. A gas-permeable membrane (OpSite, Tegaderm) that sticks to the surrounding skin provides an artificial blister over the wound. Occasionally, there is a break in the protective seal covering leakage of serum collected under the membrane. This increases the risk of infection, especially in a contaminated zone. Newer hygroscopic dressings actually absorb and retain many times their weight in water. They are permeable to oxygen yet impervious to bacteria. Infection is still a concern; however, because of occasional exposure of the wound during healing. Newer dressings, such as Mepilex, contain silver-impregnated ions that control bacterial contamination and may hasten healing and reepithelialization while keeping the patient more comfortable. Silver ion is exquisitely antimicrobial and is used for burn dressing care as well as skin graft sites.

FLAPS

The term “flap” refers to any tissue used for reconstruction or wound closure that retains part or all of its original blood supply after the tissue has been raised and moved to a new location. That part still connected through which the blood supply enters and exits is referred to as the flap base or pedicle. With local skin flaps, a section of skin and subcutaneous tissue is raised from one site and moved to a nearby area, with the base remaining attached at its original location.

Flaps can be classified according to the pattern of blood supply to the skin into random or axial pattern. Flaps can further be classified according to their tissue content into muscle, musculocutaneous, fasciocutaneous, and others.

▶ Random Pattern Flaps

Random pattern flaps consist of skin and subcutaneous tissue cut from any area of the body in any orientation, with no distinct pattern or particular relation to the blood supply of the skin of the flap. Such flaps receive their blood supply from vessels in the subdermal tissue. Although commonly used, this is the least reliable type of flap, and except when cut from facial and scalp skin, the ratio of length to width cannot safely exceed 1.5:1. Its use should be minimized.

Presently, in any reconstructive effort, one should use a flap with known reliability and a predictable blood supply.

▶ Axial Pattern Flaps

The axial pattern flap has a well-defined arteriovenous system running along its long axis. Because of good vascular supply, it can be made comparatively long in relation to width. Foremost among the axial flaps are the deltopectoral and the forehead flaps, which are based on perforating branches of the internal mammary artery and supraorbital and supratrochlear or superficial temporal vessels, respectively. Other axial flaps are the groin flap, based on the superficial circumflex iliac artery; the dorsalis pedis flap, based on the artery of the same name; the radial forearm flap; the scapular flap; the lateral upper arm flap; and various scalp and face flaps.

▶ Muscle & Musculocutaneous Flaps

Musculocutaneous flaps consist of skin and underlying muscle, which provide reliable coverage with usually one operation. The use of musculocutaneous units has developed as surgeons have gained more knowledge of the way in which blood is supplied to the skin. The technique has revolutionized reconstructive surgery.

The subdermal plexus of vessels from which skin flaps derive their blood supply is augmented or directly supplied in many areas by sizable perforating vessels arising from underlying muscles. Many muscles receive their blood supply from a single axial vessel, with only minor contributions from other sources (Figure 41-3). The skin over these muscles can be completely circumscribed and elevated in continuity with the underlying muscle up to its major vascular pedicle. If the vessels in the pedicle are preserved, the unit can be moved in wide arcs to distant areas of the body while normal or near normal blood flow is continued to the skin island as well as to the muscle. The donor sites of such flaps can often be closed primarily.

Knowledge of the anatomy of muscles and their nerve and blood supply is necessary for the successful design of musculocutaneous flaps. Although almost any skeletal muscle can be used, muscles with a dominant arterial pedicle and reliable perforating vessels to the skin are most useful.

In addition to their reliability, musculocutaneous flaps clean up recipient sites that are heavily contaminated with bacteria better than skin flaps do. This is why muscle-containing flaps are the best choice for coverage of wounds caused by radiation or osteomyelitis or those that have a high probability of infection.

The most commonly used muscles and musculocutaneous flaps are the latissimus dorsi, pectoralis major, tensor fasciae latae, rectus femoris, rectus abdominis, trapezius, temporalis, serratus anterior, gluteus maximus, gracilis, and gastrocnemius muscles.

▲ **Figure 41–3.** Arterial supply to skin from main artery supplying muscles, as occurs in musculocutaneous flaps.

A. Latissimus Dorsi

The latissimus dorsi musculocutaneous unit is supplied by the thoracodorsal vessels. Use of this unit has been widely applied in the one-stage reconstruction of the breast following radical or modified radical mastectomy (see section on Rectus Abdominis). The entire latissimus dorsi muscle can be detached from its origin and transposed to the anterior chest. An island of skin can also be included in the center of the muscle to restore the skin lost on the anterior chest wall. Refinements in technique utilize only enough muscle to carry the skin island, thus leaving intact a good portion of innervated, functional muscle. This unit is also useful for coverage of defects on the anterior chest, shoulder, head and neck, and axilla and even for restoration of flexion of the elbow. It is a popular muscle for free tissue transfer because of its long and relatively large and reliable vascular pedicle.

B. Pectoralis Major

The pectoralis major musculocutaneous unit obtains its vascular supply from the thoracoacromial axis of the subclavian artery just medial to the medial border of the pectoralis minor. It derives a dual blood supply from medial intercostal perforators branching from the internal mammary artery. The entire unit may be transposed medially, especially after disinsertion from the humerus, to cover defects of the sternum, neck, and lower face. Also, an island of skin can be outlined low on the chest and made to reach intraoral defects following cancer excision.

C. Trapezius

The trapezius musculocutaneous unit, based on the descending branch of the transverse cervical artery, is useful for covering defects in the neck, face, and scalp. When skeletonized as an island, the flap will reach the top of the head. When

it is used in conjunction with a neck dissection, the transverse cervical artery must be preserved. Functional preservation of shoulder elevation may be accomplished by selectively sparing the transverse, superior fibers of the muscle.

D. Temporalis

The temporalis muscle extends from the temporal fossa to the coronoid process of the mandible. It is supplied by the deep and superficial temporal systems. It is commonly used to fill orbital defects. However, it can cover neighboring cranial, maxillary, palatal, and pharyngeal regions.

E. Tensor Fasciae Latae

The tensor fasciae latae musculofascial unit is supplied by the lateral femoral circumflex artery, a branch of the profunda femoris. It has a wide arc of rotation anteriorly and posteriorly. It is elevated with the fascia lata and thus can be used to reconstruct the lower abdominal wall. It has been used to cover defects following excision of osteoradionecrotic ulcers of the pubis or groin. It is also the method of choice for coverage of greater trochanteric pressure ulcers.

F. Rectus Femoris

The rectus femoris, a more robust flap than the tensor fasciae latae with a shorter arc of rotation, has supplanted the latter for reconstruction of the lower abdominal wall and for coverage to postradiation ulcers in the pubis and groin. It has a dual blood supply: a muscular branch from the profunda femoris and an axial branch from the superficial femoral artery to the overlying skin and fascia.

G. Rectus Abdominis

The rectus abdominis is supplied by the deep superior and inferior epigastric vessels that run in the undersurface

of the muscle and anastomose with the segmentally arranged intercostal vessels to form the epigastric arcade. These vessels send perforating branches throughout the length of the muscle, perforating the anterior rectus sheath and supplying the overlying skin. The transverse rectus abdominis myocutaneous (TRAM) flap, when based on the superior epigastric vessel and including the infraumbilical skin, has become a workhorse for autologous tissue breast reconstruction. In situations of marked deformity, such as a radical mastectomy associated with radiation therapy or previous abdominal surgery, reconstruction of the breast can be accomplished reliably with infraumbilical skin and adipose tissue based on both rectus muscles. This superiorly based TRAM flap involves an abdominoplasty as well as reconstruction of the breast. It is a technically demanding operation but gives a very satisfying result. When based on the deep inferior epigastric vessel and using the supraumbilical skin (the “flag” flap), the flap can cover defects of the abdominal wall, flank, groin, and thigh. Using the inferior epigastric vessels to transport the skin and adipose tissue by means of microvascular surgery (see section on Free Flaps) has become a popular method of breast reconstruction. A small portion of the rectus muscle or just a main perforator vessel that supplies the overlying fat and skin is taken. This flap is known as the deep inferior epigastric perforator flap, or DIEP flap (see section on Perforator Flaps).

H. Gluteus Maximus

The gluteus maximus is useful as a muscle or musculocutaneous unit for covering pressure sores or traumatic defects over the sacrum and ischium. The muscle has a double blood supply from the superior and inferior gluteal arteries to the respective halves of the muscle. In ambulatory patients, it is advisable to perform a function-preserving operation by advancing the muscle medially and preserving its insertion laterally.

I. Gracilis

The gracilis muscle receives its dominant blood supply proximally from the medial femoral circumflex artery. Its arc of rotation makes it an excellent source of coverage for ischial pressure sores and vaginal reconstruction. Other recent uses have included transportation of the muscle alone for repair of a persistent perineal sinus following abdominal-perineal resection.

J. Gastrocnemius

The gastrocnemius musculocutaneous unit is based on either the medial or lateral head of the muscle. Each head is supplied by a sural artery, a branch of the popliteal artery that enters the muscle at its most proximal third near its

origin. The flap is most useful to cover defects of the knee and proximal anterior tibia. Coverage of exposed bone in the middle and lower leg, where this unit cannot reach, can be accomplished by use of local muscle flaps such as the soleus. Complex bone and soft tissue injuries of the middle and lower leg may require reconstruction with free muscle flaps.

► Fasciocutaneous Flaps

A plexus of vessels is located on top of the muscular fascia and is supplied from vessels that run within the intermuscular septa. These vessels tend to run axially along the fascia, sending perforators to the skin at intervals. Flaps can be designed that are safer than random flaps and that need not contain an entire muscle unit for their transfer. Furthermore, it is possible to make fasciocutaneous or septocutaneous flaps that safely exceed the traditional limits of a 1.5:1 ratio between length and width. Examples of fasciocutaneous flaps are those overlying the gastrocnemius, quadriceps, and rectus abdominis muscles. Other commonly used flaps are the radial forearm, lateral arm, scapular, and deltopectoral flaps.

► Neurocutaneous Flaps

Anatomic studies have confirmed the presence of an arterial pedicle accompanying a sensory nerve such as the sural nerve. Consequently, one may be able to outline a skin territory over the trajectory of a sensory nerve with good viability of the overlying skin.

► Free Flaps

Free flaps involve tissue transplantation using microvascular surgery. The term is actually incorrect, because the blood supply from the main axial pedicle of the flap is completely detached and then reattached at a distance to recipient vessels near the wound area.

An operating microscope with two viewing binocular lenses, specialized instruments, and swaged-on needles of 60-80 μ m are required for microsurgery; 8-0, 9-0, and 10-0 suture is used to anastomose vessels as small as 0.5 mm in diameter.

Examples of free flaps in current use are axial pattern skin and fasciocutaneous flaps, such as scapular, groin, radial forearm, and anterolateral thigh, which are used when only skin and subcutaneous tissue are needed, and muscle and musculocutaneous flaps, such as latissimus dorsi, gracilis, and rectus abdominis flaps, which are used when the bulk and vascularity of muscle are needed. Composite free flaps such as the fibular flap with its overlying skin are most helpful free flaps for reconstruction of the mandible as well as the floor of the mouth following head and neck tumor extirpations.

The vascular pedicle areas of some flaps contain functional nerves, which can also be reattached with microscopic guidance. Examples are inferior gluteal, thigh, and tensor fasciae latae flaps, which contain sensory nerves. Attempts using sensory flaps to provide protective sensation in critical areas such as the feet or the ischium in paraplegic patients have so far been clinically unsuccessful. More encouraging is the work being done to provide sensibility to the floor of the mouth with a sensory innervated radial forearm flap. Motor flaps can restore functions such as forearm flexion or facial expression.

Bone and functional joints can be transplanted as free flaps. Flaps from the ribs, fibula, and iliac crest have all been successfully transferred to areas such as the mandible and tibia. The toe-to-thumb transfer is an example of a complex transplantation, which includes bone with a functional joint, tendons, and nerves as well as skin.

► Perforator Flaps

A sophisticated variation on the use of the musculocutaneous principle has been the development of perforator flaps. This usually entails taking a branch from the major vascular pedicle that may perforate the muscle to arborize and form a subcutaneous vascular plexus that will supply a considerable amount of overlying skin. Perhaps the greatest benefit from a perforator flap is decreased donor site morbidity. Structures such as the fascia, muscle, and associated nerves may be preserved while allowing the skin to be used for reconstruction.

The DIEP flap exemplifies this well for autologous tissue breast reconstruction. While maintaining the same skin territory as the TRAM flap, the perforating vessels are carefully dissected away from the rectus abdominis. By sparing the muscle, there is potentially a reduction in excessive abdominal wall weakness at the donor site.

The anterolateral thigh flap has become the mainstay for cutaneous flaps at some institutions. Based on musculocutaneous perforators from the vastus lateralis, it can be used when a relatively thin cutaneous flap is needed, such as in head and neck reconstruction. The donor site may be closed primarily depending on the flap width.

The perforator concept has been applied to further territories of skin over the perforator segments of the gluteal, thoracodorsal, and medial plantar arteries among others.

II. PRINCIPLES OF WOUND CARE

There are many types of wounds and many factors to consider when choice of coverage procedure is made. Skin type and color, glandular association, and hair-bearing characteristics must be considered. Avascular wound beds, such as exposed bone, cartilage, or tendon, will not accept skin grafts unless viable periosteum, perichondrium, or paratenon (respectively) is present. Other areas with poor vascularity are joint capsules, radiation-damaged tissue, and heavily scarred tissue. Exposed or implanted alloplastic material cannot be used as a graft bed. Such areas must be covered with tissue that is attached to its own blood supply. Skin flaps can be used but are sometimes inadequate because their blood supply is tenuous and the layer of subcutaneous fat is even less reliably vascular and may not attach to the underlying avascular surface. Muscle or musculocutaneous flaps are generally required for avascular areas.

The coverage tissue may need to have more bulk than the original tissue. Areas such as bony surfaces and prominences, weight-bearing surfaces, densely scarred areas, and areas of potential pressure breakdown may require thick, durable covering. Again, skin grafts or skin flaps may not be of adequate thickness even though they may survive and cover the wound. Musculocutaneous flaps are more successful. Bulkiness may be undesirable in areas such as the scalp, face, neck, or hand. Defects in these areas that for other reasons require a musculocutaneous flap for coverage may need to be debulked in a secondary procedure. Axial skin flaps or free axial pattern flaps may be a better choice than musculocutaneous flaps in some areas.

Contraction begins during the proliferative phase of healing and continues to a large degree in wounds covered only by split-thickness skin grafts. The grafted area may shrink to 50% of its original size, and both the graft and surrounding tissue may become distorted. Splinting of the area for 10 days or longer may favorably alter contraction. Full-thickness skin grafts rich in dermis, attached to a fresh wound bed, will considerably reduce contraction, and skin flaps will eliminate it altogether. In an orifice or tubular passageway, such as the nasal airway, pharynx, esophagus, or vagina, absence of contraction is critical.

The effects of atrophy and gravity should also be considered when technique of coverage is chosen. A denervated muscle will atrophy up to 60% of its regular size. The muscle tissue in a musculocutaneous flap will atrophy even when the nerve to the muscle is preserved in the pedicle, because the muscle's functional tension is generally not restored. Gravity will cause sagging of any tissue that does not have enough plasticity or muscle dynamics to counteract gravitational pull. Reconstructions in the face often tend to sag.

Wounds at risk for or known to have bacterial contamination also require certain types of coverage (eg, pressure sores, lower extremity defects, and wounds resulting from incision and drainage of abscesses). If the area can be skin grafted, meshed split-thickness grafts are most effective, because bacterial exudate will not collect under these grafts. Musculocutaneous flaps are associated with fewer residual bacteria over time than are random pattern skin flaps. This is probably due to the vastly superior vascularity of musculocutaneous flaps.

Contaminated wounds or wounds that are exuding a considerable amount of fluid can be treated by negative-pressure or vacuum wound dressings. This entails the application of a sponge-like material connected to a suction device that keeps the wound dry as it suctions the excess exudates. The negative pressure on the wound also appears to have a positive effect on healing and increased revascularization. It has become a popular method of preparing a wound for definitive closure.

Wounds associated with nearby injuries that will probably require further surgery (eg, injuries to tendons or nerves) should be covered with flaps, because the flaps can be incised or undermined to allow for additional surgery. Skin grafts do not have sufficient vascularity to allow for these procedures.

► Excision & Primary Closure

The ideal type of wound closure is primary approximation of the skin and subcutaneous tissues immediately adjacent to the wound defect, producing a fine-line scar and the optimal aesthetic result in skin texture, thickness, and color match.

All excisions and wound closures should be planned with this ideal in mind. Obviously, large lesions cannot be excised and closed primarily. With invasive cancers, such as sarcomas, the primary goal is performance of adequate en bloc resection, with the type of wound closure being of secondary importance. Nevertheless, even larger excisions, such as mastectomies, can be planned with definite consideration for closure and subsequent reconstruction.

In most cases, minimal scars can be achieved only if the line or lines of incision are placed in, or parallel to, the skin lines of minimal tension. These lines lie perpendicular to the underlying muscles. On the face, they are obvious

▲ **Figure 41-4.** Sites of elliptic incisions corresponding to wrinkle lines on the face.

as wrinkles or lines of facial expression that become more pronounced with age, since they are secondary to repeated muscle contraction (Figure 41-4). On the neck, trunk, and extremities, the lines of minimal tension are most noticeable as horizontal lines of skin relaxation on the anterior and posterior aspects of areas of flexion and extension.

Langer lines, which were determined by cadaver study, probably show the direction of fibrous tissue bundles in the skin and are no longer considered accurate guides for placing skin incisions.

If the lines of expression cannot be followed, the line of incision should (if possible) be placed at the junction of unlike tissues such as the hairline of the scalp and the forehead, the eyebrow and the forehead, the mucosal and skin junction of the lips, or the areolar and skin margins of the breast. Scars will be partially hidden if incisions are placed in inconspicuous areas such as the crease of the nasal ala and cheek, the auricular-mastoid sulcus, or the submandibular-neck junction. Lines of incision should never purposely cross flexor surfaces such as the neck, axilla, antecubital fossa, or popliteal space or the palmar skin creases of the fingers and hand, because of the risk of contracture formation. A transverse oblique or S incision should be incorporated when crossing these sites.

If a lesion is to be excised, an elliptic incision placed parallel to the skin lines of minimal tension will give the best result if the amount of tissue to be excised does not preclude primary closure.

If the ellipse is too broad or short, a protrusion of skin, commonly called a “dog-ear,” will occur at each pole of the

▲ **Figure 41-5.** Correction of dog-ear.

wound closure (Figure 41-5). This is most easily corrected by excising the dog-ear as a small ellipse.

A dog-ear may also be present if one side of the ellipse is longer than the other (Figure 41-6). In this case, it may be easier to excise a small triangle of skin and subcutaneous tissue from the longer side.

A. Z-Plasty

One of the most useful and commonly used techniques in primary wound closure is the Z-plasty. The procedure is illustrated in Figure 41-7. The angles formed by the Z-shaped incision are transposed as shown in order (1) to gain length in the direction of the central limb of the Z or (2) to change the line of direction of the central limb of the Z. Ninety-degree angles would provide the greatest gain in length of the central limb, but smaller angles, such as 60-degree angles, are usually used, because the incision is easier to close and significant gain in length is still achieved. The Z-plasty is used for scar revision and reorientation of small wound incisions so that the main incision will be in a more ideal location. The lengthening function is used for the release or breakup of scar contractures across flexion creases. Frequently, many small Z-plasties in series rather than one large one are done. Occasionally, incisions will be placed under excessive vertical tension after the release of an underlying contracture, such as Dupuytren contracture in the hand.

▲ **Figure 41-7.** Z-plasty.

▲ **Figure 41-6.** Alternative method of correction of dog-ear.

B. Suture Technique

Suture technique in primary closure is important but will not compensate for poorly planned flaps, excessive tension across the incision, traumatized skin edges, bleeding, or other problems. Sometimes even a skillfully executed closure may result in an unsightly scar because of healing problems beyond the control of the surgeon.

The goal of closure is level apposition of dermal and epithelial edges with minimal or no tension across the incision and no strangulation of tissue between sutures. This is usually accomplished by placement of a layer of interrupted or running absorbable sutures in the superficial fascia and subdermal level at the base of the dermis. This suture prevents tension from forming in the upper dermis and epithelium and also causes the surface planes to be level. The epithelial edges can then be opposed with interrupted or running monofilament sutures of absorbable or permanent material. The absorbable suture is placed in the subcuticular or intradermal plane and is left in place. The permanent sutures are removed quickly according to the region of the body (within 3-4 days in the face), so the suture tracks can be avoided. Sterile adhesive tape (Steri-Strips) placed across the incision will also prevent surface marks and can be used either primarily or after surface sutures have been removed. Taping will not correct errors in suturing that have resulted in uneven edges or tension across the incision. Tape burns may occur if there is excessive tension or swelling around the incision.

The size and even the type of suture material are less important than careful suture placement and observance of previously mentioned factors. Almost any suture properly placed and removed early enough will provide closure without leaving suture marks. The use of monofilament nylon or polypropylene suture material is advised, however, because these types of sutures cause the fewest reactions of currently available suture materials, excluding stainless steel. Running subcuticular, pullout-type monofilament sutures may be left in for up to 3 weeks without causing reactions. Even buried nylon sutures are well tolerated and generally cause fewer problems than braided or absorbable sutures.

An alternative to sutures is the use of skin adhesives such as 2-octylcyanoacrylate (Dermabond). It works well in small areas without much tension or shearing. It is also advisable in children. Further studies are needed to evaluate its wider applicability.

► **Choice of Coverage**

Table 41–2 shows some of the indications for choice of coverage in various types of wounds. Once a given type of flap is chosen, there are still at least two major considerations in the selection of the exact flap to be used. The most significant consideration is the degree of injury that will occur in the donor area. There is always a trade-off when tissue is taken from one area and used in another. This trade-off is minimal when a well-designed, well-placed skin flap leaves a donor defect that can be closed primarily, but the trade-off is great when the donor defect is as severe as the original wound (eg,

skin graft donor sites that become infected or musculocutaneous donor sites that fail to heal).

The patient can often participate in the choice of donor locations and should certainly be made aware of potential donor site scars and complications. The tendency has been to use muscle flaps instead of musculocutaneous flaps to permit easy primary closure of the donor site. The muscle can then be resurfaced with a split-thickness skin graft during the same procedure to give a satisfactory result. This provides for an acceptable donor site scar rather than risking disruption of a tight closure or an otherwise ugly donor site.

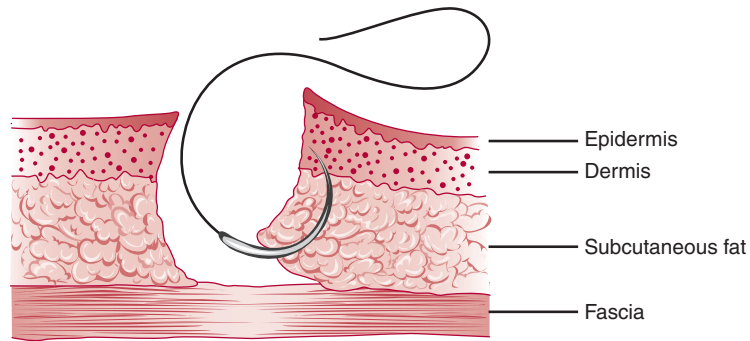

The second consideration in selection of a flap is that some or all of the graft or flap may be lost. In general, if the patient’s overall condition is poor or the loss of a flap would result in a devastating defect, a very reliable type of flap should be chosen. For example, a microvascular anastomosis can be performed on a leg with one remaining arteriosclerotic vessel to the foot, but if the anastomosis fails, the vessel may thrombose and the leg may be lost. In this case, a flap that is safer, although more time consuming to place, may be chosen, such as a cross-leg flap.

► **Elevation & Transposition of Flaps**

Additional considerations in reconstructive surgery involve the technique of elevating and transposing flaps. For random skin flaps, these considerations include proper length-to-width ratio, careful planning to allow for transposition with minimal tension and adjustments at the recipient site, accurate dissection in the subcutaneous plane to avoid injury to the subdermal plexus, and avoidance of folding or kinking of the flap.

Table 41–2. Indications for various types of tissue coverage.

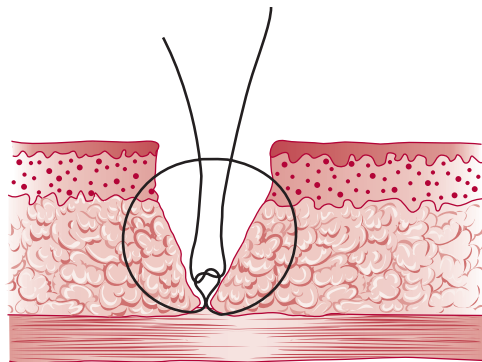

Type of Wound	Type of Coverage	Reason for Choice
Mildly (< 10 ⁵) infected wounds (including burns)	Thin split-thickness or meshed	Difficulty in obtaining successful take of thicker grafts. Donor sites may be reused sooner.
Significantly (> 10 ⁵) infected wounds (osteomyelitis)	Thin split-thickness or meshed skin grafts or muscle or musculocutaneous flaps	Rich muscle vascular supply can sterilize an infected wound.
Wounds with poorly vascularized surfaces	Thin split-thickness skin grafts or flaps	Difficulty in obtaining successful take of thicker grafts. Flap with intrinsic blood supply may be required.
Small facial defects	Full-thickness skin graft or local flap	Produces best aesthetic result.
Large facial defects	Thick split-thickness skin grafts or flaps	Cannot use full-thickness graft, because of limited size of donor sites.
Full-thickness eyelid loss	Local flap or composite graft	Repair requires more than one tissue element.
Deep loss of nasal tip	Local flap or composite graft	Repair requires thicker tissue than present in split- or full-thickness grafts.
Avulsive wounds with exposed tendons and nerves	Flap	Requires thick protective coverage without graft adherence to tendons and nerves.
Exposed cortical bone or cartilage	Skin or muscle flap	Free grafts will not survive on avascular recipient site.
Wounds resulting from radiation burns	Muscle or musculocutaneous flap	Free grafts will not survive on avascular recipient site. Damaged tissue extends deeper than may be apparent.

A. The strength of the closure lies in the dermis. Occasionally, the subcutaneous fat is incorporated to obliterate dead space.

B. The suture is placed so that the knot will lie in the deepest part of the wound. Take care to avoid incorporating the epidermis with this suture, since epithelial cysts will form and result in suture extrusion.

C. The dermal suture is tied just tightly enough to approximate the wound margins. Synthetic absorbable sutures are most commonly used for closure of the dermis.

D. After the dermis is approximated, a fine "epidermal" suture is placed to align the wound edges. This suture adds little to the tensile strength of the wound closure.

E. The epidermal suture is tied just tightly enough to approximate the epidermal edges of the wound. Since the strength of this closure lies in the dermis, the epidermal suture can be removed after 2–3 days. Skin tapes are often used to support the wound for an additional 7–10 days.

▲ **Figure 41–8.** Layered cutaneous closure (buried half-mattress [flap] sutures). (Reproduced, with permission, from Saunders CE, Ho MT, eds: *Current Emergency Diagnosis & Treatment*, 4th ed. New York: McGraw-Hill, 1992.)

Surgical technique must be atraumatic, and hemostasis must be achieved. With axial pattern flaps, the surgeon must have knowledge of the important underlying blood vessels as well.

► Closure Technique

Closure technique is as important as elevation and transposition technique. Flaps should not be allowed to dry out. The wound bed should be irrigated. Closed-system, nonreactive suction drains are routinely used in both the wound bed and the donor defect for most flaps of any significant size. Suction evacuates blood or serum that may accumulate and keeps the flap firmly pressed against the wound bed. External pressure is both ineffective and detrimental for these purposes. Sutures should accurately and completely appose skin edges without strangulating the epithelium, particularly on the flap side. Buried half-mattress (flap) sutures are recommended (Figure 41–8). Dressings over flaps should be minimal and should not cause pressure or constriction. Emollient dressings, such as petrolatum gauze, antibiotic ointment, or silver sulfadiazine cream, have been shown to aid in preventing desiccation and subsequent necrosis of areas of marginal vascularity.

After a flap is at least temporarily tacked into its final position, adequacy of vascularity can be determined by intravenous injection of fluorescein dye, 10–15 mg/kg, and examination under ultraviolet light (Wood light). Areas that fluoresce within 10 minutes following dye injection can be expected to survive. Areas that do not fluoresce usually lack arterial inflow, which may be due to temporary arterial spasm but is often due to insufficient perfusion that will result in necrosis. A good clinical evaluation of the flap on the operating table is usually sufficient. Any sign of mottling or cyanosis or flap congestion that indicates a degree of venous obstruction warrants serious consideration of reexploration.

III. SPECIFIC DISORDERS TREATED BY PLASTIC SURGERY

DISORDERS OF SCARRING

HYPERTROPHIC SCARS & KELOIDS

In response to any injury severe enough to break the continuity of the skin or produce necrosis, the skin heals with scar formation. Under ideal circumstances, a fine, flat hairline

scar will result. The details of wound healing are presented in Chapter 6.

However, hypertrophy may occur, causing the scar to become raised and thickened, or a keloid may form. A keloid is a true tumor arising from the connective tissue elements of the dermis. By definition, keloids grow beyond the margins of the original injury or scar; in some instances, they may grow to enormous size. (Figure 41–9)

Hypertrophic scars and keloids are distinct entities, and the clinical course and prognosis are quite different in each case. The overreactive process that results in thickening of the hypertrophic scar ceases within a few weeks—before it extends beyond the limits of the original scar—and in most cases, some degree of maturation occurs and gradual improvement takes place. In the case of keloids, the overreactive proliferation of fibroblasts continues for weeks or months. By the time it ceases, an actual tumor is present that typically extends well beyond the limits of the original scar, involves the surrounding skin, and may become quite large. Maturation with spontaneous improvement does not usually occur.

More recent research has shown differences on a biochemical level that can be quite complex. In essence though, it is understood that fibroblasts in both disorders display an increase in procollagen. This is compensated for in hypertrophic scars but not in keloids. This results in an increased ratio of type 1 to type 3 collagen in keloids.

► Treatment

The most frustrating aspect of hypertrophic and keloid treatment for both patient and care provider alike is the high incidence of recurrence. Much work has gone into

▲ **FIGURE 41–9.** A keloid scar—the excess growth of scar tissue at the site of a healed skin injury.

developing techniques to avoid and treat these scar problems, with mixed results. As this has become more evident, providers have become more specialized and aggressive with treatment options. More recent studies looking at treatments such as interferon, 5-fluorouracil injections and bleomycin injections have shown some promise. But no therapy has shown to conclusively treat these problems.

Since nearly all hypertrophic scars undergo some degree of spontaneous improvement, they do not require treatment in the early phases. If the scar is still hypertrophic after 6 months, surgical excision and primary closure of the wound may be indicated, but recurrence is between 45% and 100% if no other treatments are provided. Improvement may be expected when the hypertrophic scar was originally produced by excessive endothelial and fibroblastic cell proliferation, as is present in open wounds, burns, and infected wounds. However, little or no improvement can be anticipated if the hypertrophic scar followed uncomplicated healing of a simple surgical incision. Improvement of hypertrophic scars across flexion surfaces such as the antecubital fossa or the fingers requires a procedure such as a Z-plasty to change the direction of the scar.

Pressure may help flatten a potentially hypertrophic scar. It is particularly useful for burn scars. A measured elastic garment or face mask (Jobst) is applied to the scarred area and provides continued pressure that causes realignment and remodeling of the collagen bundles. Pressure should be applied early, continuously, and for 6-12 months. Use of intermittent pressure (eg, only at night) or pressure applied after the hypertrophic scar is established (6-12 months) is of little value.

Additional methods of decreasing the thickness of hypertrophied scars include silicone sheeting applied early and continuously for weeks or months. Laser therapy, such as CO₂, pulse dye, and flash lamps, have been examined with no definitive long-term success noted when used alone. Radiotherapy has a place in scar management although it is somewhat controversial due to potential carcinogenesis following procedure and the lack of long-term follow up studies. Cryotherapy has shown some success with small scars only. Interestingly enough, the simple use of paper tape over fresh surgical incisions for several weeks has shown to be a potential preventive treatment.

The first-line treatment for keloids and second-line therapy for intractable hypertrophic scars is still injection of triamcinolone acetonide, 10 mg/mL (Kenalog-10 Injection), directly into the lesion. Corticosteroid injection decreases fibroblast proliferation and collagen synthesis as well as suppressing pro-inflammatory markers. There is some evidence that keloids may respond better to early treatment rather than to late treatment.

Lesions are injected every 3-4 weeks, and treatment should not be carried out longer than 6 months. A general rule of thumb is to inject 10 mg of triamcinolone for each

centimeter in length of the scar. The following dosage schedule is used:

Size of Lesion

1-2 cm ²	20-40 mg
2-6 cm ²	40-80 mg
6-10 cm ²	80-110 mg

For larger lesions, the maximum dose should be 120 mg. The maximum doses for each treatment for children are as follows:

Age

1-2 years	20 mg
3-5 years	40 mg
6-10 years	80 mg

There is a tendency to inject the drug into the scar too often or in too high a dosage—or into the subjacent tissue, which may produce too vigorous a response, resulting in excessive atrophy of the skin and subcutaneous tissues surrounding the lesion and in depigmentation of darker skins. Both of these adverse responses may improve spontaneously in 6-12 months, but not necessarily completely. Cushing symptoms have even been reported with the overuse of corticosteroids for scar management. Topical corticosteroid therapy is of little or no value for substantial scarring but may have some place with more superficial scarring, such as in the case of dermabrasion.

At present, surgical excision is used only in conjunction with intralesional corticosteroid therapy. Excision is usually confined to the larger lesions in which steroid therapy would exceed safe dosages. (The wound is injected at the time of surgery and then postoperatively according to the schedule recommended above.) Care should be taken so that surgical incisions are not extended into the normal skin around the keloid, since the growth of a new keloid may occur in these scars.

CONTRACTURES

Contraction is a normal process of wound healing. Contracture, on the other hand, is a pathologic end stage related to the process of contraction. Generally, contractures

develop when wounds heal with too much scarring and contraction of the scar tissue results in distortion of surrounding tissues. Although scar contractures can occur in any flexible tissue, such as the eyelids or lips, contractures usually occur across areas of flexion, such as the neck, axilla, or antecubital fossa. The contracted scar brings together the structures on either side of the joint space and prevents active or even passive extension. Exceptions to this pattern of flexion contractures are extension contractures of the toes and metacarpophalangeal (MP) joints of the digits. Contraction is thought to occur via smooth muscle contractile elements in myofibroblasts, but the mechanism is not well understood. In one vertical abdominal scar, there may be an area of normal scar formation and an area of hypertrophic scar formation with visible contracture. Contracture can occur in response to the presence of foreign material such as Silastic or saline breast implants. Overall, there is a 10% incidence of some form of breast capsular contracture. Myofibroblasts are thought to play an important role, but the actual cause is not known.

Recent studies have shown that subacute infections with bacteria such as *Staphylococcus epidermidis* create a biofilm and are likely causes of implant contracture and implant complications.

The best treatment of contractures is prevention. Incisions should not be made at right angles to flexion creases or should be reoriented by Z-plasties. Wounds in areas of flexion can be covered with flaps or grafted early with thick split-thickness or full-thickness grafts to stop the process of contraction. Such wounds should also be splinted in a position of extension during healing and for 2-3 weeks after healing is complete. Vigorous physical therapy may also be helpful.

Once a contracture is established, stretching and massage are rarely beneficial. Narrow bands of contracture may be excised and released with one or more Z-plasties. Larger areas must be incised from the medial to the lateral axis across the flexion surface and completely opened up to full extension. The resulting defect can be extensive and must be resurfaced with a skin flap or skin graft. In recurrent contractures a fasciocutaneous flap is the treatment of choice. If a skin graft is used, the area must be splinted in extension for approximately 2 weeks after the graft has healed. Less aggressive surgery is likely to result in recurrence.

SKIN TUMORS

Tumors of the skin are by far the most common of all tumors in humans. They arise from each of the histologic structures that make up the skin—epidermis, connective tissue, gland, muscle, and nerve elements—and are correspondingly numerous in variety. Skin tumors are classified as benign, premalignant, and malignant.

BENIGN SKIN TUMORS

The many benign tumors that arise from the skin rarely interfere with function. Since most are removed for aesthetic reasons or to rule out malignancy, they are quite commonly treated by the plastic surgeon. The majority are small and can be simply excised under local anesthesia following the principles of elliptical excision and wound closure discussed above. General anesthesia may be necessary for larger lesions requiring excision and repair by skin grafts or flaps or those occurring in young children.

When the diagnosis is not in doubt, most superficial lesions (seborrheic keratoses, verrucae, squamous cell papillomas) can be treated by simple techniques such as electrodesiccation, curettage and electrodesiccation, cryotherapy, and topical cytotoxic agents.

► Seborrheic Keratosis

Seborrheic keratoses are superficial noninvasive tumors that originate in the epidermis. They appear in older people as multiple slightly elevated yellowish, brown, or brownish-black irregularly rounded plaques with waxy or oily surfaces. They are most commonly found on the trunk and shoulders but are frequently seen on the scalp and face.

Because the lesion is raised above the epidermis, treatment usually consists of shave excision. Care should be exercised to avoid shaving a melanoma because if that is done, it will interfere with the determination of the depth of invasion by the Breslow or Clark classifications. If there is any question about a pigmented lesion, it is preferable to do an excisional biopsy rather than to shave it.

► Verrucae

Verrucae (common warts) are usually seen in children and young adults, commonly on the fingers and hands. They appear as round or oval elevated lesions with rough surfaces composed of multiple rounded or filiform keratinized projections. They may be skin colored or gray to brown.

Verrucae are caused by a virus and are autoinoculable, which can result in multiple lesions around the original growth or frequent recurrences following treatment if the virus is not completely eradicated. They may disappear spontaneously.

Treatment by electrodesiccation is effective but is frequently followed by slow healing. Repeated applications

of bichloroacetic acid, liquid nitrogen, or liquid CO₂ are also effective. Surgical excision alone is not recommended, because the wound may become inoculated with the virus, leading to recurrences in and around the scar. However, surgical excision in conjunction with electrodesiccation, can be an effective form of treatment.

Recurrence remains a common problem; therefore, it is reasonable to delay treatment of asymptomatic lesions for several months to determine if they will disappear spontaneously.

Lee EH, Nehai KS, Disa JJ: Benign and premalignant lesions CME. *Plast Reconstr Surg* 2010;125(5):188e.

► Cysts

A. Epidermal Inclusion Cyst

Although sebaceous cyst is the commonly used term, these lesions more properly should be called epidermal inclusion cysts because they are composed of thin layers of epidermal cells filled with epithelial debris. True cysts arising from sebaceous epithelial cells are uncommon.

Epidermal inclusion cysts are soft to firm, usually elevated, and are filled with an odorous cheesy material. Their most common sites of occurrence are the scalp, face, ears, neck, and back. They are usually covered by normal skin, which may show dimpling at the site of skin attachment. They frequently present as infected cysts.

Treatment consists of surgical excision.

B. Dermoid Cyst

Dermoid cysts are deeper than epidermal cysts. They are not attached to the skin but frequently are attached to or extend through underlying bony structures. They may appear in many sites but are most common around the nose or the orbit, where they may extend to meningeal structures, necessitating CT scans to determine their extent.

Treatment is by surgical excision, which may necessitate sectioning of adjacent bony structures.

► Pigmented Nevi

Nevocellular nevi are groups of cells of probable neural crest origin that contain melanocytes that form melanin more rapidly upon stimulation than surrounding tissue. These cells migrate to different parts of the skin to give different types of nevi. They may also be distinguished by their clinical presentation.

A. Junctional Nevi

Junctional nevi are well-defined pigmented lesions appearing in infancy. They are usually flat or slightly elevated and light brown to dark brown. They may appear on any part of

the body, but most nevi seen on the palms, soles, and genitalia are of the junctional type. Histologically, a proliferation of melanocytes is present in the epidermis at the epidermal-dermal junction. It was formerly thought that these nevi give rise to malignant melanoma and that all junctional nevi should be excised for prophylactic reasons. However, most investigators now feel that the risk is very slight. If there is no change in their appearance, treatment is unnecessary. Any change such as itching, inflammation, darkening in color, halo formation, increase in size, bleeding, or ulceration calls for immediate treatment.

Surgical excision is the only safe method of treatment.

B. Intradermal Nevi

Intradermal nevi are the typical dome shaped, sometimes pedunculated, fleshy to brownish pigmented moles that are characteristically seen in adults. They frequently contain hairs and may occur anywhere on the body.

Microscopically, melanocytes are present entirely within the dermis and, in contrast to junctional nevi, show little activity. They are rarely malignant and require no treatment except for aesthetic reasons.

Surgical excision is nearly always the treatment of choice. Pigmented nevi should never be treated without obtaining tissue for histologic examination.

C. Compound Nevi

Compound nevi exhibit the histologic features of both junctional and intradermal nevi in that melanocytes lie both at the epidermal-dermal junction and within the dermis. They are usually elevated, dome shaped, and light-brown to dark-brown in color.

Because of the presence of nevus cells at the epidermal-dermal junction, the indications for treatment are the same as for junctional nevi. If treatment is indicated, surgical excision is the method of choice.

D. Spindle Cell-Epithelioma Cell Nevi

These nevi, formerly called benign juvenile melanomas, appear in children or adults. They vary markedly in vascularity, degree of pigmentation, and accompanying hyperkeratosis. Clinically, they simulate warts or hemangiomas rather than moles. They may increase in size rapidly, but the average lesion reaches only 6-8 mm in diameter, remaining entirely benign without invasion or metastases. Microscopically, the lesion can be confused with malignant melanoma by the inexperienced pathologist. The usual treatment is excisional biopsy.

E. Blue Nevi

Blue nevi are small, sharply defined, round, dark blue or grayish-blue lesions that may occur anywhere on the body

but are most commonly seen on the face, neck, hands, and arms. They usually appear in childhood as slowly growing, well-defined nodules covered by a smooth, intact epidermis. Microscopically, the melanocytes that make up this lesion are limited to (but may be found in all layers of) the dermis. An intimate association with the fibroblasts of the dermis is seen, giving the lesion a fibrotic appearance not seen in other nevi. This, together with extension of melanocytes deep into the dermis, may account for the blue rather than brown color.

Treatment is not mandatory unless the patient desires removal for aesthetic reasons or fear of cancer. Surgical excision is the treatment of choice.

F. Giant Hairy Nevi

Unlike most nevi arising from melanocytes, giant hairy nevi are congenital. They may occur anywhere on the body and may cover large areas. They may be large enough to cover the entire trunk (bathing trunk nevi). They are of special significance for several reasons: (1) Their large size is especially deforming from an aesthetic standpoint; (2) they show a predisposition for developing malignant melanoma; and (3) they may be associated with neurofibromas or melanocytic involvement of the leptomeninges and other neurologic abnormalities.

Microscopically, a varied picture is present. All of the characteristics of intradermal and compound nevi may be seen. Neurofibromas may also be present within the lesion. Malignant melanoma may arise anywhere within the large lesion; the reported rate of occurrence ranges from 1% to as high as 13.7% in one study. Malignant melanoma with metastases rarely arises in childhood or infancy.

The only full treatment is complete excision and skin grafting. Large lesions may require excision and grafting in stages. Some lesions are so large that excision is not possible and the most effective approach is using tissue expansion in combination with flaps. Split-thickness excision or dermabrasion has been successful when done in infancy.

The use of cultured epithelial autografts has been advocated for extensive lesions associated with multiple satellite nevi. Additionally, some have reported the use of laser photothermolysis of pigmented lesions that cannot be excised with favorable reconstructive outcomes. However, there is still concern over malignant transformation of remaining melanocytes, and close long-term follow-up is recommended when laser ablation is used.

► Vascular Tumors & Vascular Malformations

Our understanding of vascular tumors and vascular malformations has evolved a great deal since the description by

Mulliken and Glowacki in 1982 of the biologic classification of vascular anomalies based on their endothelial properties. In this way, infant hemangiomas appear within the first 3 weeks of life and have a proliferative endothelium that grows rapidly at first and commonly involutes usually in the first few years of life. Vascular malformations, on the other hand, have stable endothelium, grow proportionally with the child, and persist into adulthood. They can be associated with various complications, such as skeletal abnormalities, ischemia, coagulopathy, heart failure, and death.

Glucose transporter isoform 1 (GLUT1) has recently been discovered to be a distinguishing feature among various forms of vascular anomalies. It is an immunohistochemical marker that is normally restricted to endothelial cells with blood-tissue barrier function as in the brain and placenta. North and colleagues retrospectively studied specimens from vascular tumors for GLUT1. Specimens from infantile hemangiomas were universally positive. In contrast, biopsies of other vascular anomalies, including rapidly involuting congenital hemangioma (RICH), noninvoluting congenital hemangioma (NICH), pyogenic granuloma, granulation tissue, vascular malformations, and tufted angioma and kaposiform hemangioendothelioma, were all negative. In addition to providing an early diagnostic assay for hemangiomas, GLUT1 can be useful in research and in trying to explain the pathophysiology.

The International Society for the Study of Vascular Anomalies proposed a classification in 1996 based on the pioneering work of Mulliken and Glowacki. It is now the most widely accepted among specialists and in the literature. Clear classification is vitally important so that proper communication regarding diagnosis and treatment can be established. Table 41–3 shows that classification.

Table 41–3. International Society for the Study of Vascular Anomalies Classification.

Tumors
Juvenile hemangioma
Rapidly involuting congenital hemangioma (RICH)
Noninvoluting congenital hemangioma (NICH)
Kaposiform hemangioendothelioma
Tufted angioma
Vascular malformations
High-flow
Arteriovenous malformation
Low-flow
Venous malformation
Lymphatic malformation
Lymphatic-venous malformation
Capillary (or venular) malformation (port wine stain)

A. Hemangiomas of Infancy (Involuting Hemangioma)

Involuting hemangiomas are the most common tumors that occur in childhood and constitute at least 95% of all the hemangiomas that are seen in infancy and childhood. They are true neoplasms of endothelial cells but are unique among neoplasms in that they undergo complete, spontaneous involution.

Typically, they are present shortly after birth or appear during the first 2-3 weeks of life. They grow at a rather rapid rate for 4-6 months; then growth ceases and spontaneous involution begins. Involution progresses slowly but approximately 50% are involuted by 5 years of age and 70% by age 7. Involuting hemangiomas appear on all body surfaces but are seen more often on the head and neck. They are seen twice as often in girls as in boys and show a predisposition for fair-skinned individuals.

Three forms of infantile hemangiomas are seen: (1) superficial, (2) combined superficial and deep (mixed), and (3) deep. Superficial involuting hemangiomas appear as sharply demarcated, bright-red, slightly raised lesions with an irregular surface that has been described as resembling a strawberry. Combined superficial and deep involuting hemangiomas have the same surface characteristics, but beneath the skin surface, a firm bluish tumor is present that may extend deeply into the subcutaneous tissues. Deep involuting hemangiomas present as deep blue tumors covered by normal-appearing skin.

Hemangiomas are the result of angiogenic dysfunction. Multiple markers of angiogenesis are increased during the proliferative flow, including fibroblast growth factor, vascular endothelial growth factor, and matrix metalloproteinases. These all decrease with the exception of basic fibroblast growth factor during the involution phase.

As the phase of involution progresses, the histologic picture changes, with the solid fields of endothelial cells breaking up into closely packed, capillary-sized, vessel-like structures composed of several layers of soft endothelial cells supported by a sparse fibrous stroma. These vascular structures gradually become fewer and spaced more widely apart in a loose, edematous fibrous stroma. The endothelial cells continue to disappear, so that by the time involution is complete the histologic picture is entirely normal, with no trace of endothelial cells.

Treatment is not usually indicated, since the appearance following spontaneous regression is nearly always superior to the scars that follow surgical excision. Surgical excision of lesions that involve important structures such as the eyelids, nose, or lips may sometimes be necessary in order to avoid serious functional disturbances of vision and airway. Complete excision is usually not necessary.

When treatment is indicated, multiple options have been described including cryotherapy, corticosteroids, interferon

and chemotherapy. More recently, the use of the beta blocker propranolol has shown to halt hemangioma progression and dramatically shorten the involution time. Usual doses are from 2-3 mg/kg/day, and infants are usually admitted for 24 hours upon starting this therapy for cardiac monitoring. Although the actual mechanism of action remains unknown, it most likely has to do with downregulation of angiogenic growth factors. It has shown such good results that some institutions are using this as a first-line treatment for complicated infantile hemangiomas.

Ulceration is a painful and dangerous complication with hemangiomas that can develop in approximately 8% of patients. This may be accompanied by infection, which is treated by the use of compresses of warm saline or potassium permanganate and by the application of antimicrobial powders and creams. Bleeding from the ulcer can occur if there is constant irritation and inflammation. When it occurs, gentle pressure should be applied. In some situations, such as the perianal region, specific measures may be needed to keep the area clean and dry including a diverting colostomy combined with judicious serial excision. In rare cases, the platelet trapping of these lesions leads to the clinical picture of disseminated intravascular coagulopathy called **Kasabach-Merritt syndrome**.

B. Congenital Hemangiomas (RICH and NICH)

Congenital hemangiomas, as their name implies, are present at birth. They have undergone their rapid growth phase *in utero*, and in contrast to hemangiomas of infancy, they do not undergo rapid growth during the first 4-6 months of life. Because of their natural history they are divided into two subtypes: RICH and NICH. RICH are more common than NICH, although both are rare. The diagnosis of RICH is confirmed when they rapidly involute by 6-10 months of age. The NICH anomalies, on the other hand, persist into adulthood and may require surgical excision or other ablative measures. Imaging may be helpful (sonography or MRI) in order to evaluate location and extent of the tumor. Both RICH and NICH are GLUT1 negative in contrast to hemangiomas of infancy.

C. Capillary Malformations

Capillary malformations (ie, **port-wine stains**) are by far the most common of the vascular malformations. They may

involve any portion of the body but most commonly appear on the face as flat patchy lesions that are reddish to purple in color. When present on the face, they are located in areas supplied by the sensory branches of the fifth (trigeminal) cranial nerve. They usually start off light red in color yet have a propensity to deepen in color, as their name implies. Their growth is variable, but they persist into adulthood if not treated and become raised and thickened with nodules appearing on the surface (Figure 41–10).

Microscopically, port-wine stains are made up of thin-walled capillaries that are arranged throughout the dermis. The capillaries are lined with mature, flat endothelial cells. In the lesions that produce surface growth, groups of round proliferating endothelial cells and large venous sinuses are seen.

▲ Figure 41–10. 46-year-old white female with untreated port-wine stain of left face. **A.** Preoperative. **B.** Status postexcision of facial portion and reconstruction with free tissue transfer.

Results following treatment of the port-wine stain were uniformly disappointing. Because most lesions occur on the face or neck, patients seek treatment for aesthetic reasons, but as they progress in thickness and nodularity, they can become functionally disabling and can bleed spontaneously. The simplest method of treatment is camouflaging. Unfortunately, this is difficult because the port-wine stain is darker than the surrounding lighter skin, and it does not affect the natural history of the lesion.

Superficial methods of treatment such as dry ice, liquid nitrogen, electrocoagulation, and dermabrasion have been tried but are ineffective unless they destroy the upper layers of the skin, which can produce severe scarring.

Radiation therapy, including the use of x-rays, radium, thorium X, and grenz x-rays, is to be condemned. If it is administered in doses high enough to destroy the vessels involved, it also destroys the surrounding tissues and the overlying skin, and the cancer incidence after radiotherapy for skin hemangioma increases.

The best treatment to date for early and intermediate port-wine stains is with the pulsed dye laser. The pulsed dye laser produces a light with a specific wavelength of 585 or 595 nanometers. The method of treatment is termed selective photothermolysis. The beam is selectively absorbed by red-pigmented material such as hemoglobin in the blood vessels of the lesion. This produces selective heat destruction of these structures, and the treated area becomes whiter. When started early, these treatments can be very effective. Multiple treatments are necessary to obtain a satisfactory result. In darker and more advanced nodular lesions, the laser is less effective because of the thickness of the lesion and the hyperpigmentation that may develop.

If the lesion is small, surgical excision with primary closure is possible. Unfortunately, most lesions are large. In the case of long-standing untreated lesions, surgical excision may be necessary, followed by skin grafting, locoregional flaps, or at times free tissue transfer. Certain fast-growing capillary or primarily arterialized hemangiomas have been managed successfully with superselective embolization, either alone or in conjunction with surgery. This is performed under fluoroscopic control and with an expert team. There have been reports of slough of large portions of the face as a result of misdirected embolizations.

D. Venous Malformations

Venous malformations (otherwise known as cavernous hemangiomas) are bluish or purplish lesions that are usually elevated. They may occur anywhere on the body but, like other vascular lesions, are more common on the head and neck. They are composed of mature, fully formed venous structures that are present in tortuous masses that have been described as feeling like a bag of worms.

Venous malformations are usually present at birth but do not usually grow except to keep pace with normal body growth. In many cases, growth occurs later in life and may interfere with normal function.

Microscopically, venous malformations are made up of large, dilated, closely packed vascular sinuses that are engorged with blood. They are lined by flat endothelial cells and may have muscular walls like normal veins.

Treatment is difficult. In only a few cases is the lesion small enough or superficial enough to permit complete surgical excision. Most lesions involve deeper structures—including muscle and bone—so that complete excision is impossible without radical surgery. Since most lesions are no more than aesthetic problems, radical surgery is rarely indicated. Occasionally, the injection of sclerosing agents directly into the venous channels may lead to some involution or may make surgical excision easier. Great care must be used so that areas of overlying skin do not slough.

E. Arteriovenous Malformations

Arteriovenous malformations are high-flow lesions having a direct connection between an artery and a vein, bypassing the capillary bed.

Arteriovenous malformations are typically recognized at birth but are misdiagnosed as capillary malformations or involuting hemangiomas. Periods of rapid growth are found after trauma and during periods when the body is under the influence of hormonal changes.

Clinical diagnosis can be confirmed with color Doppler examination, but this does not give information concerning extent of the lesion or relation to surrounding structures. This information can be obtained via MRI or angiography, which has the additional benefit of therapeutic embolization.

Treatment for arteriovenous malformations is based on clinical stage of the lesion. Smaller arteriovenous malformations can be primarily resected. Larger, more diffuse arteriovenous malformations are best managed with superselective arterial embolization followed by surgical resection 24-48 hours after embolization in order to minimize intraoperative blood loss.

PREMALIGNANT SKIN LESIONS

► Actinic (Solar) Keratoses

Actinic keratoses are the most common of the precancerous skin lesions. They usually appear as small, single or multiple, slightly elevated, scaly or warty lesions ranging in color from red to yellow, brown, or black. Because they are related to sun exposure, they occur most frequently on the face and the backs of the hands in fair-skinned Caucasians whose skin shows evidence of actinic elastosis.

Microscopically, actinic keratoses consist of well-defined areas of abnormal epithelial cells limited to the epidermis. Approximately 15%-20% of these lesions become malignant, in which case invasion of the dermis as squamous cell carcinoma occurs.

Since the lesions are limited to the epidermis, superficial treatment in the form of curette and electrodesiccation or the application of chemical agents such as liquid nitrogen, phenol, bi- or trichloroacetic acid, or fluorouracil is curative. The application of fluorouracil (5-FU) cream is of particular benefit in preventive treatment in that it destroys lesions of microscopic size—before they can be detected clinically—without causing damage to uninvolved skin.

► Chronic Radiation Dermatitis & Ulceration

There are two distinct types of radiation dermatitis. The first and most common follows the acute administration of relatively high dosages of ionizing orthovoltage radiation over relatively short periods—almost always for the treatment of cancer. Dermatitis is characterized by an acute reaction that begins near the third week of therapy, when erythema, blistering, and sloughing of the epidermis start to occur. Burning and hyperesthesia are commonly present. This initial reaction is followed by scarring characterized by atrophy of the epidermis and dermis along with loss of skin appendages (sweat glands, sebaceous glands, and hair follicles). Marked fibrosis of the dermis occurs, with gradual endarteritis and occlusion of the dermal and subdermal vessels. Telangiectasia of the surface vessels is seen, and areas of both hypopigmentation and hyperpigmentation occur.

The second type of radiation dermatitis follows chronic exposure to low doses of ionizing radiation over prolonged periods. It is usually seen in professional personnel who handle radioactive materials or administer x-rays or in patients who have been treated for dermatologic conditions such as acne or excessive facial hair. Therefore, the face and hands are most commonly involved. The acute reaction described above does not usually occur, but the same process of atrophy,

scarring, and loss of dermal elements occurs. Drying of the skin becomes more pronounced, and deepening of the skin furrows is typically present. Fortunately, this second type of radiation dermatitis is rarely seen today.

In both types of radiation dermatitis, late changes such as the following may occur: (1) the appearance of hyperkeratotic growths on the skin surface, (2) chronic ulceration, and (3) the development of either basal cell or squamous cell carcinoma. Ulceration and cancer, however, are seen much less commonly in the first type of radiation dermatitis than in the second. When malignant growths appear, basal cell carcinomas are seen more frequently on the face and neck and squamous cell carcinomas more frequently on the hands and body.

Newer radiotherapeutic methods using megavoltage and electron beam techniques have a sparing effect on the skin. However, marked scarring and avascularity of deeper, more extensive areas may present more difficult problems.

Surgical excision is the treatment of choice. Excision should include all of the irradiated tissue including the area of telangiectasia, whenever possible, and the defect should be covered with an appropriate axial or musculocutaneous flap to provide a new blood supply.

Primary wound closure is feasible for only the smallest lesions, and even so, at some risk. Free-skin grafting is usually unsuccessful because of the damage to the vascular supply of the subcutaneous structures. Adjacent random flaps are unreliable because they depend on blood supply from the surrounding irradiated area.

MALIGNANT LESIONS

1. Intraepidermal Carcinoma

Intraepidermal carcinoma includes Bowen disease and erythroplasia of Queyrat.

► Bowen Disease

Bowen disease is characterized by single or multiple, brownish or reddish plaques that may appear anywhere on the skin surface but often on covered surfaces. The typical plaque is sharply defined, slightly raised, scaly, and slightly thickened. The surface is often keratotic, and crusting and fissuring may be present. Ulceration is not common but when present suggests malignant degeneration with dermal invasion.

Histologically, hyperplasia of the epidermis is seen, with pleomorphic malpighian cells, giant cells, and atypical epithelial cells that are limited to the epidermis.

Treatment of small or superficial lesions consists of total destruction by curette and electrodesiccation or by any of the other superficially destructive methods (cryotherapy, cytotoxic agents). Excision and skin grafting are preferred for larger lesions and for those that have undergone early malignant degeneration and invasion of the dermis.

► Erythroplasia of Queyrat

Erythroplasia of Queyrat is almost identical to Bowen disease both clinically and histologically but is confined to the glans penis and the vulva, where the lesions appear as red, velvety, irregular, slightly raised plaques. Treatment is as described for Bowen disease.

2. Basal Cell Carcinoma

Basal cell carcinoma is the most common skin cancer. The lesions usually appear on the face and are more common in men than in women. Since exposure to ultraviolet rays of the sun is a causative factor, basal cell carcinoma is most commonly seen in geographic areas where there is significant sun exposure and in people whose skin is most susceptible to actinic damage from exposure (ie, fair-skinned individuals with blue eyes and blond hair). It may occur at any age but is not common before age 40.

The growth rate of basal cell carcinoma is usually slow but nearly always steady and insidious. Several months or years may pass before the patient becomes concerned. Without treatment, widespread invasion and destruction of adjacent tissues may occur, producing massive ulceration. Penetration of the bones of the facial skeleton and the skull may occur late in the course. Basal cell carcinomas rarely metastasize, but death can occur because of direct intracranial extension or erosion of major blood vessels.

Typical individual lesions appear as small, translucent or shiny (“pearly”) elevated nodules with central ulceration and rolled, pearly edges. Telangiectatic vessels are commonly present over the surface, and pigmentation is sometimes present. Superficial ulceration occurs early.

A less common type of basal cell carcinoma is the **sclerosing or morphea carcinoma**, consisting of elongated strands of basal cell cancer that infiltrate the dermis, with the intervening corium being unusually compact. These lesions are usually flat and whitish or waxy in appearance and firm to palpation—similar in appearance to localized scleroderma. They are particularly difficult to treat because it is difficult to clinically predict the extent of the margins of growth.

The superficial **erythematous basal cell cancer** (“body basal”) occurs most frequently on the trunk. It appears as reddish plaques with atrophic centers and smooth, slightly raised borders. These lesions are capable of peripheral growth and wide extension but do not become invasive until late.

Pigmented basal cell carcinomas may be mistaken for melanomas because of the large number of melanocytes present within the tumor. They may also be confused with seborrheic keratoses.

► Treatment

There are several methods of treating basal cell carcinoma. All may be curative in some lesions, but no one method is

applicable to all. The special features of each basal cell cancer must be considered individually before proper treatment can be selected.

Because most lesions occur on the face, aesthetic and functional results of treatment are important. However, the most important consideration is whether or not therapy is curative. If the basal cell carcinoma is not eradicated by the initial treatment, continued growth and invasion of adjacent tissues will occur, resulting not only in additional tissue destruction but also in invasion of the tumor into deeper structures, making cure more difficult. Adequate treatment of basal cell carcinoma by different modalities achieves a cure rate of approximately 95%.

The principal methods of treatment are curettage and electrodesiccation, surgical excision, and radiation therapy. Chemosurgery, topical chemotherapy, and cryosurgery are not often used but may have value in selected cases.

A. Curettage and Electrodesiccation

Curettage plus electrodesiccation is the usual method of treatment for small lesions. After infiltration with suitable local anesthetic, the lesion and a 2-3 mm margin of normal-appearing skin around it are thoroughly curetted with a small skin curette. The resultant wound is then completely desiccated with an electrosurgical unit to destroy any tumor cells that may not have been removed by the curette. The process is then repeated once or twice if necessary. The wound is left open and allowed to heal secondarily.

B. Surgical Excision

Surgical excision, following the principles outlined earlier in this chapter, offers many advantages in the treatment of basal cell carcinoma: (1) Most lesions can be quickly excised in one procedure. (2) Following excision, the entire lesion can be examined by the pathologist, who can determine if the tumor has been completely removed. (3) Deep infiltrative lesions can be completely excised, and cartilage and bone can be removed if they have been invaded. (4) Lesions that occur in dense scar tissue or in other poorly vascularized tissues cannot be treated by curettage and desiccation, radiation therapy, or chemosurgery, since healing is poor. Excision and flap coverage may be the only method for treatment in these conditions. (5) Recurrent lesions in tissues that have been exposed to maximum safe amounts of radiation can be excised and covered.

Small- to moderate-sized lesions can be excised in one stage under local anesthesia. The visible and palpable margins of the tumor are marked on the skin with marking ink. The width of excision is then marked 3-5 mm beyond these margins. If the margins of the basal cell carcinoma are vague, the width of excision will have to be wider to ensure complete removal of the lesion. The lines of incision are drawn around the lesion as a circle. This tissue is

excised, taking care to leave a margin of normal-appearing subcutaneous tissue around the deep margins of the tumor. Frozen sections may be obtained at the time of excision to aid in determining whether tumor-free margins have been obtained. This is minimized with experience. It is better to err on the side of removing more normal tissue than necessary rather than to risk including tumor at the margins. Closure of the wound is accomplished in the direction of minimal skin tension, usually along the skin lines. The dog-ears are removed appropriately.

Wounds resulting from the excision of some moderate-sized tumors and nearly all large tumors may require reconstruction of function and appearance with the use of local, regional, and free flaps. This can nearly always be performed in one stage with good frozen section control.

The disadvantages of surgical excision are as follows: (1) Certain large excisions and reconstruction require specialized training and experience to master the surgical techniques. (2) Whereas curettage and desiccation may be performed in the office, surgical excision often requires specialized facilities. (3) In lesions with vague clinical margins, an excessive amount of normal tissue may have to be excised to ensure complete removal even with the use of frozen section verification. (4) Reconstruction may need to wait until permanent pathologic diagnosis and margins are available in cases involving deep or specialized structures.

To overcome some of these objections, Mohs described a new technique in 1941 that allows for serial excisions and microscopic examination of chemically fixed tissue. Newer developments have obviated the cumbersome fixation techniques, but it may still take several hours to scan an area for suspected malignant cells. The procedure is nevertheless quite useful for recurrent lesions and in areas in which maximal preservation is desirable. Nonetheless, there are no prospective comparative studies to indicate that the microscopically controlled removal of tumor by the Mohs technique, which amounts to excision of the lesion with serial review by fresh frozen section, is superior to surgical excision. An additional problem is that there is no quality control because the excising physician is also the one who evaluates the pathology slides. Many of the more extensive lesions treated with the Mohs technique require complex reconstruction to rebuild noble structures that have needed resection.

Wheiss GJ, Korn RL: Metastatic basal cell carcinoma in the era of hedgehog signaling pathway inhibitors. *Cancer* 2012 Nov 1;118(21):5310-9.

C. X-ray Therapy

X-ray therapy is as effective as any other in the treatment of basal cell carcinoma. Its advantages are as follows: (1)

Structures that are difficult to reconstruct, such as the eyelids, tear ducts, and nasal tip, can be preserved when they are invaded by but not destroyed by tumor. (2) A wide margin of tissue can be treated around lesions with poorly defined margins to ensure destruction of nondiscernible extensions of tumor. (3) It may be less traumatic than surgical excision to elderly patients with advanced lesions. (4) Hospitalization is not necessary.

The disadvantages are as follows: (1) Only well-trained, experienced physicians can obtain good results. (2) Expensive facilities are necessary. (3) Improperly administered radiation therapy may produce severe sequelae, including scarring, radiation dermatitis, ulceration, and malignant degeneration. (4) In hair-bearing areas, epilation will result. (5) It may be difficult to treat areas of irregular contour (eg, the ear and the auditory canal). (6) Repeated treatments over a period of 4-6 weeks may be necessary.

X-ray therapy should not be used in patients under age 40 except in unusual circumstances, and it should not be repeated in patients who have failed to respond to radiation therapy in the past.

3. Squamous Cell Carcinoma

Squamous cell carcinoma is the second-most common cancer of the skin in light-skinned racial groups and the most common skin cancer in darkly pigmented racial groups. As with basal cell carcinoma, sunlight is the most common causative factor in whites. The most common sites of occurrence are the ears, cheeks, lower lip, and backs of the hands. Other causative factors are chemical and thermal burns, scars, chronic ulcers, chronic granulomas (tuberculosis of the skin, syphilis), draining sinuses, contact with tars and hydrocarbons, and exposure to ionizing radiation. When a squamous cell carcinoma occurs in a burn scar, it is called a **Marjolin ulcer**. This lesion may appear many years after the original burn. It tends to be aggressive, and the prognosis is poor.

Because exposure to the sun is the greatest stimulus for the production of squamous cell carcinoma, most of these lesions are preceded by actinic keratosis on areas of the skin showing chronic solar damage. They may also arise from other premalignant skin lesions and from normal-appearing skin.

The natural history of squamous cell carcinoma may be quite variable. It may present as a slowly growing, locally invasive lesion without metastases or as a rapidly growing, widely invasive tumor with early metastatic spread. In general, squamous cell carcinomas that develop from actinic keratoses are more common and are of the slowly growing type, whereas those that develop from Bowen disease, erythroplasia of Queyrat, chronic radiation dermatitis, scars, and chronic ulcers tend to be more aggressive. Lesions that arise from normal-appearing skin and from the lips, genitalia, and anal regions also tend to be aggressive.

Early squamous cell carcinoma usually appears as a small, firm erythematous plaque or nodule with indistinct margins. The surface may be flat and smooth or may be verrucous. As the tumor grows, it becomes raised and, because of progressive invasion, becomes fixed to surrounding tissues. Ulceration may occur early or late but tends to appear earlier in the more rapidly growing lesions.

Histologically, malignant epithelial cells are seen extending down into the dermis as broad, rounded masses or slender strands. In squamous cell carcinomas of low-grade malignancy, the individual cells may be quite well differentiated, resembling uniform mature squamous cells having intercellular bridges. Keratinization may be present, and layers of keratinizing squamous cells may produce typical round "horn pearls." In highly malignant lesions, the epithelial cells may be extremely atypical; abnormal mitotic figures are common; intercellular bridges are not present; and keratinization does not occur.

► Treatment

As with basal cell carcinomas, the method of treatment that will eradicate squamous cell carcinomas and produce the best aesthetic and functional results varies with the characteristics of the individual lesion. Factors that determine the optimal method of treatment include the size, shape, and location of the tumor as well as the histologic pattern that determines its aggressiveness.

The mainstay of treatment is surgery. Radiation has also been used in some circumstances. Since basal cell carcinomas are relatively nonaggressive lesions that rarely metastasize, failure to eradicate the lesion may result only in local recurrence. Although this may result in extensive local tissue destruction, there is rarely a threat to life. Aggressive squamous cell carcinomas, on the other hand, may metastasize to any part of the body, and failure of treatment may have fatal consequences. For this reason, total eradication of each lesion is the imperative goal of treatment.

The use of sentinel lymph node biopsy (SLNB) is usually reserved for those patients with a high risk squamous cell cancer or when the lesion is larger than 2 cm. This procedure maps the first node basin that any disease would travel to if metastatic. Palpable nodes of any type are a contraindication for SLNB.

SOFT TISSUE INJURY

The plastic surgeon is often involved in emergency room assessment and treatment of soft tissue injuries. Many aspects of wound management must be considered in even a relatively simple facial laceration.

Careful analysis of the soft tissue injury should include (1) the type of wound or wounds (abrasion, contusion, etc); (2) the cause of injury; (3) the age of the injury; (4) the location of injured tissues; (5) the degree of contamination of the injured area before, during, and after trauma; (6) the nature and extent of associated injuries; and (7) the general health of the patient (eg, any chronic or acute illnesses or any allergies; any medications being taken).

The location of the wound must be noted because different healing characteristics are present in various types of skin. The face and scalp are highly vascular and therefore resist infection and heal faster than other areas, but there are many important structures in and around the face, and scars and defects are noticeable. Skin of the trunk, upper arms, and thighs is fairly thick and heals more slowly than facial or scalp skin and is more susceptible to infection. Scarring is less noticeable. The hands are a critical area because there are important structures near the surface, and the destruction caused by infection can be devastating. The lower legs are a particular problem area because the relatively poor blood supply can cause skin loss, and infection is more likely to occur.

► Treatment

The type of wound must be determined so that proper treatment can be given. Contusions and swelling require ice packs for 24 hours, rest, and elevation. Abrasions should be cleaned and dressed in a sterile manner as for a skin graft donor site or must be washed daily until a dry scab forms or healing takes place. Ground-in dirt or gravel must be entirely scrubbed out or picked out with a small blade within 24 hours after injury, or foreign material will be sealed in and traumatic tattooing will result. Extensive local anesthesia may be required to accomplish this. Imbedded particulate matter from an explosion must be removed in a similar manner. Hematomas may be treated with ice bags and pressure until stable. Evacuation is then indicated if vital structures such as the ear or nasal septal cartilage are in danger of being injured or destroyed. Lacerations over bony prominences and various types of cuts require special care that will be detailed below. Treatment must be meticulous if optimal results are to be achieved. Puncture wounds and bites are notoriously innocuous in appearance but may result in severe destruction or tetanus or gas gangrene. Antibiotic coverage, irrigation, open treatment, and observation are indicated. Most bites on the face, however, can be cleaned and safely closed. Wounds that create flaps of skin or avulsions are difficult to manage. Careful debridement

and judicious use of full-thickness or split-thickness grafts from the avulsed tissue are recommended. Timing is the first factor to consider.

Wound contamination can be caused by bacteria on the surface of the wounding agent, such as rust on a nail or saliva on a tooth, or bacteria that enter the wound when the skin is broken. Bacteria driven into tissue become more established as time passes, and it is therefore important to know the age of the wound at the time of the presentation for treatment. Other injuries associated with cuts almost always take precedence in treatment. In general, wounds other than those on the face or scalp should not be closed primarily if they occurred 8-12 hours or longer before presentation unless they were caused by a very clean agent and have been covered by a sterile bandage in the interim. Delayed primary closure as described previously is an excellent and safe alternative. Nearly any facial wound up to 24 hours old can be safely closed with careful debridement, irrigation, and antibiotic coverage.

The surgeon must decide whether or not antibiotic treatment is indicated. In general, wounds treated appropriately and early do not call for antibiotic therapy. Antibiotics should be given for wounds with delayed presentation or those for which treatment is delayed by choice (eg, wounds with known contamination; wounds in compromised patients, such as very young or old persons, debilitated persons, or persons with general ill health; wounds in areas where infection may have serious consequences, such as the lower legs and the hands; and wounds in persons in whom bacteremia might have serious sequelae, such as those with prosthetic heart valves or orthopedic appliances). Antibiotics should be started before debridement and closure. Only a few days of coverage are necessary—usually until the wound is checked at 2-3 days and found to be free of infection. Penicillin or a substitute is appropriate for wounds involving the mouth, such as through-and-through lip lacerations and bites. Other wounds are usually contaminated by *Staphylococcus aureus*, and an antibiotic effective for penicillin-resistant *S. aureus* is therefore appropriate. If gram-negative or anaerobic contamination is suspected, wound closure is risky, and hospitalization of the patient for treatment with parenteral antibiotics should be considered. Tetanus prophylaxis should be routinely given for patients who have not received current immunizations or who have wounds likely to lead to tetanus. Guidelines for this are detailed in Chapter 8.

Anesthesia is an important part of adequate soft tissue wound care and closure. Local anesthesia with either 0.5% or 1% lidocaine with epinephrine 1:200,000 or 1:100,000 is recommended for all wounds. Smaller amounts of lidocaine and epinephrine may be used in areas of appendages, such as earlobes, toes, and the penis. The injection may be given through the wound edge before debridement and irrigation for maximum patient comfort. Complete epinephrine vasoconstrictor effect occurs within 7 minutes. Overdose of

epinephrine and lidocaine injection into vessels or use of the drugs in patients sensitive to these agents should be avoided.

The importance of irrigation cannot be overstated. Over 90% of bacteria in a recently sustained and superficially contaminated wound can be eliminated by adequate irrigation. Ideally, a physiologic solution such as lactated Ringer solution or normal saline should be forcefully ejected from a large syringe with a 19-gauge needle or from other equipment designed for this purpose such as a water-jet apparatus. The wound is irrigated once to remove surface clots, foreign material, and bacteria and is then debrided and irrigated again. Detergents and antiseptic solutions are toxic to exposed tissue and should not be used.

Debridement must include removal of all obviously devitalized tissues. In special areas such as the eyelids, ears, nose, lips, and eyebrows, debridement must be done cautiously, since the tissue lost by debridement may be difficult to replace. Where tissues are more abundant, such as in the cheek, chin, and forehead areas, debridement may be more extensive. Small irregular or ragged wounds in these areas can be excised completely to produce clean, sharply cut wound edges which, when approximated, will produce the finest possible scar. Because the blood supply in the face is plentiful, damaged tissues of questionable viability should be retained rather than debrided away. The chances for survival are good.

Following adequate anesthesia, debridement, and irrigation, the wound is ready for final assessment and closure. Lighting must be adequate, and appropriate instruments should be available. The patient and the surgeon must be positioned comfortably. The skin surrounding the wound is prepared with an antiseptic solution, and the area is draped. A final check of the depth and extent of the wound is made, and vital structures are inspected for injury. Hemostasis must be achieved by use of epinephrine, pressure, cautery, or suture ligation. Important structures in facial wounds include the parotid duct, lacrimal duct, and branches of the facial nerve. These should be repaired in the operating room by microsurgical techniques.

Layers of tissue—usually muscle—in the depth of the wound should be closed first with as few absorbable sutures as possible, since sutures are foreign material within the wound. If possible, dead space should be closed with judicious use of fine absorbable sutures. If dead space cannot be closed, external pressure or small drains are sometimes effective. Skin closure should begin at the most important points of the laceration (eg, the borders of the ears and nose; the vermilion border or margins of the lip; the margins of the eyebrow [which should never be shaved]; and the scalp hairline). Subcuticular sutures are very helpful. Skin edges can be approximated without tension or strangulation with 5-0 or 6-0 monofilament suture material as outlined earlier under wound closure.

Complicated lacerations, such as complex stellate wounds or avulsion flaps, often heal with excessive scarring. Because of the associated subcutaneous tissue injury, U-shaped or trap-door avulsion lacerations almost always become unsightly as a result of wound contracture. Small lacerations of this type are best excised and closed in a straight line initially; larger flaps that must be replaced usually require secondary revision. Extensive loss of skin is generally best treated by initial split-thickness skin grafting followed later by secondary reconstruction. Primary attempts to reconstruct with local flaps may fail because of unsuspected injury to these adjacent tissues. The decision to convert avulsed tissues to free grafts that may not survive and thus delay healing requires sound surgical judgment.

Small- or moderate-sized closures on the face may be dressed with antibiotic ointment alone. The patient may cleanse the suture lines with hydrogen peroxide to clear away crusts and dirt and then reapply the ointment. Elsewhere, closures benefit from the protection of a sterile bandage. Pressure dressings are useful in preventing hematoma formation and severe edema that may result in poor wound healing. Dressings should be changed early and the wound inspected for hematoma or signs of infection. Hematoma evacuation, appropriate drainage, and antibiotic therapy based on culture and sensitivity studies may be required. Removal of sutures in 3-5 days, followed by splinting of the incision with sterile tape, will minimize scarring from the sutures themselves.

The final result of facial wound repair depends on the nature and location of the wounds, individual propensity to scar formation, and the passage of time. A year or more must often pass before resolution of scar contracture and erythema results in maximum improvement. Only after this time, a decision can be made regarding the desirability of secondary scar revision.

In wounds involving the major joints, the extracapsular soft tissue and the intracapsular structures should be considered individually to assess accurately the magnitude of the injury and to provide a prognosis. Open joint injuries that are single penetrating and without extensive soft tissue damage permit uncomplicated joint and wound closure. Injuries that are single or multiple penetrations with extensive soft tissue disruption (flaps, avulsions, degloving) often require secondary operations to attain closure. In injuries that show open periarticular fractures with extension through the adjacent intra-articular surface and with associated nerve or vascular injury requiring repair, the cornerstone for successful management is debridement, antibiotic therapy properly timed and performed, joint closure, and aggressive treatment of the bony injury. Newer techniques such as free-tissue transfer can expedite wound care, decrease morbidity, and spare some limbs from amputation.

FACIAL BONE FRACTURES

Because of the aesthetic and functional importance of the face, fractures of the facial bones—though rarely life threatening—are best treated by surgeons who have extensive experience with facial injuries and reconstruction. Operation is most successful when performed in the acute setting, usually within the first week, because reconstruction becomes much more difficult if surgery is delayed.

Facial bone fractures are usually caused by trauma from a blunt instrument, such as a fist or club, or by violent contact with the steering wheel, dashboard, or windshield during an automobile accident. Particularly in the latter case, the patient should be assessed for associated injuries. For example, cervical spine injuries are present in up to 12% of automobile accident patients and should be treated or stabilized before facial bone injuries are attended to. Injuries to the brain, eyes, chest, abdomen, and extremities must also be assessed and may require earlier treatment.

The diagnosis of facial fractures is made primarily on clinical examination. Ideally, the examination should be done immediately so that swelling will not obscure the findings. The mechanism and the line of direction of injury are important. If conscious, the patient should be asked about previous facial injuries, areas of pain and numbness, whether the jaw opens properly and the teeth come together normally, and whether vision in all quadrants is normal.

Most facial fractures can be palpated, or at least the abnormal position of bones can be noted. Beginning along the mandibular rims, one can feel for irregularities of the facial bones. The dental occlusion is noted. With bimanual palpation, placing the thumbs inside the mouth, one can elicit bony crepitus if there is an associated fracture. The maxilla and midface can be rocked forward and backward between the thumb and the index finger in the presence of a midfacial fracture. Nasal fractures may be detected by palpation. Irregularities and step-offs along the infraorbital border, lateral orbital rim, or zygomatic arch regions indicate a depressed zygomatic fracture.

Radiologic studies are additional aids to the proper diagnosis of facial fractures. Rarely is a significant fracture seen on x-ray that is not also clinically evident. Helpful views include the Waters and submentovertex projections and oblique views of the mandible. The Panorex view of the mandible is very useful to look at the condyles. CT scans of facial bones, with appropriate biplanar and 3D reconstructions so that bones can be viewed through several planes, have essentially supplanted regular radiographs in the workup of the facially injured patient. They are helpful in assessing the extent of fractures, in particular, in more posterior areas such as the ethmoid area, medial and inferior orbit, pterygoid plates, and base of the skull.

The bones of the nose are the most commonly fractured facial bones. Next in frequency are the mandible, the zygomatic-malar bones, and the maxilla.

NASAL FRACTURES

Fractures may affect the nasal bones, cartilage, and septum. Fractures occur in two patterns, caused by lateral or head-on trauma.

With lateral trauma, the nasal bone on the side of the injury is fractured and displaced toward the septum, the septum is deviated and fractured, and the nasal bone on the side away from the injury is fractured and displaced away from the septum, so that the upper part of the nose, as a whole, is deviated. Depending on the degree of violence, one or more of these displacements will be present, and the degree of comminution is variable.

Head-on trauma gives rise to telescoping and saddling of the nose and broadening of its upper half as a result of the depression and splaying of the fractured nasal bones. This of course produces severe damage to the septum, which usually buckles or actually suffers a fracture. The diagnosis of a fractured nose is made on clinical grounds alone, and x-rays are unnecessary except for medical-legal reasons.

Nasal fractures requiring reduction should be treated with a minimum of delay, for they tend to become fixed in the displaced position in a few days. The surgical approach depends on whether the fracture has resulted in deviation or collapse of the nasal bones. Local anesthesia is preferred; either topical tetracaine or cocaine intranasally or lidocaine for infiltration of the skin can be used. The nasal bones may be disimpacted with intranasal forceps or a periosteal elevator and aligned by external molding or pressure. Collapsed nasal fractures can be repositioned with Walsham nasal forceps, introduced into each nostril and placed on each side of the septum, which is then elevated to its proper position. A septal hematoma should be recognized and drained to prevent infection and subsequent necrosis of the cartilaginous septum with associated collapse of the entire nose. Compound fractures of the nose require prompt repair of the skin wound and, if possible, early reduction of the displaced nasal bones.

External splinting, which is essentially a protective dressing, and intranasal packing using nonadhering gauze are appropriate after reduction. The intranasal packing provides support for the septum in its reduced position and helps prevent development of a hematoma. It also provides counterpressure for the external splint immobilizing the nasal bones and prevents them from collapsing. The packing is usually removed within 48 hours.

In severe comminuted nasal fractures, the medial canthal ligaments, which are easily felt by applying lateral traction to the upper eyelid, may have dislodged. If they have been

avulsed, they should be reattached in position to prevent late deformities. For these severe fractures involving the entire naso-orbital and ethmoid complex, the coronal approach, which offers wide exposure, allows for proper anatomic reduction of all small nasal fragments as well as repositioning of the canthal ligaments and correction and elevation of the telescoped bone fragments at the root of the nose and glabella.

The lacrimal apparatus is commonly disrupted in these injuries and should be repaired and stented appropriately.

MANDIBULAR FRACTURES

Mandibular fractures are most commonly bilateral, generally occurring in the region of the mid body at the mental foramen, the angle of the ramus, or at the neck of the condyle. A frequent combination is a fracture at the mental region of the body with a condylar fracture on the opposite side. Displacement of the fragments results from the force of the external blow as well as the pull of the muscles of the floor of the mouth and the muscles of mastication. The diagnosis is suggested by derangement of dental occlusion associated with local pain, swelling, and often crepitation upon palpation. Appropriate x-rays confirm the diagnosis. Special views of the condyle, including tomograms, may be required. Sublingual hematoma and acute malocclusion are usually diagnostic of a mandibular fracture.

Restoration of functional dental occlusion is the most important consideration in treating mandibular fractures. In patients with an adequate complement of teeth, arch bars or interdental wires can be placed. Local nerve block anesthesia is preferable for this procedure, though certain patients may require general anesthesia. Intermaxillary elastic traction will usually correct minor degrees of displacement and bring the teeth into normal occlusion by overcoming the muscle pull. When the fracture involves the base of a tooth socket with suspected devitalization of the tooth, extraction of the tooth should be considered. Particularly in the incisor region, such devitalized teeth may be a source of infection, leading to the development of osteomyelitis and nonunion of the fracture.

Patients with more severe mandibular injuries require anatomic reduction and fixation of the fracture by the open, direct technique. These include compound, comminuted, and unfavorable fractures. An unfavorable fracture is one that is inherently unstable because muscle pull distracts the fracture segments. In this situation, intermaxillary fixation alone is insufficient. Edentulous patients also benefit from the open technique, although proper dentures or dental splints are useful to maintain normal occlusion.

Metal wire fixation of fractured segments and intermaxillary fixation for 6 weeks was a proven and popular method of fracture treatment. The more recent resurgence

in popularity of the screw-plate system is due to a number of advantages over wiring. The screw plate usually achieves rigid fixation in three dimensions, providing adequate stability; it eliminates the need for intermaxillary fixation in most cases; it is useful in complex, comminuted fractures; and it is quite easy to use after familiarity with the technique has been acquired.

With bilateral parasymphiseal fractures, anterior stabilization of the tongue may be lost, so that it may fall back and obstruct the airway. Anterior stabilization and splinting must be accomplished early in these cases.

Open reduction is rarely advised in condylar fractures; simple intermaxillary fixation for 4-6 weeks is sufficient. Indications for open reduction are severely displaced fractures, which may prevent motion of the mandible because of impingement of the coronoid process on the zygomatic arch. In children, the fracture may destroy the growth center of the condyle, resulting in maldevelopment of the mandible and gross distortion.

ZYGOMATIC & ORBITAL FRACTURE

Fractures of the zygomatic bones may involve just the arch of the zygomatic bone or the entire body of the zygoma (the malar eminence) and the lateral wall and floor of the orbit. The so-called tripod fracture characteristically occurs at the frontozygomatic and zygomaticomaxillary sutures as well as at the arch. It should be referred to as a tetrapod fracture because the anterior or posterior buttress of the maxilla is also involved in the fracture. Displacement of the body of the zygoma results in flattening of the cheek and depression of the orbital rim and floor.

Important diagnostic signs are subconjunctival hemorrhage, disturbances of extraocular muscle function (which may be accompanied by diplopia), and loss of sensation in the upper lip and alveoli on the involved side as a result of injury to the infraorbital nerve. Reduction of a displaced zygomatic fracture is seldom an emergency procedure and may be delayed until the patient's general condition is satisfactory for anesthesia. Local anesthesia will suffice only for reduction of fractures of the zygomatic arch. More extensively displaced fractures usually require general anesthesia. At least two-point fixation with direct interosseous wiring is necessary for these fractures. Here again, delicate miniplates have been used with success, providing anatomic reduction and rigid fixation.

Simple depressed fractures of the zygomatic arch can best be elevated using the Gillies technique. Through a temporal incision above the hairline, an instrument is passed beneath the superficial layer of the deep temporalis fascia and under the arch and the body of the zygoma. The fracture can also be elevated percutaneously with a hook or screw in conjunction with overlying palpation to achieve accurate reduction.

If the fracture is complex or comminuted, as is often the case with high-velocity injuries, repair through a coronal scalp approach may be necessary to obtain an anatomic and stable result.

Extensive disruption should be suspected in conjunction with the zygomatic fracture when significant diplopia and enophthalmos and posterior displacement of the globe are present. Orbital fat and extraocular muscles may herniate through the defect and become entrapped, giving rise to the signs and symptoms. A “blowout” fracture is similar disruption of the orbital floor due to blunt trauma to the globe but not associated with a fracture of the zygoma or orbital rim. Treatment in both cases demands exploration, reduction of herniated contents, and repair of the floor. The most direct approach is through a lower lid subciliary incision, which provides excellent visualization. A buccal transantral (Caldwell-Luc) approach can be used, and blind antral packing for support has been described. This is quite hazardous, because bony spicules may be pushed into the ocular globe and perhaps cause injury or blindness. In cases of extensive communication or loss of bony fragments of the floor, use of local autogenous bone or cartilage as a scaffold may be performed. At times, in cases of extensive injuries to the floor, alloplastic material in the form of titanium mesh may be necessary.

Even with careful anatomic reduction and repair of the orbital floor, ocular problems—particularly enophthalmos—may persist, possibly due to an undiagnosed fracture, especially a medial ethmoidal blowout fracture. These can be properly evaluated with CT scanning. Treatment requires reduction and repair of the defect. The injury can at times cause ischemia of herniated soft tissue and subsequent atrophy and scarring. This may result in enophthalmos, which is almost impossible to resolve completely.

MAXILLARY FRACTURES

Maxillary fractures range in complexity from partial fractures through the alveolar process to extensive displacement of the midfacial structures in conjunction with fractures of the frontonasal bones and orbital maxillary region and total craniofacial separation. Hemorrhage and airway obstruction require emergency care, and in severe cases, tracheostomy is indicated. Mobility of the maxilla can be elicited by palpation in extensive fractures. “Dish-face” deformity of the retrodisplaced maxilla may be disguised by edema, and careful x-ray studies are necessary to determine the extent and complexity of the midfacial fracture. Treatment may have to be delayed because of other severe injuries. A delay of as long as 10-14 days may be safe before reduction and fixation, but the earliest possible restoration of maxillary position and dental occlusion is desirable to prevent late complications.

In the case of unilateral fractures or bilateral fractures with little or no displacement, splinting by intermaxillary

fixation for 4 weeks may suffice. Fractures are usually displaced inferiorly or posteriorly and require direct surgical disimpaction and reduction and proper fixation with appropriate plates and screws. Early reduction may help control bleeding, as torn, stretched vessels are allowed to reestablish their normal tension. In certain severe cases, external traction may be necessary. Manipulation is directed toward restoring normal occlusion and maintaining the reduction with intermaxillary fixation to the mandible in association with direct plate fixation. Complicated fractures may require external fixation utilizing a head cap and intraoral splints in conjunction with multiple surgical incisions for direct plate fixation. Coexisting mandibular fractures usually necessitate open reduction and fixation at the same time.

CONGENITAL HEAD & NECK ANOMALIES

CLEFT LIP & CLEFT PALATE

Cleft lip, cleft palate, and combinations of the two are the most common congenital anomalies of the head and neck. The incidence of facial clefts has been reported to be 1 in every 650-750 live births, making this deformity second only to clubfoot in frequency as a reported birth defect.

The cleft may involve the floor of the nostril and lip on one or both sides and may extend through the alveolus, the hard palate, and the entire soft palate. A useful classification based on embryologic and anatomic aspects divides the structures into the primary and the secondary palate. The dividing point between the primary palate anteriorly and the secondary palate posteriorly is the incisive foramen. Clefts can thus be classified as partial or complete clefts of the primary or secondary palate (or both) in various combinations. The most common clefts are left unilateral complete clefts of the primary and secondary palate and partial midline clefts of the secondary palate, involving the soft palate and part of the hard palate.

Most infants with cleft palate present some feeding difficulties, and breast-feeding may be impossible. As a rule,

enlarging the openings in an artificial nipple or using a syringe with a soft rubber feeding tube will solve difficulties in sucking. Feeding in the upright position helps prevent oronasal reflux or aspiration. Severe feeding and breathing problems and recurrent aspiration are seen in Pierre Robin sequence, in which the palatal cleft is associated with a receding lower jaw and posterior and cephalic displacement of the tongue, obstructing the naso-oropharyngeal airway. This is a medical emergency and is a cause of sudden infant death syndrome (SIDS). Nonsurgical treatment includes pulling the tongue forward with an instrument and laying the baby prone with a towel under the chest to let the mandible and tongue drop forward. Insertion of a small (No. 8) nasogastric tube into the pharynx may temporarily prevent respiratory distress and may be used to supplement the baby's feedings. Placement of an acrylic obturator or appliance has proved quite successful in alleviating the breathing difficulties by bringing the tongue down and permitting a better nasal airway. Several surgical procedures that bring the tongue and mandible forward have been described but should be employed only when conservative measures have been tried without success. Recently, the use of distraction of the mandible has shown some beneficial effects. However, it should be done with great caution in the neonate.

► Treatment

Surgical repair of cleft lip is not considered an emergency. The optimal time for operation can be described as the widely accepted "rule of 10." This includes body weight of 10 lb (4.5 kg) or more and a hemoglobin of 10 g/dL or more. This is usually at some time after the tenth week of life. In most cases, closure of the lip will mold distortions of the cleft alveolus into a satisfactory contour. In occasional cases in which there is marked distortion of the alveolus, such as in severe bilateral clefts with marked protrusion of the premaxilla, preliminary maxillary orthodontic treatment may be indicated. This may involve the use of carefully crafted appliances or simple constant pressure by use of an elastic band.

General endotracheal anesthesia via an orally placed endotracheal tube is the anesthetic technique of choice. A variety of techniques for repair of unilateral clefts have evolved over many years. Earlier procedures ignored anatomic landmarks and resulted in a characteristic "repaired harelip" look. The Millard rotation advancement operation that is now commonly used for repair employs an incision in the medial side of the cleft to allow the Cupid's bow of the lip to be rotated down to a normal position. The resulting gap in the medial side of the cleft is filled by advancing a flap from the lateral side. This principle can be varied in placement of the incisions and results in most cases in a symmetric lip with normally placed landmarks. Bilateral clefts, because of greater deficiency of tissue, present more challenging technical problems. Maximum preservation of available

tissue is the underlying principle, and most surgeons prefer approximation of the central and lateral lip elements in a straight line closure, rolling up the vermilion border of the lip (Manchester repair).

Secondary revisions are frequently necessary in the older child with a repaired cleft lip. A constant-associated deformity in patients with cleft lip is distortion of the soft tissue and cartilage structures of the ala and dome of the nose. These patients often present with deficiency of growth of the structures of the midface. This has been attributed to intrinsic growth disturbances and to external pressures from the lip and palate repairs. Some correction of these deformities, especially of the nose, can be done at the initial lip operation. More definitive correction is done after the cartilage and bone growth is more complete. These may include scar revisions and rearrangement of the cartilage structure of the nose. Recent approaches involve degloving of the nasal skin envelope with complete exposure of the abnormal cartilage framework. These are then rearranged in proper position with or without additional grafts. Maxillary osteotomies (Le Fort I with advancement) will substantially correct the midfacial depression. A tight upper lip due to severe tissue deficiency can be corrected by a two-stage transfer of a lower lip flap known as an Abbe flap.

In utero repair of cleft lip deformities has recently become a topic of discussion. *In utero* repair affords the potential to provide a scarless repair and correct the primary deformity. Furthermore, scarless fetal lip and palate repairs may prevent the ripple effect of postnatal scarring with its resultant secondary dentoalveolar and midface growth deformities. While these suggestions make *in utero* repair attractive, the risk of fetal loss remains high. Preterm labor is a major complication and one that is directly related to the large hysterotomy required for fetal exposure. Due to the great risks associated with it, intrauterine fetal surgery is still largely reserved for severe malformations that cannot be helped significantly by postnatal intervention.

Palatal clefts may involve the alveolus, the bony hard palate, or the soft palate, singly or in any combination. Clefts of the hard palate and alveolus may be either unilateral or bilateral, whereas the soft palate cleft is always midline, extending back through the uvula. The width of the cleft varies greatly, making the amount of tissue available for repair also variable. The bony palate, with its mucoperiosteal lining, forms the roof of the anterior mouth and the floor of the nose. The posteriorly attached soft palate is composed of five paired muscles of speech and swallowing.

Surgical closure of the cleft to allow for normal speech is the treatment of choice. The timetable for closure depends on the size of the cleft and any other associated problems. However, the defect should be closed before the child undertakes serious speech, usually before age 2. Closure at 6 months usually is performed without difficulty and also aids in the child's feeding. If the soft palate seems to be long

enough, simple approximation of the freshened edges of the cleft after freeing of the tissues through lateral relaxing incisions may suffice. If the soft palate is too short, a pushback type of operation is required. In this procedure, the short soft palate is retrodisplaced closer to the posterior pharyngeal wall utilizing the mucoperiosteal flaps based on the posterior palatine artery.

Satisfactory speech following surgical repair of cleft palate is achieved in 70%-90% of cases. Significant speech defects usually require secondary operations when the child is older. The most widely used technique is the pharyngeal flap operation, in which the palatopharyngeal space is reduced by attaching a flap of posterior pharyngeal muscle and mucosa to the soft palate. This permits voluntary closure of the velopharyngeal complex and thus avoids hypernasal speech. Various other kinds of pharyngoplasties have been useful in selected cases.

CRANIOFACIAL ANOMALIES

These are congenital deformities of the hard and soft tissues of the head. Particular problems of the brain, eye, and internal ear are treated by the appropriate specialist. The craniofacial surgeon often needs the collaboration of these specialists when operating on such patients.

Serious craniofacial anomalies are relatively rare, although mild forms often go undiagnosed or are accepted as normal variants. A classification is therefore difficult, although many have been proposed. Tessier has offered a numerical classification based on clinical presentation. He considers a cleft to be the basis of the malformation, which involves both hard and soft tissues (Figure 41–11).

Other classifications are based on embryologic and etiologic features. With greater understanding and continued investigation, classification efforts will no doubt be more satisfactory.

There are well-known chromosomal and genetic aberrations as well as environmental causes that can lead to craniofacial deformity. The cause in most cases, however, is unknown. Arrest in the migration and proliferation of neural crest cells and defects in differentiation characterize most

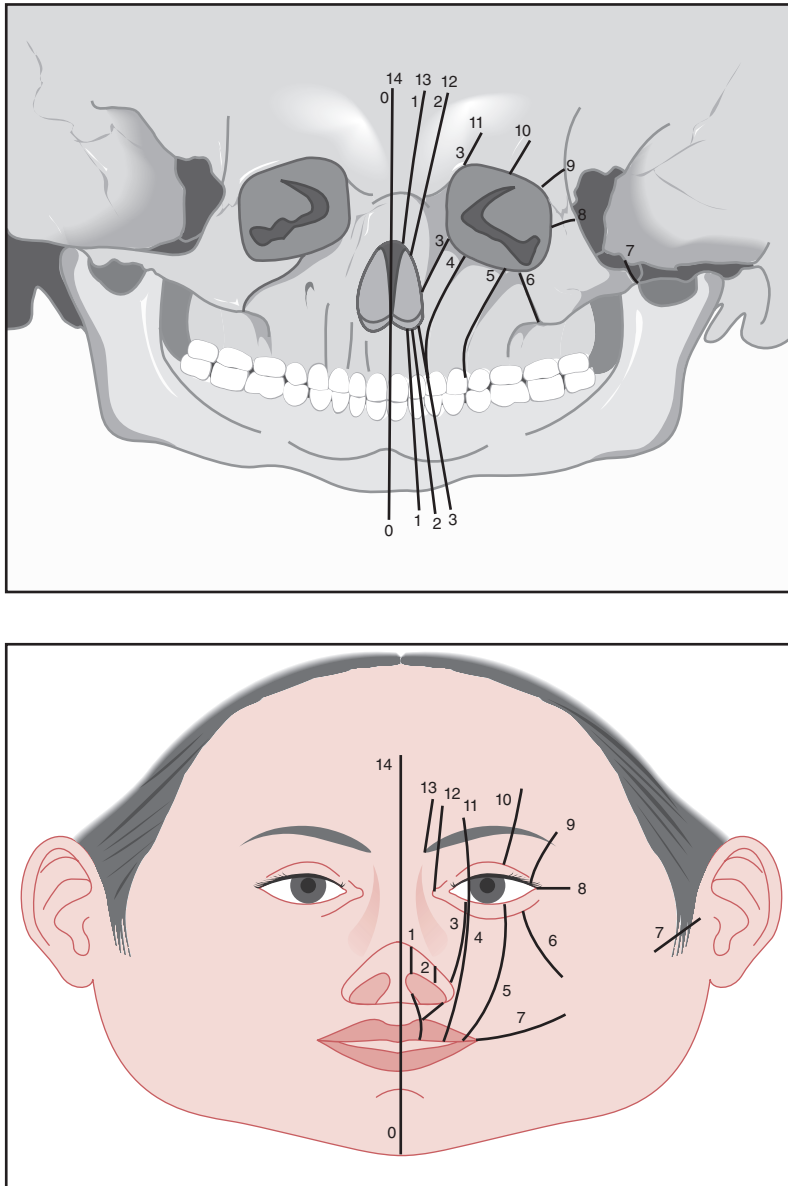

of these deformities. We describe some of the more common ones in brief terms.

Crouzon syndrome (craniofacial dysostosis) and **Apert syndrome** (acrocephalosyndactyly) are closely related, differing in the extremity deformities present in the latter. Both are autosomal dominant traits with variable expression. Both present with skull deformities due to premature closure of the cranial sutures. The cranial sutures most affected will determine the type of skull deformity. Exophthalmos, midfacial hypoplasia, and hypertelorism are also features of these two syndromes.

The facial organs and tissues proceed in great measure from the first and second branchial arches and the first branchial cleft. Disorders in their development lead to a spectrum of anomalies of variable severity. **Treacher-Collins syndrome** (mandibulofacial dysostosis) is a severe disorder characterized by hypoplasia of the malar bones and lower eyelids, colobomas, and antimongoloid slant of the palpebrae. The mandible and ears are often quite underdeveloped. The presentation is bilateral and is an autosomal dominant trait. A unilateral deformity known as **hemifacial microsomia** presents with progressive skeletal and soft tissue underdevelopment. The Goldenhar variant of hemifacial microsomia is a severe form associated with upper bulbar dermoids, notching of the upper eyelids, and vertebral anomalies.

Some of these patients show mental retardation, but in most cases, intelligence is not affected. The psychosocial problems are serious and most often related to how the patients look. Within the past two decades, craniofacial surgery has progressed so that previously untreatable deformities can now be corrected. With the anatomic work of Le Fort as a basis—and guided by the incomplete attempts of Gillies and others—Paul Tessier, in the late 1960s, proposed a set of surgical techniques to correct major craniofacial deformities. Two basic concepts soon emerged from his work: (1) Large segments of the craniofacial skeleton can be completely denuded of their blood supply, repositioned, and yet survive and heal; and (2) the eyes can be translocated horizontally or vertically over a considerable distance with no adverse effect on vision. The tendency today is to operate at approximately 6-9 months of age (if possible not later than a year) for cranial vault remodeling and fronto-orbital advancement.

A bicoronal scalp incision is utilized to expose the skull and facial bones with an intracranial or extracranial approach. The cut bones are then reshaped, repositioned, and fixed with a combination of wires or miniplates and screws. The latter have the advantage of rigid fixation and less need to maintain large movements with bone grafts. Autogenous inlay and onlay bone grafts can be used to improve contour. The entire operation is usually completed in one stage, and complications are surprisingly few. Miniplates have been used extensively in the last few years. In infants, fixation with absorbable suture material or the

▲ **Figure 41–11.** Tessier classification of craniofacial clefts. The numbering system goes from 0 to 14, and the skeletal defects mimic the soft tissue presentation.

newer absorbable plates and screws have provided effective and stable fixation. They commonly resorb at 6-9 months. They do not interfere with imaging techniques such as CT or MRI, and they seem to have less impairment of craniofacial growth and development.

Craniofacial surgery has improved the treatment not only of major congenital deformities but also of major complex

facial fractures, chronic sequelae of trauma, isolated exophthalmos, fibrous dysplasia, and aesthetic facial sculpturing.

MICROTIA

Microtia is absence or hypoplasia of the pinna of the ear, with a blind or absent external auditory meatus. The incidence

of significant auricular deformity is about one in 8000 births and is usually spontaneous. Ten percent of these defects are bilateral, and boys are afflicted twice or three times as commonly as girls. Because the ear arises from the first and second branchial arches, the middle ear is always involved, and many patients have other disorders of the first and second arches. The inner ear structures are usually spared.

Generally, correction of conductive hearing by an otology has not been long lasting or helpful, and surgery for this problem is reserved for bilateral cases.

Different techniques have been described that vary in terms of required surgeries as well as technical complexity. The Brent and Nagata techniques are the most commonly used today with the Brent requiring four stages and the Nagata only two. In any case reconstruction of the external ear usually involves a multistage procedure beginning at preschool age. Autogenous rib cartilage or cartilage from the opposite ear is used to construct a framework to replace the absent ear. The cartilage is imbedded under the skin in the appropriate area, and after adjustments are made in local tissue to reposition or recreate the earlobe and conchal cavity, the framework is elevated posteriorly and the resulting sulcus grafted to obtain projection. In cases in which local tissue is poor or unavailable, the neighboring superficial temporalis fascia is dissected and placed over the cartilage framework. This is then skin grafted with adequate tissue.

The opposite (normal) ear is occasionally altered to provide better symmetry. Excellent results have been achieved. Silastic frameworks for ear cartilage have also been used, and although their use eliminates donor site problems, rates of infection and extrusion have been unacceptable. More recently, a porous polyethylene construct has been used with better long-term results. A temporalis fascia flap is rotated to cover the allograft, and then a full-thickness skin graft is placed. They are quite useful in bilateral cases or when sufficient cartilage is not available.

Lesser deformities, such as overly large, prominent, or bent ears, are corrected by appropriate resection of skin and cartilage, “scoring” of the cartilage to alter its curve, and placement sutures to aid in contouring.

ANOMALIES OF THE HANDS & EXTREMITIES

The most common hand anomaly is syndactyly, or webbing of the digits. This may be simple, involving only soft tissue, or complex, involving fusion of bone and soft tissue. The fusion may be partial or complete. Surgical correction involves separation and repair with local flaps and skin grafts. Correction should be done before growth disturbance of the webbed digits takes place. Other anomalies, such as extra digits (polydactyly), absence of digits (adactyly), and cleft hand, also exist.

Flexion contractures of the hands or digits may require surgical release and appropriate skin grafting. Congenital ring constriction of the extremities may be associated also with congenital amputation. The ring constrictions are best treated by excision and Z-plasty.

Poland syndrome consists of a variable degree of unilateral chest deformity—usually absence of the pectoralis major muscle—associated with hand symbrachydactyly. The hand deformity is treated according to the severity. The latissimus dorsi muscles can be transposed to replace the absent pectoralis major, simulating the sites of origin and insertion. In more severe cases and in women requiring breast and chest reconstruction, the transverse rectus abdominis island flap can be used to replace the deficit.

POSTABLATIVE RECONSTRUCTION

HEAD & NECK RECONSTRUCTION

Many of the tumors discussed in Chapter 15 require surgical excision as a primary form of therapy. This often involves removal of large areas of composite tissue, such as the floor of the mouth, the maxilla, part of the mandible, or the lymph-bearing tissue of the neck. Reconstruction after such resections can be very challenging and may require special skill.

A salient advance in the complete treatment of the patient with a head or neck tumor is reconstruction, usually done in the same setting. Free flaps with microvascular techniques are the most appropriate methods even though they require a high level of skill and are time consuming. The free flaps most commonly used following ablative procedures in the head and neck include the anterolateral thigh flap or the radial forearm flap for resurfacing the floor of the mouth and the composite fibular flap, which includes fibula as well as skin, to reconstruct the mandible and the floor of the mouth. For larger defects, judicious use of the rectus abdominis muscle, latissimus dorsi, or other musculocutaneous flaps has also been helpful. For pharyngoesophageal reconstruction, either the tubed radial forearm flap or the free jejunum is most successful.

Since no two surgical resections for tumor in the head and neck are identical, the key to effective treatment is

preoperative planning. Probable extent of resection, areas that will require preoperative or postoperative radiation therapy, incision and flaps created by neck dissections, and available donor areas must all be carefully assessed. New preoperative techniques are being used that is based off of preoperative CT scanning, such as Pro-Plan. From these scans, templates are created that show exactly where excisions should be made, and for mandibular reconstruction, the size, and bending of the plate can all be done preoperatively.

Useful musculocutaneous flaps in the head and neck are the sternocleidomastoid, platysma, trapezius, pectoralis major, and latissimus dorsi muscles. Useful axial skin flaps can be obtained from the forehead, deltopectoral, and cervicohumeral areas. When these flaps are insufficient or unavailable for the reconstructive needs of the patient, free tissue transfer must be used. Although many flaps have been developed for bone and soft tissue reconstructions, the anterolateral thigh flap (cutaneous or myocutaneous), the radial forearm flap, and the osteoseptocutaneous fibula flap are the most useful free flaps for head and neck reconstruction. Healing is quick, so radiation, if necessary, may be started as early as 1 month after surgery.

BREAST RECONSTRUCTION

Reconstruction of the female breast after mastectomy is available to all patients in the United States, and new techniques continue to be developed providing women with more options. The insurance carriers now pay for this procedure as part of the treatment for breast cancer, and this includes symmetry surgery of the contralateral breast. Even women with significant defects in the anterior chest wall as a result of radical mastectomy and radiation therapy can undergo reconstructive surgery if they are otherwise appropriate candidates.

Heightened awareness of breast cancer along with well-established screening guidelines has affected surgical

treatment of the cancer and, subsequently, approaches to reconstruction of the breast. A skin-sparing, modified radical mastectomy, for example, may allow for an immediate reconstruction with autologous tissue that results in an aesthetically pleasing breast mound. Lumpectomy followed by irradiation, initially indicated for relatively small tumors, has now expanded to larger tumors and may thus result in considerable distortion and concavity in the treated breast. In the appropriate patient, concomitant bilateral reduction mammoplasty may allow for a large lumpectomy while maintaining symmetry.

The methods of reconstruction include the use of saline implants, tissue expanders, autologous tissue, or a combination of these methods. Following mastectomy, simple placement of an implant is usually unsatisfactory except in a few thin patients with relatively small contralateral breasts. The implant is usually placed in the submuscular position, utilizing the remaining pectoralis major muscle and occasionally the serratus anterior muscle for adequate muscle coverage. This results in a firm, rounded type of reconstruction and does not simulate the soft “teardrop” appearance of the normal breast. Even when adequate skin has been saved following a skin-sparing mastectomy, placement of an implant is unsatisfactory because of the high rate of complications due to skin necrosis of the saved overlying skin, which results in exposure of the implant. When doing an immediate reconstruction with implant following a skin-sparing mastectomy, it is preferable to transpose the latissimus dorsi muscle to provide another layer of cover for the implant so that if there is necrosis of the skin from the skin-sparing mastectomy, the implant will not be exposed.

The latissimus dorsi myocutaneous flap is used most often for reconstruction of the breast with an implant. The myocutaneous unit is outlined with a skin island transversely so that the scar will be transverse and covered by the bra-siere. The unit is freed up completely except for its insertion at the humerus, thus preserving the neurovascular pedicle. It is transposed as a pendulum through the anterior chest wall. The superior portion of the latissimus dorsi is sutured to the pectoralis major muscle, and the lower edge is secured to the lower skin flap as far down as it will reach. The implant is then inserted, having been covered by the latissimus dorsi inferiorly and by two layers of muscle superiorly—the latissimus dorsi and the pectoralis major. The skin island is utilized in its entirety, if necessary, or is deepithelialized appropriately, maintaining only the skin portion that is needed. This method is most suitable for patients who do not have a large amount of abdominal skin, are relatively thin, and do not object to the use of implants, which sometimes may even be inserted in the opposite breast in an effort to achieve symmetry.

The use of tissue expanders continues to be a popular method of breast reconstruction. The use of acellular dermal matrices (ADM) has made expander results more satisfying.

Rather than using muscle and tissue alone to cover the expander, ADM is used to create a sling that replicates the lower pole of a breast. This allows for increased initial fill rates, and a more natural appearing breast. (Figure 41–12) Over a period of 6 weeks to 3 months, the expander is progressively inflated with saline percutaneously. The expander is inflated at least 25% more than the desired volume. A period of time—approximately 3 months—is advisable as a waiting period to prevent the “recall phenomenon,” which

is the shrinking that may occur following removal of the expander as it is replaced by a permanent implant. ADM has come under scrutiny though due to increased rates of seroma and other complications associated with its use. Multiple studies have shown this to be true, but it remains difficult to identify the exact patient characteristics that make them more prone to these problems.

The use of radiation therapy has continued to become more commonplace for the treatment of breast cancer. When it is used, autologous tissue is the standard for breast reconstruction. Implant base reconstruction has been shown to have significantly higher complication rates when radiation therapy is involved. The transverse rectus abdominis myocutaneous (TRAM) flap based on the superior epigastric vessel(s) remains the standard for breast reconstruction so that an implant is not required. The incision at the donor site is similar to that of an abdominoplasty operation along the lower abdomen. This method of reconstruction produces the most normal and natural breast in appearance and feel, but it requires a longer operating time as well as a longer period of hospitalization than reconstruction with tissue expanders and implants alone.

If the superior epigastric system has been violated (from surgery or trauma) or if there are other factors that would question the reliability of these vessels to adequately supply the volume and region of tissue required for the reconstruction, the surgeon may favor using the inferior epigastric system and transferring the TRAM as a free flap. Typical recipient vessels are the internal mammary or the thoracodorsal vessels. Again, past surgical history, previous (or planned) radiation, and anatomic variance may dictate reconstructive strategy regarding recipient vessels and whether to use the ipsilateral or contralateral inferior epigastric system.

Because successful breast reconstruction is common, many surgeons have sought to refine autologous reconstruction by decreasing donor site morbidity. Modifications of the free TRAM flap have been made so that the rectus abdominis muscle is mostly spared (muscle-sparing TRAM) or spared in its entirety. This latter technique is referred to as a deep inferior epigastric perforator (DIEP) flap. The same skin territory as the TRAM flap is used; however, the musculocutaneous branches that supply the skin are dissected away from the rectus abdominis muscle. In this manner, the muscle itself is spared and left *in situ* in an effort to preserve muscular function and reduce abdominal wall weakness. The deep inferior epigastric vessels are then divided, the flap is inset into the thoracic defect, and the flap vessels are anastomosed to recipient vessels along the chest wall. An extension of the DIEP has been the superficial inferior epigastric artery (SIEA) free flap. Although feasible in only a minority of patients, this artery allows for free flap reconstruction that completely avoids any dissection of the rectus muscle. This means minimal abdominal wall complications for the patient.

▲ **Figure 41–12.** **A.** Reconstructed right breast with ADM in place to recreate lower breast pole **B.** Close-up of right breast with ADM and pectoralis major interface shown.

In addition to reconstruction of the affected breast, many patients undergo procedures that alter the contralateral (noncancerous) breast so that volume and ptosis are comparable. Such symmetry procedures are considered stages in postoncologic breast reconstruction. The nipple-areola complex can also be reconstructed. Current techniques for nipple reconstruction utilize adjacent flaps from the area where the nipple is to be positioned, taking skin and variable amounts of underlying fat if a TRAM flap has been used or elevating skin and lesser amounts of subcutaneous tissue if an implant (with or without the latissimus dorsi flap) was used. The areola may be reconstructed with a full-thickness skin graft followed by tattooing at a later date for color match.

LOWER EXTREMITY RECONSTRUCTION

Probably one of the most difficult areas for which to provide wound coverage and closure is the lower extremity, particularly the distal leg and foot areas. Tenuous and unstable skin grafts or poorly vascularized local or cross-leg skin flaps were once the only tissues available for resurfacing of these parts of the body. When large segments of bone were exposed or missing or when infection had become established, these grafts or flaps often were inadequate and amputation was the only recourse. Use of musculocutaneous flaps, and particularly free flaps, has greatly improved coverage in the lower extremities.

Generally, wound problems in the lower leg, ankle, and foot involve orthopedic injuries, such as compound tibial or ankle fractures. Multiple classification systems are used, but the most popular is the Gustilo and the Byrd system. These take into account the degree of fracture as well as tissue loss as well as nerve and arterial involvement.

► Treatment

Treatment depends on the extent of tissue loss and the depth of the wound. Fairly extensive wounds around the knee and upper third of the leg can be reconstructed with a gastrocnemius muscle flap (usually the medial head) and a split-thickness skin graft. Soft tissue defects of the middle third of the leg can be reconstructed in a similar manner by the soleus muscle in many cases. Large middle

third and distal third soft tissue defects are more difficult to reconstruct. When they are complicated by extensive bone and soft tissue loss, free tissue transfer may be necessary. Although there are small muscles that end in tendons in the foot, such as the peroneus brevis, flexor hallucis longus, and extensor digitorum muscles, they can provide only limited coverage. If there is a suitable recipient artery remaining in the leg, better coverage is generally provided by a free muscle flap such as the gracilis muscle for small- and medium-sized defects or the latissimus dorsi or rectus abdominis muscle for larger defects.

Large areas of the heel or the sole of the foot are difficult to replace because skin in these regions is specially adapted to bear the weight of the body without shearing or breaking down. Free muscle flaps surfaced with skin grafts have proven to be adequate, but protective sensation is missing. The use of free neurovascular axial skin flaps, such as the inferior gluteal thigh flap and the deltoid flap, may help provide coverage with some gross sensation. Neurosensory flaps—and specifically the sural flap, distally based on one of the lower septocutaneous perforators from the lateral aspect of the leg and supplied by the sural artery, which accompanies the sural nerve—have been used to resurface defects around the ankle and heel. The procedure provides good skin and fascia for a weight-bearing area such as the heel, but it usually does not provide protective sensibility.

Segmental defects of the tibia may be reconstructed with bone grafts or, if the gap is large, free bone flaps such as the contralateral fibula or iliac crest. It is also possible to reconstruct the soft tissue defect and then reconstruct the bony gap with a distraction osteogenesis technique (Ilizarov bone transport). This bone transport method consists of performing a cortical osteotomy proximal to the site of injury and then applying a distraction apparatus, which in effect lengthens the bone 1 mm per day by appropriate adjustment screws. Such lower extremity reconstruction requires a well-coordinated, cooperative effort between the plastic and orthopedic surgeons. While such limb salvage is possible, amputation may be recommended in cases where a constellation of complications are present, such as bony gaps greater than 8 cm, extensive vascular injury, greater than 6 hours of warm ischemia time, an insensate limb, loss of plantar flexion, or an overall medically unstable patient.

Osteomyelitis of the tibia or bones in the foot may be devastating and often uncontrollable. Probably because of poor vascularity in the area, even long-term antibiotic treatment has often failed to control bone infections in the leg. Recently, effective surgical treatment for bone infections has been developed. The bone is surgically debrided and covered with a microvascular free muscle flap such as the gracilis or rectus abdominis muscle. Apparently, the muscle tissue with its excellent blood supply not only covers the exposed bone but assists natural defenses in controlling infection. Antibiotics are also used, but the well-vascularized muscle

flap appears to be the deciding factor in control of infection. Reconstruction of bony defects may be accomplished at a later date.

PRESSURE SORES

Pressure sores—often less precisely called bedsores or decubitus ulcers—are another example of difficult wound problems that can be treated by plastic surgery. Pressure sores generally occur in patients who are bedridden and unable or unwilling to change position; patients who cannot change position because of a cast or appliance; and patients who have no sensation in an area that is not moved even though they may be ambulatory. The underlying cause of sores in these patients is ischemic necrosis resulting from prolonged pressure against the soft tissue overlying bone. There is also some evidence that local factors in denervated skin predispose to pressure breakdown because there is atrophy of the skin and subcutaneous tissue.

Absence of normal protective reflexes must be compensated for. Prevention is clearly the best treatment for pressure sores. Casts and appliances must be well padded, and points of pressure or pain should be relieved. Bedridden patients must be turned to a new position at least every 2 hours. Water and air mattresses, sheepskin pads, and foam cushions may help relieve pressure but are not substitutes for frequent turning. The introduction of the flotation bed system, which distributes pressure uniformly over a large surface area, has greatly aided in the management of these patients. The pressure on the skin at any time is less than the capillary filling pressure, avoiding many ischemic problems. Paraplegics should not sit in one position for more than 2 hours. Careful daily examination should be made for erythema, the earliest sign of ischemic injury. Erythematous areas should be freed from all pressure. Electrical stimulations, biomaterials, and growth factors are additional modalities to expedite wound repair, but the results are variable.

Once pressure necrosis is established, it is important to determine whether underlying tissues such as fat and muscle are affected, since they are much more likely than skin to become necrotic. A small skin ulcer may be the manifestation of a much larger area of destruction below. If the area is not too extensive and if infection and abscess due to external or

hematogenous bacteria are not present, necrotic tissue may be replaced by scar tissue. Continued pressure will not only prevent scar tissue from forming but will also extend the injury. A surface eschar or skin may cover a significant abscess.

If the pressure sore is small and noninfected, application of drying agents to the wound and removal of all pressure to the area may permit slow healing. Wounds extending down to bone rarely heal without surgery. Infected wounds must be debrided down to clean tissue. The objectives at operation are to debride devitalized tissue, including bone, and to provide healthy, well-vascularized padded tissue as a covering. All of the original tissue that formed the bed of the ulcer must be excised.

When the patient's nutritional status and general condition of health are optimal, definitive coverage can be performed. Coverage is usually accomplished with a muscle, musculocutaneous, or, sometimes, an axial flap. Well-vascularized muscle appears to help control established low-grade bacterial contamination. The muscle flaps used for the more common bedsores are as follows: greater trochanter: tensor fasciae latae; ischium: gracilis, gluteus maximus, or hamstrings; sacrum: gluteus maximus. Occasionally, it is possible to provide sensibility to the area of a pressure sore with an innervated flap from above the level of paraplegia. The most common example is the tensor fasciae latae flap with the contained lateral femoral cutaneous nerve from L4 and L5, which is used to cover an ischial sore. Rarely, an innervated intercostal flap from the abdominal wall may be used to cover an insensible sacrum. Unfortunately, attempts to provide protective sensibility with sensory flaps have not had good results. The tissue expansion techniques should not be the primary surgery treatment of decubitus ulcers but can be used in difficult cases where available tissue is insufficient to close the wound.

Postoperatively, the donor and recipient areas must be kept free of pressure for 2-3 weeks to allow for complete healing. This puts significant demands on other areas of the body that may be equally at risk or may already have areas of breakdown. The use of the air-fluidized bed has greatly aided such situations.

In spite of excellent padding provided by musculocutaneous flaps, recurrence of pressure sores is still a major problem, because the situation that caused the original breakdown usually still exists. Prevention of sores is even more important for these patients.

AESTHETIC SURGERY

Aesthetic surgery is an integral part of plastic surgery. In fact, the two terms have become almost synonymous even though aesthetic surgery is only one band in a broad spectrum. Increased interest and curiosity about the specialty results in part from increased demands for its services by an aging population but also from the development of more predictable, lasting, and safer techniques. A number of specialists other than plastic surgeons have also performed and contributed to cosmetic surgery. A skilled surgeon can perform such cosmetic operations safely and with maximum benefit to the patient.

Patient selection is probably as important for success as any other factor. Not all patients are good candidates for aesthetic procedures, and such operations are contraindicated in others. Age or poor general health of the patient may be a reason for delay or avoidance of purely elective procedures. Two other major factors must be considered. The first factor is the anatomic feasibility of the procedure. Can the alterations be made successfully and safely? Which technique will best accomplish the goal? The second factor is the psychologic makeup of the patient. Does the patient fully understand the nature of the proposed procedure and its risks and consequences? Are the patient's expectations realistic? Cosmetic changes in appearance will generally not save a failing marriage, help to procure a new job, or substantially improve a person's station in life, and persons with such expectations should not undergo aesthetic surgery. Surgery should be postponed for persons experiencing severe stress, such as is associated with divorce, death of a loved one, or other periods of emotional instability.

The ideal candidate for cosmetic surgery is an adult or mature younger person who has a realistic idea of what is to be accomplished, is not under pressure from others to have the operation done, and does not expect major changes in interpersonal relations or career potential following surgery. Personal satisfaction is a valid reason for seeking aesthetic refinements.

The more common aesthetic procedures are discussed below. Some procedures involve correction of functional problems as well and are therefore not always considered purely cosmetic procedures.

RHINOPLASTY

Surgical alterations of nasal structures are done for relief of airway obstruction (usually secondary to trauma) and to reshape the nose because of undesirable characteristics, such as a prominent dorsal hump, bulbous or drooping tip, or overly large size. There is often a combination of problems.

Procedures are generally performed through intranasal incisions. The nasal skin is usually temporarily freed from its underlying bony and cartilaginous framework, so that the framework can be altered by removal, rearrangement, or

augmentation of bone or cartilage. The skin is then redraped over the new foundation. The nasal septum and lower turbinate can also be altered to reestablish an open airway. A better understanding of nasal physiology has enabled surgeons to correct internal valve dysfunction by inserting spreader grafts—often following modification of the bony radix of the nose. Spreader grafts are small pieces of cartilage placed next to the septum and under the upper lateral cartilages. They serve to open up the internal valve in somewhat the same way as the external “breathe easy” appliances utilized by athletes.

Surgery can be done under local or general anesthesia; in either case, topical and injectable vasoconstrictors and anesthetic agents are commonly used. Hospitalization may or may not be indicated. Nasal packing is often used for hemostasis and support of the nasal mucosa during initial healing, as incisions are usually only minimally sutured with absorbable sutures. External nasal splints are placed to control swelling and provide some protection, particularly if osteotomy of the nasal bones is performed.

Convalescence requires 10-14 days before most swelling and periorbital ecchymosis subside; however, several months are often required before completely normal sensation returns, and all swelling resolves.

Nasal procedures are very commonly performed, generally quite safe, and usually effective. Complications include bleeding, internal scarring, recurrence of airways obstruction, and irregularities of contour. Infections are rare except with the use of alloplastic nasal implants.

Nassif P, Kulbersh J: Rhinoplasty and bony vault complications. *Facial Plast Surg* 2012;28(3):303.

RHYTIDECTOMY (FACELIFT)

The combined effects of gravity, sun exposure, and loss of elasticity due to aging result in varying degrees of wrinkles and sagging of skin along the cheeks, jawline, neck, and elsewhere in the facial area. These natural signs of aging can be removed to a great extent by a facelift procedure. Not all wrinkles can be removed; however, those in the forehead, around the eyes, in the nasolabial area, and around the lips are not significantly corrected without additional procedures.

Rhytidectomy is a major procedure requiring extensive incisions hidden in the scalp and in front of and behind the ears and occasionally in the submental region. The first such operations consisted of freeing up the skin and then stretching it and resuturing as it was drawn cephalad and laterally. This gave a mask-like and unnatural appearance. In the last few years, there has been a significant change in the concept of the facelift procedure, so that now it consists of elevation of the soft tissues—particularly the jowls and malar fat pads—to where they were at a younger age, giving

more prominence to the cheek bones and better delineating the jawline. Undermining of the skin is done only to approach the soft tissues to be elevated, and the excess skin is now removed and reapproximated without tension. This approach to the midface has given more natural and lasting results and provides also a 3D type of restoration of the soft tissues, giving a more youthful appearance.

For the double neck, extensive freeing up of the skin over the neck from the jawline down to the hyoid is performed, and the fat overlying the platysmal muscle is removed either by suctioning or directly with scissors. The platysma itself is tightened laterally as well as centrally to provide an effect similar to a hammock that will give a more defined neck and jaw angle.

Drains are used particularly in the neck, as well as a padded circumferential dressing to protect the face and provide light pressure during healing. The introduction of fat aspiration procedures (liposuction) has been adapted to the neck but is not recommended for the face since it may produce abnormal lines (“railroad tracks of demarcation”). In appropriate patients, liposuction in the neck does give fine definition to the chin and jawline and may substantially correct the double chin appearance.

Either local or general anesthesia may be used for this often lengthy (3-4 hours) procedure. Local vasoconstrictors are routinely used.

Complications include hematoma, skin slough, injuries to branches of the facial nerve or greater auricular nerve, scars, and asymmetry. Signs of aging often recur years later.

► Endoscopy

Endoscopy has become an integral part of plastic surgery, particularly for procedures involving the face or the breast. Smaller endoscopes are now utilized as well as different methods of achieving a desired optical field other than by distention of natural cavities with fluid or gases. In the face and in the breast, the optical cavity is usually obtained by tractioning the skin with appropriate elevators or sutures.

Endoscopy has been most effective for the forehead, where in appropriate circumstances it has replaced the coronal incision, which goes from ear to ear, peeling the scalp down to the supraorbital rims. By means of endoscopy, the forehead lift becomes a more physiologic operation in that one frees up the forehead skin at the subperiosteal level, dividing the periosteum at the supraorbital rim and then removing the depressors of the eyebrows (the procerus and corrugator muscles in the glabella region), thus allowing the frontalis muscle to act unopposed to elevate the eyebrows.

The key to the procedure appears to be the division of the periosteum, which by itself frees up the eyebrows and elevates them for at least 5-10 mm. In addition, removal of the glabellar muscles seems to ameliorate in a lasting way the vertical wrinkles in the glabella region. For suspension of the elevated eyebrows, different methods have been advocated that include soft tissue to bony anchoring, the use of temporary screws in the skull as well as miniplates, or, most simply, by providing external traction tied in between staples with nylon sutures. It appears that it is only necessary to maintain that elevation for a short period of time (3-5 days) until the periosteum reattaches at the higher level.

Endoscopy has also been effectively utilized to do a mid-facelift, and this procedure is applicable to younger patients where there is no excess skin in the face or neck and where scars will be unattractive.

Endoscopy is also utilized for the breasts—particularly for insertion of breast implants in the submammary or subpectoral plane through an axillary incision. An endoscope attached to a right-angle retractor allows excellent visualization of the cavity where the implant is to be inserted, and it allows the development of a pocket inferiorly down to—and if necessary below—the submammary fold and also the division of the lower portion of the origin of the pectoralis major muscle from the sternum to permit insertion of a saline implant and to provide acceptable cleavage. Appropriate instruments for dissection as well as hemostasis have been developed for this procedure, which recently has gained in popularity.

BLEPHAROPLASTY

Blepharoplasty involves removal of redundant skin of the upper and lower eyelids and removal of periorbital fat protruding through sagging orbital septa. It is done alone or as part of a facelift procedure.

Incisions are made in the upper lids surrounding previously marked redundant skin, which is removed. A subciliary incision is generally used in the lower lids. The orbicularis oculi muscle may be altered if necessary. The periorbital fat compartments are opened, and protruding fat is removed. The extent of redundant skin in the lower lid is gauged, and the skin is resected. External sutures are used. Minimal or no dressing is required.

Local anesthesia in the form of lidocaine with epinephrine is usually adequate. Swelling and ecchymosis subside in 7-10 days, and sutures are removed in 3-4 days.

Complications include bleeding, hematoma formation, epidermal inclusion cysts, ectropion, and asymmetry. Patients are usually satisfied with the results. Recurrence is much less of a problem than with facelift procedures.

In recent years there have been significant changes in the concept of the blepharoplasty procedure. For the upper lids, the change consists of the recognition of senile ptosis due

to either disruption or stretching of the levator mechanism. This can be corrected by imbrication of the levator mechanism with sutures.

The lower eyelid operation has undergone even more changes. A general trend has been to do less surgery or dissection but still obtain the same satisfactory results. Less disruption of the orbicularis muscle and orbital septum with “no touch” techniques have become popular. Also, less removal of fat but rather redistribution has gained wider acceptance. The subconjunctival removal of fat has been advocated and is particularly applicable to young patients with congenital fat hernias. The subconjunctival approach is also utilized in conjunction with the laser, which has the effect of tightening the skin of the lower lid and ameliorating the periorbital wrinkles.

Another important concept is the recognition of the proper position of the lower lid, especially the lateral canthal area. A youthful appearance is restored by elevating this to a more normal level.

MAMMOPLASTY

Aside from procedures related to breast cancer, surgery of the female breast is generally done for one of the following reasons: to increase the size of the breasts (augmentation mammoplasty), to decrease the size of the breasts (reduction mammoplasty), or to lift the breasts (mastopexy). Augmentation, lifting of the breasts, and correction of asymmetry are nearly always done for cosmetic reasons. Reduction of hypertrophied breasts may, however, be done for functional reasons, since such breasts can cause poor posture, back and shoulder pain, and discomfort due to grooves from brassiere straps.

► Augmentation Mammoplasty

In procedures for augmentation of the breasts, a silicone bag filled with saline solution or silicone is placed beneath the breast tissue in the submammary or subpectoral plane. Incisions are concealed in the periareolar margin, inframammary fold area, or axilla. Dissection is then carried out above or below the pectoralis major muscle, and the implant is placed in the pocket created. Drains are not generally used, and a padded dressing providing light pressure is applied. The subpectoral plane is preferred by most surgeons for augmentation mammoplasty because it does not interfere with mammography, but it does necessitate division of the lower portion of the origin of the pectoralis major muscle up to approximately 3 o'clock in relation to the nipple to provide adequate cleavage.

After a prolonged investigation by the FDA, silicone gel-filled implants have recently become available again in the United States for cosmetic purposes. During the investigation, silicone gel-filled implants were found to be safe; however, long-term data concerning these implants (ie, capsular

contracture, deflation and rupture rates) remains unknown. Nevertheless, patients and surgeons now have the opportunity to review the data and choose the type of implant used during breast augmentation.

The procedure can be done on an outpatient basis with local anesthesia, although this may not be satisfactory when subpectoral implants are used. General anesthesia is often used for augmentation procedures.

Although patient satisfaction is excellent in most cases, a significant rate of capsular contracture remains a problem in about 10%. Scar tissue around the implant may contract in variable degrees even in the same patient. Control of this process is difficult even though the best possible environment for healing is provided (ie, appropriate implants are used, infection is controlled, bleeding is not present, debris is removed, and movement is restricted). Implants placed in the subpectoral position appear to be associated with a lesser degree of capsular contracture and less severe deformity if contracture occurs. Deflation of saline implants occurs at a rate of 1% per year.

Other complications include hematoma, infection, exposure of the implant, deflation or rupture of the implant, asymmetry of the breasts, and external scars. Breast function and sensation are usually not altered in any way.

► Mastopexy

Mastopexy is another common procedure used for correction of sagging or ptotic breasts. Although some breasts develop in a ptotic manner, most cases are caused by normal relaxation of aging tissues, gravity, and atrophy after pregnancy and lactation. It is not clear whether use of a brassiere alters this process in any significant manner. The degree of deformity is defined by the relationship of the areola to the inframammary fold and the direction of the nipple. A ptotic breast will have a nipple that is below the inframammary line and pointing down towards the toes.

Correction may be done with simultaneous reduction or augmentation. An incision must be made around the areola, and the breast tissue itself is imbricated or, better still, an inferiorly based flap of breast tissue is designed and placed underneath the remnant superior part of the breast and over the pectoralis major muscle, serving as an autoaugmenta-

tion as one brings the lateral breast columns together. This procedure gives a more lasting effect than merely decreasing the skin envelope. Attempts at making more lasting corrections of ptosis of the breasts through the periareolar incision, which decreases the scarring, have included wrapping the breast with prosthetic material such as polyglycolic meshes or, more recently, by wrapping it around with segments of pectoralis major muscle.

Nonetheless, significant scarring may occur, particularly around the periareolar incision.

General anesthesia is usually necessary, and recovery from mastopexy may take 7-10 days. Complications include bleeding, infection, tissue loss, altered sensation or loss of function of the nipple and areolar areas, scars, and asymmetry of the breasts.

Patient satisfaction with the results is often not as great as with other procedures. Satisfaction often depends on how well the patient is prepared to accept the resulting scars.

► Reduction Mammoplasty

Reduction mammoplasty is similar to mastopexy, since nearly all hypertrophic breasts are ptotic and must be lifted during correction. Enlargement can occur during puberty or later in life. Massive breasts can become a significant disability to the patient.

Although various techniques have been developed for breast reduction, nearly all require a pedicle to carry the nipple areola to its new position and a circumareolar incision as well as a vertical or inverted T incision beneath the areola. In gigantomastia, the nipple-areola is often removed as a free full-thickness graft and positioned appropriately. Most tissue is removed from the center and lower poles of the breast.

Vertical reduction mammoplasty has aroused considerable recent interest because of the decrease in amount of scarring. It can be accomplished through an incision made circumferentially around the areola and then a vertical incision that extends to and sometimes slightly below the inframammary fold. Resection of the breast tissue is done from below as well as from the lateral aspect of the breast. Considerable wrinkling of the skin occurs in an effort to avoid "T-ing off" the incision at the inframammary fold, but pleating of the skin usually resolves over a period of weeks. General anesthesia is nearly always required because dissection is considerable, but blood loss can be minimized by the use of epinephrine as a vasoconstriction agent. Transfusions are rarely indicated, and postoperative drains are often not used. The procedure can be done on an outpatient basis.

Although problems with nipple-areola loss, bleeding, infection, asymmetry of breasts, and scarring may occur; these women are generally among the most satisfied and appreciative of patients.

ABDOMINOPLASTY & BODY CONTOURING PROCEDURES

Other procedures usually classified as aesthetic are abdominoplasty and various body contouring procedures that serve to remove excess tissue from the lower trunk, thighs, and upper arms. Patients with sagging tissue due to aging, pregnancies, multiple abdominal operations, or significant or massive weight loss are usually good candidates for body contouring procedures. With the increased popularity of bariatric surgery, more people are seeking surgery to remove and correct large amounts of excess and redundant skin and soft tissue of the trunk and extremities. These types of procedures are not indicated as a treatment for obesity. This involves a complete regimen of diet, exercise, and lifestyle modifications.

Abdominoplasty usually involves removal of a large ellipse of skin and fat down to the wall of the lower abdomen. Dissection is carried out in the same plane up to the costal margin. The naval is circumscribed and left in place. After the upper abdominal flap is stretched to the suprapubic incision, excess skin and fat are excised. The fascia of the abdominal wall midline can be plicated and thus tightened. The umbilicus is exteriorized through an incision in the flap at the proper level, and the wound is closed over drains with a long incision generally in an oblique line or W shape just above the os pubis and out to the area below the anterior iliac crests (so-called bikini line). When the extent of excess abdominal tissue is severe, better results can be obtained with what is called a circumferential abdominoplasty. The incision is carried around the patient and this requires changing the position of the patient at least on one occasion. Proper markings preoperatively are essential in order to obtain a satisfactory and symmetrical result.

Spinal anesthesia may be used in some cases. Hospitalization is routinely required for up to a few days. Blood transfusions are rarely necessary. Proper deep vein thrombosis prophylaxis is important in these and other extensive procedures.

Complications involve blood or serum collections beneath the flap, infection, tissue loss, and wide scars. Results are generally quite dramatic with excellent patient satisfaction in properly selected cases.

Various surgical procedures have been devised to remove excess skin and fat from the upper arms, buttocks, and thighs. These procedures commonly result in extensive incisions that can produce significant scarring, and there may be difficulty in achieving a smooth transition between the end point of the contour alteration and normal tissue. Careful planning and counseling of the patient is imperative in order to obtain a satisfactory result. The use of a suction-assisted lipectomy with appropriate cannulas to remove localized excess fat deposits has become widespread. It is clear, however, that patient selection and judicious use of liposuction

are necessary to avoid complications, including hypovolemia due to blood loss, hematoma formation, skin sloughs, excess laxity of the skin and soft tissues and waviness and depressions in the operative site. Used with discretion, liposuction can offer definition to areas of the abdomen, flanks, thighs, and buttocks.

SUCTION-ASSISTED LIPECTOMY

Suction-assisted lipectomy, or liposuction, has now become the most common cosmetic surgical procedure performed in the United States. As presently practiced, it consists of infiltration of a “wetting” or “tumescent” solution to provide vasoconstriction and anesthesia to the operative sites. A common mixture consists in a solution of Ringer lactate with the addition of 1 mg of epinephrine per 1000 mL of Ringer and 250 mg of plain lidocaine—the former to provide vasoconstriction and the lidocaine to provide a certain amount of anesthesia and thus reduce the depth of general anesthesia. Some surgeons perform the entire operation under local anesthesia, necessitating the use of larger amounts of lidocaine.

Once the solution has been infiltrated sufficiently to produce the proposed effects, a small cannula is introduced through a small incision and suction is applied either with a syringe or with a suction machine. The fat layer that has been enlarged by the injection of tumescent solution dislodges easily and disrupts much faster than the blood vessels and the nerves.

Suction-assisted lipectomy is effective in removing abnormal bulges of localized fat throughout the body, particularly in the trochanters or the abdomen and flanks, but it is not considered a weight reduction technique.

The procedure is safe when done by well-trained surgeons respecting sterility and technique and in adequately equipped operating rooms. Safety in the use of up to 35 mg of lidocaine per kilogram has been established by clinical studies. Although fatalities have been reported with suction-assisted lipectomy—which is distressing in an entirely elective procedure—they are due to pulmonary embolization, perforation of the intestines, or severe infections of the abdominal wall. Fortunately, fatalities have markedly decreased since the American Society of Plastic and Reconstructive Surgeons established safety guidelines. High-volume liposuction (ie, over 5000 cc of aspirate) should be done in a hospital or accredited ambulatory facility and that combined procedures should be carefully monitored.

Complications of suction-assisted lipectomy include irregularities of contour, dimpling, and, rarely, local infection at the entrance points.

Ultrasonic liposuction, external and internal, has also been advocated. External ultrasonic liposuction has the effect of a massage to disperse the infiltrated tumescent solution. Internal ultrasonic liposuction, on the other hand,

emulsifies the fat with ultrasonic energy, which produces heat, so that this emulsified fat needs to be suctioned with standard suctioning equipment. The problems with ultrasonic liposuction include seroma formation, the need for larger portals of entrance, the possibility of burns of the skin or perforations of the skin (end hits) if the cannula is misdirected.

FAT GRAFTING

With the continued popularity of lipectomy and the desire for contouring of other body regions, the use of fat grafting has continued to gain popularity. In essence, fat is removed from one part of a patient, prepared via several different techniques, and then placed where further soft tissue enhancement is required. It can be used in the face, the breast, and soft tissue defects in almost all areas of the body. With the discovery of adipose derived stem cells, this technique will continue to gain popularity.

TELANGIECTASIAS (SPIDER VEINS)

When there is no trace of primary or secondary varicosities, most telangiectasias, or spider veins, are viewed as a cosmetic problem. However, one should be aware that in some cases spider veins may be an indication of deep venous valvular insufficiency. Factors that may play a role in the formation of spider veins include venostasis with decreased flow rate due to atony of the venous wall, chronic venous inflammation, trauma to the site, hormonal influences, or venous compression at the saphenofemoral valve.

Treatment of spider veins is with sclerosing agents, which may include hypertonic saline, sodium tetradecyl sulfate, and polidocanol (Asclera) injections. These agents are injected directly into the spider veins with the objective of creating intimal damage that will result in fibrosis and obliteration of the lumen. The technique is simple and effective, but when the sclerosing agent extravasates into the soft tissue, it might produce superficial skin necrosis.

MULTIPLE CHOICE QUESTIONS

- An advantage of full thickness skin graft (FTSG) versus split-thickness skin grafts (STSG) is:
 - Increased contracture rate
 - Decreased amount of skin appendages
 - Improved overall aesthetics
 - Less resilient to trauma
- The maximum safe length to width ratio for a random pattern flap is:
 - 1:1
 - 1.5:1
 - 2:1
 - 2.5:1
 - 3:1
- A 25-year-old man presents with a long-standing ischial pressure sore. After debridement and partial ischiectomy, the best choice for tissue coverage is:
 - Rectus femoris
 - Gracilis
 - Split-thickness skin graft
 - Primary closure
- Which of the following is characteristic of an arteriovenous malformation (AVM)
 - GLUT-1
 - Rapid growth
 - Growth proportional with patient
 - Sporadic involution
- A 40-year-old woman presents after mastectomy and radiation therapy. The best aesthetic method for breast reconstruction is:
 - Implants alone
 - Tissue expanders followed by implants
 - Acellular dermal matrices (ADM) with implants
 - Latissimus flap
 - TRAM flap

Hand Surgery

42

David M. Young, MD
Scott L. Hansen, MD

Both in industry and in the home, the hand is the most commonly injured part of the body. Disorders of the hand rarely jeopardize life but can significantly affect the ability to function.

INTRODUCTION

The prime functions of the hand are feeling (sensibility) and grasping. Sensibility is most important on the radial sides of the index, middle, and ring fingers and on the opposing ulnar side of the thumb, where one must feel and be able to pinch, pick up, and hold objects. The skin on the ulnar side of the small finger and its metacarpal, upon which the hand usually rests, must register the sensations of contact and pain to avoid burns and other trauma.

Mobility is critical for grasping. The upper extremity is a cantilevered system extending from the shoulder to the fingertips. It must be adaptable to varying rates and kinds of movements. Stability of proximal joints is essential for good skeletal control distally.

The specialization of the thumb has allowed humans to have superior aptitudes for defense, work, and dexterity. The thumb has exquisite sensibility and is a highly mobile structure with well-developed adductor and thenar (pronating) musculature. It is the most important digit of the hand, and every effort must be made to preserve its function.

The **position of function** of the upper extremity favors reaching the mouth and perineum and achieves a comfortable, forceful, and unfatiguing grip and pinch. The elbow is held at or near a right angle, the forearm neutral between pronation and supination, and the wrist extended 30 degrees with the fingers flexed to almost meet the opposed (pronated) tip of the thumb (Figure 42-1A). This is the desired position of the extremity if stiffness is likely to occur, and it should be maintained when joints are immobilized by splinting, arthrodesis, or tenodesis.

Opposite to the position of function is the **position of rest**, in which the flexed wrist extends the digits, making grip and pinch awkward, uncomfortable, weak, and fatiguing (Figure 42-1B). The forearm is usually pronated, and the elbow may be extended. This habitus is assumed, without intention, after injury, paralysis, or the onset of a painful stimulus. For that reason, it is also called the **position of the injury**. Immobility in this position jeopardizes function.

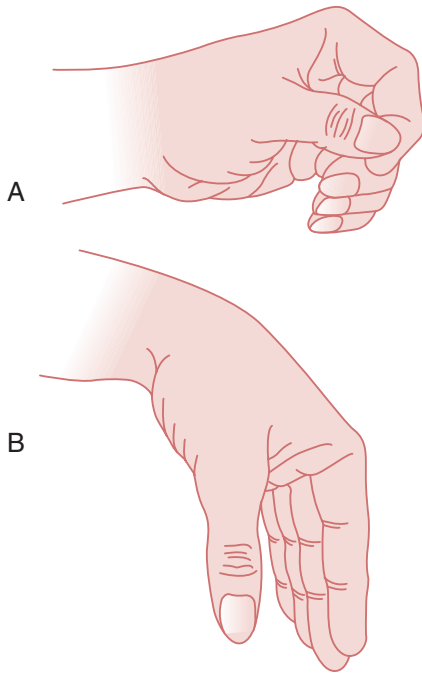

ANATOMY

All references to the forearm and hand should be made to the radial and ulnar sides (not lateral and medial) and to the volar (or palmar) and dorsal surfaces. The digits are identified as the thumb, index finger, middle finger, ring finger, and small finger.

The skin is an elastic outer sleeve and glove of the arm and hand. Sacrifice of its surface area or elasticity by debridement and fibrosis can severely diminish the range of motion and constrict circulation. In the adult hand, the dorsal skin stretches about 4 cm in the longitudinal and in the transverse planes when the palm is flattened and spread. The long finger can have as much as 48 cm² of skin cover, and the whole hand (exclusive of digits) has 210 cm².

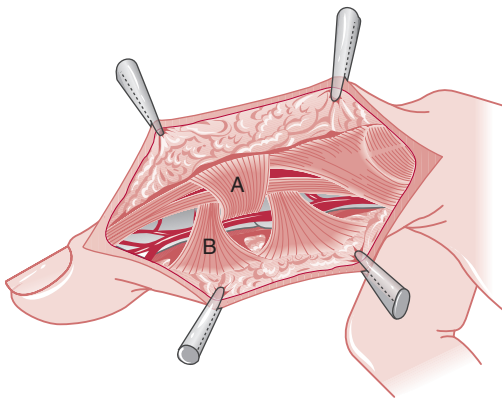

Fascia anchors the palmar skin to bone to make pinch and grip stable; the midlateral fibers of the Cleland and Grayson ligaments keep the skin sleeve from twisting around the digit (Figure 42-2). In the form of sheaths and pulleys, fascia holds tendons in the concavity of arched joints to convey mechanical efficiency and power. The fascial sleeve of the forearm, hand, and digits must sometimes be released along with skin to prevent or relieve congestion (eg, compartment syndrome). Any fascial compartment of the hand provides a space for infection or an avenue for its dissemination.

Each finger has three joints, the distal interphalangeal joint (DIP), the proximal interphalangeal joint (PIP), and

▲ **Figure 42-1.** Positions of function (A) and rest (injury) (B).

the metacarpophalangeal joint (MCP). The thumb contains the IP, the MCP, and the carpometacarpal joint (CMC). The wrist is the “key joint” of the hand, governing motion of the digits, and may need to be included in the immobilization required for a major finger or hand problem. The position of the wrist governs the efficiency of extrinsic muscle contraction. The wrist is composed of a proximal and distal row of carpal bones. The proximal row contains the scaphoid,

▲ **Figure 42-2.** A: Cleland ligament. B: Transverse retinacular ligament.

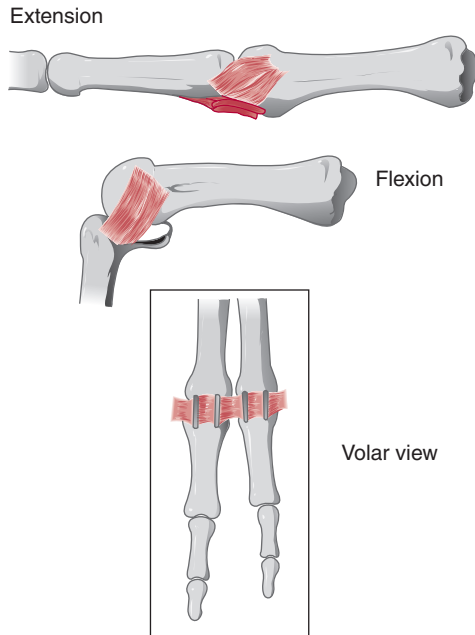

▲ **Figure 42-3.** Longitudinal (top) and transverse (bottom) arches.

lunate, triquetrum, and pisiform, while the distal row contains the trapezium, trapezoid, capitate, and hamate. The stability of the digital joints and their planes of motion are governed by the length of the ligaments and the anatomy of their articulating surfaces. The longitudinal and transverse arches of the hand (Figure 42-3) are architectural prerequisites to gripping, pinching, and cupping, and are maintained by the active contraction and passive tone of intact muscles. The arches create the position of function. When the arches are collapsed, the hand assumes the position of injury. Loss of these arches is most often initiated by edema. They may be preserved by splinting in the position of function, elevation without constriction, and early restoration of active joint motion.

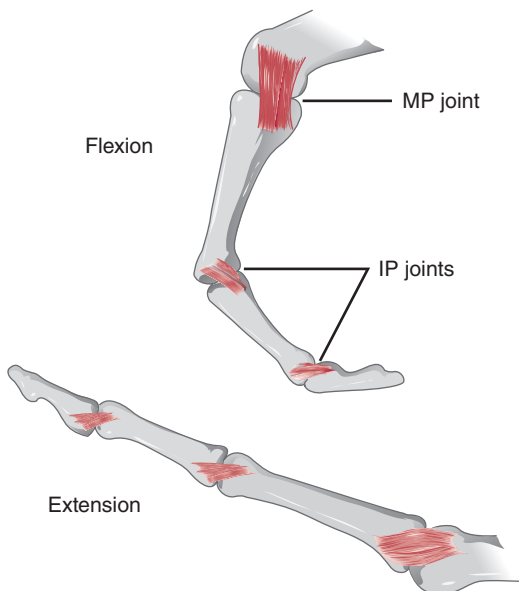

Each MCP and PIP joint has a distally anchored volar plate (Figure 42-4) in addition to collateral ligaments stabilizing the joint on either side (Figure 42-5). The thickened lateral portions of the volar plate form the checkrein ligaments, which prevent IP hyperextension.

The extrinsic flexor tendons are contained in fibrous **sheaths** to prevent bowstringing and preserve mechanical efficiency as the digits flex into the palm. Pulleys (hypertrophied sections of the sheath) resist the points of greatest tendency to bowstringing. The retinacular pulley system contains five annular bands and three cruciform bands. Sheaths are inelastic and relatively avascular. Therefore, they crowd and congest any swollen, inflamed, or injured tendons and curtail glide by friction, constriction, and the generation of inelastic adhesions. The A-2 and A-4 pulleys must be maintained to prevent tendon bowstringing. These are located over the proximal and middle phalanges, respectively. The A-1, A-3, and A-5 pulleys are located over the

▲ **Figure 42-4.** Volar plate.

MCP, PIP, and DIP joints, respectively. Five flexor tendon zones have been described. Zone II, or “no man’s land,” is the zone from the middle of the palm to just beyond the PIP joint, wherein the superficialis and profundus tendons lay

▲ **Figure 42-5.** Collateral ligaments.

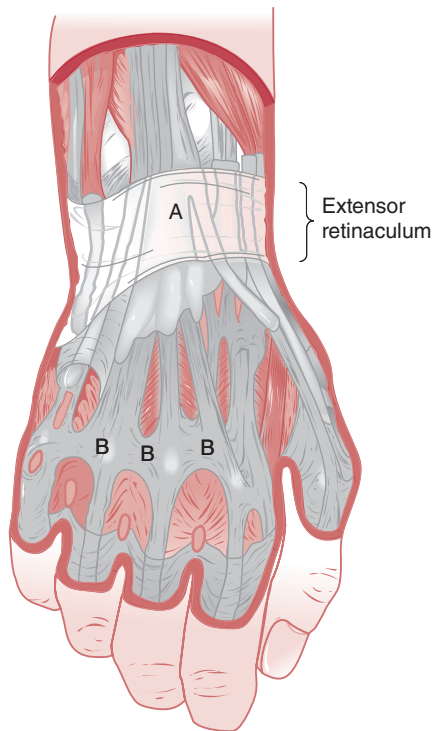

▲ **Figure 42-6.** Carpal tunnel and no man’s land.

ensheathed together and where recovery of glide is difficult after wounding (Figure 42-6).

Across the wrist, the dense volar transverse carpal ligament closes the bony carpal canal (**carpal tunnel**) through which passes all eight finger flexors as well as the flexor pollicis longus and median nerve (Figure 42-6). The **ulnar bursa** is the continuation of the synovium around the long flexors of the small finger through the carpal tunnel, encompassing the other finger flexors which interrupted their separated bursa at the midpalm level. The **radial bursa** is the synovium around the flexor pollicis longus contained through the carpal tunnel. These two bursas may intercommunicate. **Parona space** is the tissue plane over the pronator quadratus in the distal forearm deep to the radial and ulnar bursas.

The extensor tendons are ensheathed in six individual compartments at the wrist beneath the extensor retinaculum (Figures 42-7 and 42-8), which predisposes to adhesions. Its role as a pulley is not as vital.

The nerves of greatest importance to hand function are the musculocutaneous, radial, ulnar, and median nerves. The importance of the musculocutaneous and radial nerves combined is forearm supination and of the radial nerve alone is innervation of the extensor muscles. The ulnar

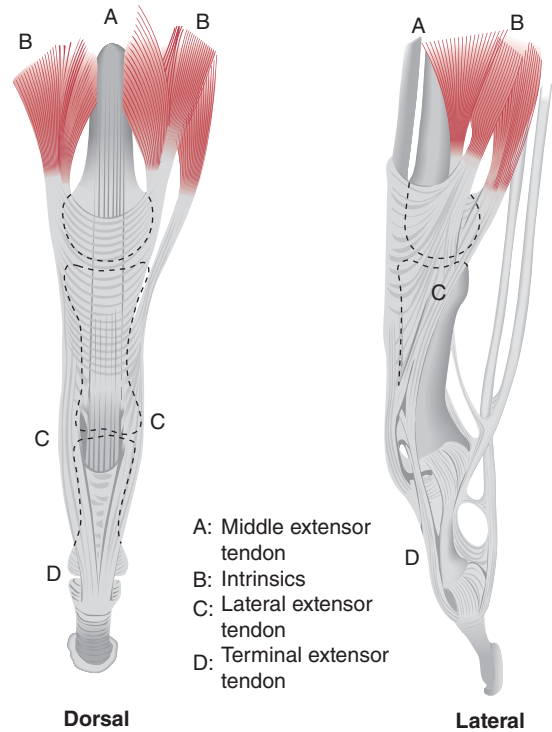

▲ **Figure 42-7.** A: Extensor retinaculum over six tendon compartments. B: Juncturae tendinum (conexus intertendineus).

nerve innervates 15 of the 20 intrinsic muscles. The median nerve provides sensation to the thumb, index finger, middle finger, and the radial aspect of the ring finger; through its motor innervation, it maintains most of the long flexors, the pronators of the forearm, and the thenar muscles. Figure 42-9 shows the sensory distribution of the ulnar, radial, and median nerves.

CLINICAL EVALUATION OF HAND DISORDERS

The presenting complaint must be assessed in complete detail with regard to its mechanisms of onset, evolution, aggravating factors, and relieving factors. Age, sex, hand dominance, occupation, preexisting hand problems, and relevant matters pertaining to the patient's general health must also be noted.

The examination should follow an orderly routine. Observe the neck, shoulders, both upper extremities, and the action and strength of all muscle groups, and be certain that all parts can pass painlessly and coordinately through a normal range of motion, starting with the head and neck and working down to the fingertips. Compare both upper

▲ **Figure 42-8.** Extensor hood mechanism.

extremities and keep detailed notes, diagrams, and measurements. Having the patient reach for the ceiling and simultaneously open and close both fists and then spread and adduct the fingers and, finally, oppose the thumbs sequentially to each fingertip will immediately demonstrate any abnormalities.

Observe habitus, wasting, hypertrophy, deformities, skin changes, skin temperature, scars, and signs of pain (including when the patient attempts to bear weight on the palms). Feel the wrist pulses and the sweat of the finger pads, and test reflexes and the sensibility of the median, ulnar, and radial nerves.

Serial x-rays and laboratory studies may clarify a problem with an indolent evolution (eg, Kienböck avascular necrosis of the lunate, causing unexplained wrist pain). Contralateral and multiple-view x-rays in different planes are often helpful. In addition, computed tomography (CT) scans, magnetic resonance imaging (MRI), bone scans, or all of these may aid in diagnosis. This is especially true in patients who have persistent bone and joint pain or limited motion or in patients who have not attained adult growth. In the case of wrist problems, arthrograms and arthroscopy may be of diagnostic value. MRI can be quite helpful in the diagnosis of subtle carpal bone problems.

▲ **Figure 42-9.** Sensory distribution in the hand. Light-shaded area, ulnar nerve; diagonal area, radial nerve; darker area, median nerve.

The diagnosis is often made by noting the response to therapy. This is particularly true in the case of local corticosteroids injected at the site of noninfectious inflammatory conditions (eg, carpal tunnel syndrome, trigger finger).

▲ **Figure 42-10.** Proper placement of skin incisions.

GENERAL OPERATIVE PRINCIPLES

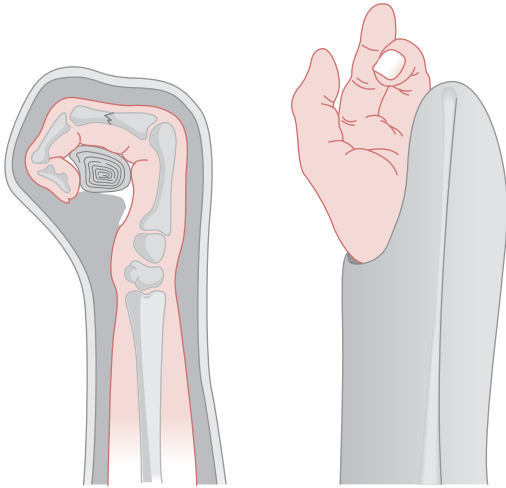

A bloodless field (eg, by tourniquet ischemia) is essential for accurate evaluation, dissection, and management of tissues of the hand. This is achieved by elevating or exsanguinating the extremity and then inflating a padded blood pressure cuff around the arm to 100 mm Hg above systolic pressure. This is readily tolerated by the unanesthetized arm for 30 minutes and by the anesthetized arm for 2 hours.

Incisions (Figure 42-10) must be either zigzagged across lines of tension (eg, must never cross perpendicularly to a flexion crease), termed Brunner incisions, or run longitudinally in “neutral” zones (eg, connecting the lateral limits of the flexion and extension creases of the digits), and whenever possible, must be designed so that a healthy skin-fat flap is raised over the zone of repair of a tendon, nerve, or artery.

Proper evaluation and treatment of an acute injury often requires extension of the wound. Normal structures can then be identified and traced into the zone of injury, where blood and devitalized tissue can make their identification difficult or impossible.

Constriction and tension by dressings must be avoided. The dressing should be applied evenly to the skin without wrinkles. The wound should be covered with a single layer of fine-mesh gauze followed by a moist spongy medium (fluffs, Rest-On, Kling, or Kerlix). Moisture facilitates the drainage of blood into the dressing, which should be applied with gentle pressure to restrict dead space.

Splinting and immediate elevation are paramount in controlling swelling and pain postoperatively. In general, plaster (fast-setting) or fiberglass is preferred because of its adaptability to specific requirements. More often than not,

▲ **Figure 42-11.** Casting.

the wrist requires immobilization along with any other part of the hand (Figures 42-11 and 42-12).

It must be appreciated that effective immobilization of a finger most often requires concomitant immobilization of one or more adjacent fingers, usually in the position of function. Straight splints such as tongue blades involve a hazard of digital stiffness and distortion and should not be used across the MCP joint.

Persistence of pain signifies inadequate immobilization and, if throbbing is present, congestion. Congestion must be promptly relieved by elevation and sectioning of the cast and dressing and, if necessary, the skin and fascia.

▲ **Figure 42-12.** Casting.

CONGENITAL ANOMALIES OF THE HAND

Major congenital hand anomalies are not rare, with approximately 1 in 700 live births affected. When minor deformities are included, approximately 3% of all births are affected. Camptodactyly (bent finger), polydactyly (more than five fingers), and syndactyly (two or more fingers are joined together) are the most common malformations. Newborns with hand anomalies should be carefully examined for other malformations because multisystem syndromes can be present in 5% of patients (eg, vertebral, anal atresia, cardiac, trachea, esophageal, renal, and limb [VACTERL] syndrome with radial head dysplasia).

Anomalies may be inherited, caused by environmental factors (drugs, viral infections, irradiation, alcohol), or idiopathic. Major genetic or major environmental causes are infrequently found, suggesting that the cause of most defects is multifactorial.

In order to simplify an extremely complex clinical problem, the American Society for Surgery of the Hand (ASSH) and all major international hand societies have adopted a single classification system that divides anomalies into six main categories: failures of formation (absent digits, phocomelia [seal limb]), failures of differentiation (syndactyly), duplication (polydactyly), undergrowth (brachydactyly), overgrowth (macroductyly), and constriction ring syndrome (focal necrosis, intrauterine amputation). There is considerable overlap in the categories, as might be expected.

Ideally, surgery is performed early in the first 2 years of life, but timing is individually tailored to the problem.

TENDON DISORDERS OF THE HAND

Movement of the muscles of the hand and arm are transmitted into finger and wrist motion by the tendons. The tendons are strong, compact units that glide within their individual compartments. Disruption of the tendon by trauma or loss of tendon gliding by inflammation hinders tendon excursion and therefore limits active motion of the joints. Passive motion of the joint is still possible with an isolated tendon problem and distinguishes tendon disorders from joint disorders when both active and passive motions are limited.

Tendon disruption can result from any penetrating injury and can be diagnosed by physical examination. A tendon injury should be suspected when the patient is unable to actively move a joint. Certain tendon lacerations, such as an isolated flexor digitorum superficialis disruption, may

be masked because the profunda tendon can still move the entire finger. Blocking of profunda function by blocking flexion in the neighboring fingers (the profunda tendons are joined in the palm) reveals the injury to the superficialis when the injured PIP joint cannot be flexed.

The state of the wound and the complexity of the injury are the principal issues the hand surgeon must weigh in choosing between a primary or secondary tenorrhaphy. Clean wounds generally favor primary tenorrhaphy. Primary tenorrhaphy is defined as one that is done within 24-72 hours after injury. When wounds are unstable, contaminated, or complicated by fracture or ischemia, formal tenorrhaphy may have to be delayed for weeks or months until the tendon bed is more favorable to healing and glide. However, interim tacking of the tendons—together, to tendon sheaths, or to bone—to maintain the fiber length of a muscle may be done as a preliminary procedure.

Preoperative treatment of fresh lacerations consists of wound closure, immobilization, and prophylactic antibiotics. Such cases can be deferred for definitive primary repair for 24 hours or more. The timing of delayed secondary procedures depends on the resolution of wound edema and fibrous callus (ie, how soft and pliable it is). After 6-8 weeks, tendons that retract over 2.5 cm may defy full excursion because muscle elasticity has been lost or because the tendon is recoiled and congealed in scar.

Tenorrhaphy must be done without surface trauma along the tendon or its bed. The repair is made end to end or by weaving one tendon with the other, using a 3-0 or 4-0 braided synthetic polyester material, Prolene or nylon sutures. A flexor tendon graft is anchored distally to bone (Figure 42-13). Tenodesis will occur if the surface of the tendon and the surface where adherence is desired are roughened. The position of immobilization should relieve tension on the tendon juncture. The duration of immobilization after tenorrhaphy is generally no more than 3-4 weeks. Controlled early, passive or active mobilization after tenorrhaphy may be initiated as early as 1 week to minimize excessive tendon scarring. This requires a very cooperative patient and close supervision by the hand therapist to avoid rupture of the repaired tendon.

Adhesions invariably form wherever tendons are even slightly inflamed or injured and can severely limit tendon function. Even so, adhesions are necessary for a tendon to reestablish continuity. With continuous active and passive

▲ **Figure 42-13.** Flexor tenorrhaphy by advancement or graft. Pulleys are saved.

▲ **Figure 42-14.** Mallet finger with swan-neck deformity.

movement over months, tendon glide can be increased with maturation and molding of the collagen in the adhesions. If the adhesions remain thick and tendon excursion is limited, surgical release of the tendon adhesions (tenolysis) needs to be performed. Successful surgery requires the release of all adhesions limiting tendon glide without rupturing the tendon repair. Movement of the tendon as soon as possible after surgery (within 24-48 hours) under the guidance of the hand therapist is critical to avoid recurrence of adhesions.

The access to tenolysis should be through an incision offering effective exposure and placed where the immediate active and passive joint motion that must follow will not jeopardize healing of the wound by undue stretching or direct pressure. Performing a concomitant procedure requiring immobilization such as a neuroorrhaphy should be avoided. The patient must understand that joint mobilization after tendon surgery is a time-consuming process, often taking many weeks or months to achieve maximum recovery.

Mallet finger (“baseball” or “drop” finger) (Figure 42-14) is due to disruption of the extensor tendon to the distal phalanx. A distal joint that can be passively but not actively extended is diagnostic. The injury most commonly results from sudden forceful flexion of the digit when it is held in rigid extension. Either the extensor is partially or completely ruptured or the dorsal lip of the bone is avulsed. Less frequently, the injury is due to direct trauma such as a laceration. An x-ray should be taken to determine the presence and extent of any fracture.

Treatment requires 6-8 weeks of continuous splinting in full distal joint extension (not hyperextension) with or without 40 degrees of PIP joint flexion. Patient education and compliance are essential for good results. Joint fixation internally with a percutaneous Kirschner wire or externally with padded aluminum, plastic, or plaster splints are equally effective. A lacerated tendon should be repaired. When a significantly displaced fracture fragment represents one-third or more of the surface of the joint, it should be reduced by wiring or pinning. If there is sufficient articular surface disruption, one may consider joint fusion.

Swan-neck deformity (Figure 42-14) is a frequent complication of mallet finger, but it may also be the result of disparity of pull between the extrinsic flexors and extensor hood with or without attenuation of the DIP joint extensor.

▲ **Figure 42–15.** Buttonhole deformity.

It is seen in congenitally hypermobile joints, spastic, and rheumatoid states, and following resection of the superficialis tendon. The dorsal hood acts to extend the distal joint but is held back by its insertion at the base of the middle phalanx, which it therefore hyperextends. This in turn increases the tension on the profundus, which hyperflexes the DIP joint. If the mallet deformity is 25 degrees or less and there is some active distal joint extension, it may be treated by undermining and elevating the extensor hood at the PIP joint and severing its insertion on the base of the middle phalanx. Otherwise, the deformity may be corrected by tethering PIP joint extension with one slip of the flexor digitorum superficialis threaded through the flexor pulley of the proximal phalanx with the PIP joint flexed 20 degrees.

The **boutonnière**, or “**buttonhole**,” deformity (Figure 42–15) appears as the opposite of the swan-neck deformity: hyperextension of the DIP joint and flexion of the PIP joint. There is attenuation or separation of the dorsal hood, so that the middle extensor tendon becomes ineffective and the lateral extensor tendons shift volar to the PIP joint axis and the joint buckles dorsally. The entire extrinsic-intrinsic force on the hood passes onto the lateral extensor tendons, which flex the PIP joint and hyperextend the DIP joint. This deformity may develop suddenly or, more often, insidiously after closed blunt or open trauma over the dorsum of the PIP joint.

To avoid this complication, sutured extensor tendon lacerations and severe contusions over the PIP joint should always have the PIP joint alone splinted in extension for 3–4 weeks. Established deformities can be treated by such immobilization but more often require operative correction.

STENOSING TENOSYNOVITIS

In stenosing tenosynovitis, there is a disproportion between the clearance inside a tendon pulley or tunnel and the diameter of the tendon or tendons that must glide through it. Any pulley or tunnel may be implicated. The more common sites are as follows:

1. The proximal digital (A1) pulleys in the distal palm, causing **trigger finger** or thumb. There is local tenderness of the pulley; pain, which may be referred to the PIP joint; and (usually but not always) locking of the digit in

flexion with a painful “pop” as it goes into extension (ie, as the bulge in the tendon or tendons passes through the tight pulley).

2. The pulley over the radial styloid housing the abductor pollicis longus and extensor pollicis brevis (first extensor compartment), causing **de Quervain tenosynovitis**. Local tenderness and pain occur if these tendons are actively stretched (eg, Finkelstein test). The Finkelstein test is performed by having the patient bend the thumb into the palm and grasp with the fingers. The wrist is then bent ulnarly, and the first extensor compartment palpated. Pain in this area suggests de Quervain tenosynovitis.

Relief of the symptoms can be achieved by local injections of triamcinolone mixed with lidocaine. Immediate surgery is justified if the constriction is so tight that the tendon is locked. Surgical section of the constricting tendon sheath is also indicated if symptoms persist or recur. When releasing the flexor tendon, care is taken not to resect more than the section of sheath restricting the tendon or else the tendon will pull away from the finger like a bowstring and weaken the grip.

SKELETAL INJURIES OF THE HAND

Injuries to the bones and joints of the hand are the most common skeletal injuries treated by physicians. Recognition of the injury, appropriate diagnostic tests, and timely treatment are essential for minimizing the complications of these injuries. Some patients may neglect obvious fractures and dislocations in hope of spontaneous recovery. More subtle injuries to the wrist are more often neglected by the patient and sometimes even missed by physicians until further damage is done. The use of the fluoroscope, found in many offices, greatly enhances the surgeon’s ability to diagnose fractures. The machine allows real-time assessment of the bones as part of the physical examination. A common late sequela of skeletal injury at the articular surfaces is osteoarthritis, which is difficult to treat. Patients with symptoms related to the hand or wrist but without a discernible cause should be referred early to a hand specialist.

METACARPALS & PHALANGES

► Fractures

Fractures of the metacarpal and phalangeal bones such as distal phalanx tuft of the fingers caught in closing doors and metacarpal shaft fractures of the ulnar side of the hand (boxer's fractures) create an obvious deformity and are easy to diagnose. Adequate x-rays of the specific site of the fracture with anteroposterior, lateral, and oblique views are essential for developing a treatment plan.

Fractures of the shaft can usually be treated with closed reduction and a cast or splint holding the hand in the position of function (Figure 42-1) for 3-4 weeks. Residual angulation of a metacarpal shaft fracture of up to 30 degrees in the fifth finger and 20 degrees in the fourth finger is functionally well tolerated, although a dorsal bump may be aesthetically unpleasant. However, even a small rotational misalignment of the fracture at the metacarpal bone results in scissoring of the fingers in flexion and causes severe dysfunction.

When fractures do not remain reduced, fixation with Kirschner pins placed through the skin is required. Placement of more than one pin is usually needed to keep the fracture reduced. The pins are removed after the fracture is healed. Displaced and comminuted fractures may require opening of the fracture site and reduction under direct visualization. Pins, lag screws, and small, low-profile metal plates and screws are used to maintain reduction. Metal plates provide strong support to the fracture site and allow earlier mobilization of the hand. However, plates are more invasive and occasionally interfere with tendon function due to excessive scar formation postoperatively.

Fractures through an articular surface need to be carefully evaluated. Nondisplaced fractures can be treated by casting. Displaced fractures require open reduction and accurate pin or lag screw fixation because discrepancies of the articular surface will eventually result in degenerative arthritis.

Fractures of the distal phalanx from crush injuries require attention to the disrupted nail bed. The nail is removed to decompress the painful subungual hematoma and provide irrigation of the open fracture and careful reapproximation of the nail matrix. Large disruptions in the nail matrix may result in deformity of the regenerating nail. The nail is replaced under the nail fold (eponychium) as a splint. A protective splint is placed over the finger to hold the distal fragment in extension.

An intra-articular fracture of the base of the thumb metacarpal bone with subluxation (displacement) of the metacarpal leaving a volar pyramidal shaped fragment attached to the trapezium is called a **Bennett fracture**. The anterior oblique ligament, responsible for stability of the thumb base, is left attached to the pyramidal fragment. The remainder of the thumb metacarpal is unstable and limits use of the thumb. The fracture must be reduced and stabilized with Kirschner

pins, plate, or lag screws. Accurate reduction of the articular surface is crucial in reducing complications. Even despite adequate treatment, most patients eventually develop arthritis.

► Dislocations

Dislocations are most common in the PIP joint. Injuries are classified according to the position of the distal digit as hyperextension, dorsal displacement, or volar displacement. The type of dislocation determines which structures, such as the volar plate, collateral ligaments, and extensor tendon, are likely to be disrupted.

The MCP and CMC joints are better protected by surrounding soft tissue but can still be dislocated. The MCP joint of the thumb is most frequently injured by forced abduction. The ulnar collateral ligament is torn, as occurs with forced use of a ski pole or as historically described in gamekeepers when twisting the neck of birds ("gamekeeper's thumb"). Of the CMC joints, the fifth is most commonly injured. A fracture analogous to a Bennett fracture (reverse Bennett fracture) can occur. Examination to determine injury to the deep motor branch of the ulnar nerve in this area should be done.

Radiographs are occasionally useful for diagnosis, but the physical examination is most important. Since pain often limits the extent of the examination, regional anesthesia with a wrist or finger block allows a more detailed examination. Partial tears of ligaments without dislocation or instability are treated by splints. Dislocations can usually be reduced, and the need for surgical therapy is determined by the stability of the joint after reduction. Stable reductions are treated with early mobilization to decrease stiffness.

Fracture dislocations usually require surgical repair. Instability after reduction can be treated by repair of the torn collateral ligament or volar plate. Severe dislocations of the PIP and MCP joints can result in interposition of disrupted soft tissue in the joint, making closed reduction impossible. The joint must be opened and the trapped soft tissue removed and repaired to correct the dislocation. A complete disruption of the ulnar collateral ligament in a gamekeeper's thumb injury can result in interposition of the adductor aponeurosis between the torn ends of the ulnar collateral ligament. The ends of the ligament must be reduced and repaired under direct vision.

WRIST & FOREARM INJURIES

► Fractures

Fractures in the wrist and forearm usually result from falls on the outstretched hand. The distal radius is most commonly fractured. Many classification systems and eponyms have been used based on the extent and displacement of the fracture and involvement of the articular surface. The hyperextended wrist also exposes the scaphoid bone to

injury in a fall. Since the scaphoid is crucial to wrist motion, displacement of the fracture is poorly tolerated. In addition, the blood supply enters the distal part of the bone and makes ischemic necrosis of the proximal fragment a problem.

Diagnosis of distal radius fractures is not difficult, but scaphoid fractures can easily be missed. Special radiographic views of the wrist or CT or MRI scans may be needed in difficult cases. If the clinical picture is suspicious but the radiographs are inconclusive, the wrist should be immobilized. Repeat radiographs in 7-10 days may demonstrate the fracture. Untreated scaphoid fractures lead to debilitating arthritis and collapse of the wrist.

Distal radius fractures are treated by reduction and immobilization. As with other fractures, articular irregularities and unstable fractures need to be treated by open reduction and internal fixation. Use of bone grafting and external fixation devices to initially treat the fracture has been advocated. Scaphoid fractures require careful and prolonged immobilization. Displaced fractures or nonhealing fractures require operative treatment with screw compression, bone grafts, and/or scaphoid replacement.

► Dislocations & Sprains

Dislocations and ligamentous injuries of the wrist are the most difficult hand injuries to diagnose and treat. Wrist injuries often present as a painful wrist after minor trauma. Routine radiographs are often normal, and physical findings can be unimpressive. Still, these injuries can lead to chronic problems. Special stress radiographs, fluoroscopy, and physical maneuvers (scaphoid shift test) help delineate the injury.

The scaphoid lunate ligament is most often injured. Instability of the joint is best treated by repair or reconstruction of the ligament. Injury of the ligaments of the radio-carpal-radioulnar joint is likewise difficult to determine. Surgical treatment involves repair of the disrupted ligament.

NERVE DISORDERS

Nerve disorders of the hands are conveniently organized into compression neuropathies, injuries of peripheral nerves, and various problems located more proximal to the upper extremities (spinal cord or central nervous system). For nerve dysfunction due to strokes, cerebral palsy, and spinal cord injury, readers are referred to more specific textbooks on hand surgery.

► Compression Neuropathies

Compression of the nerves of the upper extremities due to an increase in surrounding tissue pressure occurs in specific locations and causes predictable signs and symptoms. Tissue edema from a variety of causes such as crushing injuries, vascular disorders, and prolonged repetitive hand motions can compress nerves traveling within tight compartments of the arm and produce nerve ischemia. Prolonged ischemia results in axonal destruction and sensory and motor dysfunction.

The median nerve can be compressed by local structures at the elbow (pronator syndrome), the anterior interosseous branch, and the wrist (carpal tunnel syndrome). Compression of the median nerve at the elbow causes forearm pain and sensory changes in the radial four fingers. The anterior interosseous branch of the median nerve is purely a motor nerve, and lesions produce only weakness of thumb and index finger flexion and no pain. Carpal tunnel syndrome presents with weakness in the hand, sensory abnormalities of the fingers sparing the small finger and ulnar aspect of the ring finger, and exacerbation of symptoms on forced flexion of the wrist (Phalen sign) or tapping the nerve at the wrist (Tinel sign). Shoulder, elbow, and forearm pain is also common. Atrophy of thenar muscles occurs in long-standing cases.

The ulnar nerve can be compressed at the elbow (cubital tunnel syndrome) or the wrist (Guyon canal). Sensory abnormalities in the small finger and weakness of intrinsic hand muscles occur with compression in either area. Segmental nerve conduction velocity tests help to localize the abnormality to one site or the other. Compression of the radial nerve occurs most frequently from fractures of the humerus. Compression of the nerve along the proximal radius (radial tunnel syndrome) causes diffuse pain around the elbow but occurs rarely.

Abnormal findings on nerve conduction studies and clinical manifestations of nerve compression are adequate for diagnosis. Electromyography (EMG) demonstrating denervation patterns in the corresponding muscles or slowing of nerve conduction velocities indicates injury to the nerve. Although helpful, these tests only complement the physical examination, since electrodiagnostic tests can occasionally be inaccurate.

Early or mild cases of compression are treated by controlling tissue swelling. Resting the extremity with splints

and using nonsteroidal anti-inflammatory medications as well as local injection of steroids often resolves the problem. If repetitive motions, such as typing, are thought to be the cause, changing the motion or hand position should help. If clinical manifestations are severe or if nonsurgical therapy fails, surgical decompression of the nerve is advocated.

Carpal tunnel syndrome is the most common type of compression neuropathy and one of the most common hand disorders. Surgical therapy of median nerve entrapment in the carpal tunnel or any of the compression neuropathies requires detailed knowledge of the anatomy. Division of the constricting structures results in partial or complete reversal of the symptoms. In the carpal tunnel, the median nerve is surrounded on three sides by carpal bones. Incision of the transverse carpal ligament, which forms the roof of the tunnel, decompresses the nerve. Occasionally, internal fibrosis of the nerve occurs and internal neurolysis with an operating microscope is required to allow the nerve to recover. Endoscopic release of the carpal tunnel through a smaller skin incision has been advocated.

► Nerve Injuries

Injury to individual peripheral nerves of the arm results in predictable and defined deficits. Proximal injuries involving the brachial plexus have more variable manifestations. Nerve conduction can be disrupted in the absence of structural changes due to compression, blunt injury, or ischemia (neuropraxia). More severe injury results in disruption of the axon with preservation of the epineurial covering of the nerve (axonotmesis). Both types of injury are followed by spontaneous recovery of function of good quality. Complete disruption of the nerve (neurotmesis), as with a laceration, requires surgical repair. Wallerian degeneration of the distal nerve occurs in both neurotmesis and axonotmesis, and recovery depends on the growth of the cut axon to the end organ. However, with neurotmesis, orientation of the proximal and distal axons is lost and recovery may be incomplete, especially in mixed motor and sensory nerves. Methods to differentiate sensory from motor fascicles have been used during repairs with some benefit.

A patient with loss of the radial nerve is unable to extend the fingers, wrist, and thumb. In addition, the patient will have sensory loss to the dorsum of the hand. Median nerve dysfunction causes problems with opposition of the thumb and grip of the fingers. Sensory loss is to the radial four digits and can significantly impair use of the hand. An ulnar neuropathy causes dysfunction of the intrinsic muscles of the hand, clawing of the ulnar two digits, and weakness in gripping smaller objects. Sensation is lost along the ulnar side of the hand.

Diagnosis of nerve injury is mainly by the physical examination. Understanding the functional anatomy of the peripheral nerves allows adequate evaluation of nerve loss.

Electrodiagnostic studies are used to distinguish between partial and complete lesions and to follow functional recovery.

Obvious and complete disruption of the nerve is treated best by early surgical exploration and repair. An incomplete lesion or questionable disruption of nerve integrity is best treated with close observation, splinting to prevent contractures, and surgical exploration if no recovery occurs. Segmental loss of nerves requires nerve grafts, usually taken from a minor sensory nerve, such as the sural nerve, to bridge the gap. Results of primary repair are better than the results of grafts, and repairs done soon after injury are better than delayed repairs. Recovery of protective sensation of the hand is crucial for good functional recovery.

Motor dysfunction due to nerve damage can be treated by arthrodesis (stabilization of flail joints) and tendon transfers. Tendon transfers should utilize a muscle unit that is unaffected by the nerve injury, have direction of force and excursion similar to those of the damaged muscle, and produce no further deficits due to loss of the donor muscle. For radial nerve palsy, the pronator teres to extensor carpi radialis transfer provides wrist extension, the flexor carpi radialis to extensor digitorum communis transfer gives finger extension, and the palmaris longus or flexor digitorum superficialis of the fourth finger transfer to the extensor pollicis longus extends the thumb. Restoration of thumb opposition is most important with median nerve palsies, and the use of several donor muscles to achieve this result has been described including the extensor indices proprius and flexor digitorum superficialis from the middle or ring fingers. Tendon transfers to control claw deformity and strengthen key pinch are used for ulnar nerve palsies.

▼ HAND INFECTIONS

Small breaks in the skin or nails of the hand can lead to widespread infection and abscess. The original injury often cannot be identified. Poor venous and lymphatic drainage

of the upper extremity, especially when held in a dependent position, aggravate the situation. Immunocompromised patients (diabetics, HIV-positive patients) are prone to develop extensive infections very quickly and should be treated more carefully.

The hallmark of infection (pain, swelling, and erythema) may be widespread in the hand and make localizing the infection difficult. Swelling of the dorsum of the hand is common even with palmar infections, and knowledge of the tissue planes of the hand is crucial to understanding how infections spread. Lymphatic streaks (lymphangitis) extending up the arm indicate rapid extension of the infection and must be treated urgently.

Oral antibiotics effective against staphylococcus and common anaerobic organisms (ie, first-generation cephalosporins and penicillin) are adequate to treat most infections. Infections from animal bites (*Pasteurella multocida*) and human bites (oral flora) also respond to penicillin. The intravenous route is reserved for severe infections or for those not responsive to oral antibiotics. Once the situation improves, oral antibiotics are given for 7-10 days. Equally as important, the infected hand needs to be immobilized and elevated. Pillows and trapezes help to elevate the arm, but elbow slings aggravate the dependent position of the arm and should not be used. The best results are obtained when the patient is convinced that elevation of the extremity is beneficial.

Once treatment of a hand infection has begun, improvement within 24 hours is expected. If prompt improvement does not occur, an occult abscess may be present. Obvious abscesses should be drained at the point of maximum tenderness or the point of maximum fluctuance, where the overlying tissues are thinnest. The drainage wound should run parallel to and not across the paths of nerves, arteries, and veins. Wounds should be made long enough and should be zigzagged, when necessary, to avoid secondary contractures. Ultrasonography may be useful when a definite abscess cannot be located.

► Pyogenic Granuloma

Pyogenic granuloma is a mound of granulation-like tissue 3-20 mm (or more) in diameter. It usually develops under a chronically moist dressing and may form around a suture. A small granuloma (6-7 mm in diameter) exposed to the air will soon dry up and epithelialize, whereas larger ones should be scraped flush with the skin under local anesthesia and covered with a thin split-thickness skin graft. If the granuloma is adjacent to the nail and the nail is acting as a foreign body aggravating the reaction, the nail must be removed.

► Nail Infections

The nail fold is often traumatized and becomes secondarily inflamed, leading to a **paronychia** on the radial or ulnar side. The lesion is termed an **eponychia** if it involves the base

▲ **Figure 42-16.** Incision and drainage of paronychia.

of the nail, although the entire fold can be involved; and it is called a **subungual abscess** if pus develops and extends under the nail plate. Because of the early and unrelenting tissue tension that develops, these entities are quite painful. Early treatment before abscess formation consists of soaking, elevation, immobilization, and antibiotics. Most abscesses can be drained painlessly with a scalpel; the insensate necrotic skin cap should be cut through where it points (Figure 42-16). Sagittal incisions, which form a “trapdoor” of the eponychium, should be reserved for the long-standing case in which a dense fibrous callus of the nail fold must be excised. Occasionally, the nail must be basally excised or totally avulsed, after which the eponychial fold should be separated from the nail matrix by a thin, loose pack. Chronically wet nails of dishwashers may develop tissue changes and nail deformities, which are best treated by removing the nail plate. Fungal infections should be diagnosed and treated, and the fingers should be protected from water or excessive sweating.

► Deep Space Abscess

A **felon** is an abscess in the pulp of the fingertip and is often deep and very painful. Untreated or inadequately drained abscesses may lead to osteomyelitis of the distal phalanx. Incision and drainage with disruption of the many vertical fibrous septa of the pulp space are required to adequately drain the abscess (Figure 42-17). The traditional fishmouth incision is no longer recommended for drainage since it may expose the underlying bone and because it often heals in a tender scar. Instead, lateral through-and-through incisions

▲ **Figure 42-17.** Cross section of distal phalanx.

▲ **Figure 42-18.** Incision of felon (distal fat pad infection).

or direct incisions on the pulp, where the abscess points, have better results (Figure 42-18).

The **web spaces** are the path of least resistance for pus from infected distal palm calluses, puncture wounds, and infections of the lumbrical canals. Infection and abscess formation in the dorsum of the thumb web may be the result of extension from the volar thenar space (collar button). A dorsal incision is usually made between the fingers to drain both spaces. A dorsal incision in the web of the thumb may be zigzagged to prevent contracture (Figure 42-10).

The **midpalmar space** becomes infected by direct puncture or by extension of infections from the flexor sheaths of the index, middle, or ring fingers (Figure 42-6). Only the skin should be incised over the point of fluctuance. The rest of the dissection should be carried out by gentle spreading with a blunt clamp to avoid injury to arteries, nerves, and tendons. Infection spreads easily from this space along the lumbrical canals and to the thenar space.

A hypothenar space abscess is usually a product of a penetrating wound and should be drained at the point of greatest fluctuance. The same is true for a thenar space abscess, which may point in the palm rather than the thumb web.

Infection within the synovium of the flexor tendon is difficult to diagnose. **Pyogenic tenosynovitis** spreads easily down the tendon sheath to affect the other fingers. Untreated, the infection causes adhesions of the tendon to the surrounding soft tissues and permanently limits movement of the fingers.

The signs of flexor tendon infection described by Kanavel include fusiform swelling of the digit, severe pain on passive finger extension, a fixed flexed position of the finger, and most importantly, tenderness over the extent of the tendon sheath into the palm. Ultrasonography of the distal palm can also be helpful when the diagnosis is unclear. The probe is held across the palm and reveals swelling of the involved tendon and fluid around the tendon at the proximal flexor sheath.

Only unresponsive, tensely swollen, and toxic cases need immediate incision and drainage. With rest, elevation, and antibiotics, it is safe to observe most cases for several

▲ **Figure 42-19.** Drainage and irrigation for septic tenosynovitis. The antibiotic solution drips in through the distal catheter and drains out through the proximal one.

hours. The most common method of incision and drainage (Figure 42-19) is to make a short sagittal midline distal wound immediately over the tendon and introduce a small plastic catheter into the synovial bursa for irrigating with an antibiotic solution. The catheter should pass through the sheath and exit by a counterincision in the palm to allow for drainage of the fluid. Not all surgeons advocate placement of an irrigation catheter, however. When a catheter is placed, it should remain for only 24-48 hours. These incisions do not cross flexion creases. The hand should then be elevated and immobilized in the position of function and covered by a dressing. Phlegmonous tenosynovitis usually requires opening of the entire synovial sheath (often through a lateral midaxial digital incision or longitudinally across the wrist for extensor sheath infections) and, frequently, excision of necrotic tendon and sometimes amputation of a digit.

► Other Infections

Necrotizing soft tissue infections of the upper extremity are rare but devastating when they occur. The condition has been called many different names such as necrotizing fasciitis, Meleney ulcer, and streptococcal gangrene. The organisms responsible include clostridium species, *Streptococcus pyogenes*, and mixed infections. The hallmarks are the rapid spread of infection and the extensive necrosis of soft tissue. Treatment includes wide debridement of the necrotic tissue and intravenous antibiotics.

Human bite wounds of the hand occur most often during altercations when the fist strikes an opponent's tooth. The MCP joint can be entered. The injury is often ignored by the patient until infection of the joint has begun. The joint must be explored and cleaned and the patient treated with antibiotics to cover oral flora (penicillin). Once the infection

reaches the joint, destruction of the cartilage often occurs despite all therapy.

An inordinate amount of pain, with little or no swelling or induration, predating and accompanying the appearance of multiple tiny vesicles, suggests **herpes simplex (herpetic whitlow)**. The vesicles may appear cyclically. They contain clear fluid and not pus and should be distinguished from paronychia. Antibiotics are not indicated in this self-limited viral infection. Acyclovir 5% ointment applied topically for 7 days decreases the severity and duration of symptoms but is of no value in prophylaxis.

Tuberculous infection of the hand is usually chronic and may be relatively painless. Some cultures take months to become positive. Tuberculosis commonly involves only one hand, which may be the only focus of infection in the body. Bones and joints may be infected, but the process more commonly involves the tendon synovium, which becomes matted to the tendons. Treatment is by synovectomy and antituberculous drug therapy for 6-12 months.

Leprosy causes neuritis of the median and ulnar nerves, resulting in sensory and motor loss to the hand. Crippling claw deformities develop as a result of intrinsic muscle palsy. Open sores appear on the hands as a result of trauma to anesthetic digits. Reconstructive surgery and occupational training are required.

Fungal infections involve primarily the nails. Tinea unguium (onychomycosis) may be caused by many organisms, including *Epidermophyton floccosum*, *Trichophyton*, and *Candida albicans*. Prolonged treatment with antifungal drugs—griseofulvin systemically or nystatin topically—may be necessary, along with daily applications of fungicidal agents such as tolnaftate. Removal of the nail is advocated for chronic intractable cases.

INFLAMMATORY DISORDERS OF THE HAND

DUPUYTREN CONTRACTURE

► Palmar Fasciitis

The cause of Dupuytren contracture, which is common particularly among white populations of Celtic origin, is not known. It occurs in one of three types (acute, subacute, and chronic), predominately in men over 50 who have been

in sedentary occupations, and is bilateral in about half of cases. There is a hereditary influence, and the incidence is higher among idiopathic epileptics, diabetics, alcoholics, and patients with chronic illnesses. The contracture may develop in people who do not work and (in laborers) in the hand that does the least work, so that it is not considered work related. It is frequently found in the plantar fascia of the instep and occasionally in the penis (Peyronie disease).

Dupuytren contracture manifests itself most commonly in the palm by thickening, which may be nodular, and therefore mistaken for a callosity, or may be cord-like, and therefore mistaken for a tendon abnormality because it passes into the digits and restricts their extension. This process typically involves the longitudinal and vertical components of the fascia but at times seems to exist apart from anatomically distinct fascia. The skin may fuse with the underlying fascia and become raised and hard, or it may be greatly shrunken and sometimes drawn into a deeply puckered crevasse. The disorder invades the palm at the expense of fat but is never adherent to vessels, nerves, or musculotendinous structures (though it may be adherent to flexor tendon sheaths). It has an unpredictable rate of progression, but the earlier it starts in life, the more destructive and recurrent it is apt to be.

Dupuytren fasciitis may involve any digit or web space, but it affects predominantly the ring and small fingers. In long-standing cases, the fingers may be drawn tightly into the palm, resulting in secondary contracture of joint capsule and ligaments, flexor sheaths, and atrophic muscles.

The most recent addition for the treatment of Dupuytren contracture is enzyme (collagenase) injection. Based on early studies, it appears that this treatment works best on MCP contractures rather than PIP contractures in patients with a well-defined cord. This treatment does require two office visits, one for the injection and a follow-up visit to manipulate and rupture the cord.

Surgery is indicated when the disorder has progressed sufficiently, especially when it causes more than 30 degrees of flexion at the MCP joint or any flexion contracture of the PIP joint. The patient must be warned about the increasing technical difficulty with progressive flexion and adduction contractures and the potential for recurrence after surgery. Fasciectomy is the surgical procedure that gives the best long-term results. In selected cases where only the longitudinal pretendinous fascial band is involved and the skin moves freely over it, subcutaneous fasciotomy done through a small longitudinal incision may release a contracture quite well with only a few days of postoperative disability. In the occasional case with acute and rapid onset of a tender nodule, local triamcinolone may be used for subjective and even objective relief.

Depending on the amount of cutaneous shrinkage, skin grafts may be required for wound closure after fasciectomy. The overlying dermis has been implicated as an inductive mechanism in this process. Thus, skin grafting may diminish

the recurrence rate in severe cases. The hopelessly contracted little finger must sometimes be amputated.

Motion should be started within 3-5 days after surgery. Dynamic splints and postoperative injection of corticosteroids into joints and the zone of surgery may help the well-motivated patient.

The potential complications of surgery are wound breakdown (loss of skin flaps), hematoma, fibrosis and stiffness, digital nerve injury, recurrence of contractures and digital ischemia secondary to digital artery injury. Reflex sympathetic dystrophy, a painful, debilitating neurologic disorder of the hand, can occur after surgery and must be treated aggressively. In general, the functional reward for the patient is great at any age.

DEGENERATIVE & RHEUMATOID ARTHRITIS

Arthritis of the hand is divided into two categories. **Degenerative changes** are usually due to some trauma resulting in damage to the bone or cartilage or to the supporting ligamentous structures. The increased wear to the joint results in inflammation and damage to the cartilage or underlying bone followed by reactive new bone formation (spurs). The wrists, hips, and knees are most commonly affected. **Rheumatoid arthritis** is a systemic disease characterized by synovial inflammation. The diseased synovium destroys adjacent tendons and joints in a specific way, leading to characteristic deformities in the hand.

Patients with degenerative arthritis complain of pain, aching, and stiffness in the area of the affected joint. Progression of the problem leads to immobility of the joint that affects the entire hand. Radiographic studies demonstrate joint narrowing and periosteal thickening early in the problem, progressing to bone spurs, loss of the articular surface, and bone destruction later. Patients with rheumatoid arthritis often present with very severe deformities without pain. Nodules around the olecranon and dorsum of the hand are often found. Both flexor and extensor tendons at the wrist can be inflamed, limiting tendon movement and resulting in rupture of the tendon. Involvement of the tendons and ligaments at the digits and MCP joints results in ulnar deviation of the digits, MCP joint destruction and dislocation, and swan-neck and boutonnière deformities. Destruction of the wrist joint is also common.

Arthritis is common among older patients and usually treated by primary care physicians and rheumatologists with anti-inflammatory medications and modification of the

patient's activities. In most cases, it is only when symptoms greatly hinder the patient's lifestyle that they are referred to a hand surgeon. Physical therapy, splints, and medications are often no longer effective for these patients.

Surgical treatment of painful joints includes replacement with a prosthetic joint and partial or full fusion. Prosthetic joints of metal or Silastic permit near-normal movement but can become unstable and dislocate or degenerate over time. For a durable solution to the problem, fusion of the joint is recommended. Motion is severely limited, but pain relief is complete. There are more therapeutic options for the wrist, such as replacement, local fusion of only the affected carpal bone, or complete excision of the proximal row of carpal bones, leaving motion and stability to the distal carpal bones and ligaments.

Therapy for synovial inflammation in rheumatoid disease includes excision of the synovium to increase tendon excursion and prevent rupture, repair of ruptured tendons, and excision of painful nodules. Tendon-balancing procedures can help ulnar deviation of the MCP joints and improve joint movement. The most important concept of treating patients with rheumatoid hand disease is that often the patients have adapted well to their functional deficits. Correcting a physical deformity in a well-compensated patient may actually result in more problems for that patient.

SCLERODERMA & LUPUS ERYTHEMATOSUS

These systemic diseases of unknown cause have distinctive—though not necessarily pathognomonic—manifestations in the hands.

Scleroderma initially produces joint stiffness, hyperhidrosis, and Raynaud phenomenon. Unchecked, it leads to marked tautness of skin and rigidity of joints with associated osteoporosis (even atrophy and ultimate resorption of the distal phalanges) and soft tissue calcifications.

Lupus erythematosus, which may be initiated or aggravated by certain drugs, foreign proteins, or psychic states, often causes polyarthritis indistinguishable from that of rheumatoid arthritis. It does not usually lead to similar joint destruction. Vasospasm in both lupus and scleroderma can

cause severe ischemia of the hand and digits and may require therapy to prevent gangrene.

GOUT

Gout is a metabolic disorder of uric acid metabolism that affects about 1% of the population; approximately 50% of patients with gout have **cheiragra** (gouty hands).

The diagnosis is suggested by a rapid onset of severe pain and inflammatory signs about the joints and musculotendinous structure, simulating a phlegmonous infectious cellulitis with marked induration (most dramatically seen about the elbow). The usual duration of an attack is 5-10 days. The serum uric acid is elevated in 75% of cases. Gout may coexist with rheumatoid disease. The diagnosis is confirmed by identification of uric acid crystals in joint fluid or tissue biopsy.

In time, typical tophi form, consisting of toothpaste-like infiltrates of urate crystals, arising in multilobulated form about soft tissue structures that have been invaded. X-rays show characteristic punched-out lesions at the margins of articular cartilage.

Prophylactic treatment of gouty arthritis consists of diet, colchicine, allopurinol (a urate-blocking agent) or probenecid (a uricosuric agent), and avoidance of stress. Colchicine, 0.6 mg/h with a glass of water for six to eight doses or to the point of gastrointestinal distress, is the time-honored means of interrupting an attack, but phenylbutazone, topical corticosteroid gel, and systemic corticosteroids are also of value.

Surgical measures consist of drainage of abscessed tophi (seldom needed) and tophectomy. The latter procedure is more often of cosmetic rather than functional value. Tophectomy consists of removal of as much tophaceous material as can be fairly easily recovered. The surgeon should be careful not to destroy ligaments, tenoretinacular structures, nerves, and vessels in the process.

BURNS & FROSTBITE OF THE HAND

► Thermal Burns

The hands are a common site of thermal (including frictional), electrical, chemical, and radiation burns. Function is imperiled in all instances by swelling and scar formation. Prompt measures to preserve existing function are often urgently required. Burns over other areas of the body may be more life threatening and require more urgent attention,

but burns of the hand should never be neglected. Delay in therapy leads to irreversible impairment and deformity that are impossible to correct later.

As in other areas of the body, thermal burns are grouped into three degrees. Superficial (first-degree) burns are red and painful; partial-thickness (second-degree) burns develop blisters; and full-thickness (third-degree) burns are insensate and appear like leather or charred tissue. The prognosis and therapy depend on the location, depth, and extent of the burn.

All burns to the hand cause swelling of the tissues, and the need for elevation of the arm to relieve pain and prevent stiffness cannot be overemphasized. Tetanus immunization should be given. Cold compresses may help alleviate the pain in first-degree burns. Second-degree burns must be watched more carefully. Large blisters restricting motion are broken. Otherwise, since they are sterile, they should be left intact. Treatment with thrice-daily washing and silver sulfadiazine is usually adequate. Patients with third-degree burns or superficial burns that fail to heal and patients unable to care for their burns at home should be admitted to the hospital.

Deeper burns require close observation and more extensive treatment. In the first few hours after injury, circumferential or near-circumferential burns may cause ischemia in the extremity. Because evaluation of sensory function and capillary refill is nearly impossible in these limbs, escharotomies should be performed if compartment syndrome is suspected. If done correctly, escharotomies have few complications, since these burns usually require surgical debridement anyway. Incisions are placed to avoid exposure of neurovascular structures.

Partial-thickness burns heal spontaneously. Deeper burns on the dorsum of the hand are best treated with early excision of the eschar and placement of skin grafts to prevent contractures. Palmar burns are best left to heal spontaneously because skin grafts function very poorly in this area. Some hand surgeons believe that excision and grafting of superficial burns should be performed to prevent contractures. This is true if adequate therapy has not been available. In burn units with good rehabilitation services, surgeons are treating superficial second-degree burns without surgery and obtaining results as good as with skin grafting. Pigskin, cadaver homografts, or a number of commercially available biologic dressings can be used to cover the wounds temporarily, decreasing pain and keeping the wound moist until autologous skin grafts are placed.

Neglected burns of the hands result in contracture deformities that often require extensive surgery to restore function. Delayed healing and wound contractures often result in a claw hand with MCP hyperextension and fusion of the digits with loss of the web space (syndactyly). Burns on the volar surface leave flexion contractures. Some contractures can be treated with release and skin grafting of the tissue gap. Web space contractures and released contractures with

exposed tendons or nerves must be covered with skin or muscle flaps. Web space release is done with skin flaps from the dorsum folded down to create the space. Large flaps can be obtained by attaching the hand to the groin, allowing the tissue to adhere and vascularize before cutting the flap away from the groin. Recently, free tissue transfer from other parts of the body using microsurgical techniques has allowed more extensive reconstruction of severely burned hands.

► Electrical Burns

Electrical burns of the upper extremity may not appear extensive on initial inspection. The skin may be burned only in a very small area of the entry point of the current or by ignited clothing. The current tends to spare the skin but damage underlying muscles, vessels, and nerves. Often, the extent of dead tissue is not evident for several days.

Initial treatment is the same as for thermal burns. Since muscle damage may be extensive, it is important to prevent renal failure from myoglobinuria by maintaining a high output of alkaline urine. Arteriography, fluorescein injections, and radionuclide studies may help delineate the extent of necrosis. Examination of the patient in the operating room is still the most accurate method of assessing the extent of tissue damage. All obviously dead tissue should be removed during the initial evaluation. Two or three days later, the patient is reexamined in the operating room and any additional debris is removed. The wounds are closed when only clearly viable tissue remains.

► Frostbite

Frostbite occurs most often in people under the influence of alcohol or with psychiatric illness. The lower extremity is affected more often than the upper. Freezing tissue causes cellular death and vascular thrombosis. Hypothermia of the entire body must first be treated. The frozen part should be quickly rewarmed by immersion in warm water (40°C). Elevation of the extremity minimizes edema. Skin wounds are treated like burns with silver sulfadiazine cream. The extent of necrosis may not be obvious for several weeks, and debridement or amputation should be delayed until demarcation of the injury occurs. Sympathectomy may help ameliorate the sequelae of frostbite, such as cold sensitivity and pain. Children with frostbite may develop premature closure of phalangeal epiphyses, which creates growth disturbances of the bone.

MASSES OF THE HAND

Only 2% of all masses in the hand are malignant lesions; the majority are benign neoplasms, cysts, or a myriad of other masses. Though the clinician must be ever vigilant to identify malignancy, a mass of the hand is highly likely to be benign—excisional biopsies are thus reserved for subcutaneous lesions that are rapidly growing or for skin lesions that may be carcinomas. Otherwise, masses can be observed over a period of time to determine that they are not growing. They may be removed for functional or cosmetic reasons.

Ganglions are formed by herniation of the synovial lining of joints or tendons into the surrounding soft tissue. These cysts are filled with a viscous fluid thought to be modified joint fluid. Trauma to the wrist or hand may cause extrusion of the synovium, but it is more likely that the ganglion was already present and that trauma to that area merely brought the lesion to the surgeon's attention.

Ganglions can arise from any joint of the hand but most commonly appear on the dorsal wrist over the scapholunate ligament and the volar wrist near the radial artery. Tendon ganglions are most common on the flexor sheath at the metacarpal head (A1 pulley). Pain and tenderness are due to compression of adjacent nerves by the mass.

Ganglions have a typical appearance, and diagnosis is simple. If any doubt exists, aspiration with a large-bore needle of the viscous fluid confirms the diagnosis and occasionally cures the lesions. Injection of the empty sac with steroids and lidocaine may help to keep the mass from reappearing, but the majority recurs. Ganglions need not be treated unless they cause pain or interfere with hand function. Often, it is enough just to reassure the patient that the mass is benign.

Operative removal of ganglions should be done using loupe magnification and a tourniquet. The entire ganglion should be removed, including all attachments to the joint capsule and the underlying ligament, without injuring the surrounding structures. Prolonged splinting after removal of ganglions does not decrease recurrence rates but does cause hand stiffness. Unfortunately, despite careful surgical removal of the lesion, recurrence of ganglions is relatively common.

Epidermal cysts are rests of epidermis located in the subcutaneous tissue. Many are thought to be due to traumatic disruption of epidermal cells into the soft tissue (inclusion cyst). The cells proliferate just as skin does and form a cyst filled with creamy keratin, the remains of dead epidermal cells that usually desquamate from the skin. Infected cysts become inflamed and form abscesses. Removal of the entire cyst wall is required to prevent abscess formation.

Pyogenic granuloma may form in any chronic wound. Histologically, it consists of vascular tissue identical to granulation tissue. Just as for hypertrophic granulation

tissue elsewhere on the body, excision or cauterization of the material flush to skin level allows epidermis to migrate over the wound.

Giant cell tumors are benign, multilobulated, solid masses found on the lateral aspects of the finger. They are often attached to the tendon sheath. The mass may be quite complex and extend throughout the adjacent nerves, vessels, tendons, and ligaments. The entire lesion should be removed, but recurrence is relatively common.

The most common bone tumors are **enchondromas**. Multiple enchondromas (Ollier disease) are associated with other skeletal deformities. The lesion appears on x-ray as thinned cortical bone with speckled calcifications. Fractures through the tumors usually do not heal spontaneously. The tumor should be removed with a curette. Bone graft taken from the distal radius is used to fill the gap if needed.

A **carpal boss** is due to abnormal bone formation at the base of the second or third metacarpal bones and presents as a hard mass on the dorsum of the hand. The excess growth of bone can be removed if symptomatic.

Glomus tumors are composed of blood vessels and unmyelinated nerves of a heat-regulating arteriovenous malformation. They are usually found in the fingertip or under the fingernail and can be extremely painful. Local excision of the tumor is curative. Occasionally, when the tumor is large and disrupts the nail matrix, a split-thickness nail graft from another digit is needed to reconstruct the defect.

The most common malignant tumor of the hand is **squamous cell carcinoma**, though **basal cell carcinomas** and **melanomas** also occur. Subungual melanomas are often difficult to diagnose because they are difficult to examine. These tumors should be treated just the same as elsewhere on the body. Particular care should be taken to examine for spread of tumor in the lymphatic drainage at the supratrochlear and axillary nodes.

Other tumors include lipomas, fibromas, hemangiomas, arteriovenous malformations, neurofibromas, sarcomas, and various skin lesions. These tumors act no differently in the hand than elsewhere in the body. However, because of the close proximity of the nervous and vascular structures within the small spaces of the hand, these tumors cause compressive signs and symptoms sooner. CT scans or MRI help delineate the extent of soft tissue tumors and may help in preoperative planning.

COMPLEX HAND INJURIES

► Crush Injuries & Amputations

Advances in microvascular surgery have greatly increased our ability to treat complex hand injuries. Mangled and amputated digits, hands, as well as entire upper extremities have been replanted or repaired. Complex nerve repairs, microvascular free tissue transfers of muscle flaps, and toe-to-hand reconstructions have made it possible to restore more function to severely injured hands. The end result must be a sensate, painless, and useful extremity. Patients who undergo multiple surgical procedures and prolonged rehabilitation with only marginal results would have benefited from early amputation. A surgeon with extensive experience can best assess the patient's injuries, occupational requirements, and psychosocial needs to determine if salvage is worthwhile.

Complex hand injuries often result from improper use or malfunction of machinery. Heavy machinery in the workplace or motorized cutting tools at home, such as rotary saws, are often cited as the mechanism of injury. Sharply amputated or partially devascularized parts are most likely to be saved. Severe crushing or avulsion of the part produces wider nerve and vessel injury. The extent of this type of damage is difficult to determine and often impossible to repair.

The decision to try to salvage a damaged part must be individualized to each situation, but some general principles apply. The thumb is crucial to hand function, and all efforts are made to save the entire digit or as much length as possible. When multiple digits or half of the hand is damaged or amputated, a greater effort is made to repair the part. Children can recover function in badly damaged extremities far better than adults can, and any amputated parts in children should be replanted. Replantation of the entire arm at the elbow and above is controversial. The usefulness of these replanted limbs is limited by the slow nerve regeneration, and some hand surgeons believe that amputations in these cases result in better function.

Patients with complex hand injuries should be immediately referred to a regional center with the staff and facilities to manage the problems. Occasionally, in the rush to transfer patients with these very obvious injuries, intra-abdominal, neurologic, and other less obvious injuries have been overlooked. The entire patient must be evaluated and stabilized prior to transfer. A clean, moist dressing should be placed on the wound and the extremity elevated. The amputated part is wrapped in a plastic bag and placed in ice water. The amputated part should never be frozen.

The accepting hand surgeon evaluates the patient's overall condition, potential for rehabilitation, and personal wishes before coming to a decision. To revascularize or replant a part, the patient must be taken urgently to the operating room. Ischemia over 6 hours is often associated

with failure of revascularization, but—depending on the metabolic needs of the constituent tissues—extremities that have undergone periods of ischemia longer than this can be successfully replanted.

Bone must first be stabilized with Kirschner wires or metal plates before vascular repairs are performed. Arterial and venous repairs are done with microscopic magnification, and the ischemic tissue is reperfused. Failure of a replanted part is more often due to venous outflow problems than arterial inflow. Systemic and local anticoagulants help to maintain perfusion but are not always needed. Leeches placed on the part release a potent local anticoagulant and can decrease venous congestion. Nerve and tendon repairs must also be performed. When there is inadequate local soft tissue to cover the repaired structures, muscle or skin flaps from a distant site must be transferred using microsurgical methods to the area. Although these operations are not life threatening, blood loss can be extensive and transfusions are sometimes required.

Secondary procedures to free tendon adhesions, reduce bulky flaps, and transfer tendons in motor nerve injuries may need to be done. Reconstruction of unsuccessful replantations is being done more often. The original method using toes to reconstruct thumbs has also been used to make fingers. These reconstructions give patients the ability to grasp objects. Because these digits are sensate, they can even perform fine movement tasks not possible with prosthetic devices. Patients with loss only of the thumb are better treated with transfer of the index finger to the thumb position (pollicization).

Partial or total loss of a single digit is less critical. Hand function is better without a stiff or painful digit. When a decision is made to amputate a digit, care must be taken to leave a painless stump with good sensate soft tissue coverage. The flexor tendon must not be sutured to the extensor tendon for soft tissue coverage, since this will cause the tendons to pull each other rather than move the joint. Local flaps to cover the stump are preferred to skin grafts or cross-finger flaps, since they usually provide better sensation. A short amputation stump on the long or ring finger is often bothersome because small objects such as coins tend to fall out of the palm, and a ray amputation eliminates the problem. For cosmetic purposes, ray amputations are far less noticeable than partial amputations. The loss of hand breadth with a ray amputation can decrease grip strength, however.

The loss of part of all of the hand can be compensated both functionally and cosmetically by a variety of prostheses. Their use involves careful adaptation to the requirements of the patient, who must receive appropriate training to ensure success.

INJECTION INJURIES OF THE HAND

High-pressure devices used in industry to apply material such as air, grease, paint, and oil cause a unique hand injury.

The typical case is injection of the material into the index finger of the nondominant hand of a factory worker. A pinpoint injection site may be the only external evidence of injury, and the hand appears discolored or pale, or swollen due to the injected material.

The examination should include a careful hand evaluation and an x-ray to demonstrate the distribution of material or gas in the hand. All such cases require continued, unremitting scrutiny, even if the part seems completely normal. If there is any evidence of retained foreign material, swelling, or ischemia, early surgical exploration is advocated to release the tourniquet effect of the skin and fascia and to remove as much of the material as possible without injuring healthy tissue. Prophylactic antisludging agents (dextran 40), corticosteroids, and antibiotics may help.

Often, the pressure forces the material to spread along the tendon sheaths throughout the hand and even into the forearm. Expansion of the foreign material in a closed space and the chemical irritation cause congestion, inflammation, vascular thrombosis, and gangrene. The injected material is difficult to remove completely, and a foreign-body response leads to fibrosis so extensive that it often destroys the function of the hand.

MINIMALLY INVASIVE HAND SURGERY

The goal of reconstructive hand surgery is return of normal function, including pain-free movement, normal active and passive range of motion, premonitory strength, and intact sensation. Yet the process of incising, dissecting, and sewing is associated with significant scarring and pain. Scarring is especially troublesome in the hand, since it leads to stiffness, ligamentous tightening, and arthritis. As a result, any procedure in the hand that minimizes postoperative scarring or pain will contribute to an improved result.

Surgical care in the past decade has been revolutionized by the introduction and incorporation of minimally invasive surgical techniques. Laparoscopies and thorascopies have permitted the resection of hollow and solid organs through

1 cm incisions, reducing the need for laparotomies and thoracotomies. Likewise, urologists have employed cystoscopy for evaluation and treatment of bladder and kidney disorders, while orthopedic surgeons have used arthroscopy to similar effective ends in the knee, ankle, elbow, and shoulder.

Two areas of hand surgery incorporate minimally invasive techniques: Wrist arthroscopy has expanded the options for evaluating the chronically painful wrist, and endoscopic carpal tunnel release (ECTR) provides a less invasive method than open release for decompressing the median nerve. While ECTR theoretically allows for a faster recovery, it may in fact offer only limited advantages.

WRIST ARTHROSCOPY

Diagnostic wrist arthroscopy was first successfully used in 1970. Over the past three decades, it has taken its place among traditional imaging techniques as a low-morbidity method for evaluating chronic wrist pain. As the hardware for examining the wrist has become more sophisticated and as hand surgeons have become more familiar with the arthroscopic view of the wrist, increasingly aggressive attempts have been made to use the arthroscope to treat as well as to diagnose wrist problems.

► Indications & Contraindications

Diagnostic wrist arthroscopy is a useful technique to evaluate patients with wrist pain, whether chronic or acute. In patients with chronic pain, this technique can be used to augment information offered by plain radiographs, CT, MRI, or wrist arthrography. It can confirm an uncertain diagnosis or be used to reevaluate a patient who has failed other treatments. In contrast, patients with acute symptoms—such as those suffering from mechanical wrist pain—may complain of pain localized over the joint, catching and popping sensations, and relief with rest. Here, the wrist can be manipulated during arthroscopy to localize the source of the symptoms. In general, the technique is useful for evaluating articular cartilage, ligaments, the triangular fibrocartilage complex (TFCC), and the synovium. Interestingly, diagnostic wrist arthroscopy may provide too comprehensive an examination. Only some of the lesions that are visualized during an examination may be responsible for a patient's symptoms. The hand surgeon must critically correlate arthroscopic findings with the patient's examination to arrive at the appropriate diagnosis.

Therapeutic wrist arthroscopy is useful for the treatment of ligament tears, TFCC lesions, articular cartilage lesions, subtle distal radius and carpus fractures, dorsal wrist ganglions, removal of isolated carpal bones up to and including the proximal carpal row, and disorders of the distal radioulnar joint. It is useful also in the management of lesions arising from rheumatoid arthritis. It has been successfully used in completing synovectomies, proximal row carpectomies in

the case of scaphoid nonunion or scapholunate collapse, radial styloidectomy, and isolated symptomatic chondral defects.

► Procedure

Equipment for diagnostic wrist arthroscopy includes an apparatus for elevating and distracting the wrist, an arthroscopic telescope, a video camera, a fluid infusion system, and both manual and powered instruments.

Either general or regional anesthesia may be used. A tourniquet is placed at the mid-arm to provide a blood-free field during the operation. The distal forearm, wrist, and hand are prepared into the operative field. Traction is applied to the hand, usually via sterile finger traps, and a distraction force is applied across the wrist.

Individual skin incisions are then made at standard portal sites determined by the goal of the operation. Portal sites are described according to their relationship with the radius and ulna, the carpal bones, and the extensor tendons. The relationship to the extensor tendons is indicated by listing the extensor compartments on either side of the incision. Typical portals include the 3-4 radiocarpal, through which the scaphoid and lunate facets can be visualized; the 4-5 radiocarpal, through which the TFCC and the ulnocarpal ligaments can be seen; and the 6R radiocarpal, through which the extensor carpi ulnaris tendon and ulnar wrist are approached. The midcarpal joint is approached through any of three portals, including the midcarpal ulnar, the midcarpal radial, and the scaphotrapezium-trapezoid.

Once abnormalities are identified, therapeutic wrist arthroscopy can be used to effect repairs. Partial ligament tears and tears of the TFCC can be debrided arthroscopically using knife blades and motorized shavers. Carpal bone resections can be completed with miniature osteotomes and powered saw blades.

► Outcomes

Operations employing diagnostic and therapeutic wrist arthroscopy typically result in less swelling, less postoperative pain, and less stiffness than comparable open wrist procedures. There is a concomitant earlier return to function and work. Therapeutic wrist arthroscopy even of dorsal wrist ganglia, the most superficial of wrist abnormalities, is followed by fewer—or no more—recurrences than the open technique.

► Complications

The rate of complications associated with diagnostic and therapeutic wrist arthroscopy is estimated to be 2% and is due to a variety of causes. The continuous traction necessary to properly distract the wrist can cause problems, including ligament strain at the MCP joints with concomitant joint edema and stiffness and stretching of peripheral nerves.

Establishment of the operative portals can damage articular cartilage, ligaments, tendons, cutaneous nerves, the radial artery, and cutaneous and deep veins. Such injuries include abrasions, contusions, lacerations, and transections. A high proportion of complications of therapeutic wrist arthroscopy are associated with inadequate relief of symptoms or a diminished return of function. A now less common complication of therapeutic wrist arthroscopy results from the fluid infusion. Forearm compartment syndromes have resulted from extravasation of infusion fluid during endoscopic repair of distal radius fractures; this problem is now avoided by circumferential compression of the forearm during the procedure.

ENDOSCOPIC CARPAL TUNNEL RELEASE

Endoscopic release of the transverse carpal ligament is an increasingly popular method of treating carpal tunnel syndrome. Advocates of the procedure claim that it is associated with decreased postoperative morbidity and earlier return to work. Others caution that there is little if any short-term difference between endoscopic and open carpal tunnel release, no long-term difference, and that endoscopic carpal tunnel release is associated with an increased likelihood of significant nerve injury.

► Indications & Contraindications

Endoscopic carpal tunnel release is easier to perform in patients with larger wrists. Ease of access to the carpal tunnel correlates with the wrist circumference and the height and age of patients. Surgeons should be aware that the procedure is likely to be more difficult in small patients with small wrists and are advised to maintain a lower threshold for conversion to the open technique to avoid neurologic complications.

Absolute contraindications to endoscopic carpal tunnel release include masses in the carpal canal and other space-occupying lesions, abnormalities in canal anatomy, and wrist stiffness that precludes proper positioning.

► Procedure

In the United States, most surgeons use one of two techniques—either Chow or Agee. The two differ primarily in the number of incisions, or portals, needed to gain access. The Chow technique, first described in 1989, employs two portals, while the Agee technique requires only one.

Either operation can be performed under local anesthesia with a brachial tourniquet. An initial transverse incision is made proximal to the wrist flexion crease between the palmaris longus and flexor carpi ulnaris tendons. The space between the transverse carpal ligament and the flexor tendons is defined with a dissector. In the Agee procedure, the endoscope is advanced under the transverse carpal liga-

ment, radial to the hook of the hamate along the axis of the ring finger. The ligament is incised along its entire length, with care taken to avoid the Guyon canal and the superficial palmar arch. In the Chow operation, a second transverse incision is made just distal to the transverse carpal ligament along the axis of the ring finger. The wrist is dorsiflexed, and a slotted cannula is advanced into the proximal incision, deep to the transverse carpal ligament, and out the distal incision. The endoscope is then used to visualize the ligament while the knife divides it. The wounds are closed, and the patient's wrist placed in dorsiflexion.

► Outcomes

Several studies have compared open versus endoscopic carpal tunnel release, focusing on the incidence of recovery from symptoms, the time span until the patient returns to work, and the incidence of recurrence of symptoms. Overall, both techniques have equivalent outcomes.

Many of the most convincing studies are prospective randomized trials. One such study, comparing open and endoscopic carpal tunnel release among 32 hands in 29 patients, found no difference in postoperative recovery time or surgical result. The only significant difference noted by the authors was transient numbness on the radial side of the ring finger in three endoscopic carpal tunnel release patients.

In another study, the authors compared in a prospective randomized manner the early outcome of carpal tunnel release using either a conventional open carpal tunnel release procedure in 40 patients or a two-portal endoscopic release in 56 patients. They found no statistically significant difference between the groups in postoperative pain, recovery from paresthesias, or time taken to return to work. However, the endoscopic group demonstrated better grip strength recovery at 1 and 3 months. No surgical complications were observed in either group.

Nonrandomized studies have supported this trend. An analysis of 191 consecutive patients undergoing carpal tunnel release with an average 2-year follow-up showed that none of the patients undergoing open release had a recurrence, while 7% of patients undergoing endoscopic release had recurrences. Another study observed a higher incidence of incomplete release of the carpal tunnel with endoscopic techniques than with standard open releases.

The factors identified with poor outcomes in endoscopic carpal tunnel release are similar to those seen in open release. Less satisfactory results were present in workers' compensation cases; patients with normal motor latencies on nerve conduction studies; patients with preoperative hand weakness, widened two-point discrimination, myofascial pain syndrome, or fibromyalgia; and patients involved in litigation, those with multiple compressive neuropathies, and those with abnormal psychologic factors.

► Complications

Only a limited number of studies include a sufficient number of patients to compare complication rates and type between endoscopic and open carpal tunnel release. Overall, the types and rates of complications between the two forms of release are similar. Nonetheless, isolated but severe complications from endoscopic release over the past decade tend to dramatize its risk.

The study by Boeckstyns and Sorensen is perhaps the most comprehensive to date. These authors analyzed 54 published series of endoscopic and open releases comprising 9516 and 1203 patients, respectively. Irreversible nerve damage from the procedure occurred in 0.3% of endoscopic and 0.2% of open releases, including such injuries as transection of the median nerve. While reversible nerve injuries were more common with endoscopic release than with open release (4.4% vs 0.9%, respectively, among prospective controlled and randomized studies), tendon lesions, reflex sympathetic dystrophy, hematoma, and wound problems were equally common with either technique.

A less compelling analysis—a retrospective survey of hand surgeons who had performed either open or endoscopic carpal tunnel release over the preceding 5 years—found major complications with both approaches, including median nerve lacerations, ulnar nerve lacerations, digital nerve lacerations, vessel lacerations, and tendon lacerations. While the authors could not reach a conclusion about the rate of complications for one procedure versus the other, their results demonstrate the potentially devastating sequelae of carpal tunnel release even in experienced hands.

Carpal tunnel symptoms may persist or recur following either open or endoscopic release. In patients who have persistent symptoms following endoscopic release, many authors recommend open carpal tunnel release as definitive therapy.

- C. The thumb should be in the opposed (pronated) position
 - D. The hand should be in the position of rest
 - E. Fiberglass casting materials are preferred for their flexibility.
2. Incisions on the hand should be
 - A. Never made on the palm
 - B. Across lines of tension
 - C. Only made along the medial and lateral surfaces of the fingers
 - D. Zigzagged across lines of tension
 - E. Carried perpendicularly across the wrist crease
 3. Major congenital hand anomalies
 - A. Occur in about 1 in 10,000 live births
 - B. Can include camptodactyly
 - C. Are rarely accompanied by other anomalies (< 1%)
 - D. Are not known to be associated with environmental factors
 - E. Are usually treated by surgery delayed until after age 15 years
 4. Stenosing tenosynovitis
 - A. Can be treated by local injections of corticosteroid
 - B. Is usually best treated by early surgery
 - C. Is always associated with a locked tendon that is trapped and frozen in the tendon sheath
 - D. Can be confused with trigger finger or thumb, and must be differentiated
 - E. Can be improved with immobilization
 5. Management of carpal tunnel syndrome
 - A. Typically requires emergent operation
 - B. Cannot be done by endoscopic approaches
 - C. Should be usually incision of the transverse carpal ligament, which forms the roof of the tunnel
 - D. Is uncommon among hand disorders
 - E. Should include surgery, not delayed by attempts at nonoperative treatment

MULTIPLE CHOICE QUESTIONS

1. All of the following are true about applying a cast to the hand, except
 - A. The wrist should be extended 30 degrees
 - B. The fingers should be flexed

Pediatric Surgery

43

James Wall, MD
Craig T. Albanese, MD

Pediatric surgical patients are not merely small adults. The surgical care of children differs markedly from that of adults in many respects, including unique physiologic demands that vary according to age and development. The neonate's physiologic development is closer to that of a fetus, while adolescents are similar to adults, and infants or children have problems unique to their chronologic and developmental age. Infants and children also suffer from congenital abnormalities and diseases not seen in adults, and their management requires an intimate understanding of the relevant embryology and pathogenesis.

NEWBORN CARE

► Neonatal Intensive Care

The newborn infant with a surgically correctable lesion often has other disorders that threaten survival. The care of these babies—particularly the premature and small-for-gestational-age babies, has improved with the emergence of the intensive care nursery. Dramatic advances have been made in the technology of infant monitoring and respiratory support. Low-birth-weight infants can now receive ventilatory support from sophisticated infant respirators for prolonged periods in a precisely controlled microenvironment. Surfactant therapy and high-frequency ventilation has allowed a population of extremely premature infants to survive. Temperature is controlled by servoregulation, while pulse and blood pressure are continuously recorded. Ventilation is monitored by transcutaneous O₂ and CO₂ electrodes or by indwelling arterial catheters. The metabolic consequences of prematurity and intrauterine growth retardation are monitored by frequent measurement of glucose, calcium, electrolytes, and bilirubin in microliter quantities of blood. Nutritional requirements for growth and development can be provided by enteral or parenteral routes. This kind of specialized care of critically ill newborns requires

trained personnel and specialized equipment. The care of such babies is best accomplished in designated regional centers capable of providing pediatric surgical and neonatal intensive care.

► Classification

Newborn infants can be classified according to their level of maturation (weight) and development (gestational age). A normal full-term infant has a gestational age of 37–42 weeks and a body weight greater than 2500 g. The gestational age of the infant is calculated from the date of the last normal menstrual period. However, clinical assessment of gestational age by morphologic and neurologic examination of the small infant can be more accurate than calculation from the menstrual history.

Four signs may be useful in assessing gestational age. Infants less than 37 weeks' gestational age have (1) fine fuzzy hair with thin, semitransparent skin, (2) ears that lack cartilaginous support, (3) a breast nodule less than 3 mm in diameter, and (4) few transverse creases on the balls of the feet anteriorly. In males, the testicles are incompletely descended and reside in the inguinal canal, and the scrotum is small with few rugae. In females, the labia minora are relatively enlarged and the labia majora are small.

Preterm infants are those born before 37 weeks' gestation. Several physiologic abnormalities may coexist in preterm infants. Apneic and bradycardic episodes are common and may represent an immature central nervous system (CNS) or, conversely, may represent signs of physiologic instability, most notably with sepsis. The lungs and retinas of preterm infants are very susceptible to high oxygen levels. Retinopathy of prematurity from oxygen toxicity may lead to blindness. Relatively brief exposures to high oxygen concentrations, often coupled with barotrauma from the mechanical ventilator, may damage the lungs, resulting in bronchopulmonary dysplasia. Shunting across a patent

ductus arteriosus is common and may lead to pulmonary hemorrhage and congestive heart failure. The preterm infant has a friable choroids plexus and is thus susceptible to intraventricular hemorrhage when stressed in the first week of life. The premature infant may be unable to tolerate oral feeding due to a weak suck reflex. Tube feeds or total parenteral nutrition may be required. Preterm infants have increased requirements for glucose, calcium, and sodium as well as a propensity for hypothermia, impaired bilirubin metabolism, polycythemia, and metabolic acidosis. These problems are accentuated in very low-birth-weight (VLBW) infants or “micropremies” (birth weight < 1000 g).

A small-for-gestational age (SGA) infant is one who is less than the 10th percentile in weight for their gestational age. An SGA infant is the product of a pregnancy complicated by any one of several placental, maternal, or fetal abnormalities. Although body weight is low, their body length and head circumference are age-appropriate. Compared with the premature infant of equivalent weight, the SGA infant is developmentally more mature and faces different physiologic problems. Intrauterine malnutrition results in reduced body fat and decreased glycogen stores. Their relatively large surface area and high metabolic rate predisposes them to hypothermia and hypoglycemia. SGA infants also have an increased risk of meconium aspiration syndrome. Polycythemia (which may lead to complications of hyperviscosity syndrome) is common and necessitates close monitoring of their hematocrit. Due to their relatively mature organ development and function (compared to preterm infants), retinopathy of prematurity, intraventricular hemorrhage, and hyaline membrane disease are uncommon.

► Temperature Regulation

Infants and children are susceptible to heat loss because they have a relatively greater body surface area and a thinner subcutaneous fat layer compared with adults. Heat loss occurring by conduction, convection, evaporation, and radiation may be four times that of the adult and is further increased in the preterm infant. Infants are homeotherms and will expend metabolic energy to stay warm at the cost of other functions. Heat is generated not by shivering but by metabolizing brown fat reserves (nonshivering thermogenesis) in response to norepinephrine. This has practical consequences since brown fat may be rendered inactive by some medications (pressors and anesthetic agents) and may be depleted by poor nutrition. Exposure to cold environments increases metabolic work and caloric consumption. Due to limited energy reserves and thin skin, prolonged exposure may rapidly cause hypothermia. Resultant catecholamine secretion increases the metabolic rate (particularly in the myocardium) and produces vasoconstriction with impaired tissue perfusion and increased lactic acid production.

Thus, it is important to maintain the sick newborn in an optimal thermal environment. This is the ambient temperature in which a baby, at a minimal metabolic cost, can maintain a constant and normal body temperature by vasomotor control. To attain such an environment, the gradient between the skin surface and the environmental temperature must be less than 1.5°C. As the skin surface temperature averages 35.5°C, the optimal environmental temperature is 34°C (slightly higher for premature infants). The neonate’s environmental temperature is best controlled by placing the infant in an enclosed incubator. An open radiant warmer is used when the infant is sick and frequent access is necessary. Either the ambient temperature of the incubator can be monitored and maintained at thermoneutrality, or a servo system can be used. The latter regulates the incubator temperature according to the infant’s skin temperature. Heat loss may be further reduced by wrapping the head, extremities, and as much of the trunk as possible in wadding, plastic wrap, plastic sheets, or aluminum foil.

In the operating room, the temperature of the infant must be continuously recorded by placing a thermistor in the rectum or esophagus. Body heat may be conserved by a heating pad, circulated warm air around the child (bear-hugger), infrared lamp, and warm irrigation fluids. The operating room should be prewarmed and the temperature kept at 20–27°C. Wet sponges and drapes exaggerate evaporative heat losses. Plastic drapes contain body heat and keep the skin dry. One of the most effective means of regulating body temperature is to heat and humidify the inhalational anesthetic gases.

► Ventilation

Assisted ventilation is often necessary because of underlying disease (eg, persistent fetal circulation and pulmonary hypertension), medications (eg, opioids, PGE₂), or physiologic changes imposed by a surgical procedure (eg, closure of an abdominal wall defect or diaphragmatic hernia). At birth, the baby should be warmed, dried, and stimulated. If the baby shows signs of respiratory distress, the pharynx should be aspirated of mucus, amniotic fluid, or meconium. Inadequate respiration should be assisted with positive pressure via mask and escalated to an endotracheal tube as necessary. There is an evolving role for a laryngeal mask airway (LMA) in newborns over 2.5 kg to establish ventilation, especially in cases of difficult airways due to congenital anomalies where intubation may not be possible. The diameter of an endotracheal tube (uncuffed) should approximate that of the 5th digit or the nares, usually between 2.5 and 4 mm. The full-term newborn usually requires a 3.5-mm tube. An orotracheal tube is preferred to a nasotracheal one to minimize trauma and subsequent infection in the nasal passages. The trachea from the glottis to the carina in the newborn is 7.5-cm long, and placement of the tube into the right or left

bronchus must be avoided. For infants, optimal tube placement can be estimated as body weight (kg) + 6 as follows: 7 cm from the lips in a 1-kg infant; 8 cm in a 2-kg infant; and 9 cm in a 3-kg infant. Once placed, the endotracheal tube is firmly fixed in place and connected to an infant ventilator. A small air leak between the endotracheal tube and the airway is necessary to minimize laryngeal and tracheal trauma.

Most infant ventilators are time-cycled flow generators capable of delivering both continuous positive airway pressure (CPAP) and intermittent mandatory ventilation (IMV). IMV is a synthesis of simple mechanical ventilation and CPAP breathing that allows the baby to breathe independently between mandatory breaths provided by the ventilator while a continuous positive pressure is maintained on the airway. CPAP breathing helps keep the terminal airways open and is particularly useful when alveolar collapse develops, such as in hyaline membrane disease or with persistent atelectasis.

The gas mixture flowing into the system should be carefully controlled by an air-oxygen mixing device, and the inspired oxygen concentration should be regulated to avoid excessive oxygen delivery. A reasonable goal for arterial PO_2 is around 60-80 torr. The gas should be humidified by using a heated nebulizer as nonhumidified circuits can lead to insensible losses. When the arterial PO_2 exceeds 80 torr, the inspired oxygen concentration is gradually lowered toward room air; the end-expiratory pressure is incrementally lowered. When PCO_2 is less than approximately 45 torr, the IMV rate can be decreased as well. In this way, the baby is gradually weaned from oxygen and mechanical ventilation. Upon removal of the tube, nasal CPAP can be provided, and the inspired oxygen concentration can be increased if necessary.

In severe respiratory compromise (eg, congenital diaphragmatic hernia [CDH], meconium aspiration syndrome), more complex ventilatory strategies are needed. High-frequency ventilation (jet and oscillatory modes) utilizes low tidal volumes at high rates (up to 600 breaths/min) to minimize the deleterious effects of high airway pressure. Inhaled nitric oxide (iNO) can be administered via the ventilatory circuit and may help relax the small airways and pulmonary vasculature. There is a trend toward allowing higher PCO_2 levels (permissive hypercarbia) and lower PO_2 levels in order to lessen pulmonary trauma from pressure and oxygen. This has been termed "gentle ventilation." If gentle ventilation, permissive hypercapnia, and the high-frequency modes of ventilation are ineffective, oxygenation and gas exchange can be accomplished using extracorporeal membrane oxygenation (ECMO). This temporary bypass unit oxygenates the blood through an external circuit as the lungs are left to mature or recover from the underlying disease process. The clinical need for ECMO has diminished with the increased widespread use of iNO, surfactant, high-frequency ventilation and the adoption of permissive hypercapnea as a ventilatory strategy.

Guidry CA, Hranjec T, Rodgers BM, Kane B, McGahren ED: Permissive hypercapnia in the management of congenital diaphragmatic hernia: our institutional experience. *J Am Coll Surg* 2012 Apr;214(4):640-645, 647.

► Fluids & Electrolytes

Effective fluid and electrolyte management involves (1) calculating the fluid and electrolyte requirements for maintaining metabolic functions, (2) replacing losses (evaporative, third space, external), and (3) considering preexisting fluid deficits or excesses. Taking these factors into consideration, a tentative program is devised for fluid and electrolyte administration. The patient's response is monitored, and the program is adjusted accordingly.

Monitoring fluid status and acid-base balance can be accomplished by both noninvasive and invasive means. Commonly used noninvasive devices include pulse oximetry, urine output, transcutaneous CO_2 monitoring, and sphygmomanometry. For critically ill infants, more invasive means are necessary to assess homeostasis. Blood gas analysis via heelstick (capillary), venous catheter, or arterial catheter is frequently employed. Polyvinyl catheters may be placed via an umbilical artery into the aorta, with the tip positioned at the level of T6-T9 or L3-L4 (confirmed radiographically). Indwelling arterial catheters can also be placed in the radial, femoral, or temporal arteries, either percutaneously or by incision. Central venous access may assist in cases where prolonged venous access is needed or parenteral nutrition is necessary or when blood is frequently sampled. It may be obtained via the umbilical vein; a percutaneously inserted central catheter (PICC) via the saphenous, cephalic, median basilic, or temporal veins; or using a Broviac catheter via the femoral, internal jugular, facial, or subclavian veins.

A. Calculating Maintenance Needs

In the newborn infant, the basic maintenance requirement of water is the volume required for growth and replacement of losses from the skin, lungs, and stool. Requirements during the first day of life are unique because of the greatly expanded extracellular fluid volume in the newborn baby, which decreases after 24 hours. For example, infants born with intestinal obstruction (eg, intestinal atresia) are initially not hypovolemic as a result of fluid adjustments across the placenta. Up to 10% of a newborn infant's birth weight is lost in the first 3-7 days; the majority is water loss, with minor contributions from meconium and urine. During the first 24 hours of life, basic maintenance fluid should range from 60 to 80 mL/kg/d for term infants, and from 80 to 100 mL/kg/d for preterm infants. This requirement gradually increases to a minimum 80-100 mL/kg/d by 4 days of life in normal infants. For children and adolescents, the most commonly used method of calculating fluid requirements is based on body weight (Table 43-1). However, because of the many

Table 43–1. Calculation of maintenance fluid requirements.

Body Weight	Fluid Volume per 24 h
1-10 kg	100 mL/kg
11-20 kg	1000 mL + 50 mL for each kg over 10 kg
> 20 kg	1500 mL + 20 mL for each kg over 20 kg

Reproduced, with permission, from Albanese CT: Pediatric surgery. In: Norton JA. *Surgery*. New York, NY: Springer; 2000.

factors affecting maintenance requirements, there is no close or constant relationship between body weight and fluid and electrolyte needs.

B. Perioperative Fluid Management

In the surgical patient, fluid, serum electrolyte, and acid-base abnormalities are corrected before operation, when feasible. Intraoperative fluid requirements consist of the estimated maintenance requirement plus replacement of preexisting deficits (if uncorrected) plus replacement of intraoperative losses, including blood.

Postoperatively, losses from intestinal drainage and fistulas are directly measured and replaced with an appropriate electrolyte solution (Table 43–2). In neonates, it is wise to measure the electrolytes in the fluid to more accurately guide replacement, especially for proximal intestinal stomas or fistulas. Protein-rich losses (eg, chest tube drainage of a chylothorax) can be replaced with colloid such as an albumin solution or fresh frozen plasma (FFP). Internal losses into body cavities or tissues (third space losses) cannot be measured; adequate replacement of these losses depends on careful monitoring of the patient's vital signs and urine output. Following an operation such as a laparotomy or thoracotomy, the fluid requirement may exceed 150 mL/kg/d for several days postoperatively. Isotonic fluids are better in the

immediate postoperative period in patients over 6 months of age when significant third space losses are possible.

C. Electrolyte Considerations

Basic electrolyte and energy requirements are provided by sodium, 3-4 mEq/kg/d (up to 5 mEq/kg/d for preterm infants) in 5% or 10% dextrose, with the addition of potassium, 2-3 mEq/kg/d, once urine production has been established. Calcium gluconate (200-400 mg/kg/d) may be added, especially in preterm infants. Additional electrolytes such as bicarbonate and magnesium are added, as needed.

Many stressed newborn infants develop low blood levels of potassium, calcium, magnesium, and glucose. A deficiency of any one of these will produce such signs as vomiting, abdominal distention, poor feeding, apneic spells, cyanosis, lethargy, eye rolling, high-pitched cry, tremors, or convulsions. Convulsions and tetany due to hypocalcemia should be treated with intravenous 10% calcium solution given at a rate of 1 mL/min while the EKG is carefully monitored. Although hypocalcemia can be largely eliminated by adding calcium salts to intravenous solutions, caution is required since subcutaneous infiltration may produce severe vasoconstriction and skin necrosis. If there is no response to correction of a documented calcium deficiency, hypomagnesemia should be suspected and a serum magnesium level obtained.

Rapid determination of the blood glucose level can be done in the neonatal unit with blood glucose reagent strips. This may be correlated at intervals with serum glucose determinations, the frequency depending on the stability of the infant. Generally, intravenous fluids should contain a minimum of 10% dextrose, and if non-dextrose-containing solutions such as blood or plasma are being administered, close monitoring of the blood glucose level is essential. The treatment of hypoglycemia consists of giving 50% glucose, 1-2 mL/kg intravenously, followed by a continuous infusion of 10%-15% glucose solutions at a rate equivalent to that needed for maintenance water requirements.

Table 43–2. Replacement of abnormal losses of fluids and electrolytes.

Type of Fluid	Electrolyte Content				Replacement
	Na ⁺ (mEq/L)	K ⁺ (mEq/L)	Cl ⁻ (mEq/L)	HCO ₃ ⁻ (mEq/L)	
Gastric (vomiting)	50(20-90)	10(4-15)	90(50-150)	...	5% dextrose in half-normal (0.45%) saline plus KCl 20-40 mEq/L
Small bowel (ileostomy)	110(70-140)	5(3-10)	100(70-130)	20(10-40)	Lactated Ringer
Diarrhea	80(10-140)	25(10-60)	90(20-120)	40(30-50)	Lactated Ringer with or without HCO ₃ ⁻
Bile	145(130-160)	5(4-7)	100(80-120)	40(30-50)	Lactated Ringer with or without HCO ₃ ⁻
Pancreatic	140(130-150)	5(4-7)	80(60-100)	80(60-110)	Lactated Ringer with or without HCO ₃ ⁻
Sweat					
Normal	20(10-30)	4(3-10)	20(10-40)
Cystic fibrosis	90(50-130)	15(5-25)	90(60-120)

Choong K, Arora S, Cheng J, Farrokhyar F, Reddy D, Thabane L, Walton JM: Hypotonic versus isotonic maintenance fluids after surgery for children: a randomized controlled trial. *Pediatrics* 2011 Nov;128(5):857-866.

► Nutrition

Newborns require a relatively large caloric intake because of their high basal metabolic rate, caloric requirements for growth and development, energy needs to maintain body heat, and limited energy reserve. An infant requires calories at a rate of 100-130 kcal/kg/d and protein at a rate of 2-4 g/kg/d to achieve a normal weight gain of 10-15 g/kg/d (Table 43-3). Thirty percent to 40% of the total non-protein calories should be provided as fat. These requirements decline with age but increase with surgery, sepsis, and trauma or burns. Caloric requirements are increased 10%-25% by surgery, more than 50% by infection, and 100% by burns.

A. Enteral Alimentation

The best means of providing calories and protein is through the gastrointestinal (GI) tract. If the GI tract is functional, standard infant formulas, blenderized meals, or prepared elemental diets can be given by mouth, through nasogastric or nasojejunal feeding tubes, or through gastrostomy or jejunostomy tubes placed surgically. Gastric feeding is preferable because it allows for normal digestive processes and hormonal responses, a greater tolerance for larger osmotic loads, and a lower incidence of dumping. The use of nasoduodenal or nasojejunal tubes is reserved for infants who cannot tolerate intragastric feeding (eg, delayed gastric emptying, gastroesophageal reflux [GER], depressed gag reflex).

The availability of nutritionally complete liquid diets of low viscosity allows continuous feeding through small-

diameter catheters. Elemental diets made by mixing crystalline amino acids, oligosaccharides, and fats can be completely absorbed in the small intestine with little residue. Their use is limited because they cause diarrhea as a result of the high osmolality of full-strength formulas. This can be avoided by administering dilute solutions by continuous drip. Initially, the volume of dilute solution is gradually increased, and the concentration is then progressively increased in a stepwise fashion—ie, half strength, three-fourths strength, and full strength. Formulas that remain below 500 mOsm are best.

Small Silastic or polyethylene catheters such as those used for intravenous infusion can be passed through the nose or mouth into the stomach or jejunum. In more complex cases, a surgically placed gastrostomy or jejunostomy may be necessary for postoperative feeding. A variety of techniques and methods are employed in their construction. In the case of a gastrostomy, either a balloon catheter is used (ie, Foley) or a low-profile gastrostomy button is placed. Silastic is superior to other plastics because it does not become rigid when exposed to intestinal contents. Parenteral nutrition combined with enteral feeding is often necessary for infants with short bowel syndrome until intestinal adaptation occurs.

B. Parenteral Alimentation

The indications for parenteral alimentation include the following: (1) expected period of prolonged ileus (eg, following repair of gastroschisis or high jejunal atresia); (2) intestinal fistulas; (3) supplementation of oral feedings, as in intractable diarrhea, short bowel syndrome, or various malabsorption syndromes; (4) intrauterine growth retardation; (5) catabolic wasting states such as infections or tumors when gastric feedings are inadequate or not tolerated; (6) inflammatory bowel disease; (7) severe acute alimentary disorders (pancreatitis, necrotizing enterocolitis [NEC]); and (8) chylothorax.

Concentrated solutions (12.5% glucose or more) thrombose peripheral vessels. Placement of a central venous catheter (PICC or Broviac) into the superior or inferior vena cava allows the large blood flow to dilute the solution immediately, allowing more concentrated sugar solutions (15%-30% glucose) to be administered. The catheter may be placed percutaneously through the subclavian or internal jugular vein or inserted by cut down into the external jugular, anterior facial, internal jugular, cephalic, brachial, or saphenous veins. For long-term use, Broviac (single lumen) or Hickman (double lumen) catheters, with Dacron cuffs positioned near the exit site of the skin, are preferred to minimize infection and to prevent accidental dislodgment.

Intravenous alimentation solutions containing an amino acid source (2%-5% crystalline amino acids or protein hydrolysate), glucose (10%-40%), electrolytes, vitamins, and trace minerals are used. The electrolyte composition

of the protein solution should be known so that the desired composition of the final solution can be adjusted by appropriate additives according to the individual patient's requirements. A standard solution suitable for infants and young children must contain calcium, magnesium, and phosphate to allow for growth. Trace minerals are also added to the basic solution (Table 43–4). These solutions should be infused at a constant rate with an infusion pump to avoid blood backing up the catheter and clotting and to prevent wide fluctuations of blood glucose and amino acid concentrations. If it is necessary to restrict the volume of infusion, more concentrated glucose solutions can be used to increase the caloric intake.

Complications of prolonged intravenous alimentation are numerous. The most frequent problem is catheter sepsis. Although catheter removal will quickly treat the problem, a trial of antibiotics effective against gram-positive and gram-negative pathogens is indicated. Catheter removal is indicated in the presence of worsening sepsis, three positive blood cultures, or documented yeast infection (with antifungal treatment after catheter removal). Clotting in the catheter may be controlled by adding 1 unit of heparin per milliliter of solution. Emphasis on a constant rate of infusion will minimize hyperglycemia or hypoglycemia. Analysis of serum electrolytes (including calcium and phosphate) may be necessary several times a week initially, but the interval is decreased to once a week when the patient is

stable. Patients must be observed for hyperammonemia and for vitamin or trace mineral deficiency. Progressive hepatomegaly and jaundice of uncertain origin can occur after prolonged parenteral alimentation. This syndrome may subside when the parenteral solution is discontinued or when it is infused for a period of 12-16 hours and then the infusion is stopped for 8-12 hours (cycling) or when augmented with enteral feeding. Use of an ω -3 fatty acid based emulsion (Omegaven) has shown potential in moderating the effects of TPN cholestasis.

► Blood Loss

Total blood, plasma, and red blood cell (RBC) volumes are higher during the first few postnatal hours than at any other time in an individual's life. Several hours after birth, plasma shifts out of the circulation, and total blood and plasma volume decrease. The high RBC volume persists, decreasing slowly to reach adult levels by the seventh postnatal week. Age-related estimations of blood volume are summarized in Table 43–5.

Although not clinically significant, both the prothrombin time and the partial thromboplastin time may be slightly prolonged at birth due to relative deficiencies of clotting factors. Defects in the coagulating mechanism may occur in newborn infants as a result of vitamin K deficiency, thrombocytopenia, inherited disorders, and temporary hepatic insufficiency due to immaturity, asphyxia, or infection. It is standard to administer 1.0 mg of vitamin K intramuscularly to all newborns.

The blood lost during operation varies greatly according to the complexity of the operative procedure, the underlying

Table 43–5. Blood volume based on age.

Preterm infants	85-100 mL/kg
Term infants	85 mL/kg
Age > 1 month	75 mL/kg
Age 3 months to adult	70 mL/kg

disease, and the effectiveness of hemostasis. Mild blood loss, amounting to less than 10% of the blood volume, usually does not require transfusion. It is imperative to develop methods for closely monitoring the amount of blood lost during operations since significant blood loss is often underestimated in the newborn, especially the preterm infant. Dry sponges should be used and weighed shortly after use to minimize error from evaporation. The suction line, connected to a calibrated trap on the operating table, should be short to diminish the dead space of the tubing and to provide immediate data about accumulated blood loss. Visual observation may be used as a rough guide, but it tends to give a falsely low estimate of the loss.

Before operation, newborn infants should receive vitamin K, 1.0 mg intravenously or intramuscularly. If an extensive surgical procedure is anticipated, the patient's blood should be typed and crossmatched in case transfusion is required. In infants with hematocrits greater than 50%, blood loss may be replaced by infusing lactated Ringer's solution or FFP to compensate for losses of up to 25% of total blood volume. Greater blood losses should be replaced with packed RBCs. A transfusion of RBCs at a volume of 10 mL/kg should raise the hematocrit 3%-4%. The transfused blood should be prewarmed to body temperature by running it through coiled tubing immersed in water at 37°C. With excessive blood loss, clotting factors and platelets can be depleted rapidly, and FFP and platelets of identical blood type should be available. With massive transfusion a ratio of 1:1 of FFP to RBCs and 1:2 of platelets to RBCs has been shown to improve outcomes.

► Perioperative Considerations

A. Gastrointestinal Decompression

The importance of gastric decompression in the surgical newborn cannot be overemphasized. The distended stomach carries the risk of aspiration and pneumonia and may also impair diaphragmatic excursion, resulting in respiratory distress. For example, oxygenation and ventilation in a neonate with CDH may become progressively impaired as the herniated intestine becomes distended with air and fluid. With gastroschisis, omphalocele, and diaphragmatic hernia, the ability to reduce the prolapsed intestine into the abdominal cavity is impaired by intestinal distention. It is critical to avoid bag-mask ventilation in these patients. A double-lumen (sump) tube, such as a 10F Replogle or Anderson tube, is preferred, utilizing low continuous suction. If a single-lumen tube is used, intermittent aspiration by syringe or machine is required. The correct position of the tube in the stomach is confirmed by carefully measuring the tube prior to insertion and by radiographs. Careful taping of the tube is essential to avoid displacement.

B. Preoperative Blood Sampling

Blood analyses should be restricted to those studies essential for diagnosis and management. The volume of blood drawn for laboratory tests should be documented as these small volumes cumulatively represent significant blood loss in a small infant. Generally, the only "routine" preoperative blood analyses for a neonate consist of a complete blood count and a blood specimen for type and crossmatch (in the case of major newborn surgery). Electrolytes in the first 12 hours of life simply reflect the mother's electrolytes. Coagulation studies (eg, PT, PTT, ACT) are rarely indicated.

C. Preoperative NPO Guidelines

The following are general guidelines, but institutional practices vary considerably. The guiding principles in setting a standard include: risk of hypoglycemia associated with NPO status, tolerance or comfort level of the NPO child, and the desire to have an empty stomach upon induction of general anesthesia to mitigate aspiration risk.

1. Patients younger than 6 months—No solids, breast milk, or formula 4 hours prior to the procedure. Infants may have clear liquids (water, oral electrolyte mixtures, glucose water, or apple juice) until 2 hours prior to the procedure.

2. Patients from 6 months to 18 years—Nothing to eat or drink after midnight except clear liquids (water, apple juice, oral electrolyte mixtures, gelatin dessert, white grape juice), which can be continued until 2 hours prior to the procedure.

3. Patients older than 18 years—Nothing to eat or drink after midnight except clear liquids (water, apple juice, plain gelatin desserts) until 4-6 hours prior to the procedure.

D. Bowel Preparation Instructions

The bowel is mechanically cleansed for elective bowel resection. Opinion varies about whether a bowel preparation is needed for certain procedures as well as about what to use to accomplish it and whether to do it at home or in the hospital. An inpatient regimen begins the day prior to surgery and consists of polyethylene glycol-electrolyte solution (GoLYTELY), 25 mL/kg/h for 4 hours or until the effluent is clear. Metoclopramide (0.1 mg/dose IV) is given 1 hour before the GoLYTELY. Pedialyte can be given ad lib until the time to have nothing by mouth.

Outpatient preparations are reserved for patients over 1 year of age. Clear liquids are given the day before surgery. Bisacodyl (Dulcolax) suppositories and 8-oz lukewarm tap water enemas can be given the morning and in the evening the day before surgery. For children over 5 years of age,

magnesium citrate is added (1 oz per year of age up to a maximum of 8 oz) and given orally in the morning and evening the day before surgery, along with 16-oz tap water enemas.

LESIONS OF THE HEAD & NECK

DERMOID CYSTS

Dermoid cysts are congenital inclusions of skin and skin appendages commonly found on the scalp and eyebrows and in the midline of the nose, neck, and upper chest. They present as painless swellings that may be completely mobile or fixed to the skin and deeper structures. Dermoid cysts of the eyebrows and scalp may produce a depression in the underlying bone that appears as a smooth, punched-out defect on radiographs of the outer table of the skull. They do not extend intracranially. In contrast, cysts of the face and scalp that are located in the midline may represent an alternative diagnosis of encephalocele and would be handled much differently so it is imperative to obtain an MRI or CT scan preoperatively. Dermoid cysts of the midline neck may be confused with thyroglossal duct cysts. However, dermoids do not move with swallowing or protrusion of the tongue since they are not deep to the strap muscles, unlike thyroglossal cysts. All dermoids contain a cheesy material that is produced by desquamation of the cells of the epithelial lining. Care should be taken when planning the operative approach to facial dermoids to avoid either incomplete excision or unnecessary surgical scarring in cosmetically sensitive areas. Dermoids should be excised intact, since incomplete removal will result in recurrence. Those lesions arising near the eyebrows should be excised through an incision adjacent to the hairline. The eyebrows should not be shaved nor should the incision go through any eyebrow follicles since a permanent glabrous area will develop. Recently, tunneled endoscopic approaches originating from behind the hairline have been used successfully to avoid facial scarring.

BRANCHIOGENIC ANOMALIES

During the first month of fetal life, the primitive neck develops four external clefts and four pharyngeal pouches that are separated by a membrane. Between the clefts and pouches are branchial arches. The dorsal portion of the first cleft becomes the external auditory canal; the other clefts are obliterated. The pharyngeal pouches persist as adult organs. The first pouch becomes the auditory tube, the middle ear cavity, and the mastoid air cells. The second pouch incompletely regresses and becomes the palatine tonsil and the supratonsillar fossa. The third pouch forms the inferior parathyroid glands and thymus; the fourth forms the superior

▲ **Figure 43-1.** Branchiogenic fistula from second branchial cleft origin. The fistula extends along the anterior border of the sternocleidomastoid muscle and courses between the internal and external carotid arteries and cephalad to the hypoglossal nerve to enter the tonsillar fossa.

parathyroid glands. Branchial anomalies are remnants of this fetal branchial apparatus.

A tract of branchial origin may form a complete fistula, or one end may be obliterated to form an external or internal sinus, or both ends may resorb, leaving an aggregate of cells forming a cyst (Figure 43-1). Fistulas that arise above the hyoid bone and communicate with the external auditory canal represent persistence of the first branchial cleft. These tracts are always lined by squamous epithelium. Cysts and sinuses of second or third branchial origin are lined by squamous, cuboidal, or ciliated columnar epithelium. Fistulas that communicate between the anterior border of the sternocleidomastoid muscle and the tonsillar fossa are of second branchial origin, and those that extend into the piriform sinus are derived from the third branchial pouch. Cysts developing from branchial structures usually appear later in childhood as opposed to sinuses and fistulas. Branchiogenic anomalies occur with equal frequency on each side of the neck, and 15% are bilateral. Second branchial cleft abnormalities are most common, occurring six times more frequently than first cleft anomalies.

► Clinical Findings

A sinus or fistulous opening along the anterior border of the sternocleidomastoid muscle may be noted at birth and usually discharges a mucoid or purulent material. The patient may complain of a foul-tasting discharge in the mouth upon massaging the tract, but the internal orifice is rarely

recognized. Some may present with an acute infection. The cysts are characteristically found anterior and deep to the upper third of the sternocleidomastoid muscle, or they may be located within the parotid gland or pharyngeal wall, over the manubrium, or in the mediastinum. Sinuses and cysts are prone to become repeatedly infected, producing cellulitis and abscess formation. Incomplete branchial sinuses appear as a dimple that contain cartilage and do not drain or communicate with the deep structures of the neck.

► Differential Diagnosis

Granulomatous lymphadenitis due to mycobacterial infections may produce cystic lymph nodes and draining sinuses, but these are usually distinguishable by the chronic inflammatory reaction that precedes the purulent discharge. Suppurative lymphadenitis, most commonly due to *Staphylococcus aureus*, may resemble an infected branchial remnant. However, treatment and complete healing of the lymphadenitis is curative, whereas an identifiable branchial remnant will persist after the infection resolves. Hemangiomas and lymphatic malformations (LM) are soft, spongy tumor masses that might be confused with branchial cysts, but the latter have a firmer consistency. LM may transilluminate, while branchial cysts do not. Carotid body tumors are quite firm, are located at the carotid bifurcation, and occur in older patients. Lymphomas produce firm masses in the area where branchial remnants occur, but multiple matted nodes rather than a solitary cystic tumor distinguish these lesions. Mucoïd material may be expressed from the openings of branchial sinuses or fistulas, and a firm cord-like tract may be palpable along its course.

► Treatment

Nearly all branchial abnormalities should be excised early in life since repeated infection is common, making resection more difficult. Asymptomatic, small cartilaginous remnants may be watched, but they are usually removed for cosmetic reasons as well as the smaller risk of infection, compared to the true cyst/fistula. Infected sinuses and cysts require initial incision and drainage. Excision of these tracts is staged and usually performed approximately 6 weeks later, when the acute inflammatory reaction has subsided. Every effort should be made to excise the entire cyst wall or fistula tract (including the skin punctum, if present) since recurrence and infection are common with incomplete removal. Excision should be undertaken cautiously, as the tracts may lie adjacent to the facial, hypoglossal, and glossopharyngeal nerves as well as the carotid artery and internal jugular vein.

Al-Khateeb TH, Al Zoubi F: Congenital neck masses: a descriptive retrospective study of 252 cases. *J Oral Maxillofac Surg* 2007;65(11):22242-22247.

PREAURICULAR LESIONS

Preauricular sinuses, cysts, and cartilaginous rests arise from anomalous development of the auricle and are unrelated to branchial anomalies. The sinuses are often short and end blindly. They can be cosmetically unappealing and often become infected. Superficial skin tags and cartilaginous rests are easily excised without risk to other structures. Preauricular sinus tracts, however, may be very deceptive in their extent, and one should be prepared to proceed with extensive dissection that risks damage to branches of the facial nerve.

LYMPHATIC MALFORMATION (CYSTIC HYGROMA, LYMPHANGIOMA)

LMs are benign multilobular, multinodular cystic masses lined by lymph channel endothelial cells. They result from maldevelopment and obstruction of the lymphatic system. Since they are not proliferative lesions, they should be distinguished from hemangiomas; hence the favored term of lymphatic malformation is currently favored over the more frequently encountered misnomer lymphangioma. Cystic hygroma is another misnomer frequently encountered for cervical lymphatic malformation. Eventually, sequestrations of lymphatic tissue that do not communicate with the normal lymphatic system develop. Fifty percent to 65% appear at birth and 90% by the second year of life. They are located most commonly in the posterior triangle of the neck (75%) (Figure 43-2) and axilla (20%), with the remainder located in the mediastinum, retroperitoneum, pelvis, and groin.

► Clinical Findings

Cervical lymphatic malformations may communicate beneath the clavicle with an axillary hygroma, mediastinal hygroma, or, rarely, both. The majority may be asymptomatic; however, the occult LM usually presents following an upper aerodigestive tract infection as a result of increased or infected lymph flow, or following hemorrhage into the LM from a web of adherent microvasculature. Occasionally, very large lesions occur with involvement of the floor of the mouth, these can cause *in utero* hydrops or asphyxiation at birth when associated with airway compromise. There is a recognized association between cervical LM and Turner syndrome. These lesions grow along fascial planes and around neurovascular structures; they are infiltrative but not invasive. Large lesions may be recognized prenatally using ultrasound or MRI examination.

► Treatment

There are two modes of treatment, sclerotherapy or excision, the choice of which is based on imaging studies (CT, MRI). Intralesional injection of a sclerosing agent is most effective

▲ **Figure 43-2.** Typical neonatal macrocystic lymphatic malformation arising from the posterior cervical triangle. (Reproduced, with permission, from Filston HC: Hemangiomas, cystic hygromas, and teratomas of the head and neck. *Semin Pediatr Surg* 1994;3:147.)

for unilocular or macrocystic lesions. Examples of agents that have been used are OK-432 (a lyophilized mixture of *Streptococcus pyogenes* and penicillin G potassium), bleomycin, and doxycycline. Excision is carried out with bipolar cautery to ensure a hemostatic dissection and decrease the incidence of lymph leak and nerve injury. Nevertheless, postoperative lymph leak is common and is treated by closed suction drainage for days to weeks. Intraoperative cyst rupture increases the difficulty of the dissection since the thin-walled cyst is difficult to identify and the margins are obscured. The persistence rate following surgery can be as high as 50% since incomplete excision is the rule rather than the exception in order to avoid potential injury to adjacent neurovascular bundles. Given their infiltrative nature, persistence or symptomatic recurrence following surgical excision and unavoidable surgical scarring, the trend has been increasingly toward sclerotherapy for superficial accessible macrocystic LMs.

Nehra D, Jacobson L, Barnes P, Mallory B, Albanese CT, Sylvester KG: Doxycycline sclerotherapy as primary treatment of head and neck lymphatic malformations. *J Pediatr Surg* 2008 Mar;43(3):451-460.

THYROGLOSSAL DUCT REMNANT

During the fourth week of gestation, the thyroid gland develops from an evagination in the floor of the primitive pharynx located between the first pair of pharyngeal pouches. If the anlage of the thyroid does not descend normally, the gland may form at the base of the tongue or remain as a mass anywhere in the midline of the neck along its truncated path of descent. If the thyroglossal duct persists, the epithelial tract forms a cyst that usually communicates with the foramen cecum of the tongue. The thyroglossal duct descends through the second branchial arch anlage, which becomes the hyoid bone, prior to its fusion in the midline. Because of this, the tract of a persistent thyroglossal duct often extends through the hyoid bone (Figure 43-3).

► Clinical Findings

The most common physical finding is a rounded cystic mass of varying size in the midline of the neck just below the hyoid bone. The acute inflammatory reaction of an infection may herald the presence of a cyst. The fluid in the cyst is usually under pressure and may give the impression of being a solid tumor. Cysts and aberrant midline thyroid glands move up and down with swallowing and with protrusion of the tongue since they are deep to the cervical strap muscles. In contrast, lingual thyroid tissue is a rare clinical entity and may produce dysphagia, dysphonia, dyspnea, hemorrhage, or pain.

▲ **Figure 43-3.** Thyroglossal cyst and duct course through the hyoid bone to the foramen cecum of the tongue.

► Differential Diagnosis

Lymph nodes, dermoid cysts, and enlarged Delphian nodes containing tumor metastases may be confused with thyroglossal remnants in the midline of the neck. Dermoid cysts do not move with swallowing. Lingual thyroids may be confused with a hypertrophied lingual tonsil or with a ranula, fibroma, angioma, sarcoma, or carcinoma of the tongue. These lesions and thyroglossal cysts may be distinguished from aberrantly located thyroid glands by needle aspiration or by radioiodine scintiscan.

► Complications

Thyroglossal cysts are prone to infection, and spontaneous drainage or incision and drainage of an abscess will often result in a chronically draining fistula. Excision of an ectopic thyroid may remove all thyroid tissue, producing hypothyroidism. There is a malignant potential of the dysgenetic thyroid tissue located in a thyroglossal duct cyst; carcinoma develops more frequently in ectopic thyroid tissue than in normal thyroid glands.

► Treatment

Complete excision is indicated because of the risk of infection and the possibility of the development of papillary carcinoma later in life. Acute infection in thyroglossal tracts should be treated with antibiotics. Abscesses should be incised and drained. After complete subsidence of the inflammatory reaction (approximately 6 weeks), a thyroglossal cyst and its epithelial tract should be excised. The mid portion of the hyoid bone should be removed en bloc with the thyroglossal tract to the base of the tongue (Sistrunk procedure). Recurrences occur when the hyoid is not removed and when the cyst was previously infected or drained.

Gallagher TQ, Hartnick CJ: Thyroglossal duct cyst excision. *Adv Otorhinolaryngol* 2012;73:66-69.

LaRiviere CA, Waldhausen JH: Congenital cervical cysts, sinuses, and fistulae in pediatric surgery. *Surg Clin North Am* 2012 Jun;92(3):583-597.

TORTICOLLIS

Torticollis presents with a hard, nontender, fibrotic mass within the sternocleidomastoid muscle. It may be present at birth but is usually not noticed until the second to sixth weeks of life. The mass appears with equal frequency in both sexes and on each side of the neck. Rarely, there is more than one mass in the muscle or both sternocleidomastoid muscles are involved. A history of breech delivery is present in 20%-30% of these children.

► Clinical Findings

Torticollis is manifested when the sternocleidomastoid muscle is shortened and the mastoid process on the involved side is pulled down toward the clavicle and manubrium. As a result, the head is abducted to the ipsilateral side and rotated to the contralateral side (toward the opposite shoulder). The shoulder on the affected side is raised, and there may be cervical and thoracic scoliosis. Passive rotation of the head to the side of the involved muscle will be resisted and limited to varying degrees, and the muscle will appear as a protuberant band. Because of persistent pressure when the patient is recumbent, the ipsilateral face and contralateral occiput will be flattened. Facial hemihypoplasia and plagiocephaly (flattening of the ipsilateral posterior skull) occurs in untreated cases, usually within 6 months.

► Treatment

Surgery is rarely necessary for this disorder. Torticollis is treated with active range of motion exercises. The child's shoulders are held flat to a table and the head is tilted and rotated in a full range of motion. This procedure should be performed at least four times a day, usually for 2-3 months. The firm "tumor" often disappears well before the torticollis is cured. If the muscle continues to become progressively shortened, with facial and occipital skull deformity, both heads of the sternocleidomastoid muscle should be divided through a small transverse incision just above the clavicle. This procedure does not reverse the bony changes that have already developed but prevents progression of the process. Recently, endoscopic approaches have been described in order to avoid unsightly surgical scarring in the head and neck region.

Dutta S, Albanese CT: Transaxillary subcutaneous endoscopic release of the sternocleidomastoid muscle for treatment of persistent torticollis. *J Pediatr Surg* 2008 Mar;43(3):447-450.

CERVICAL LYMPHADENOPATHY

SUPPURATIVE LYMPHADENITIS

Infections in the upper respiratory passages, scalp, ear, or neck produce varying degrees of secondary lymphadenitis. Most of the causative organisms are streptococcal or staphylococcal species. In infants and young children, the clinical course of the suppurative lymphadenitis may greatly overshadow a seemingly insignificant or inapparent primary infection. Scalp or ear infections produce preauricular or postauricular and suboccipital lymph node involvement; submental, oral, tonsillar, and pharyngeal

infections affect the submandibular and deep jugular nodes.

► Clinical Findings

With significant lymphadenitis, the regional lymph nodes become greatly enlarged and produce local pain and tenderness. Enlargement of cervical nodes is most common, followed by occipital and submandibular nodes. Fever is high initially and then becomes intermittent and may persist for days or weeks. The regional nodes may remain enlarged and firm for prolonged periods, or they may suppurate and produce surrounding cellulitis and edema. Subsequently, the nodes may involute or a fluctuant abscess may form, resulting in redness and thinning of the overlying skin. Infected, matted nodes may become so hard as to be indistinguishable (on palpation) from a solid mass.

► Differential Diagnosis

A smoldering lymphadenitis that neither resolves nor forms an abscess can be confused with granulomatous lymphadenitis, lymphoma, or metastatic tumor. Excisional biopsy is required to differentiate these lesions. After several weeks, there will usually be a reduction in the size and firmness of suppurative adenitis, especially after antibiotic treatment has been started. Recently, methicillin-resistant *S. aureus* (MRSA) is being encountered at near epidemic levels as a causative agent of suppurative lymphadenitis in the ambulatory setting. A high suspicion of an MRSA infection should be entertained in all children presenting with either a first episode or more certainly in recalcitrant and recurrent cases.

► Treatment

In the acute phase, the patient should be treated with oral or intravenous antistaphylococcal antibiotics. In the subacute or chronic phase, the presence of pus in the node may be confirmed by needle aspiration of the mass. When an abscess is present, it should be incised and drained under general anesthesia. In those cases of MRSA infection, a prolonged course of either vancomycin or linezolid may be required for complete eradication even after drainage.

GRANULOMATOUS LYMPHADENITIS

Although typical tuberculous cervical adenitis is very rare in the United States, atypical mycobacteria (eg, *Mycobacterium avium-intracellulare*) is encountered and may present as a nonsuppurative area (usually cervical, axillary, or inguinal) of matted nodes with tenderness and a draining sinus. Granulomatous lymphadenitis and caseation may occur in the regional nodes draining the inoculation site of BCG. Cat-scratch disease causes a caseating lymphadenitis in regional lymph nodes (eg, epitrochlear and axillary nodes enlarge after an upper extremity cat scratch).

► Clinical Findings

Children under age 6 years are most frequently affected. The initial manifestation is a painless, progressive enlargement of the lymph nodes in the deep cervical chain and the parotid, suboccipital, submandibular, and supraclavicular nodes. The duration of lymphadenopathy is usually 1-3 months or longer. The nodes may be large and mobile or, with progressive disease, may become matted, fixed, and finally caseate to form an abscess. Incision or spontaneous overlying skin breakdown will result in a chronically draining sinus. In tuberculosis, both sides of the neck or multiple groups of nodes are infected, and the chest radiograph indicates pulmonary involvement. In atypical mycobacterial lymphadenitis, pulmonary disease is rare and the cervical adenitis is unilateral. The tuberculin skin test is weakly positive in over 80% of patients with atypical mycobacterial infection. Skin test antigens from the various strains of atypical mycobacteria are available. A positive skin test helps differentiate granulomatous adenitis from malignant lymphadenopathy. A fluctuant node can be confused with a branchial cleft remnant or a thyroglossal duct cyst.

Cat-scratch disease is usually acquired by a bite or scratch from a kitten. It is caused by a pleomorphic gram-negative bacillus (*Bartonella henselae*) that is detected in tissues by a silver stain or via serologic testing. It is an acute illness characterized by fever, malaise, possible musculoskeletal manifestations and occasionally a pustular lesion at the site of the scratch. Tender lymph node enlargement usually develops. Two to 4 weeks later, regional lymphadenitis persists, producing painful, fixed suppurative nodes that may develop into a chronically draining sinus.

► Treatment

Atypical tuberculous lymphadenitis may be treated with rifampin (10 mg/kg/d), though definitive treatment usually requires nodal excision. Trimethoprim-sulfamethoxazole may shorten the course of cat-scratch disease and prevent suppuration. When antibiotics are ineffective, the procedure of choice is excision of involved nodes before caseation occurs. Once the nodes become fluctuant or a draining sinus forms, a wedge of involved skin should be excised and the underlying necrotic nodes should be curetted out (rather than excised), taking care not to injure neighboring nerves. The wound edges and skin should be closed primarily. The value of continuing chemotherapy is influenced by sensitivity tests on the cultured material. Excision and primary closure usually result in excellent healing with good cosmetic results.

CONGENITAL CHEST WALL DEFORMITIES

STERNAL CLEFT

Failure of fusion of the two sternal bars during embryonic development produces congenital sternal cleft, which may involve the upper, lower, or entire sternum. In its severe form, this defect is usually associated with protrusion of the pericardium and heart (ectopia cordis) and congenital heart lesions. Defects may be associated with extracardiac anomalies, including cleft lip, cleft palate, hydrocephalus, and other CNS disorders, or may be one component of the pentalogy of Cantrell. Operative correction is performed in the neonatal period since the chest wall is so pliable; it consists of simple suture approximation of the two sternal halves. More complex defects associated with ectopia cordis are often incompatible with life.

PECTUS EXCAVATUM

This depression deformity is the most common congenital chest wall abnormality, occurring in one in 300 live births, with a 3:1 male predominance. It is associated with other musculoskeletal disorders (Marfan syndrome, Poland syndrome, scoliosis, clubfoot, syndactyly), and 2% have congenital heart disease. There is a familial form. It results from the unbalanced posterior growth of costal cartilages that are often fused, bizarrely deformed, or rotated. The body of the sternum secondarily exhibits a prominent posterior curvature, usually involving its lower half (Figure 43–4). Commonly, the xiphoid is the deepest portion of the depression. The third, fourth, and fifth costal cartilages are usually affected, though the second to eighth costal cartilages may be involved. The severity of the defect varies greatly from a mild, insignificant depression to an extreme where the xiphoid bone is adjacent to the vertebrae. The depression may be symmetrical or asymmetrical with varying degrees of sternal rotation.

► Clinical Findings

These patients are typically round shouldered, with stooped posture, relative abdominal prominence, flared costal margins, and an asthenic appearance. They may be withdrawn and refuse to participate in sports activities, particularly if their deformity might be exposed. Few patients complain of easy fatigability or inability to compete in exertional activities. Cardiopulmonary function studies rarely demonstrate impairments; this is predominantly a cosmetic deformity with potentially severe psychosocial sequelae.

► Treatment & Prognosis

There is no standard age for repair. Undeniably, it is an easier operation in younger children compared to adolescents. Drawbacks of an early operation include a higher

▲ **Figure 43–4.** Adolescent with a pectus excavatum deformity. Note that the most pronounced sternal curvature is in the lower half.

risk of recurrence during the adolescent growth spurt and the inability of a young child to comprehend and assent to a predominantly cosmetic operation. Traditionally, an open repair (Ravitch technique) was performed in which the abnormal cartilages were resected and the sternum was fractured and fixed in a corrected position. Recently, the Ravitch technique has been supplanted by the less invasive Nuss procedure in which a preformed sternal strut is passed, either blindly or with thoracoscopic assistance, under the chest wall muscles, into each hemithorax, and across the mediastinum under the sternum via two small incisions in the midaxillary line. The curved bar is passed upside down and “flipped” into position under the sternum, effectively lifting the sternum and chest wall into a corrected position. The bar is left in place for 2 years, and the patient can resume activity in 3 months. The long-term good to excellent results of the Nuss procedure are better than 95%. The latest evolution in less invasive techniques involves placement of

▲ **Figure 43–5.** Severe pectus carinatum deformity. (Reproduced, with permission, from Shamberger R: Congenital chest wall deformities In: O’Neill JA, Rowe MI, Grostedt JL [editors]: *Pediatric Surgery*. 5th ed. Philadelphia, PA: Mosby Company;1998.)

opposing magnetic field implants to draw the chest deformity forward and effect remodeling. In general, there is no cardiopulmonary benefit after chest wall repair except in rare instances when the deformity is excessive. Otherwise, the repair is performed solely to improve appearance. However, the psychosocial benefits of repair of this often embarrassing deformity cannot be minimized.

PECTUS CARINATUM

This is a protrusion deformity, also referred to as pigeon breast or chicken chest. It is approximately ten times less frequent than pectus excavatum. It results from the overgrowth of costal cartilages, with forward buckling and secondary deformation of the sternum (Figure 43–5). Atypical and asymmetric forms with rotation are common. There is a familial form. It is associated with Marfan disease, neurofibromatosis, Poland syndrome, and Morquio disease. Unlike pectus excavatum, the deformity is typically mild or nearly imperceptible in early childhood and becomes increasingly prominent during the rapid growth in early puberty.

► Treatment & Prognosis

As with pectus excavatum, there is no cardiorespiratory compromise with this deformity, and repair is performed

solely to achieve an improved cosmetic appearance. Mild deformities should be left alone and the patient followed to observe for progression. Moderate to severe defects should be repaired, particularly when the patient indicates a desire for improvement. The deformed cartilages are resected, leaving the costochondral membranes (perichondrium) intact. Sternal fracture is usually not necessary. To ensure that the costal cartilages grow back on a straighter line, “reefing” sutures are placed in the perichondrium to shorten them. The costal cartilages regenerate within 6 weeks. A thorough procedure will provide an excellent cosmetic result in nearly all cases. Recurrences are rare. An alternative approach to operative repair is chest bracing via an orthotic vest that needs to be fitted and worn by the affected child for several hours daily over several years. This procedure may eventually replace the operative approach, particularly for those patients who are motivated to wear the brace for a majority of each day (about 16 hours).

SURGICAL RESPIRATORY EMERGENCIES IN THE NEWBORN

Certain aspects of respiration unique to the infant must be appreciated. Except during periods of crying, the newborn baby is an obligate nasal breather. The ability to breathe through the mouth may take weeks or months to acquire. Inspiration is accomplished chiefly by diaphragmatic excursion; the intercostal and accessory muscles contribute little to ventilation. Impaired inspiration results in retraction of the sternum, costal margin, and neck fossae; the resulting paradoxical motion may contribute to respiratory insufficiency. The airway is small and flaccid, so that it is readily occluded by mucus or edema, and it collapses readily under slight pressure. Dyspneic infants swallow large volumes of air, and the distended stomach and bowel may further impair diaphragmatic excursion.

► Classification

A. Upper Airway Disorders

1. Micrognathia—Pierre Robin syndrome
2. Macroglossia—Muscular hypertrophy, hypothyroidism, lymphatic malformation, Beckwith-Wiedemann syndrome

3. Anomalous nasopharyngeal passage—Choanal atresia, Treacher-Collins syndrome, Apert syndrome, and Crouzon syndrome
4. Tumors, cysts, or enlarged thyroid remnants in the pharynx or neck
5. Laryngeal or tracheal stenosis, webs, cysts, tumors, or vocal cord paralysis
6. Epiglottitis
7. Tracheomalacia
8. Tracheal stenosis with or without complete tracheal rings

B. Intrathoracic Airway Disorders

1. Atelectasis
2. Pneumothorax and pneumomediastinum
3. Pleural effusion or chylothorax
4. Pulmonary cysts, sequestration, and tumors
5. Congenital lobar emphysema
6. Diaphragmatic hernia or eventration
7. Esophageal atresia with or without tracheoesophageal fistula
8. Anomalies of the great vessels (eg, double aortic arch, aberrant left subclavian artery, anomalous origin of left pulmonary artery)
9. Mediastinal tumors and cysts (foregut duplications, thymomas, substernal goiter, lymphoma)

PIERRE ROBIN SYNDROME

Pierre Robin syndrome is a congenital defect characterized by micrognathia and glossoptosis, often associated with cleft palate. The small lower jaw and strong sucking action of the infant allow the tongue to be sucked back and occlude the laryngeal airway and may be life threatening.

Infants with mild cases should be kept in the prone position during care and feeding. A nasogastric or gastrostomy tube may be necessary for feeding. Nasohypopharyngeal intubation is effective in preventing occlusion of the larynx. If conservative measures fail, prompt attention to maintaining an open airway by tracheostomy is indicated. Surgical treatment involves tongue placation in which the tongue is sutured forward to the lower jaw, but this frequently breaks down. In time, the lower jaw develops normally. These infants eventually learn how to keep the tongue from occluding the airway.

CHOANAL ATRESIA

Complete obstruction at the posterior nares from choanal atresia may be unilateral and relatively asymptomatic. It may be membranous (10%) or bony (90%). When it is bilateral,

severe respiratory distress is manifested at birth by marked chest wall retraction on inspiration and a normal cry.

There is arching of the head and neck in an effort to breathe, and the baby is unable to eat. The diagnosis is confirmed by the inability to pass a tube through the nares to the pharynx. With the baby in a supine position, radiopaque material may be instilled into the nares and lateral x-rays of the head taken to outline the obstruction. A CT scan of the nasopharynx will define bony occlusion.

Emergency treatment consists of maintaining an oral airway by placing a nipple, with the tip cut off, in the mouth. The membranous or bony occlusion may then be perforated by direct transpalatal excision, or it may be punctured and enlarged with a Hegar dilator. The newly created opening must be stented with plastic tubing for 5 weeks to prevent stricture.

CONGENITAL TRACHEAL STENOSIS & MALACIA

There are three main types of congenital tracheal stenosis: generalized hypoplasia; funnel-like narrowing, usually tapering to a tight stenosis just above the carina; and segmental stenosis of various lengths that can occur at any level. Tracheomalacia is a functional obstruction in a “soft” trachea that collapses with inspiration. It is often secondary to external compression by vascular anomalies or tumors or from a chronically dilated upper esophageal pouch in those with esophageal atresia.

► Diagnosis

The diagnostic approach to an infant with respiratory distress and possible distal tracheal obstruction must be carefully integrated with plans for management of the airway, since the compromised infant airway is easily occluded by edema or secretions. This is especially true in distal tracheal lesions, where an endotracheal or tracheostomy tube may not relieve the distal obstruction. The diagnostic value of every procedure must be weighed against the threat of precipitating airway obstruction. Tracheal lesions can be visualized using esophagography, angiography, or CT/MRI scans. Dynamic lesions such as tracheomalacia and vascular compression syndromes are best defined by videotape fluoroscopy or cineradiography with barium in the esophagus. Angiography may be necessary. Flow-volume curves can define the level of obstruction (intrathoracic vs extrathoracic) and the type of obstruction (stenosis vs malacia).

Although bronchoscopy often provides the best delineation of tracheobronchial lesions, it is an invasive procedure that can precipitate acute obstruction from edema or inflammation. A ventilating infant rigid bronchoscope with Hopkins optics should be kept above the critical area to avoid precipitating obstruction. Flexible transnasal awake bronchoscopy is most useful in demonstrating functional abnormalities (eg, malacia).

► Treatment

Noncritical stenotic and malaciatic lesions in infants and children should be managed as conservatively as possible, preferably without intubation. “Temporary” stenting of these lesions is seldom temporary, since the presence of the tube itself ensures continued trauma and irritation such that the tube cannot be removed without airway obstruction. If an infant or child cannot be managed without intubation, surgical correction must be considered. Tracheal reconstruction via resection or a variety of tracheoplasty techniques has proved to be the treatment of choice for tracheal lesions. Severe tracheomalacia is treated by addressing the underlying cause. Aortopexy or an endotracheal stent is often necessary. Tracheostomy is a last resort.

CONGENITAL DIAPHRAGMATIC HERNIA

CDH is a highly lethal or morbid disease that affects 1 in 2000 live births (Figure 43–6). Anatomically, CDH results from an embryologic fusion defect, allowing herniation of intra-abdominal contents into the chest. Fusion of the transverse septum and pleuroperitoneal folds normally occurs during the eighth week of embryonic development. If diaphragmatic formation is incomplete, the pleuroperitoneal hiatus (foramen of Bochdalek) persists. Intestinal nonrotation is common as the bowel herniates into the thorax rather than undergoing its normal sequence of rotation and fixation. Severe defects

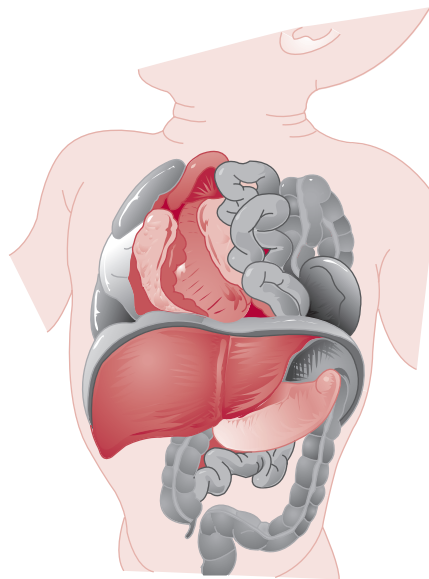

cause pulmonary hypoplasia, pulmonary hypertension, and cardiac dysfunction. The larger the hernia and the earlier it occurs, the more severe the pulmonary hypoplasia.

► Clinical Findings

A. Symptoms and Signs

Infants with large diaphragmatic defects are usually symptomatic in the delivery room, with tachypnea, grunting respirations, retractions, and cyanosis, and may require urgent intubation. Smaller defects may not become symptomatic until the infant is several days or months old. Typically, the abdomen is scaphoid since much of the abdominal viscera are in the hemithorax. The chest on the side of the hernia may be dull to percussion, but bowel sounds are not usually appreciated. The left side of the diaphragm is affected four or five times as frequently as the right, with a rate of associated anomalies of 20% (chromosomal abnormalities, neural tube defects, and congenital heart disease). When the hernia is on the left, the heart sounds may be heard best on the right side of the chest.

The development of symptoms with CDH correlates with the degree of pulmonary hypoplasia and pulmonary hypertension. Prenatal diagnosis is occurring more and more frequently and allows the mother and the fetus to be referred to an institution where sophisticated perinatal and pediatric surgical units are available.

▲ **Figure 43–6.** Congenital posterolateral (Bochdalek) diaphragmatic hernia. Bowel, spleen, and liver sometimes herniate into the chest and severely compromise lung development *in utero* and ventilation after birth.

B. Imaging Studies

A chest radiograph may demonstrate the following: a paucity of gas within the abdomen, radiopaque hemithorax if the bowel does not contain a significant amount of gas or if the left lobe of the liver occupies the majority of the hemithorax, loss of normal ipsilateral diaphragmatic contour, bowel in the thorax, contralateral mediastinal shift, and a coiled nasogastric tube in the hemithorax. Right-sided hernias can be difficult to distinguish from a diaphragmatic eventration. This can be differentiated by an MRI scan. MRI or CT scan can also distinguish between CDH and a cystic lung lesion (eg, congenital cystic adenomatoid malformation).

▶ Treatment

A nasogastric tube should be placed in the stomach to aspirate swallowed air and to prevent distention of the herniated bowel, which would further compress the lungs. Repair of the diaphragmatic defect is not a surgical emergency, it is rather a physiologic emergency requiring resuscitation, with surgery performed once the infant has stabilized and demonstrated minimal to no pulmonary hypertension. Early (before 48 hours postnatally) hernia repair has been shown to transiently worsen pulmonary function by decreasing pulmonary compliance and increasing airway reactivity. A subcostal abdominal incision should be made and the herniated bowel reduced from the pleural space. Some surgeons prefer a thoracic approach, particularly for right-sided defects. The negative pressure between the bowel and the chest wall may make reduction difficult. Following reduction of the bowel, placement of a chest tube in the pleural space is optional; if used, it is connected to a water seal and not to suction as it may cause physiologically significant mediastinal shift. The diaphragmatic defect should be closed by nonabsorbable sutures. In many instances, a synthetic material is required to close large defects. The abdominal cavity may be too small and underdeveloped to accommodate the intestine and permit closure of the abdominal wall muscle and fascial layers. In such cases, abdominal wall skin flaps should be mobilized and closed over the protruding bowel or a silo created to allow for gradual visceral reduction with concomitant abdominal domain expansion and staged closure of the abdominal wall.

Respiratory support and treatment of hypoxemia, hypercapnia, and acidosis are required before and often after repair. Persistent pulmonary hypertension may result in right-to-left shunt and produce severe hypoxemia in the lower aorta. Nitric oxide added to the ventilation gases can induce pulmonary vasodilation, improve pulmonary perfusion, and reverse the right-to-left shunt. The persistent fetal circulation physiology may be treated successfully in many cases by extracorporeal membrane oxygenation and permissive ventilatory strategies (high-frequency ventilation). Hypoxemic myocardopathy may require infusion of

dopamine to enhance cardiac output. Prenatal treatment for severe CDH (temporary fetal tracheal occlusion to promote lung growth) has been extensively studied and may offer benefit in severe cases of CDH.

▶ Prognosis

The death rate for infants with CDH depends upon the severity of pulmonary hypoplasia, the presence or absence of associated anomalies, and the quality of care provided for these critically ill infants. When diagnosed *in utero*, prognosis depends on the presence or absence of liver herniation into the left hemithorax, the gestational age at diagnosis, and an ultrasonographic estimation of lung size (the lung-to-head ratio). Long-term, there are a number of measurable physiologic abnormalities that are not necessarily clinically significant such as a reduction in total lung volume, restrictive or obstructive lung disease, and abnormal lung compliance. However, a small subset of patients will survive as “pulmonary cripples” and remain oxygen dependent or ventilator dependent, often requiring tracheostomies. Since there may be deficient periesophageal muscular tissue or an abnormal orientation of the gastroesophageal junction, GER is common. It is most commonly treated nonoperatively, but refractory cases may require a surgical antireflux procedure. Recurrent diaphragmatic hernia occurs in 10%-20% of infants and should be considered in any child with a history of CDH who presents with new GI or pulmonary symptoms. Recurrence is most common when a prosthetic patch is used for the repair.

Surgical units that are immediately adjacent to obstetric services report death rates as high as 80%, because infants with severe pulmonary hypoplasia will be recognized and treated immediately. Infants who survive transfer to surgical centers remote from the delivery area usually have less severe disease, and the death rates reported from these facilities are usually under 40%.

With improvements in prenatal ultrasonographic imaging, many of these defects can be appreciated early enough so that planned delivery at a tertiary facility is possible. Excluding those infants with severe associated anomalies, the overall survival rate using maximal medical therapy has been increasing over the past several years due to advanced ventilation strategies and is well over 70%.

FORAMEN OF MORGAGNI HERNIA

The foramen of Morgagni occurs at the junction of the septum transversum and the anterior thoracic wall. This anterior, central diaphragmatic defect accounts for only 2% of diaphragmatic hernias. It may be parasternal, retrosternal, or bilateral. Unlike Bochdalek hernias, children are typically asymptomatic and the defect is discovered later in life on a chest radiograph taken for reasons unrelated to the hernia. The lateral chest radiograph demonstrating an air-filled

mass extending into the anterior mediastinum is pathognomonic. Repair is indicated in the asymptomatic patient due to the risk of bowel obstruction. The viscera are reduced and any associated hernia sac excised. The defect is closed by suturing the posterior rim of diaphragm to the posterior rectus sheath since there is no anterior diaphragm. A prosthetic patch closure is frequently required given the tension that results with native tissue repairs given the absence of anterior diaphragm. Laparoscopic approaches to this type of repair are increasingly being performed. There is no associated pulmonary hypoplasia or hypertension. This defect, when noted in newborns, can be associated with the pentalogy of Cantrell, a disorder with considerable morbidity and mortality that consists of the anterior diaphragmatic defect, distal sternal cleft, epigastric omphalocele, apical pericardial defect, and congenital heart disease (usually a septal defect). Excluding patients with the pentalogy of Cantrell, survival is nearly 100%.

EVENTRATION OF THE DIAPHRAGM

Diaphragmatic eventration is an abnormally elevated or attenuated portion of the diaphragm (or both). It may be congenital (usually idiopathic, but can be associated with congenital myopathies or intrauterine infections) or acquired (as a result of phrenic nerve injury during forceps delivery or surgery). In the congenital form, there is variable thinning or absence of diaphragmatic muscle, at which point its distinction from CDH with a persistent hernia sac is obscure. The elevated hemidiaphragm may produce abnormalities of chest wall mechanics with impaired pulmonary function. Respiratory distress and pneumonia are frequent presenting symptoms, although GI symptoms such as vomiting or gastric volvulus have been reported.

The diagnosis is made by chest radiograph. It is confirmed by fluoroscopy or ultrasound, which demonstrate paradoxical movement of the diaphragm during spontaneous respiration. Incidentally discovered small, localized eventrations do not need repair. Eventrations that are associated with respiratory symptoms should be repaired by plicating the diaphragm using interrupted nonabsorbable sutures.

CONGENITAL LOBAR EMPHYSEMA

Congenital lobar emphysema results from hyperinflation of a single lobe; rarely, more than one lobe is affected. The upper and middle lobes are most frequently involved. Pathologically, there are three forms; hypoplastic emphysema, polyalveolar lobe, and bronchial obstruction.

Hypoplastic emphysema is distinguished by a segment, lobe, or whole lung that has a reduced number of bronchial branches with a diminished number and smaller size of blood vessels. The number of alveoli is abnormally decreased, but the air spaces are too large. The hyperlucent region seen on chest radiograph is normal or small in volume, and since it does not affect the surrounding normal lung, surgical treatment is unnecessary.

Poyalveolar lobe is characterized by a normal size and number of bronchial branches, but there is an abnormal number of alveoli from each respiratory unit. These alveoli are prone to expand excessively, producing emphysema, which encroaches on the surrounding normal lung and therefore requires removal.

Bronchial obstruction may occur from deficient bronchial cartilage support, redundant mucosa, bronchial stenosis, mucous plug, or bronchial compression by anomalous vessels or other mediastinal lesions. With inspiration, the bronchus opens to allow air into the lung, but on expiration the bronchus collapses, trapping the air, and with each respiratory cycle there is progressive expansion of the lobe.

► Clinical Findings

In one-third of patients, respiratory distress is noted at birth; in only 5% of cases do symptoms develop after 6 months. Males are affected twice as frequently as females. The signs include progressive and severe dyspnea, wheezing, grunting, coughing, cyanosis, and difficulty feeding. An increased anteroposterior dimension of the chest and retractions may be seen. The chest is hyperresonant, and decreased breath sounds may be noted over the affected lobe. A chest radiograph may demonstrate radiolucency of the emphysematous lobe, with bronchovascular markings extending to the lung periphery. Compression atelectasis of the adjacent lung, shift of the mediastinum, depression of the diaphragm, and anterior bowing of the sternum can be seen. The emphysematous lobe may continue to expand, compressing adjacent lung and airways, producing progressively severe respiratory distress.

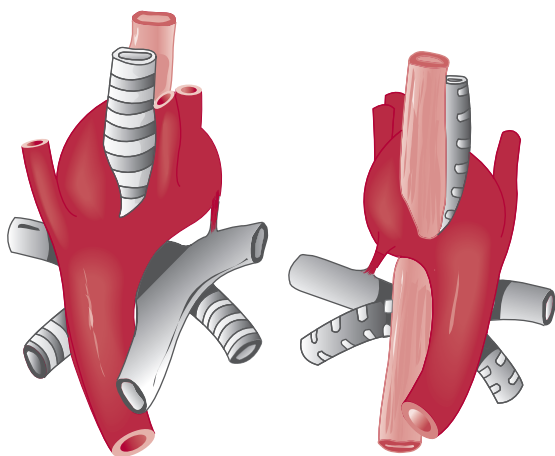

► Treatment & Prognosis

Occasionally, the emphysema may be due to a foreign body or mucous plug in the bronchus that may be aspirated by bronchoscopy. Compression of the bronchus by mediastinal masses may be relieved by removal of the tumor or repair of anomalous vessels.

Treatment of asymptomatic and mildly symptomatic cases may not be necessary. Many patients with lobar emphysema, however, are severely symptomatic, and pulmonary lobectomy is necessary. For those who are breathing spontaneously prior to operation, anesthesia should not be started until all personnel are ready for a rapid thoracotomy since positive-pressure ventilation may acutely enlarge the emphysematous lobe, thereby compressing the normal lung tissue and heart. The prognosis following surgical relief of the lobar emphysema is excellent. Rarely patients may show residual disease in the remaining lung. At long-term follow-up, lung volumes are normal, but the airflow rates are diminished.

GREAT VESSEL ANOMALIES

Tracheobronchial and esophageal compression by the great vessels may occur as a result of anomalies of the aortic arch or of abnormally located or enlarged pulmonary and subclavian arteries. While the most common abnormality is an aberrant right subclavian artery, the most important is the double aortic arch, as it often causes serious respiratory distress in young infants (Figure 43-7). Affected infants have a characteristic inspiratory and expiratory wheeze, stridor, or croup-like cough. Echocardiography, CT, and MRI can demonstrate the anomalous anatomy. Esophagoscopy and bronchoscopy may be helpful in assessing the degree and level of compression. The surgical approach is through the left hemithorax. Following removal of the thymus, the aortic arch and its branches are skeletonized and the anatomy is identified. For the double aortic arch, the smallest arterial component is divided; an anomalous right subclavian artery

▲ **Figure 43-7.** Anterior (left) and posterior views of double aortic arch constricting the trachea and esophagus.

is divided at its origin. The accompanying fibrous bands and sheaths constricting the trachea and esophagus must also be divided. The ductus arteriosus (or its fibrous remnant) is also divided.

MEDIASTINAL MASSES

Mediastinal masses are relatively common in infants and children and can be classified according to the compartment of the mediastinum from which they arise. The mediastinum is classically divided into anterior, middle, and posterior compartments. Anatomically, the anterior mediastinum consists of the area between the sternum and the anterior aspect of the trachea and pericardium. The middle compartment contains the trachea, major bronchi, and paratracheal spaces. The posterior segment extends from the posterior aspect of the trachea to the spine.

Anterior masses make up one-third and are most commonly teratomas and lymphomas. Teratomas may be cystic or solid and may also be found within the pericardium (middle compartment). Approximately 20% are malignant. Other masses include thymic cysts, thymomas, substernal goiters, and lymphangiomas. Middle mediastinal masses are rare but when present are most likely to be bronchogenic cysts. Sixty percent of mediastinal masses are located within the posterior compartment. Neurogenic tumors are most common and include neuroblastoma, ganglioneuroblastoma, ganglioneuroma, neurofibroma, and neurofibrosarcoma. Common symptoms include respiratory distress (via tracheal or lung compression), Horner syndrome, and pain. Enterogenous cysts or duplications are also commonly seen in the posterior compartment. They are termed neurenteric when there is an associated cervical or thoracic vertebral anomaly.

CONGENITAL LUNG LESIONS

Congenital lung lesions, which arise from anomalous development of the foregut, are classified as follows: (1) bronchogenic cyst, (2) congenital pulmonary airway malformation (CPAM), (3) pulmonary sequestration, and (4) bronchopulmonary foregut malformation. Embryonic tissues that are destined to form bronchi and lung become anomalous isolated structures within or outside of the lung. These lesions produce symptoms from their size and position, resulting in compression of bronchi or lung parenchyma, or from infection and abscess formation within the cyst and surrounding normal lung. There is a growing number of congenital lung lesions being diagnosed due to improvements in prenatal imaging. Most lesions warrant a postnatal CT angiogram to determine the anatomic location of the lesion and the presence of systemic feeding vessels.

BRONCHOGENIC CYST

Bronchogenic cysts are lined by cuboidal or ciliated columnar epithelium and are filled with mucoid material. Repeated infection in the cyst may produce squamous epithelial metaplasia. About half arise in the mediastinum and do not communicate with the bronchi. They appear as radiopaque masses on chest radiographs. When located within the lung parenchyma, the cysts usually communicate with the airways and consequently are prone to abscess formation. Bronchogenic cysts arise in the right lung three times more often than in the left. They are more common in the lower lobes but may be found in any lobe. Partial compression of bronchi produces hyperinflation of the involved lung, while complete obstruction produces atelectasis. Rupture of a cyst that communicates with bronchi may present as a tension pneumothorax. Treatment of a noninfected cyst is by excision. Infected cysts first require drainage (usually percutaneous) and intravenous antibiotic therapy followed by resection after the inflammation subsides (no sooner than 6 weeks after drainage).

CONGENITAL PULMONARY AIRWAY MALFORMATION

This lesion is a multicystic lung mass resulting from proliferation of terminal bronchiolar structures. It is typically lined by a polypoid proliferation of bronchial epithelium surrounded by striated muscle and elastic tissue, but there is an absence of mucous glands and cartilage. They are most often lobar and are classified radiologically based on cyst size: type I are large (> 2 cm) cysts, type II are smaller cysts (< 2 cm), and type III have cysts that are so small as to impart a solid appearance. These malformations occur with equal frequency in both lungs, with a slight predominance in the upper lobes. Associated renal and nervous system anomalies may be present.

► Clinical Findings

A large lesion can compress the fetal lung, resulting in pulmonary hypoplasia at birth, or may distort or obstruct the esophagus, producing polyhydramnios. In addition, compression of venous return to the heart with exudation of protein into the lung fluid may cause fetal congestive heart failure, hydrops fetalis, and death *in utero*. Large lesions that do not cause fetal hydrops can remain stable or involute during fetal life, producing little or no symptoms of respiratory distress at birth.

► Treatment

If prenatal ultrasound can recognize the presence of this disorder in association with hydrops, resection *in utero* is an option for select cases. Steroids have recently shown promise in the prenatal treatment of CPAM with hydrops. Children

in whom hydrops did not occur before birth may be born asymptomatic (small lesions) or may have variable degrees of respiratory distress due to compression of the ipsilateral normal lung. Asymptomatic children may be observed, but resection (pulmonary lobectomy) is recommended since these lesions often become infected and there are case reports of malignant transformation occurring in untreated, long-standing cysts. Often the plain chest radiograph does not demonstrate the small, asymptomatic lesion.

PULMONARY SEQUESTRATION & BRONCHOPULMONARY FOREGUT MALFORMATION

A sequestration consists of normally developed bronchioles and alveoli supplied by systemic rather than pulmonary arteries. Sequestrations occur in the lower chest, most commonly on the left, adjacent to the mediastinum. Rarely, sequestrations may occur in the upper or middle lobes or even below the diaphragm. They usually have a systemic arterial blood supply from the aorta, either above or below the diaphragm. On rare occasions, a sequestration will communicate with the esophagus or stomach, a condition termed bronchopulmonary foregut malformation. Sequestrations may be intralobar or extralobar. Intralobar lesions drain through the pulmonary veins, are in communication with the tracheobronchial tree, and are prone to infection and lung abscess formation. Extralobar lesions drain into the azygous venous system, do not communicate with the lung, and are commonly asymptomatic. They are often found in association with CDH. Histologic evidence suggests that these lesions have embryologic origin similar to that of bronchogenic cysts and congenital cystic adenomatoid malformations. However, unlike the latter, sequestrations rarely grow large enough to produce hydrops and demise *in utero*. Treatment is by excision of the extralobar sequestration or lobectomy in cases of intralobar sequestration.

CONGENITAL GASTROINTESTINAL LESIONS

ESOPHAGEAL ANOMALIES

The trachea and esophagus are derived from the primitive foregut. Initially, they appear as a common ventral diverticulum at about the nineteenth day of gestation.

▲ **Figure 43-8.** **A:** Pure (long gap) esophageal atresia. **B:** Esophageal atresia with proximal tracheoesophageal fistula. **C:** Esophageal atresia with distal tracheoesophageal fistula. **D:** Esophageal atresia with proximal and distal fistulas. **E:** Tracheoesophageal fistula without esophageal atresia. (Reproduced, with permission, from Grosfeld JL: *Pediatric surgery*. In: Sabiston DC, ed. *Textbook of Surgery*. Philadelphia, PA: Saunders; 1991.)

Beginning several days later, elongation and separation of the diverticulum into the airway and esophagus occurs in a caudal to cephalad direction. Errors in this process result in esophageal atresia, tracheoesophageal fistula, and their variants (Figure 43-8).

► Classification

A. With Esophageal Atresia

1. There is a blind proximal pouch and a fistula between the distal end of the esophagus and the distal one-third of the trachea (type C, 85% of cases).
2. There is a blind proximal esophageal pouch, no tracheoesophageal fistula, and a blind, short distal esophagus (type A, 10% of cases). This is referred to as “pure or long gap” atresia.
3. There are fistulas between both proximal and distal esophageal segments and the trachea (type D, 2% of cases).
4. There is a fistula between the proximal esophagus and the trachea and a blind distal esophagus without fistula (type B, 1% of cases).

B. Without Esophageal Atresia

1. There is an “H”-type tracheoesophageal fistula that is usually present in the low cervical region (type E, 4%-5% of cases).
2. There is esophageal stenosis consisting of a membranous occlusion (often containing cartilage) between the mid and distal third of the esophagus (rare).

3. There is a laryngotracheoesophageal cleft of varying length, consisting of a linear communication between these structures (very rare).

► Clinical Findings

Shortly after birth, the infant with esophageal atresia is noted to have excessive salivation and repeated episodes of coughing, choking, and cyanosis. Attempts at feeding result in choking, gagging, and regurgitation. Infants with tracheoesophageal fistula in addition to esophageal atresia will have reflux of gastric secretions into the tracheobronchial tree, with resulting pneumonia. Pulmonary infiltrates are usually noted first in the right upper lobe. Diagnosis may be delayed (several months) in cases of H-type tracheoesophageal fistula who are able to feed but may present with recurrent respiratory infections due to aspiration.

A size 10F catheter should be passed into the esophagus by way of the nose or mouth; if esophageal atresia is present, the tube will not go down the expected distance to the stomach and will coil in the upper esophageal pouch. If a tracheoesophageal fistula connects to the lower esophageal segment, air will be present in the stomach and bowel on plain radiographs. Absence of air below the diaphragm usually means that a distal tracheoesophageal fistula is not present.

Abdominal distention is a prominent finding because the Valsalva effect of coughing and crying forces air through a fistula into the stomach and bowel. The presence and position of the fistula can be determined by bronchoscopy.

Laryngotracheoesophageal cleft produces symptoms similar to those of tracheoesophageal fistula but of much greater severity. Laryngoscopy may show the cleft between

the arytenoids extending down the larynx. Bronchoscopy is the best means of outlining the cleft.

There is a 50% incidence of associated anomalies: cardiac (patent ductus arteriosus, septal defects), GI (imperforate anus, duodenal atresia), genitourinary, and skeletal. The VACTERL association (vertebral, anorectal, cardiac, tracheoesophageal, renal, and limb anomalies) is present in 25% of cases. Isolated esophageal atresia has been associated with various genetic abnormalities, including trisomy 18 and trisomy 21. Echocardiogram, renal ultrasound, anorectal exam and genetic testing should be considered in the workup of all patients with TEF.

► Treatment

A sump suction catheter should be placed in the upper esophageal pouch and the head of the bed elevated. An echocardiogram is required to determine the position of the aortic arch since a right-sided arch makes the standard right thoracotomy (or thoracoscopic) repair difficult and is present in 5% of infants. If possible, aspiration pneumonia is treated before repair.

The goal of operative therapy is to divide and ligate the fistula and repair the atresia in one stage, if possible. This is usually performed using a right posterolateral thoracotomy with an extrapleural dissection, although a transpleural thoracoscopic approach is gaining popularity for those stable, full-term infants. Also, thoracoscopic approaches are gaining acceptance as minimal invasive techniques continue to evolve. In those with an H-type tracheoesophageal fistula, the fistula is located above the thoracic inlet in two-thirds of cases. These fistulas may be divided through a left transverse cervical incision. A feeding gastrostomy tube is no longer routinely inserted except when the esophageal repair is under extreme tension, when there is long gap atresia not amenable to single-stage repair, and when there are severe associated anomalies (eg, congenital heart disease). A transanastomotic feeding tube is placed for postoperative feeding pending demonstration of a leak-free anastomosis by esophagogram obtained 7 days after surgery.

Staged operations are reserved for extremely premature babies, those who have severe aspiration pneumonitis, and those with severe anomalies or long gaps between the esophageal pouches. There are several strategies for repairing these defects. These include cervical esophagostomy, division of the fistula, and insertion of a gastrostomy tube. Several months later a staged reconstruction by esophageal replacement with colon or stomach interposition can be undertaken. Another alternative is a gastrostomy tube alone with intermittent bougienage and stretching of the upper esophageal pouch, followed by primary esophageal anastomosis and immediate interposition grafting.

Esophageal narrowing or webs in the distal esophageal segment readily respond to esophageal dilation. This is usually

accomplished with Hurst or Maloney bougies. Dilations are repeated until healing occurs without recurrence of the web. Esophagoscopy and excision of portions of a tough or thick web, using biopsy forceps or the endoscopic laser, may be required in addition to dilation. A lower esophageal stricture containing cartilage requires excision and anastomosis.

► Prognosis

The survival rate for a full-term infant without associated anomalies is excellent. However, deaths occur as a result of pulmonary complications, severe associated anomalies, prematurity, and sepsis due to anastomotic disruption. Anastomotic leaks occur because of tension or poor blood supply. In performing the anastomosis, the extrapleural approach prevents the development of empyema and confines a leak and possible infection to a small localized area.

Swallowing is a reflex response that must be reinforced early in infancy. If establishment of esophageal continuity is delayed for more than 4-6 weeks, it may take many months to overcome oral aversion and learn to swallow. Babies with cervical esophagostomies should be encouraged to suck, eat, and swallow during gastrostomy feedings.

Dysphagia may occur for months or years following successful repair of esophageal atresia and is multifactorial. An anastomotic stricture is not uncommon and may require one or more dilations under anesthesia. Swallowed foreign bodies will lodge at the site of anastomosis and require removal with esophagoscopy. Another cause of dysphagia is poor peristalsis of the distal esophageal segment. This frequent problem improves with age.

Most of these infants have an alarming, barking cough and rattling sound on respiration from tracheomalacia. This results from *in utero* compression of the trachea by the dilated proximal esophageal pouch. This frequently improves with age and is rare after 5 years of age. GER is common after successful repair and may result in recurrent aspiration pneumonitis, dysphagia, failure to thrive, and recurrent anastomotic stricture. Medical therapy with an H₂-blocker or proton pump inhibitor should be instituted in all patients after repair and a surgical antireflux procedure may be necessary if medical therapy fails.

INTESTINAL OBSTRUCTION IN THE NEWBORN

Since fetuses continually swallow amniotic fluid into their GI tracts and excrete it in their urine, intestinal obstruction may be noted on prenatal ultrasound by the presence of polyhydramnios (increased amniotic fluid level). The presence of polyhydramnios correlates with the level of

the obstruction; it is most common with proximal GI tract obstruction (eg, esophageal and duodenal atresia), is rarely noted with ileal atresia, and is never noted in association with anorectal obstruction.

After birth, vomiting is the principal symptom, and it is bile stained if the obstruction is distal to the ampulla of Vater. It is important to note that bilious vomiting in the newborn is pathologic until proved otherwise. On physical examination, the presence and degree of abdominal distention depends on the level of the obstruction and should be noted. For example, there is no significant distention with duodenal obstruction versus massive distention with colonic obstruction (eg, Hirschsprung disease). A careful perineal examination should be performed to determine whether the anus is present, patent, and in the normal location. Meconium, the first newborn stool, passes in the first 24 hours of life in 94% of normal full-term infants and by 48 hours in 98%. Failure to pass meconium may be indicative of lower GI tract obstruction. However, 30%-50% of newborn infants with intestinal obstruction will pass meconium.

Depending on the pathology, the plain abdominal radiograph may demonstrate dilated bowel loops, air-fluid levels, calcifications (if *in utero* perforation occurred), or a gasless abdomen. Unlike in adult patients, one cannot differentiate small from large bowel by their usual markings on a plain radiograph of the newborn's abdomen. If a lower GI tract obstruction is suspected, a contrast (usually water-soluble contrast) enema is the most useful study since it can be both diagnostic and therapeutic in the majority of cases (see below). An upper GI series is rarely indicated unless malrotation is to be ruled out. The CT, MRI, or ultrasound scans are virtually never indicated in the workup of newborn intestinal obstruction.

HYPERTROPHIC PYLORIC STENOSIS

Pyloric stenosis is the most common surgical disorder producing emesis in infancy. It results from hypertrophy of the circular and longitudinal muscularis of the pylorus and the distal antrum of the stomach with progressive narrowing of the pyloric canal (Figure 43-9). The cause is not known. The male:female incidence is 4:1. The disorder is more common in firstborn infants and occurs four times more often in the offspring of mothers who had the disease as infants than in those whose fathers had the disease. If one monozygotic twin is affected, the other will also have the disorder in two-thirds of cases. A seasonal variation is noted in the occurrence of symptoms, with peaks in spring and fall.

► Clinical Findings

A. Symptoms and Signs

Typically, the affected infant is full term when born and feeds and grows well until 2-4 weeks after birth, at which

▲ **Figure 43-9.** Hypertrophic pyloric stenosis. Note that the distal end of the hypertrophic muscle protrudes into the duodenum (arrow), accounting for the ease of perforation into the duodenum during pyloromyotomy.

time occasional regurgitation of some of the feedings occurs. Several days later, however, the vomiting becomes more frequent and forceful. The vomitus contains the previous feeding and no bile. Blood may be seen in the vomitus in 5% of cases, and coffee grounds or occult blood is frequently present. Shortly after vomiting, the infant acts starved and will feed again. The stools become infrequent and firm in consistency as dehydration occurs. With dehydration, infants often have sunken fontanelles, dry mucous membranes, and poor skin turgor. Weight loss follows progressive feeding intolerance. Jaundice with indirect hyperbilirubinemia occurs in fewer than 10% of cases. Gastric peristaltic waves can usually be seen moving from the left costal margin to the area of the pylorus. In over 90% of cases, the pyloric “tumor,” or “olive,” can be palpated when the infant is relaxed. Abdominal relaxation may be accomplished by sedating the infant or by feeding clear fluids and simultaneously aspirating the stomach contents with a gastric tube.

B. Imaging Studies

An imaging study is indicated when the pyloric tumor cannot be palpated. Abdominal ultrasound, the most sensitive and specific test, will identify hypertrophic pyloric stenosis when the muscle thickness is greater than 4 mm and the length of the pylorus is greater than 16 mm. A dynamic ultrasound may also show no passage of ingested fluid. A contrast upper GI series is indicated if an experienced ultrasonographer is unavailable or if there is a reasonable chance that the patient's symptoms are not due to pyloric stenosis (eg, a premature, 1-week-old baby) since this examination can demonstrate other entities in the differential. A positive upper GI series can include the following diagnostic signs: (1) outlining of the narrow pyloric channel by a single “string sign” or “double track” owing to folds of mucosa; (2) a pyloric “beak” where the pyloric entrance from the

antrum occurs; (3) the “shoulder” sign, in which the pyloric mass bulges into the antrum; and (4) complete obstruction of the pylorus.

► Differential Diagnosis

Repeated nonbilious vomiting in early infancy may be due to overfeeding, intracranial lesions, pylorospasm, antral web, GER, pyloric duplication, duodenal stenosis, malrotation of the bowel, or adrenal insufficiency.

► Complications

Repeated vomiting with inadequate intake of formula results in hypokalemic hypochloremic alkalosis, dehydration, and starvation. Gastritis and reflux esophagitis occur frequently. Aspiration of vomitus may produce pneumonia.

► Treatment & Prognosis

The operative treatment is the Fredet-Ramstedt pyloromyotomy, in which the pylorus is incised along its entire length, spread widely exposing but not breaching the underlying mucosa. Surgery should be undertaken only after dehydration and the hypokalemic hypochloremic alkalosis have been corrected, heralded by a normal serum chloride (which is a proxy for a normal serum bicarbonate) as well as a urine output greater than 1 cc/kg/h. There are three approaches to the pyloromyotomy: a right upper quadrant transverse skin incision, a circumumbilical or intraumbilical skin incision, or a laparoscopic approach with the telescope in the umbilicus and the two working instruments placed directly through the abdominal wall. The laparoscopic approach offers advantages in postoperative recovery with equivalent outcomes in experienced hands. Successful myotomy is evident when the submucosa is seen to herniate out of the myotomy site. If, during the pyloromyotomy, the mucosa is inadvertently entered (usually on the duodenal side), it is closed with fine nonabsorbable sutures and an omental patch is placed. Large perforations are managed by closing the pyloromyotomy, rotating the pylorus 90 degrees, and repeating the myotomy.

Multiple postoperative feeding schedules have been described, ranging from immediate full feeds to delayed feeds with incremental advances in volume. This has stemmed from the observation that nearly all patients with pyloric stenosis vomit after surgery, presumably due to gastric ileus, gastritis, GER, or all of the above. An incomplete pyloromyotomy (usually on the antral side) is suspected when vomiting persists beyond 1-2 weeks postoperatively and stems from a short myotomy or incomplete division of the muscle. Incomplete myotomy should be evaluated by upper GI series as ultrasound will likely show ongoing hypertrophy.

Pyloric stenosis never recurs, and there is a uniformly excellent outcome.

CONGENITAL DUODENAL OBSTRUCTION

The various causes of duodenal obstruction are atresia, stenosis, mucosal web (complete or variably perforate), annular pancreas, preduodenal portal vein, and peritoneal bands (Ladd bands) from malrotation. Duodenal atresia is distinguished from more distal GI atresias since it is due to failure of recanalization of the duodenum early in gestation rather than due to mesenteric vascular abnormality late in gestation. Atresia of the duodenum is twice as common as in the jejunum or ileum. In about half of cases, multiple congenital anomalies are present, including Down syndrome in 30% and congenital heart disease in 20%. Birth weight is less than 2500 g in half of these infants. Mucosal webs or stenoses occur as often as pure atresia. Annular pancreas is almost always associated with hypoplasia of the duodenum at the level of the ampulla. The cause is a developmental defect characterized by circumferential persistence of the gland around the duodenum at the site of the embryonic ventral anlage, leading to duodenal obstruction and an accessory pancreatic duct.

► Clinical Findings

In 75% of cases, duodenal obstruction occurs distal to the ampulla of Vater, causing bile to be diverted to the proximal duodenum and stomach. Bilious emesis occurs shortly after birth and during attempted feedings. The upper abdomen is rarely distended. Meconium is passed in over 50% of cases.

The plain abdominal radiograph demonstrates an air-distended stomach and duodenum (“double bubble” sign). Gas in the small and large intestine indicates incomplete obstruction. Contrast upper GI series is used to identify the presence or absence of malrotation in those cases with incomplete obstruction since obstruction from intestinal malrotation is a surgical emergency.

► Treatment

Surgery is performed using a right upper transverse abdominal incision or via laparoscopy. A Kocher maneuver should be performed, with complete mobilization of the third and fourth portions of the duodenum. Obstruction from Ladd bands requires simple division of the bands and correction of the malrotation (see below). Duodenoduodenostomy is performed for duodenal atresia and annular pancreas. A

mucosal web can be excised if technically feasible, taking care to avoid injury to the adjacent ampulla. Commonly, the duodenum is hugely dilated above the obstruction, which results in impaired aboral progression of ingested feedings. This problem is resolved by excision or plication of a portion of the antimesenteric wall of the bowel to normalize the lumen diameter (tapered duodenoplasty). Gastrojejunostomy should not be done because the blind duodenal pouch may cause repeated vomiting. The distal bowel should be irrigated and assessed for associated intrinsic obstruction if possible. However, the rate of associated distal atresia is low (0.5%-3% incidence) and most commonly seen in conjunction with an “apple peel” deformity). Mortality is related to prematurity and associated anomalies.

ATRESIA & STENOSIS OF THE JEJUNUM, ILEUM, & COLON

Atresia and stenosis of the jejunum, ileum, and colon are caused by a mesenteric vascular accident *in utero*, which may result from hernia, volvulus, or intussusception, producing aseptic necrosis and resorption of the necrotic bowel. Although atresia may occur in any portion of the intestine, most cases occur in the distal ileum or proximal jejunum. Colonic atresia is very rare, accounting for no more than 1% of all intestinal atresias. A short area of necrosis may produce only stenosis or a membranous web occluding the lumen (type I) (Figure 43–10). A more extensive infarct may leave a fibrous cord between the two bowel loops (type II), or the proximal and distal bowel may be completely separated with a V-shaped defect in the mesentery (type IIIa). Multiple atresias occur in 10% of cases (type IV). A type III variant (type IIIb) is commonly called apple-peel or Christmas tree atresia, in which there is a blind-ending proximal jejunum, absence of a long length of mid small bowel, and a terminal ileum coiled around its tenuous blood supply from an ileocolic vessel.

► Clinical Findings

Vomiting of bile, abdominal distention, and failure to pass meconium indicate intestinal obstruction. The plain abdominal radiograph will give an estimate of how far along the intestine the obstruction exists. A contrast enema may be

▲ **Figure 43–10.** The anatomic spectrum of intestinal atresia. Type I is a stenosis or mucosal web. Type II, a fibrous cord between two bowel ends. Type IIIa, blind-ending proximal and distal bowel loops with a V-shaped mesenteric defect. Type IIIb (apple peel deformity, Christmas tree deformity) consists of a blind ending proximal jejunum, absence of a large portion of the midgut, and a terminal ileum that is coiled around its ileocolic blood supply. Type IV, multiple atresias of any kind. (Reproduced, with permission, from Grosfeld JL et al: Operative management of intestinal atresia based on pathologic findings. *J Pediatr Surg*. 1979 June;14(3):368–375.)

indicated to detect the level of obstruction. In obstructions that occur in the distal bowel and appear relatively early in gestation, the colon is empty of meconium and appears abnormally narrow (microcolon). When the obstruction is proximal or when it occurs late in pregnancy, meconium is passed into the colon. The contrast enema will then outline a more generous-sized colon with its contents (meconium). In older children with evidence of partial intestinal obstruction, a small bowel series may be indicated to identify intestinal stenosis.

► Treatment

There are three main goals of operation: (1) to restore the continuity of the bowel; (2) to preserve as much intestinal length as possible; and (3) to retain the ileocecal valve if possible (the minimum length of bowel needed to sustain full enteral nutrition doubles in the absence of the ileocecal valve). A transverse upper abdominal incision is preferred.

Infants with jejunal or ileal atresia usually have a segment of the proximal bowel adjacent to the atresia that is dilated out of proportion to the rest of the proximal bowel. This is referred to as the “club” and it lacks normal peristaltic activity. If left in or not tapered, it may become a source of persistent functional obstruction. It is tapered when it is a very proximal bowel segment, near the ligament of Treitz; otherwise it should be resected. A great discrepancy between the diameter of the segments of intestine proximal and distal to the atresia is the rule. Atresia of the proximal colon should be treated by resection of the dilated bowel and ileocolostomy. Atresia of the distal colon may be treated by proximal end colostomy or by a side-to-side colostomy. Later, the continuity of the distal colon may be established by end-to-end anastomosis.

Infants born with extensive small bowel loss may benefit from a Bianchi procedure, where the entire greatly dilated bowel is divided longitudinally into two lengths of bowel. An alternative bowel lengthening procedure termed the STEP (serial transverse enteroplasty procedure) is quickly gaining acceptance as the procedure of choice for gaining length from dilated and shortened intestine. The end of the jejunum in continuity with the duodenum is anastomosed to the proximal end of the divided bowel.

In contrast to duodenal atresia, associated anomalies are unusual in small bowel and colon atresia. Following repair, return of GI function can be prolonged and feeds should be introduced accordingly.

DISORDERS OF INTESTINAL ROTATION

The fetal intestine begins as a somewhat straight tube that grows faster than the abdominal cavity and thus herniates out into the body stalk (future umbilicus) at about 4-6 weeks' gestation. At 10-12 weeks, the bowel returns to the abdominal cavity, rotates, and becomes fixed to the retroperitoneum along a long diagonal axis extending from the level of the left of the T12 vertebra to the level of the right of the L5 vertebra. The duodenojejunal portion of gut rotates posterior (counterclockwise) to the superior mesenteric vessels for 270 degrees and becomes fixed at the ligament of Treitz and located to the left of and cephalad to the superior mesenteric artery. The cecocolic portion of the midgut also rotates 270 degrees, but clockwise (anterior) to the superior mesenteric artery. The cecum becomes fixed in the right lower abdomen (L5 level).

► Classification

Anomalies of rotation and fixation are twice as common in males as in females. They may be classified as (1) nonrotation, (2) incomplete rotation, (3) reversed rotation, and (4) anomalous fixation of the mesentery.

A. Nonrotation

With nonrotation, the midgut is suspended from the superior mesenteric vessels; the small bowel is located predominantly on the right side of the abdomen and the large bowel in the left abdomen. No fixation occurs, and adhesive bands are not present. This is the fetal anatomy prior to 10 weeks' gestation. Because its base is so short, the mesentery is narrow, which predisposes to volvulus, with clockwise twisting of the bowel about the superior mesenteric vessels. This anomaly is usually found in patients with omphalocele, gastroschisis, and CDH.

B. Incomplete Rotation

Incomplete rotation (commonly called malrotation) may affect the duodenojejunal segment, the cecocolic segment, or both. Adhesive bands (Ladd bands) are usually present. In the most common form, the cecum stops rotating and fixes near the origin of the superior mesenteric vessels, and dense peritoneal bands extend from the right flank to the cecum and obstruct the second or third portion of the duodenum or other segments of the small bowel. The duodenojejunal segment also only partially rotates, usually stopping at or to the right of the vertebral bodies. The intestinal mesentery is fixed posteriorly, but is very narrow, only extending the distance between the cecum and the duodenojejunal segment. This predisposes to volvulus (Figure 43-11).

C. Reversed Rotation

In reversed rotation, the bowel rotates varying degrees in a clockwise direction about the superior mesenteric axis. The duodenojejunal loop is anterior to the superior mesenteric artery. The cecocolic loop may be prearterial or may be rotated clockwise or counterclockwise in a retroarterial position. In either case, the cecum may be right sided or left sided. The most frequent anomaly is retroarterial clockwise rotation, which causes obstruction of the right colon.

D. Anomalous Fixation of Mesentery

Anomalies of mesenteric fixation account for internal mesenteric and paraduodenal hernias, a mobile cecum, or obstructing adhesive bands in the absence of anomalous bowel rotation. Excessive rotation of the duodenojejunal junction may result in superior mesenteric artery compression of the third portion of the duodenum.

▲ **Figure 43–11.** Malrotation of the midgut with volvulus. Note cecum at the origin of the superior mesenteric vessels. Fibrous bands cross and obstruct the duodenum as they adhere to the cecum. Volvulus is untwisted in a counterclockwise direction.

► Clinical Findings

A. Symptoms and Signs

Anomalies of intestinal rotation may cause symptoms related to intestinal obstruction, peptic ulceration, or malabsorption. The majority of patients who develop intestinal obstruction are infants. Older patients may develop intermittent obstruction. The obstruction is in the duodenum or upper jejunum as a result of adhesive bands or midgut volvulus, respectively. Vomiting of bile occurs initially. Older patients may be thin and underweight because of chronic postprandial discomfort or malabsorption. Malabsorption with steatorrhea may result from partial venous and lymphatic obstruction, which is associated with coarse rugal folds in the small bowel. With duodenal obstruction from bands, abdominal distention is not prominent. Midgut volvulus, however, produces marked abdominal distention. Bloody stools and signs of peritonitis are manifestations of intestinal infarction. Peptic ulcer

occurs in 20% of patients, presumably as a result of antral and duodenal stasis.

B. Imaging Studies

With obstructing Ladd bands, plain abdominal radiographs may show a “double bubble” sign that mimics duodenal stenosis. Distribution of gas throughout the intestines may be normal, although there may be a paucity of it. When volvulus occurs, the proximal bowel will be distended with gas early, but over time, a “gasless” abdomen may appear as the gas is resorbed in the ischemic bowel. The intestinal walls are thickened.

The identification of inverted superior mesenteric artery and superior mesenteric vein position on ultrasound is highly suggestive of malrotation and warrants further investigation; however, ultrasound can miss 10%-15% of cases. Upper GI series is the gold standard for diagnosis and demonstrates distention of the duodenum, abnormal positioning of the duodenojejunal segment (usually to the right of the midline), and narrowing at the point of obstruction. The small bowel is commonly visualized on the right side of the abdomen and the colon on the left. Contrast enema demonstrates abnormal position of the cecum, although the cecum can complete its rotation and fixation after birth, so the contrast enema is not a valuable diagnostic test for malrotation.

► Treatment & Prognosis

Through a transverse upper abdominal incision, the entire bowel should be delivered from the abdominal cavity to assess the anomalous arrangement of the intestinal loops. Volvulus should be untwisted in a counterclockwise direction. The Ladd procedure is used for incomplete rotation with obstruction of the duodenum by congenital bands. It consists of division of the bands between the proximal colon and the lateral abdominal wall that cover and compress (obstruct) the duodenum. The mesentery is often folded upon itself due to intermesenteric adhesions, and these are incised. The appendix is removed. The cecum is then placed in the left lower quadrant, and the duodenum dissected and straightened as much as possible with a final position to the right of the midline. In essence, one is creating nonrotated intestinal anatomy much like the anatomic situation in early fetal life (prior to 10 weeks' gestation). The Ladd procedure has increasingly been performed using laparoscopic techniques for those cases without suspected volvulus.

Approximately 30% of infants treated for volvulus die of complications of midgut ischemia and gangrene. If the anomaly is corrected before irreversible bowel damage occurs, the long-term results are good. Some patients tend to form adhesions that cause recurrent intestinal obstruction. Recurrent volvulus is rare after the Ladd procedure.

MECONIUM ILEUS

In 10%-20% of infants born with cystic fibrosis, the thick mucous secretions of the small bowel produce obstruction by inspissated meconium. This usually occurs in the terminal ileum. Although there is no clear correlation between pancreatic insufficiency and the development of inspissated meconium, meconium ileus also occurs in patients with pancreatic duct obstruction and pancreatic aplasia. Meconium obstruction with no apparent cause has also been described in newborn infants.

► Clinical Findings

A. Symptoms and Signs

The infant typically has a normal birth weight and very distended abdomen. No meconium is passed, and bilious emesis occurs early. Loops of thick, distended bowel may be seen and palpated.

B. Imaging Studies

Plain abdominal radiographs show loops of bowel that vary greatly in diameter; the thick meconium gives a ground-glass appearance. Air mixed with the meconium produces the “soap bubble” sign, which is usually located in the right lower quadrant. Radiographs taken shortly after the infant has been placed in an upright position may fail to show air-fluid levels because the thick, viscid meconium fails to layer out rapidly. Contrast enema will show microcolon with rare meconium flecks. Reflux of contrast medium through the ileocecal valve demonstrates a small terminal ileum containing “pellets” of inspissated mucus; more proximally, the bowel is progressively distended with packed meconium. Antenatal perforation may be detected by the presence of abdominal calcifications since the meconium becomes saponified.

► Complications

Meconium ileus may be complicated by a segmental (not midgut) volvulus due to the heavy, distended loops of distal ileum. If this occurs early in fetal life, the volvulus may progress to gangrene of the affected bowel segment. This can heal completely, with abdominal calcifications as the only manifestation that it occurred. Conversely, it may heal in such a way that an intestinal atresia is formed. Perforation late in gestation may lead to meconium peritonitis or a large meconium pseudocyst at birth.

Other common complications of meconium ileus are related to the almost universal presence of cystic fibrosis. These infants are susceptible to repeated pulmonary infection with chronic bronchopneumonia, bronchiectasis, atelectasis, and lung abscess. Malabsorption due to pancreatic insufficiency requires pancreatic enzyme replacement. Rectal prolapse and intussusception may be produced by strained passage of inspissated stools. Nasal polyps and chronic sinusitis are frequent. Biliary cirrhosis and bleeding varices from portal hypertension are late manifestations of bile duct obstruction by mucus.

► Treatment & Prognosis

Nonoperative treatment is successful in 60%-70% of cases. A nasogastric tube should be inserted and connected to suction. A contrast enema can be both diagnostic and therapeutic. It should be performed with a slightly hypertonic water-soluble contrast agent (never barium). The addition of *N*-acetylcysteine, which is mucolytic, may be necessary to disperse the meconium in uncomplicated cases. The infant must be well hydrated, and intravenous fluids must be continued during and after the procedure in order to prevent hypovolemia from the effects of the hypertonic contrast solution. If this fails to relieve the obstruction, laparotomy is indicated. The ileum is opened and, if possible, flushed clear. The bowel can be reanastomosed or brought out as a double-barrel stoma. Alternatively, a T-tube may be placed in the bowel and brought out of the anterior abdominal wall for postoperative irrigations. Compromised intestine is resected, and appendectomy is performed because of the high rate of appendicitis in patients with cystic fibrosis.

All patients should be evaluated for cystic fibrosis. Pancreatic enzyme replacement may be required. A formula low in long-chain fatty acids and high in medium-chain triglycerides may give better absorption and growth than standard formulas. The patient must be placed in an environment with high humidity to keep tracheobronchial secretions fluid. Postural drainage with cupping of the chest should be taught to the parents so that they will continue to maintain tracheobronchial toilet indefinitely. Older children and adolescents may develop a meconium ileus-like syndrome termed distal ileal obstruction syndrome. This is ileal obstruction due to inspissated stool. It can occur when patients are not compliant with their medications or become dehydrated. Most often, it is successfully treated with hypertonic contrast enemas.

Carlyle BE, Borowitz DS, Glick PL: A review of pathophysiology and management of fetuses and neonates with meconium ileus for the pediatric surgeon. *J Pediatr Surg* 2012 Apr;47(4):772-781.

HIRSCHSPRUNG DISEASE

Hirschsprung disease is due to failure in the cephalocaudal migration of the parasympathetic myenteric nerve cells into the distal bowel. Therefore, the absence of ganglion cells always begins at the anus and extends a varying distance proximally. The aganglionic bowel produces functional obstruction because the bowel fails to relax in response to distention. Short-segment aganglionosis involving only the terminal rectum occurs in about 10% of cases; the disease extends to the sigmoid colon in 75%; more proximal colon in 10%; and the entire colon with small bowel involvement in 5%. Extensive involvement of the small bowel is rare.

Males are affected four times more frequently than females when the disease is limited to the rectosigmoid. Females tend to have longer aganglionic segments. A familial association occurs in 5%-10% of cases—more frequently when females are affected. The length of involvement tends to be consistent in familial cases. Down syndrome occurs in 10%-15% of patients.

► Clinical Findings

A. Symptoms and Signs

The absence of ganglion cells results in a functional obstruction since the affected area fails to relax due to unopposed sympathetic tone. The symptoms vary widely in severity but almost always occur shortly after birth. The infant passes little or no meconium within 24 hours. Thereafter, chronic or intermittent constipation usually occurs. Progressive abdominal distention, bilious emesis, reluctance to feed, diarrhea, listlessness, irritability, and poor growth and development follow. A rectal examination in the infant may be followed by expulsion of stool and flatus, with remarkable decompression of abdominal distention. In older children, chronic constipation and abdominal distention are characteristic. Passage of flatus and stool requires great effort, and the stools are small in caliber. Children with constipation from Hirschsprung disease do not exhibit soiling of their diapers or undergarments, distinguishing this form of constipation from idiopathic constipation (encopresis). These children are sluggish, with wasted extremities and flared costal margins. Rectal examination in older children usually reveals a normal or contracted anus and a rectum without feces. Impacted stools in the greatly dilated and distended sigmoid colon can be palpated across the lower abdomen.

B. Imaging Studies

Plain abdominal radiographs in infants show dilated loops of bowel, but it is difficult to distinguish small and large bowel in infancy. A contrast enema should be performed. There should be no rectal examination or attempt to clean out the stool before the fluoroscopic examination, for this can

dilate the rectum and obscure the change in caliber between aganglionic and ganglionic bowel. The contrast enema often demonstrates a contracted (aganglionic) segment that appears relatively narrow compared with the dilated proximal bowel. The proximal aganglionic intestine can be dilated by impacted stool or enema, giving a false impression of the level of the normal colon. Irregular, bizarre contractions (saw-toothed pattern) that do not encircle the aganglionic portion of the bowel may also be recognized. The dilated proximal bowel may have circumferential, smooth, parallel contractions (similar in appearance to those of the jejunum) that are exaggerated contraction waves. The contrast enema may not show a transition zone in the first 6 weeks after birth, since the liquid stool can pass into the aganglionic bowel and the proximal intestine may not be dilated. Lateral projection radiographs should be taken to demonstrate the rectum, the transition zone, and the irregular contractions that may otherwise be obscured by a redundant sigmoid colon on anteroposterior views. Normally, the neonatal rectum is wider than the rest of the colon (including the cecum), and when the rectum is seen to be narrower than the proximal colon, then Hirschsprung disease is suspected. Radiographs of the abdomen and lateral pelvis should be repeated after 24-48 hours. The contrast agent will be retained for prolonged periods, and saline enemas may be required to evacuate it. The delayed film may show the transition zone and the bizarre irregular contractions more clearly than the initial study.

C. Laboratory Findings

Definitive diagnosis is made by rectal biopsy. Mucosal and submucosal biopsies may be taken from the posterior rectal wall with a suction biopsy capsule at the bedside. Serial sections may demonstrate the characteristic lack of ganglion cells and proliferation of nerve trunks in Meissner plexus. If the findings are equivocal, it is necessary to remove a 1-cm or 2-cm full-thickness strip of mucosa and muscularis from the posterior rectum proximal to the dentate line under anesthesia. A sample of this size is sufficient for the pathologist to determine the presence or absence of ganglion cells in Meissner plexus or in Auerbach plexus. Manometric studies will show a failure of relaxation of the internal sphincter following rectal distention by a balloon, although this test is rarely performed except in older children.

► Differential Diagnosis

Low intestinal obstruction in the newborn infant may be due to rectal or colonic atresia, meconium plug syndrome (see below), or meconium ileus as well as a variety of functional causes such as hypermagnesemia, hypocalcemia, hypokalemia, and hypothyroidism. Hirschsprung disease in patients who develop enterocolitis and diarrhea may mimic other causes of diarrhea. Chronic constipation due to functional

causes may suggest Hirschsprung disease. Although functional constipation may occur early in infancy, the stools are normal in caliber, soiling is frequent, and enterocolitis is rare. In functional constipation, stool is palpable in the lower rectum, and a contrast enema shows uniformly dilated bowel to the level of the anus. However, short segment Hirschsprung disease may be difficult to differentiate, and rectal biopsy may be necessary. Segmental dilation of the colon is a rare entity that causes constipation similar to that found in Hirschsprung disease.

► Treatment

Traditionally, the surgical treatment was staged and consisted of a leveling colostomy followed several months later by resection of the aganglionic bowel and performance of a pull-through procedure. The trend recently has been toward performing a single-stage procedure (no colostomy) in the newborn period. This paradigm is as follows: bowel obstruction and enterocolitis (if present) may be relieved by placement of a large (30F) rectal tube and repeated warmed saline irrigations in 10 mL/kg aliquots preoperatively. Infants with moderate to severe enterocolitis should be treated with a diverting colostomy. At the time of surgery, frozen section analysis of the colonic muscle is required in order to establish the correct (ganglionic) level for the stoma. Infants who are not ill may undergo any one of three effective operative procedures: Swenson operation, Duhamel operation, or Soave operation. The main operative principles for these procedures are removal of most or all of the aganglionic bowel—while preserving the surrounding nerves to the pelvic organs—and anastomosing ganglionic bowel (confirmed by frozen section analysis) to the rectum just above the dentate line. In contrast to the Swenson and Soave procedures, the Duhamel operation leaves a cuff of aganglionic rectum along which the ganglionic bowel is stapled, creating a mini-reservoir. Historically, these operations have been performed via a low transverse abdominal incision. However, the laparoscopic approach has become the method of choice. A solely transanal mucosectomy has been used for those babies with short-segment disease. In total aganglionic colon, ileostomy is necessary. Nonoperative treatment with enemas is ineffective because it fails to prevent further obstruction and enterocolitis.

► Prognosis

The mortality for untreated aganglionic megacolon in infancy may be as high as 80%. Nonbacterial, nonviral enterocolitis is the principal cause of death. This tends to occur more frequently in infants but may appear at any age. The cause is not known but seems to be related to the high-grade partial obstruction, poor motility in the “normal” bowel, a frequently competent ileocecal valve, and hypertonic rectal sphincters. There is no correlation between the

length of aganglionosis and the occurrence of enterocolitis. Perforation of the colon and appendix may result from distal bowel obstruction. Atresia of the distal small bowel or colon secondary to bowel obstruction due to Hirschsprung disease *in utero* has been reported.

Anastomotic leak with perirectal and pelvic abscess is the most serious complication following the pull-through procedure. This complication should be treated immediately by proximal colostomy until the anastomosis has healed. Necrosis of the pulled-through colon may occur if the bowel has not been mobilized sufficiently to prevent tension on the mesenteric blood supply.

Long-term patients who are properly treated for Hirschsprung disease do well. Incontinence and soiling may occur in a few cases despite a prompt diagnosis and a perfect operation. Episodic constipation and abdominal distention are more common, since the aganglionic internal anal sphincter is intact. Patients with these symptoms can respond to anal dilation. Occasionally, an internal sphincterotomy may be necessary. Smaller children may still develop enterocolitis after definitive treatment, and they should be treated with a large rectal tube and enemas. It is rare after age 5 years. Postoperative enterocolitis is more common in children with Down syndrome.

Giuliani S, Betalli P, Narciso A, Grandi F, Midrio P, Mognato G, Gamba P: Outcome comparison among laparoscopic Duhamel, laparotomic Duhamel, and transanal endorectal pull-through: a single-center, 18-year experience. *J Laparoendosc Adv Surg Tech A* 2011 Nov;21(9):859-863.

NEONATAL SMALL LEFT COLON SYNDROME (MECONIUM PLUG SYNDROME)

This problem of newborn infants consists of low intestinal obstruction associated with a left colon of narrow caliber and a dilated transverse and right colon. The infants are in most cases otherwise normal, though approximately 30%-50% are born to diabetic mothers and are large for gestational age. Most are over 36 weeks' gestational age and have normal birth weights. Two-thirds are male. Hypermagnesemia has been occasionally associated when the mother has been treated for eclampsia by intravenous magnesium sulfate.

► Clinical Findings

Rectal examination may be normal or may reveal a tight anal canal. Little or no meconium is passed, and progressive abdominal distention is followed by vomiting. After thermometer or finger stimulation of the rectum, some meconium and gas may be evacuated. Contrast enema shows a very small left colon, usually to the level of the splenic flexure. Proximal to this point, the colon and commonly the small bowel are greatly distended. In about 30% of cases, a meconium plug is present at the junction of the narrow and

dilated portion of the bowel, and the enema (using water-soluble contrast) will dislodge it.

► Differential Diagnosis

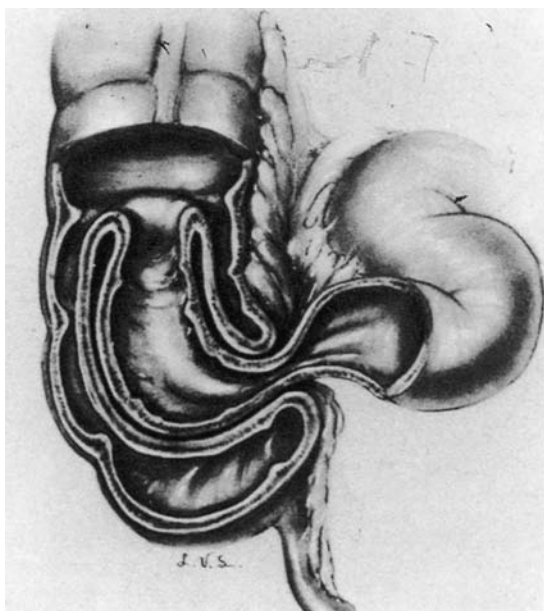

The small left colon syndrome may be confused with Hirschsprung disease or meconium ileus. These lesions rarely cause obstruction at the level of the splenic flexure, and when the colon readily decompresses without further obstruction, Hirschsprung disease is unlikely.

► Treatment

A nasogastric tube should be inserted and intravenous fluids started. A contrast enema is required to differentiate the various causes of low intestinal obstruction. When the left colon is narrow and contrast material refluxes into the dilated proximal colon, the diagnosis is most likely the small left colon syndrome. The contrast enema is usually followed by evacuation of copious meconium and decompression of the bowel. Incomplete evacuation of the meconium or persistent symptoms after the enema mandates a suction rectal biopsy to rule out Hirschsprung disease.

INTUSSUSCEPTION

Telescoping of a segment of bowel (intussusceptum) into the adjacent segment (intussusciens) is the most common cause of intestinal obstruction in children between 6 months and 2 years of age (Figure 43–12). The process of intussusception

▲ **Figure 43–12.** Intussusception.

may result in gangrene of the intussusceptum. The most common form is intussusception of the terminal ileum into the right colon (ileocolic intussusception). In 95% of infants and children, it is idiopathic. The disease is most common in mid-summer and midwinter, and there is a correlation with adenovirus infections. In most cases, hypertrophied Peyer patches are noted on the leading edge of bowel. Mechanical factors such as Meckel diverticulum, polyps, hemangioma, enteric duplication, intramural hematoma (Henoch-Schönlein purpura), and intestinal lymphoma are present with increasing frequency in patients over 2 years old. Postoperative intussusception can occur at any age, is usually ileoileal or jejunojejunal, and is due to differential return of bowel motility, often after retroperitoneal surgery. The ratio of males to females is 3:2. The peak age is in infants 5-9 months of age; 80% of patients are under the age of 2 years.

► Clinical Findings

The typical patient is a healthy child who suddenly begins crying and doubles up because of abdominal pain. The pain occurs in episodes that last for about 1 minute, alternating with intervals of apparent well being. Reflex vomiting is an early sign, but vomiting due to bowel obstruction occurs late. Blood from venous infarction and mucus produce a “currant jelly” stool. In small infants and in postoperative patients, the colicky pain may not be apparent; these babies become withdrawn, and the most prominent symptom is vomiting. Pallor and sweating are common signs during colic. Repeated vomiting and bowel obstruction will produce progressive dehydration. A mass is usually palpable along the distribution of the colon, most commonly in the right upper quadrant of the abdomen. Occasionally, intussusception is palpable on rectal examination. Prolonged intussusception produces edema and hemorrhagic or ischemic infarction of the intussusceptum.

► Treatment & Prognosis

The contrast enema is diagnostic as well as therapeutic in 60%-80% of cases (Figure 43–13). Contrast enema (using either barium or air) should not be attempted until the patient has been resuscitated enough to allow an operative procedure to be performed safely. It is contraindicated if peritonitis is present. If barium is used, the column of contrast should not stand more than 100 cm above the patient in order to minimize the risk of perforation. Air is pumped into the colon at a pressure of 60-80 mm Hg (never > 120 mm Hg). A successful study reduces the intussusceptum and demonstrates reflux of barium or air into the terminal ileum. Several attempts should be made before taking the child to surgery. A contrast enema will not reduce gangrenous bowel.

Operation is required for unsuccessful enema reduction or signs of bowel perforation and peritonitis. The procedure

▲ **Figure 43-13.** Contrast enema demonstrating obstruction to retrograde flow of barium by a filling defect (intussusceptum) in the mid transverse colon. (Reproduced, with permission, from Albanese CT. Pediatric surgery. In: Norton JA, ed. *Surgery*. New York, NY: Springer; 2000.)

may be performed either by laparotomy or laparoscopically. In the absence of gangrene, reduction is accomplished by gentle retrograde compression of the intussusciens, not by traction on the proximal bowel. Resection of the intussusception is indicated if the bowel cannot be reduced or if the intestine is gangrenous.

Intussusception recurs after 5% of enema reductions and 1% of operative reductions. Deaths are rare but occur if treatment of gangrenous bowel is delayed.

ANORECTAL ANOMALIES (IMPERFORATE ANUS)

The normal continence mechanism for bowel control consists of an internal sphincter composed of smooth muscle and the striated muscle complex from the levator ani and external sphincter. The striated muscles assume a funnel shape, originating from the pubis, pelvic rim, and sacrum. These muscles converge at the perineum while interdigitating with the internal and external sphincters. Most of the striated muscle complex consists of horizontal muscles that contract against the wall of the rectum and anus while longitudinal muscle fibers run in a cephalocaudal direction and elevate the anus.

▲ **Figure 43-14.** **A:** Low female anomaly. Perineal fistula. **B:** Low female anomaly. Fourchette/vestibule fistula. (Reproduced, with permission, from Pena A: *Atlas of Surgical Management of Anorectal Malformations*. New York, NY: Springer-Verlag; 1990)

Anomalies of the anus result from abnormal growth and fusion of the embryonic anal hillocks. The rectum is normally developed, and the sphincter mechanism is usually intact. With proper surgical treatment, the sphincter will function normally. Anomalies of the rectum develop as a result of faulty division of the cloaca into the urogenital sinus and rectum by the urorectal septum. In these anomalies, the internal sphincter and striated muscle complex are hypoplastic. Therefore, surgical repair results in varying degrees of continence.

► Classification

Physical examination of the perineum and imaging studies determine the extent of malformation of the anus or rectum. When an orifice is evident at the perineum or distal introitus, the anomaly is referred to as a low imperforate anus; the absence of an obvious orifice at the perineal level suggests a high imperforate anus (Figures 43-14 to 43-17). In most instances, with high imperforate anus, there is a

▲ **Figure 43-15.** **A:** High female anatomical anomaly. Low vaginal fistula. **B:** High female anomaly. High vaginal fistula. (Reproduced, with permission, from Pena A: *Atlas of Surgical Management of Anorectal Malformations*. New York, NY: Springer-Verlag; 1990.)

▲ **Figure 43-16.** **A:** Low male anomaly. Perineal fistula. **B:** Low male anomaly. Rectobulbar urethra fistula. (Reproduced, with permission, from Pena A: *Atlas of Surgical Management of Anorectal Malformations*. New York, NY: Springer-Verlag; 1990.)

communication (fistula) of the rectum with the urethra or bladder in the male or with the upper vagina in the female. Distinguishing between a high and low anomaly may be possible radiologically by determining the position of the rectum in relation to the levator ani or pubococcygeal line.

A. Low Anomalies

In low anomalies, the anus may be ectopically placed anterior to its normal position or it may be in the normal position with a narrow outlet due to stenosis or an anal membrane. There may be no opening in the perineum, but the skin at the anal area is heaped up and may extend as a band in the perineal raphe completely covering the anal opening. A small fistula usually extends from the anus anteriorly to open in the raphe of the perineum, scrotum, or penis in the male or the vulva in the female. These babies often have well-developed perineal and gluteal musculature and rarely have sacral vertebral anomalies.

▲ **Figure 43-17.** **A:** High male anomaly. Rectoprostatic urethra fistula. **B:** High male anomaly. Rectovesical neck fistula. (Reproduced, with permission, from Pena A: *Atlas of Surgical Management of Anorectal Malformations*. New York, NY: Springer-Verlag; 1990.)

B. High Anomalies

In high anomalies, the rectum may end blindly (10%), but more commonly there is a fistula to the urethra or bladder in the male or the upper vagina in the female. In the female, a very high fistula may extend between the two halves of a bicornuate uterus directly to the bladder. Patients with high imperforate anus often have deficient pelvic and gluteal innervation and musculature, a high incidence of sacral anomalies (caudal regression), and a poor prognosis for continence after surgical repair. The most severe of the high deformities is a cloacal anomaly in which there is a common channel between the poorly developed pelvic structures (urogenital sinus and rectum) with a single perineal opening.

► Clinical Findings

A. Signs

The best means of establishing the type of anorectal anomaly is by physical examination. In low anomalies, an ectopic opening from the rectum can be detected in the perineal raphe in males or in the lower vagina, vestibule, or fourchette in females. A high anomaly exists when no orifice or fistula can be seen upon examination of the perineum or when meconium is found at the urethral meatus, in the urine, or in the upper vagina. Absence of external sphincter contraction with cutaneous stimulation of the anus may also help differentiate between high and low lesions.

B. Imaging Studies

No single test is ideal in the evaluation of imperforate anus, so several studies are used to define the neonatal anatomy. Radiographs are sometimes useful when the clinical impression is unclear. A lateral film of the pelvis with the baby inverted (Wangensteen invertogram), once commonly used, is an inaccurate method of establishing the lower extent of the rectum because swallowed air may not have completely displaced the meconium from the rectum; or the striated muscle complex may be contracted, which obliterates the lumen and makes it look as if the gas in the rectum ends high in the pelvis. With crying or straining, the puborectalis muscle and rectum may actually descend below the ischium, giving a falsely low estimate of rectal height. Gas in the bladder clearly indicates a rectourinary fistula. Lower abdominal and perineal ultrasound, CT, and MRI have been used to define the pelvic anatomy and location in relation to the rectal musculature. Anomalies of the vertebrae and the urinary tract occur in two-thirds of all patients with high anomalies and in one-third of male patients with low anomalies. Vertebral abnormalities in females invariably indicate a high imperforate anus. Anomalies of the sacrum warrant MRI of the lumbosacral area to identify spinal cord anomalies such as a tethered filum terminale.

► Complications

Associated anomalies occur in up to 70% in those with a high anomaly. Imperforate anus is associated with the VACTERL syndrome (see Esophageal Anomalies). The possible constellation of anomalies includes esophageal atresia, anomalies of the GI tract, hemivertebrae or agenesis of one or more sacral vertebrae (agenesis of S1, S2, or S3 is associated with corresponding neurologic deficits, resulting in neuropathic bladder and greatly impaired continence), genitourinary anomalies (up to 50% incidence with high imperforate anus), and anomalies of the heart and upper limbs/digits.

Delay in diagnosis of imperforate anus may result in excessively large bowel distention and perforation. The presence of a rectourinary fistula allows reflux of urine into the rectum and colon, and absorption of ammonium chloride may cause acidosis. Colon contents will reflux into the urethra, bladder, and upper tracts, producing recurrent pyelonephritis.

► Treatment

The three main goals of treatment are (1) to allow passage of stool (ie, relieve obstruction), (2) to place the rectal pouch on the perineum in good position, and (3) to close the fistula.

A. Low Anomalies

Low anomalies are usually repaired from the perineal approach in the newborn period using a muscle stimulator to precisely determine the location of the sphincter complex. The anteriorly placed anal opening is completely mobilized and transferred to the normal position. After healing, the anal opening must be dilated daily for 3-5 months to prevent stricture formation and to allow for growth.

B. High Anomalies

Traditionally, a high deformity was treated by a three-stage repair consisting of colostomy and mucous fistula formation, a posterior sagittal anorectoplasty 4-6 weeks later, and closure of the colostomy several months after that. Recently, the staged approach has been challenged and a one-stage repair has been performed by both posterior sagittal and laparoscopic approaches. Because the anal sphincters are poorly developed—especially the internal sphincter—continence is most dependent upon a functioning striated muscle complex, which requires conscious voluntary contraction. Care must be taken to preserve the afferent and efferent nerves of the defecation reflex arc as well as the existing sphincter muscles. In all cases, the surgically created anus must be dilated for several months to prevent circumferential cicatrix formation.

► Prognosis

Surgical complications include damage to the nervi erigentes, resulting in poor bladder and bowel control and

failure of erection. Division of a rectourethral fistula some distance from the urethra produces a blind pouch prone to recurrent infection and stone formation, while cutting the fistula too short may result in urethral stricture. Erroneously attempting to repair a high anomaly from the perineal approach may leave a persistent rectourinary fistula. An abdominoperineal pull-through procedure performed for a low anomaly invariably produces an incontinent patient who might otherwise have had an excellent prognosis. Injury to the vas deferens and ureter is possible during repair of high anomalies.

Patients with imperforate anus tend to have varying degrees of constipation as an inherent part of the defect, believed to be due to poor inherent motility of the rectosigmoid. Patients with low anomalies usually have good sphincter function. Children with high anomalies do not have an internal sphincter that provides continuous, unconscious, and unfatiguing control against soiling. However, in the absence of a lower spine anomaly, perception of rectal fullness, ability to distinguish between flatus and stool, and conscious voluntary control of rectal discharge by contraction of the striated muscle complex can be achieved. When the stools become liquid, sphincter control is usually impaired in patients with high anomalies.

GASTROINTESTINAL TRACT ABNORMALITIES

GASTROESOPHAGEAL REFLUX

Studies of esophageal motility, including manometric measurements of the cardioesophageal junction, show absence of the high-pressure zone (lower esophageal sphincter) in the terminal esophagus in most normal newborns. Evolution to the normal adult pattern of peristalsis and cardioesophageal sphincter function occurs after several months. Until this happens, many infants experience varying degrees of regurgitation after feeding. Rarely, repeated gastric reflux may produce peptic esophagitis and interfere with the development of a competent sphincter. Unlike adults, children rarely have a hiatal hernia as a cause of GER.

► Clinical Findings

A. Symptoms and Signs

Symptoms consist of repeated effortless regurgitation of feedings, particularly when the baby is placed in a recumbent position. The baby will be hungry and will readily feed after regurgitating. Persistent regurgitation may result in

poor weight gain (failure to thrive), peptic esophagitis with appearance of blood in the vomitus, or occult bleeding, producing anemia. One cause for apnea and acute life-threatening events (ALTE) is GER and aspiration. Lesser degrees of aspiration, particularly during sleep, may produce recurrent pneumonia. Stricture formation of the lower esophagus and metaplasia of the esophageal mucosa, producing Barrett esophagus, are possible late effects. Almost half of infants and children with GER have neurologic disorders related to perinatal asphyxia or congenital nervous system anomalies; seizure disorders are very common in this population. Abnormal motility of the esophagus and gastric dysmotility and impaired gastric emptying are frequently present. Gastroesophageal reflux is associated with esophageal atresia, CDH, and abdominal wall defects.

B. Imaging Studies

The standard diagnostic test is lower esophageal 24-hour pH monitoring. An upper GI series is less sensitive but is useful to rule out other disorders (eg, intestinal malrotation) and to assess for esophageal stricture. Gastric emptying may be assessed by technetium pertechnetate scan. There is virtually no role for esophageal manometric studies in young children except for those in whom one suspects the relatively rare achalasia or diffuse esophageal spasm.

► Treatment

Nonoperative treatment is successful in most cases. Feedings should be thickened with rice cereal, and GER is lessened if the baby is maintained upright in an infant seat or in a prone position after feeding. Persistent symptoms mandate drug therapy with an antacid (eg, H₂-blocker or proton pump inhibitor) with or without a prokinetic agent (eg, metoclopramide). If a prolonged trial of nonoperative therapy fails or if complications of reflux can be documented (ie, esophagitis, stricture, asthma, recurrent aspiration pneumonia, failure to thrive), an antireflux procedure is indicated. The Nissen fundoplication has become the standard surgical treatment, although many variations on fundoplication exist. The open operation has been virtually replaced by the more cosmetic laparoscopic procedure that also provides for better visualization.

ACUTE APPENDICITIS

Acute appendicitis is one of the most common causes of an acute abdomen in childhood. This diagnosis must be considered in all age groups, but it is most common between the ages of 4 and 15 years.

► Clinical Findings

The diagnosis is most often made by obtaining a careful clinical history and performing a thorough physical examination. In some patients, observation and periodic reexamination by the same physician may be necessary to confirm or exclude the diagnosis. In young children, the diagnosis of appendicitis can be difficult to arrive at, as the clinical history may be difficult to elicit. The classic presentation includes the onset of epigastric or periumbilical pain followed by anorexia, nausea, and vomiting. Anorexia is a significant finding, as the child will often refuse favorite foods. A fever will usually develop, and the pain then localizes to the right lower quadrant. Rovsing sign (right lower quadrant pain during palpation of the left lower quadrant), localized right lower quadrant tenderness, and involuntary spasm of the right hemirectus muscle indicate the presence of peritonitis.

A white blood count with differential and urinalysis should be obtained. The white blood cell count is greater than 10,000/ μ L (often with a left shift) in more than 80% of patients with appendicitis. Radiologic evaluation should include a chest film to exclude right lower lobe pneumonia. Findings on flat and erect abdominal radiographs are often nonspecific, though they may infrequently demonstrate the presence of a fecalith. Ultrasound (particularly in females) and CT scans are being used with increasing frequency, especially for those without the classic history and physical examination results.

► Differential Diagnosis

Gastroenteritis is often confused with appendicitis. Vomiting follows periumbilical pain in appendicitis but often precedes abdominal pain in gastroenteritis. In addition, the patient with gastroenteritis commonly has diffuse abdominal pain and frequent copious watery diarrhea. Intussusception, intestinal obstruction and volvulus, mesenteric adenitis, Meckel diverticulitis, Henoch-Schönlein purpura, ruptured ovarian cyst, and Crohn disease must also be considered in the differential diagnosis for children. In adolescent girls, information regarding the menstrual cycle, previous episodes of pelvic inflammatory disease, and an accurate sexual history is important to exclude gynecologic causes of an acute abdomen.

► Treatment

Once the diagnosis is made, fluid resuscitation is performed and antibiotics are administered. Appendectomy is

accomplished through a right lower quadrant incision or laparoscopically. In cases of perforation, the peritoneal cavity is irrigated and aspirated dry but drainage is not performed, unless there is a mature abscess cavity. The wound is closed in all cases. Antibiotics are continued for 3-7 days or until the white blood cell count and fever normalize. Overall, the morbidity and mortality of appendicitis in children have gradually decreased with the increased use of powerful broad-spectrum antibiotics. However, perforated appendicitis with abscess formation remains the variant with increased morbidity when compared to nonperforated cases. Interval appendectomy after management of perforated appendicitis with antibiotics and abscess drainage when necessary is a viable option. The criteria for which patients to initially manage nonoperatively are still under debate.

DUPLICATIONS OF THE GASTROINTESTINAL TRACT

Duplications may occur at any point along the GI tract from the mouth to the anus. Duplications occur (in order of decreasing frequency) in the ileum (50% of cases), mediastinum, colon, rectum, stomach, duodenum, and neck. Intrathoracic and small bowel duplications are usually spherical; colonic duplications are commonly long and tubular (Figure 43-18). Characteristically, the intra-abdominal spherical duplications are on the mesenteric side of the intestine and do not share a common wall with the intestine.

Based on embryology, duplications have been categorized as foregut, midgut, and hindgut. Foregut duplications include the pharynx, respiratory tract, esophagus, stomach, and the first portion and proximal half of the second portion of the duodenum. Midgut duplications include the distal half of the second part of the duodenum, the jejunum, ileum, cecum, appendix, the ascending colon, and the proximal two-thirds of the transverse colon. The hindgut is composed of duplications of the distal third of the transverse colon, the descending and sigmoid colon, the rectum, anus, and components of the urologic system. Combined thoracoabdominal duplications also occur in which the thoracic sacular component extends through the esophageal hiatus or a separate diaphragmatic opening to empty into the duodenum or jejunum. A thoracic duplication, associated

▲ **Figure 43-18.** Duplications of the gastrointestinal tract. Duplications may be saccular or tubular. They usually arise within the mesentery, having a common wall with the intestine. Thoracoabdominal duplications arise from the duodenum or jejunum and extend through the diaphragm into the mediastinum.

with a cervical or thoracic vertebral anomaly, in which the duplication communicates with the subarachnoid space, is called a neurenteric cyst. Associated cardiovascular, neurologic, skeletal, urologic, and GI anomalies occur in more than a third of cases. Carcinoma may arise within intestinal duplications later in life.

► Clinical Findings

A. Symptoms and Signs

Two-thirds of patients with duplications are symptomatic in the first year of life. Duplications of the neck and mediastinum produce respiratory distress by compression of the airway. Thoracic duplications may ulcerate into the lung and lead to pneumonia or hemoptysis. Intestinal duplications usually produce abdominal pain owing to spastic contraction of the bowel, excessive distention of the duplication, or peptic ulceration and bleeding resulting from ectopic gastric mucosa in the duplication. Intestinal obstruction due to

intussusception, volvulus, or encroachment on the lumen by an intramural cyst also occurs. An isolated asymptomatic mass may be the only finding. Sixty percent of duplications are diagnosed by 6 months of life and 85% by 2 years.

B. Imaging Studies

Studies include radiographs of the chest and thoracolumbar spine, CT scan of the chest and abdomen, contrast enema, esophagography, and upper GI series. If an intraspinal extension of a duplication is suspected, MRI is indicated. Ultrasonography may show a cystic or tubular mass within the mediastinum or abdomen. A Meckel scan (technetium pertechnetate) can also be used to visualize those duplications with ectopic gastric mucosa.

► Treatment

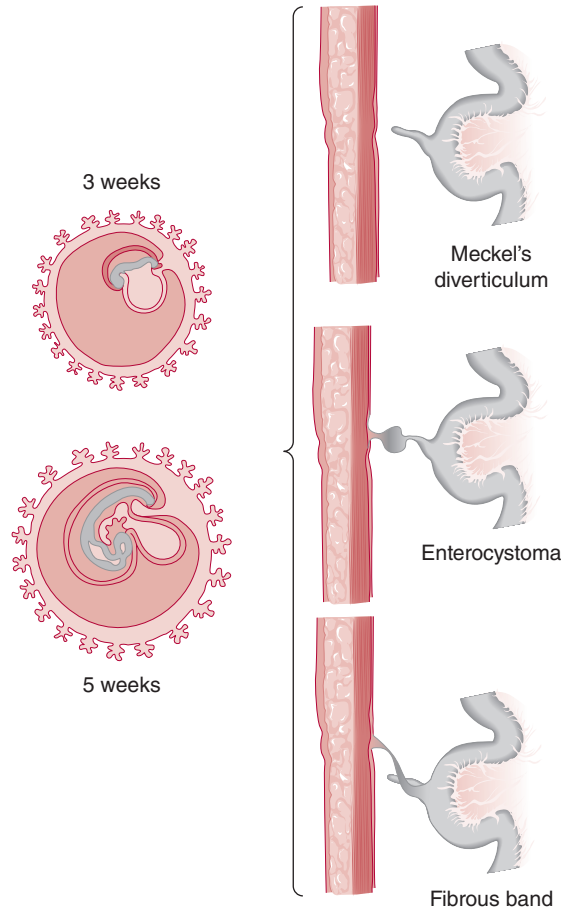

Duplications not intimately adherent to adjacent organs should be excised. Isolated spherical duplications can be excised with the adjacent segment of bowel and an end-to-end anastomosis of the bowel performed. Long tubular duplications can be decompressed by establishing an anastomosis between the proximal and distal ends of adjacent bowel. Noncommunicating duplications, which would require radical resection of surrounding structures, should be drained by a Roux-en-Y technique. Duplications that cannot be removed completely and which contain gastric mucosa should be opened (without jeopardizing the blood supply of the normal bowel) and the mucosal lining excised. Extension of a mediastinal duplication into the spine or abdomen should be resected. An intra-abdominal extension is closed at the level of the diaphragm, and complete excision by laparotomy is accomplished.

OMPHALOMESENTERIC DUCT ANOMALIES

The omphalomesenteric (vitelline) duct is a remnant of the embryonic yolk sac. When the entire duct remains intact postnatally, it is recognized as an omphalomesenteric fistula. When the duct is obliterated at the intestinal end but communicates with the umbilicus at the distal end, it is called an umbilical sinus. When the epithelial tract persists but both ends are occluded, an umbilical cyst or intra-abdominal enterocystoma may develop. The entire tract may be obliterated, but a fibrous band may persist between the ileum and the umbilicus (Figure 43-19).

The most common remnant of the omphalomesenteric duct is Meckel diverticulum, which is present in 1%-3% of the population. Meckel diverticulum may be lined wholly or in part by small intestinal, colonic, or gastric mucosa, and it

▲ **Figure 43-19.** Omphalomesenteric duct anomalies arise from the primitive yolk sac. Remnants include Meckel diverticulum, enterocystoma, and a fibrous band or fistulous tract between the ileum and the umbilicus.

may contain aberrant pancreatic tissue. Heterotopic tissue is found in 5% of asymptomatic and 60% of symptomatic cases. In contrast to duplications and pseudodiverticula, Meckel diverticulum is located on the antimesenteric border of the ileum, 10-90 cm from the ileocecal valve. Meckel diverticulum occurs with equal frequency in both sexes. It is usually asymptomatic and is seen as an incidental finding during operation for other disease. Of those with Meckel diverticulum, the lifelong risk of complications is 4%, and 40% of these cases occur in children under 10 years of age.

► Clinical Findings

Symptomatic omphalomesenteric remnants (male:female incidence 3:1) produce painless rectal bleeding in 40%,

intussusception in 20%, diverticulitis or peptic perforation in 15%, umbilical fistula in 15%, intestinal obstruction in 7%, and abscess in 3% of cases. Rectal bleeding associated with Meckel diverticulum is due to peptic ulceration of the adjacent ileum caused by ectopic gastric mucosa. Over 50% of these patients are under 2 years of age. The blood is mixed with stool and is most often dark red or bright red; tarry stools are unusual. A history of a previous episode of bleeding may be elicited in 40% of cases. Occult bleeding from Meckel diverticulum is very rare. Younger patients tend to bleed quite briskly and may exsanguinate rapidly. Diverticulitis or free perforation will present with abdominal pain and peritonitis similar to acute appendicitis. The pain and tenderness occur in the lower abdomen, most commonly near the umbilicus. Periumbilical cellulitis may be present.

Intestinal obstruction may develop as a result of volvulus of the bowel about a persistent band between the umbilicus and the ileum or as a result of herniation of bowel between the mesentery and a persistent vitelline or mesodiverticular vessel. Obstruction is the most common presentation in adults. An infected umbilical sinus or omphalomesenteric fistula may present with mucoid, purulent, or enteric discharge, recurrent cellulitis, or a deep abdominal wall abscess about the umbilicus. This can be diagnosed by cannulation and contrast injection via the umbilical tract.

Upper and lower contrast studies rarely outline the primary defect. Technetium Tc 99m pertechnetate may localize in gastric mucosa lining Meckel diverticulum and may identify the source of hematochezia or melena. Retention of dye in the mucous and parietal cells is enhanced by giving cimetidine, 30 mg/kg intravenously, 30 minutes before administration of the radiotracer nuclide.

► Treatment

Resection is accomplished by laparotomy or laparoscopy. An omphalomesenteric remnant with a narrow base may be treated by amputation and closure of the bowel defect (usually with a surgical stapler). In cases where the anomaly has a wide mouth with ectopic tissue or where an inflammatory or ischemic process involves the adjacent ileum, intestinal resection with the diverticulum and anastomosis may be necessary.

Chan KW, Lee KH, Mou JW, Cheung ST, Tam YH: Laparoscopic management of complicated Meckel's diverticulum in children: a 10-year review. *Surg Endosc* 2008 Jun;22(6):1509-1512. [Epub 2008 Mar 6.]

NECROTIZING ENTEROCOLITIS

Necrotizing enterocolitis (NEC) is the most serious and frequent GI disorder of predominantly premature infants, with a median onset of 10 days after birth. The incidence is increasing given the therapeutic advances in neonatal

intensive care that have allowed ever more premature infants to survive. It is characterized by necrosis, ulceration, and sloughing of intestinal mucosa, which frequently progresses to full-thickness necrosis and perforation. This process progresses from the submucosa through the muscular layer to the subserosa. Gas-producing bacteria in the intestinal wall may lead to pneumatosis, a finding that may be noted on gross examination as well as on plain abdominal radiographs. The terminal ileum and right colon are usually affected first, followed in descending order of frequency by the transverse and descending colon, appendix, jejunum, stomach, duodenum, and esophagus. The most extreme case, pan-necrosis, is defined as necrosis of 75% or more of the bowel. Eighty percent of cases occur in premature infants weighing less than 2500 g at birth, and 50% are under 1500 g. However, the disorder may also occur in full-term infants. Contrary to earlier impressions, there is no established relationship between NEC and stressful perinatal events such as premature rupture of membranes with amnionitis, breech delivery, intrauterine bradycardia, umbilical vessel catheterization with or without exchange transfusion, respiratory distress syndrome, sepsis, omphalitis, and congenital heart disease. An associated patent ductus arteriosus is common. In older infants and children, NEC is usually preceded by malnutrition and gastroenteritis. The clustering of cases in nurseries suggests that an infectious agent may be responsible.

► Clinical Findings

Clinical findings include increased gastric residual, bilious vomiting, abdominal distention, bloody stools, lethargy, and poor skin perfusion. When intestinal perforation occurs, guarding is evident on abdominal examination, but in weak premature infants this may not be obvious. There are a variety of nonspecific clinical findings that suggest physiologic instability such as apnea, bradycardia, hypoglycemia, and temperature instability. On examination, abdominal distention and fixed loops of intestine may be appreciated. The presence of abdominal wall erythema, edema, and crepitus may be a sign of bowel necrosis. Laboratory evaluation is nonspecific since the white blood cell count may be low or high, but thrombocytopenia and acidosis develop with perforation and sepsis.

Supine and cross-table lateral abdominal radiographs show small bowel distention early, followed by pneumatosis intestinalis. Gas within the portal venous system can be seen but it is fleeting. Serial examinations may show a loop or loops of bowel that are fixed in position and dilated. Perforation with peritoneal air develops in 20% of cases. Infants who develop ascites without pneumoperitoneum should have paracentesis and examination of the fluid for bacteria, which would signify perforation. Contrast studies are hazardous and contraindicated, as they may easily lead to perforation.

► Treatment

Treatment includes cessation of feedings, orogastric suction, systemic antibiotics, and correction of hypoxemia, hypovolemia, acidosis, and electrolyte abnormalities. The only absolute indication for intervention is pneumoperitoneum. Relative indications are portal vein air, clinical deterioration, a fixed intestinal loop on serial radiographs, erythema of the abdominal wall, an abdominal mass, and a paracentesis demonstrating bacteria. At laparotomy, necrotic bowel is resected and the proximal bowel is made into a stoma. Rarely is primary anastomosis safe. Severe disease may not be amenable to operation or require extensive bowel resection, resulting in short bowel syndrome. An alternative treatment option in very low-birth-weight (VLBW) infants (< 1500 g) that is gaining acceptance for documented perforation is bedside drainage of the peritoneal cavity in the right lower quadrant using local anesthesia. A recent prospective randomized trial comparing laparotomy to drain placement for VLBW infants demonstrated equivalent outcomes in mortality and short-term morbidity for these two modalities.

In one-third of cases, the disorder resolves without further treatment, and the overall survival rate is more than 50%. Intestinal stricture may occur as a late complication following healing. For this reason, a contrast enema is used to evaluate the defunctionalized distal bowel before closing the stoma.

Leaf A, Dorling J, Kempley S, McCormick K, Mannix P, Linsell L, Juszcak E, Brocklehurst P: Early or delayed enteral feeding for preterm growth-restricted infants: a randomized trial. *Pediatrics* 2012 May;129(5):e1260-e1268.

GASTROINTESTINAL BLEEDING

Significant GI bleeding in children is rare. When it occurs, it can be alarming and anxiety provoking for caregivers and parents. The diagnostic approach used in the evaluation of these children is similar to that used in adults, but the causes vary depending on the age of the child. Rarely is the GI bleeding massive, and the majority of causes are benign. A diagnosis can be established in over 85% of cases. Usual presenting symptoms include hematemesis, hematochezia, and melena. Depending on the amount of bleeding, the child may have sunken fontanelles, dry mucous membranes, and cool skin. Tachycardia, oliguria, and hypotension may be present. Intravenous access should be obtained, fluid and blood administered as needed, and an evaluation begun. Laboratory tests include serial hematocrit measurements and coagulation studies. Following stabilization and physical examination, evaluation should then proceed to the appropriate diagnostic tests.

► Upper Gastrointestinal Bleeding

Upper GI bleeding originates above the ligament of Treitz. The presence of melena and the presence of blood on passage

of an orogastric tube can help differentiate between upper and lower GI bleeding. Upper GI bleeding in infants and young children is most often associated with stress ulcers or erosions, but in older children it may also be caused by duodenal ulcer, esophagitis, and esophageal varices particularly in children with underlying liver disease. The majority of these diseases are benign. Evaluation following stabilization of the child begins with flexible esophagoduodenoscopy. Once the diagnosis is made, treatment is usually amenable to antacids (H_2 -blockers, proton pump inhibitors). Variceal hemorrhage may require more aggressive intervention, including the use of octreotide, endoscopic varix sclerosis or band ligation, and, in extreme cases, transjugular intrahepatic portocaval shunt (TIPS), mesocaval shunt, or liver transplantation.

► Lower Gastrointestinal Bleeding

Although diverticulitis, cancer, and angiodysplasia are the most common causes of lower GI bleeding in adults, those diseases are rare in children. The causes of lower GI bleeding in infants and children can be categorized in diagnostic age groups where the age of the patient, the amount of bleeding, and the color of the blood passed provide some guidance to the probable source of bleeding.

Bleeding in the neonate may be caused by swallowing maternal blood at delivery, an anoctal fissure, upper GI bleeding secondary to gastritis or ulceration, necrotizing enterocolitis, volvulus, and an incarcerated hernia. The Apt test for maternal blood, physical examination of the rectum and inguinal canal, and evaluation of the upper GI tract can quickly rule out most of these causes. Bleeding from necrotizing enterocolitis is rarely life threatening, and the diagnosis is commonly made based on the premature delivery of the infant and radiologic evaluation. If bleeding from malrotation with midgut volvulus is suspected, prompt laparotomy is indicated.

In infants, anal fissures continue to be the most common cause of rectal bleeding. Other causes include intestinal volvulus, intussusception, intestinal duplication, Meckel diverticulum, milk or formula protein allergy and infectious diarrhea. Contrast studies and appropriate stool cultures guide treatment. Children have a differential diagnosis similar to that of infants with the addition of rectal prolapse and a variety of polyps of the colon (juvenile, Peutz-Jeghers, polypoid lymphoid hyperplasia, and, rarely, adenomatosis). These entities are diagnosed by physical examination and proctosigmoidoscopy. If no source of bleeding is identified, colonoscopy is indicated, while capsule endoscopy is gaining acceptance as a diagnostic modality for occult causes of GI bleeding in appropriately sized patients. Juvenile polyps are the single most common cause of lower GI bleeding in children (20%-30%). Most juvenile polyps are single (80%) and often pass spontaneously without treatment. However, when bleeding continues to occur, the polyp can be snared and

excised endoscopically. Adolescents may manifest signs and symptoms of inflammatory bowel disease (ulcerative colitis, Crohn disease), familial adenomatous polyposis, and small vascular lesions such as telangiectasias. Diagnosis is made by colonoscopy, and treatment is disease specific.

GASTROINTESTINAL FOREIGN BODIES

Children aged 9 months to 2 years are at particular risk for the ingestion or aspiration of foreign bodies given their newly acquired mobility, curiosity, and the tendency to place objects in their mouths. The type of foreign body and the location in the airway or GI tract dictate management.

► Esophageal Foreign Bodies

Typical foreign bodies found in the esophagus include coins, food, and small toys. The three most common sites of obstruction are at the level of the cricopharyngeus muscle, at the level of the aortic arch, and at the gastroesophageal junction. Previous areas of repair/anastomosis as in esophageal atresia or injury predispose to obstruction due to scar and narrowing. Common symptoms include drooling, feeding intolerance, dysphagia, and pain. Perforation is rare but is dictated by the ingested object's shape, composition, and time in the esophagus. The diagnosis is easily obtained by anteroposterior chest or lateral neck radiography if the ingested object is radiopaque. Otherwise, esophagoscopy or an upper GI series is needed.

Because of the risk of erosion, aspiration, perforation, and late stricture, impacted objects should be removed. Extraction can be performed using balloon catheter retrieval under fluoroscopic control or under direct visualization using esophagoscopy with general anesthesia. The latter technique is generally preferred if the nature of the object is unknown, or is sharp, or the ingestion was 24-48 hours previously. A Hopkins rod lens endoscopy system allows visualization of the object and retrieval with specially designed forceps for grasping small objects.

Ninety-five percent of foreign bodies that pass beyond the gastroesophageal junction proceed uneventfully through the GI tract. Operative retrieval is reserved for batteries, which must be removed, and for cases where ingested objects cause obstruction (bezoars), intestinal injury or have been in place for more than 1 week.

► Tracheal Foreign Bodies

Children, particularly those 1-2 years of age, can occlude the airway by aspiration of a foreign body. The most common

objects are peanuts and popcorn. Obstruction tends to occur at the level of the laryngeal inlet, the subglottis, or the right main stem bronchus. Because this can be a life-threatening problem, witnessed events should be treated with back blows, abdominal thrusts, or the Heimlich maneuver, which may dislodge the object.

Symptoms include coughing, choking, wheezing, dyspnea, and fever. Unilateral wheezing and rhonchi may be present. Air trapping may result when the foreign-body forms a ball-valve obstruction leading to hyperinflation of the affected lung and mediastinal shift away from the affected side. On the other hand, complete obstruction may lead to loss of air volume with atelectasis and mediastinal shift to the ipsilateral side. Inspiratory and expiratory radiographs or bilateral decubitus films in infants may demonstrate air trapping; the foreign body is rarely noted on radiographs.

With a worrisome history, a foreign body suggested on a radiograph, or any symptoms, the child should undergo bronchoscopic evaluation under general anesthesia. Working in tandem with the anesthesiologist to allow ventilation during rigid endoscopy, the foreign body can be readily identified. Lighted grasping forceps made specifically for foreign-body extraction are placed through the sheath of the bronchoscope; the foreign body is grasped; and the forceps, foreign body, and sheath are removed as one unit. Rarely, an unrecognized aspirated foreign body presents as chronic lung infection and can require removal of the affected lung.

LIVER & BILIARY TRACT DISORDERS

Jaundice in the first 2 weeks of infancy is usually due to indirect (unconjugated) hyperbilirubinemia. The causes include (1) "physiologic jaundice" due to immaturity of hepatic function (eg, that associated with breast-feeding); (2) Rh, ABO, and rare blood group incompatibilities, which produce hemolysis; and (3) infections. Jaundice that persists beyond the first 2 weeks in which the indirect and conjugated bilirubin levels are elevated should prompt a more thorough workup aimed at diagnosing potential surgical disorders. The most frequent cause (60%) of prolonged jaundice in infancy is biliary atresia; various forms of hepatitis occur in 35%; and choledochal cyst is found in 5% of cases of obstructive jaundice. Intestinal obstruction can intensify jaundice by increasing the enterohepatic circulation of bilirubin. Finally, jaundice is an early and important sign of sepsis in the newborn.

BILIARY ATRESIA

Biliary atresia is the absence of patent bile ducts draining the liver. Familial cases and frequent association with the polysplenia syndrome indicate a congenital onset. However, biliary atresia probably develops after birth because jaundice is not usually remarkable in the newborn period but becomes evident more than 2 weeks later. Furthermore, conjugated bilirubin is not cleared by the placenta as unconjugated bilirubin is, and jaundice due to conjugated hyperbilirubinemia with biliary obstruction has not been recognized in newborn infants. The atretic ducts consist of solid fibrous cords that may contain occasional islands of biliary epithelium.

The extent of duct involvement varies greatly. There are three anatomic patterns of obstruction: (1) the proximal extrahepatic bile ducts are patent and the ducts distal to the cystic duct are obliterated; (2) the gallbladder, cystic duct, and common bile duct are patent and the proximal hepatic ducts are occluded; and (3) the entire extrahepatic ductal system is obstructed. Liver biopsy demonstrates proliferation of the bile canaliculi containing inspissated bile. Over time, the failure to excrete bile out of the liver results in progressive periportal fibrosis and obstruction of the intrahepatic portal veins, resulting in biliary cirrhosis.

► Clinical Findings

A. Symptoms and Signs

The infant with biliary atresia often has an uneventful neonatal course until jaundice is noted at 2-3 weeks of age. Stools may be normal or clay colored, and the urine may be dark. The stools contain an increased quantity of fat but are of normal consistency and not frothy. The liver may be of normal size early, but it becomes enlarged with time. A hard liver may develop as a consequence of progressive cirrhosis. Splenomegaly usually develops. Ascites and portal hypertension do not become manifest for several months.

B. Laboratory Findings

The workup of biliary atresia consists of analysis of liver function tests, complete blood count, and metabolic and serologic screening. The bilirubin levels may vary considerably from day to day, but direct bilirubin levels over 3 mg/dL are common. Alkaline phosphatase levels are often elevated to 500-1000 U/L, and γ -glutamyltranspeptidase levels are greater than 300 U/L.

C. Imaging Studies

Ultrasonography may demonstrate absence or inability to visualize a contracted gallbladder. Radionuclide scanning using technetium Tc 99m-labeled iminodiacetate compounds (IDA, HIDA, PIPIDA, DISIDA) to observe the intensity of uptake within the liver and evidence of secretion

into the bowel is valuable, usually preceded by a 2- to 3-day course of phenobarbital to promote tracer uptake. Core needle biopsy of the liver may be safely performed at any age if the clotting tests are normal. A diagnosis based on needle biopsy is accurate in 60%, equivocal in 16%, and erroneous in 24% of cases. Unless the workup has conclusively diagnosed another entity, all children suspected of having biliary atresia should undergo operative cholangiography with the intention of proceeding to exploration of the porta hepatis and portoenterostomy as necessary.

► Other Causes

Other causes of obstructive jaundice are choledochal cyst, inspissated bile syndrome, and any one of several neonatal hepatitises. A choledochal cyst is identified by the presence of a palpable mass in the right upper quadrant and ultrasonographic confirmation. Inspissated bile syndrome follows a hemolytic process in which a large bilirubin load is excreted into the bile ducts, where it becomes coalesced and impacted, or may occur after a prolonged period of bowel rest with total parenteral nutrition. The syndrome is recognized by abdominal ultrasound. Hepatitis is most commonly of unknown cause. It may be due to a variety of infections, often of maternal origin, such as toxoplasmosis, cytomegalovirus, rubella syndrome, herpes simplex, coxsackievirus, and varicella. Serum should be tested for elevated antibody titers to these agents. Neonatal physiologic jaundice is self-limited and also responds to phototherapy.

Genetic metabolic diseases producing jaundice include α_1 -antitrypsin deficiency, galactosemia, and cystic fibrosis. Other rare causes include sepsis, parenteral alimentation cholestasis, Gilbert disease, and Alagille syndrome.

► Treatment

Surgical exploration for neonatal jaundice is indicated as early in infancy as possible, when biliary atresia is the likely cause. Delayed treatment will result in progressive cirrhosis. Fluoroscopy should be available in the operating room. The gallbladder is cannulated through a transverse abdominal incision or via laparoscopy. Water-soluble contrast should be gently instilled into the biliary tree. If the image shows a patent common bile duct but no reflux into the liver, a rubber-shod bulldog clamp may be placed on the distal common duct and the cholangiogram repeated. A liver biopsy should be performed in all cases.

Confirmed biliary atresia requires hepatic portoenterostomy (Kasai procedure). The scarred bile ducts and gallbladder are removed, and a Roux-en-Y limb of jejunum is sutured to an area of the hilum bounded laterally by the hepatic artery branches. Some surgeons utilize empiric postoperative antibiotic coverage to prevent cholangitis that can lead to scarring and ongoing occlusion of the bile canaliculi that may remain patent. Steroids have also been used both

preoperatively and postoperatively in an effort to prevent ongoing biliary and hepatic fibrosis though outcomes via scientific studies on this topic are equivocal.

► Prognosis

A good long-term outcome is related to a meticulously performed procedure, age at operation less than 2 months, absence of cirrhosis at the time of operation, and establishment of adequate bile flow. In general, one-third of the infants will have excellent bile flow and do not develop liver failure; one-third never have bile flow and require early liver transplantation; and one-third have initially good bile flow but months to years later develop progressive biliary cirrhosis requiring liver transplantation. The average life span for infants with uncorrectable biliary atresia without transplantation is 19 months. Death is due to progressive liver failure, bleeding from esophageal varices, or sepsis. For those with established bile flow postoperatively, the most common complication is cholangitis, and this may recur. Most often, the cause is unknown and not readily correctable by surgical means.

CHOLEDOCHAL CYST

A choledochal cyst is a dilation or diverticulum of all or a portion of the common bile duct. Estimates of incidence range from 1:2,000,000 to 1:13,000. There is a female predominance (3:1), and the lesions are more common in Asians, with a large majority of the reported cases from Japan. Numerous theories exist as to the cause of this abnormality, including infectious agents, reflux of pancreatic enzymes into the bile duct via a long common channel, genetic factors, and biliary autonomic dysfunction.

Choledochal cysts are classified into one of five subtypes. Type I is a fusiform dilation of the extrahepatic bile duct. Type II is a saccular outpouching of the common bile duct. Type III is referred to as a choledochoceles and is a wide-mouth dilation of the common bile duct at its confluence with the duodenum. Type IV is cystic dilation of both the intrahepatic and extrahepatic bile ducts. Type V consists of lakes of multiple intrahepatic cysts with no extrahepatic component and, when associated with hepatic fibrosis, is termed Caroli disease. Type I and type IV are the most common lesions, with type I cysts accounting for 85% of these abnormalities. Caroli disease appears to be a congenital syndrome and often follows an autosomal recessive pattern of inheritance in association with various other anomalies such as polycystic kidney disease and renal tubular ectasia.

If left untreated, a choledochal cyst may cause cholangitis and cholangiocarcinoma. The risk of cholangiocarcinoma in the first decade of life is only 0.7%; however, this increases to 14% at 20 years and is postulated to increase even further throughout life.

► Clinical Findings

The clinical manifestations of a choledochal cyst are recurrent abdominal pain, episodic jaundice, and a right upper quadrant mass, though in most cases one of these features is missing. As children grow older, the cyst may become painful or infected. On rare occasions, children have been described with bile peritonitis secondary to perforation of a cyst. In adults, an abdominal mass is rarely appreciated, and patients present more commonly with symptoms of cholangitis or pancreatitis. Gallstones and cholangitis may develop due to biliary stasis.

The diagnosis is most often established by the clinical presentation and abnormal ultrasonography. Technetium Tc 99m-labeled IDA scan, CT and MRI scans, endoscopic retrograde cholangiopancreatography, and operative cholangiography may be necessary. Ultrasonography is increasingly responsible for detecting choledochal cysts in the fetus.

► Treatment

In the past, the cysts were not removed but drained into a limb of intestine. However, many of these patients developed carcinoma in the cyst years later. Presently, the treatment is complete excision with Roux-en-Y hepaticojejunostomy. The duodenal end of the bile duct should be oversewn without injury to the anomalous entry of the pancreatic duct, limiting the amount of residual biliary tissue at risk for malignancy. Side-to-side choledochoduodenostomy is controversial due to a high incidence of reflux bile gastritis. However, it has been used successfully in high volume centers in Asia and is growing in popularity in the United States. Cholecystectomy is always performed. Biliary cirrhosis and portal hypertension, occurring from prolonged ductal obstruction, may be assessed with liver biopsy. The results of choledochal cyst excision with hepaticojejunostomy reconstruction are consistently excellent, but these children do require lifelong follow-up because of the risk of anastomotic stricture and intrahepatic stone formation. There is currently a trend toward laparoscopic approaches to the treatment of choledochal cyst disease.

INGUINAL & SCROTAL DISORDERS

INGUINAL HERNIA & HYDROCELE

Inguinal hernia is a common condition in infancy and childhood, occurring in 1%-3% of all children. Unlike hernias in adulthood, these nearly always result from a patent processus vaginalis (indirect hernia) and not from a weakness in the floor of the inguinal canal (direct hernia). The processus vaginalis follows the descent of the testis into the inguinal canal. Failure of obliteration of the processus may

▲ **Figure 43-20.** Spectrum of inguinoscrotal disorders. **A:** Normal anatomy. The processus vaginalis is obliterated and there is a small remnant, the tunica vaginalis, adjacent to the posterior surface of the testis. **B:** Scrotal hydrocele. **C:** Communicating hydrocele. Note the proximal patency of the processus vaginalis. **D:** Hydrocele of the spermatic cord. **E:** Inguinal hernia. **F:** Inguinoscrotal hernia. (Reproduced, with permission, from Sheldon CA: Inguinal and scrotal disorders. In: Rowe MI et al, eds. *Essentials of Pediatric Surgery*. St. Louis, MO: Mosby; 1995.)

lead to a variety of anomalies, including hernia, communicating hydrocele, noncommunicating hydrocele, hydrocele of the spermatic cord, and hydrocele of the tunica vaginalis (Figure 43-20).

The processus vaginalis remains patent in over 80% of newborn infants. With increasing age, the incidence of patent processus vaginalis diminishes. At 2 years, 40%-50% are open, and in adults 25% are persistently patent. Actual herniation of bowel into a widely patent processus vaginalis develops in 1%-4% of children; 25% occur within the first year of life. Indirect inguinal hernia occurs four to six times more frequently in males. Direct and femoral hernias occur in children but are very rare.

Hernias are found on the right side in 60% of cases, on the left side in 30%, and bilaterally in 10%. Conditions

associated with an increased risk of inguinal hernia include prematurity, family history, history of an abdominal wall defect (eg, gastroschisis), cryptorchidism, intersex anomalies, connective tissue disorders, and ascites. The processus vaginalis may be obliterated at any location proximal to the testis or labium.

► Clinical Findings

The incidence of a clinically detectable inguinal hernia varies with gestational age: 9%-11% in preterm infants and 3%-5% for full-term infants. The diagnosis of hernia in infants and children can be made only by the demonstration of an inguinal bulge originating from the internal ring. The bulge can be elicited during times of Valsalva (crying, coughing,

straining). Having an assistant hold the infant's arms over his or her head and legs straight will often elicit crying and straining that will aid in the physical examination. Indirect signs, such as a wide external ring and the "silk glove" sign (palpable thickening of the spermatic cord) are not dependable. One must always locate the position of the testis during examination for a hernia since an inguinal bulge due to an undescended or retractile testis may be mistaken for a hernia.

Incarcerated inguinal hernia accounts for approximately 10% of childhood hernias, and the incidence is highest in infants. In the majority of girls with incarcerated hernia, the sac contains the ovary and portion of the tube. These structures are usually a sliding component of the sac. In boys, small bowel, colon, or appendix can be within the sac.

A hydrocele is fluid within the remnant processus vaginalis. It is characteristically an oblong, nontender soft mass. It may be around the testicle only (testicular hydrocele), extend up from the testicle into the inguinal region (inguinoscrotal hydrocele), or be contained within a segment of the processus adjacent to the spermatic cord (hydrocele of the cord) or communicated with the peritoneal cavity (communicating hydrocele). With a noncommunicating hydrocele (the first three hydroceles described above), the processus vaginalis has closed proximally. The normal spermatic cord can usually be palpated above the level of the hydrocele. Transillumination is not reliable in the newborn since intestine and fluid transilluminate equally well. A communicating hydrocele is suspected by a history of size variation (smallest in the morning after sleep, largest during the day after the upright posture or repeated straining).

► Differential Diagnosis

A hydrocele under tension may be confused with an incarcerated inguinal hernia. The sudden appearance of fluid confined to the testicular area may represent a noncommunicating hydrocele secondary to torsion of the testis or testicular appendage, epididymo-orchitis, pan-serositis from a recent viral syndrome, or idiopathic scrotal edema. Rectal examination and palpation of the peritoneal side of the inguinal ring may distinguish an incarcerated hernia from a hydrocele or other inguinoscrotal mass, but this is only reliable in the first 2-3 months of age as the internal ring is difficult to reach thereafter.

► Complications

The principal risk of not treating an inguinal hernia is incarceration (viscus stuck in sac) and subsequent strangulation (ischemia of said viscus, usually the bowel, not the ovary). Compression of the spermatic vessels by an incarcerated hernia may produce hemorrhagic infarction of the ipsilateral testicle.

► Treatment

In general, hydroceles that do not communicate with the peritoneal cavity are physiologic and the vast majority resolve by 18 months of age. Those that persist after 1 year or those that demonstrate changes in size (communicating hydroceles) should be repaired.

Inguinal hernia in infancy and childhood should be repaired; they never resolve spontaneously. In premature infants under constant surveillance in the hospital, hernia repair may be deferred until the baby is ready to be discharged. High ligation of the hernia sac by obliteration of the internal ring (leaving enough space for the spermatic cord) is all that is required. Historically, it was recommended that all boys under 2 years of age and all girls under 5 years undergo operative exploration of the contralateral inguinal canal in search of a clinically silent patent processus vaginalis. This approach has been replaced, in large part, by laparoscopic exploration. This is performed either through the ipsilateral hernia sac, through the umbilicus, or in-line with the internal ring (at the lateral border of the rectus muscle) using a needle scope. If a patent processus vaginalis is demonstrated, a second inguinal incision is made and the procedure is repeated as described above. Recently, a completely laparoscopic repair has been advocated, which has the advantage of simultaneous exploration of the contralateral side and virtually no manipulation of the spermatic cord. The incidence of complications from uncomplicated inguinal hernia repair (recurrence, wound infection, and damage to the spermatic cord) should be 2% or less.

An incarcerated hernia in an infant can usually be reduced initially before operation. This is accomplished by sedation and by elevation of the foot of the bed to keep intra-abdominal pressure from being exerted against the inguinal area. When the infant is well sedated, the hernia may be reduced by gentle constant pressure over the internal ring in a manner that milks the bowel into the abdominal cavity. This is a two-handed maneuver in which one hand "squeezes" the incarcerated mass while the other directs it posteriorly into the internal ring. If the bowel is not reduced within an hour, operation is required. If the hernia is reduced, operative repair should be delayed for 48 hours to allow edema in the tissues to subside. An incarcerated ovary may not be able to be reduced but is usually asymptomatic, and repair at the next available operating room time is sufficient since torsion is rare and the blood supply, unlike that of the intestine, is not compromised by being trapped in the canal. Bloody stools and edema and red discoloration of the skin around the groin suggest a strangulated hernia, and reduction of the bowel should not be attempted. Emergency repair of incarcerated inguinal hernia is technically difficult because the edematous tissues are friable and tear readily. When gangrenous intestine is encountered, the bowel should be resected and an end-to-end intestinal anastomosis performed.

UNDESCENDED TESTIS (CRYPTORCHIDISM)

In the seventh month of gestation, the testicles normally descend into the scrotum. A fibromuscular band—the gubernaculum—extends from the lower pole of the testis to the scrotum, and this band probably acts by guiding the path for descent during differential growth of the fetus rather than by pulling the testes down. Undescended testis (cryptorchidism) is a form of dystopia of the testis that occurs when there is arrested descent and fixation of the position of the testis retroperitoneally, in the inguinal canal, or just beyond the external ring. Continued descent of the testes may progress after birth, but descent comes to a halt before 2 years of age.

Another form of dystopia is ectopic testis, in which the gubernaculum may have guided the testis near the pubis, penis, perineum, or medial thigh or to a subcutaneous position superficial to the inguinal canal. In these instances, the testis has descended beyond the external ring of the inguinal canal, and the vascular supply is sufficiently developed so as to pose little difficulty in operative repair.

Normal spermatogenesis requires the cooler temperature range provided in the scrotum. When the testis remains undescended and subjected to normal body temperature, degenerative changes in the seminiferous tubules occur in which the lining cells become progressively atrophic and hyalinized, with peritubular fibrosis. The degenerative changes begin to occur at 2 years of age. Unless the disorder is corrected, all bilaterally cryptorchid adult males become sterile.

The incidence of undescended or partially descended testis is 1%-2% in full-term infants and up to 30% in premature babies. The right testis is affected in 45% of cases, the left testis in 30%, and both testes in 25%. A patent processus vaginalis is present in 95% of patients with cryptorchidism, and approximately 25% develop a clinical hernia.

Anomalies associated with cryptorchidism occur in about 15% of cases and include a wide variety of syndromes such as Klinefelter syndrome, hypogonadotropic hypogonadism, the prune belly syndrome, horseshoe kidneys, renal agenesis or hypoplasia, exstrophy of the bladder, ureteral reflux, gastroschisis, and cloacal exstrophy.

► Clinical Findings

Physical examination demonstrates an “empty hemiscrotum” with absent rugae. Cryptorchidism must be differ-

entiated from a retractile testis. Because of the very active cremaster of children under 3 years of age and the small size of the testis, the gonad can retract into the external inguinal ring or within the inguinal canal—this is called a retractile testis—and it is a variant of normal. The retractile testis can be manually manipulated into the mid to lower scrotum and no therapy is required.

► Treatment

Operation is indicated after 12-18 months since degenerative changes begin to take place in these testes that may impair spermatogenesis and lead to malignant transformation. Additionally, cryptorchid testes are more susceptible to trauma and torsion, often have an associated inguinal hernia, and may cause adverse psychosocial effects. The incidence of testicular cancer in a cryptorchid testis is 30 times higher than in the normal population and is not lessened by repair. The role of repair is to allow reliable examination for a testicular mass later in life.

Orchidopexy is the surgical method for mobilizing the testis—based on the testicular vessels and the vas deferens—from its ectopic location into the scrotum. When the dystopic testis is not palpable preoperatively, 17% are absent, 33% are intra-abdominal, and 50% are in the inguinal canal or just beyond the inguinal ring. If the testis is not palpable when the child is anesthetized, laparoscopy should be performed before making an inguinal incision. Increasingly, the complete operation (diagnosis and intra-abdominal mobilization) is performed laparoscopically. This will allow for identification of an abdominal testis or the diagnosis of an absent testis (usually due to *in utero* torsion). Very high testes with a short blood supply can be brought into the scrotum by a two-stage repair (dividing the spermatic artery and vein with clips or laser followed by positioning in the scrotum 6-8 weeks later) based on collateral blood supply via the vas deferens and the gubernaculum. Testes confined in the inguinal canal (25% of cases) can usually be brought into the scrotum in one stage. Ectopic testicles located outside the inguinal canal, such as in the subcutaneous inguinal pouch, occur in over 50% of cases, and the testicular vessels are so well developed that scrotal placement is rarely a problem. The prognosis for fertility following orchidopexy in unilateral maldescent is 80%, whereas fertility after bilateral orchidopexy is about 50%. Due to variable degrees of tension and tenuous blood supply, the testis after an orchidopexy is often smaller than the contralateral one.

TESTICULAR TORSION

Testicular torsion is most frequent in late childhood and early adolescence, though the range can include the fetus and the adult. Anatomically, there are two forms of testicular torsion depending on where the spermatic cord is twisted with respect to the tunica vaginalis: intravaginal torsion (bell-clapper deformity), the most common form, and extravaginal torsion that occurs principally in neonates and in children with an undescended testis. Rarely, the testis may twist on a long epididymal mesentery. In children and adolescents, testicular torsion is either idiopathic or occurs after activity or trauma.

► Clinical Findings

Acute scrotal or testicular pain that may radiate to the lower abdomen is usually present. Progressive swelling, edema, and erythema of the hemiscrotum occur. The testis is exquisitely tender to palpation. The testicle may be foreshortened, the epididymis may lie anteriorly, and the cremasteric reflex may be absent—though these signs are difficult to elicit. Fetal or neonatal torsion is probably responsible for the “absent” testis noted during laparoscopy.

The diagnosis of testicular torsion is based mainly on clinical examination. Although one may utilize Doppler ultrasonography and radionuclide scanning to aid in the diagnosis, these tests are time consuming and, in the case of ultrasound, operator specific.

► Differential Diagnosis

Torsion of the testicular appendices (vestigial müllerian duct structures) and epididymitis may mimic testicular torsion. With epididymitis, there is often pyuria, voiding symptoms, and fever. Torsion of the testicular appendices often has a gradual onset, and careful palpation may reveal point tenderness rather than diffuse tenderness. There may be a visible necrotic lesion on scrotal transillumination (blue dot sign).

► Treatment

If the diagnosis is strongly suspected, the best “test” is operative scrotal exploration. The testicular salvage rate if detorsion is performed within 6 hours after onset of symptoms is up to 97%, versus less than 10% if delayed more than 24 hours. At operation, the torsion is corrected and the gonad, if viable, is fixed to the hemiscrotum in three places. Because the paired testicle is at risk for torsion since the testicular anatomy tends to mirror itself, contralateral orchiopexy (suture fixation) should be performed in all cases. Torsion of the testicular appendices tends to be self-limiting since necrosis and autoamputation usually occur. Treatment is with warm baths, limited activity, and an anti-inflammatory agent. If significant pain persists after 2-3 days and the appendix has not autoamputated, excision is indicated. Testicular salvage after neonatal testicular torsion is very rare.

ABDOMINAL WALL DEFECTS

UMBILICAL HERNIA

A fascial defect at the umbilicus is frequently present in the newborn, particularly in premature infants. The incidence is highest in African-American children. In most children, the umbilical ring progressively diminishes in size and eventually closes. Fascial defects less than 1 cm in diameter close spontaneously by 5 years of age in 95% of cases. When the fascial defect is greater than 1.5 cm in diameter, it seldom closes spontaneously. Unlike inguinal hernias, protrusion of bowel through the umbilical defect rarely results in incarceration in childhood. Surgical repair is indicated if the intestine becomes incarcerated, when the fascial defect is greater than 1.5 cm, and in all children over 4 years of age. Both open and laparoscopic approaches are associated with uniformly excellent results.

OMPHALOCELE

This is a midline abdominal wall defect noted in 1:5000 live births. The abdominal viscera (commonly liver and bowel) are contained within a sac composed of peritoneum and amnion from which the umbilical cord arises at the apex and center (Figure 43–21). When the defect is less than 4 cm,

▲ **Figure 43–21.** Neonate with omphalocele. The liver and bowel herniated through a midline abdominal wall defect and are surrounded by a sac of amnion and chorion from which the umbilical cord emanates. (Reproduced, with permission, from Albanese CT: *Pediatric surgery*. In: Norton JA. *Surgery*. New York, NY: Springer; 2000.)

it is termed as hernia of the umbilical cord; when greater than 10 cm, it is termed a giant omphalocele. Associated abnormalities occur in 30%-70% of infants and include, in descending order of frequency, chromosomal abnormalities (trisomy 13, 18, 21), congenital heart disease (tetralogy of Fallot, atrial septal defect), Beckwith-Wiedemann syndrome (large-for-gestational-age baby; hyperinsulinism; visceromegaly of kidneys, adrenal glands, and pancreas; macroglossia, hepatorenal tumors, cloacal extrophy), pentalogy of Cantrell, and prune belly syndrome (absent abdominal wall muscles, genitourinary abnormalities, cryptorchidism). Small omphaloceles are most often linked to chromosomal defects and Beckwith-Wiedemann syndrome, especially when the liver is not in the hernia sac.

► Treatment

The primary goal of surgery is to return the viscera to the abdominal cavity and close the defect. With an intact sac, emergency operation is not necessary, so a thorough physical examination and workup for associated anomalies is performed. An orogastric tube should be placed on suction to minimize intestinal distention.

The success of primary closure depends on the size of the defect and of the abdominal and thoracic cavities as well as the presence of associated problems (eg, lung disease). It is wise to leave the sac *in situ* since primary closure may not be possible, and in this way one has maintained the best biologic dressing for the viscera. Supplemental coverage with plastic wrap or a bowel bag can be used to prevent heat loss. If the viscera reduce but abdominal wall closure is not possible, there are three options: staged repair, prosthetic patch repair, or delayed operative management with initial epithelialization and compression for gradual return of domain. A staged repair aims to create a protective extra-abdominal extension of the peritoneal cavity (termed a silo), allowing gradual reduction of the viscera and gradual abdominal wall expansion using two parallel sheets of reinforced Silastic sheeting sutured to the fascial edges or a preformed one-piece silo with a collapsible ring at its base for ease of insertion. A prosthetic patch repair bridges the fascial gap with a synthetic material (eg, polytetrafluoroethylene) and the skin is closed over the patch. The silo is progressively compressed to invert the amniotic sac and its contents into the abdomen and to bring the edges of the linea alba together by stretching the abdominal wall muscles. This usually requires 5-7 days, after which the defect is then primarily closed. The intra-abdominal pressure produced by the silo should not exceed 20 cm H₂O to avoid impairing venous return from the bowel and kidneys. When abdominal relaxation is sufficient to allow the rectus muscles to come together, the silo is removed, the amnion is left inverted into the abdominal cavity, and the defect is closed.

Delayed operative management is appropriate for infants with severe associated anomalies or a giant omphalocele. The amnion is allowed to dry and form an eschar. The membrane becomes vascularized beneath the eschar, and contraction of the wound with skin growth covers the defect. This can be further facilitated by creation of a compression orthotic that allows for the gradual return of abdominal contents and recreation of abdominal domain. A ventral hernia results, which is repaired electively when the patient is stable. The survival rate for infants with small omphaloceles is excellent. Deaths associated with larger omphaloceles are principally from wound dehiscence with subsequent and ensuing infection or from associated anomalies.

GASTROSCHISIS

Gastroschisis is a defect in the abdominal wall that usually occurs to the right of a normal insertion of the umbilical cord (Figure 43-22). It is believed to arise at the site of involution of the right umbilical vein, though a less popular theory holds there is some evidence that it results from rupture of an omphalocele sac *in utero*. It is twice as common as omphalocele and the defect is usually smaller. The remnants of the amnion are usually reabsorbed. The skin may continue to grow over the remnants of the amnion, and there may be a bridge of skin between the defect and the cord. The small and large bowel, stomach, and often the fallopian tube/ovary/testis herniate through the abdominal wall defect. Unlike an omphalocele, the liver is virtually never present in the defect. Having been bathed in the amniotic fluid and with compression of the mesenteric blood supply at the

▲ **Figure 43-22.** Neonate with a gastroschisis. The defect is to the right of the umbilical cord, and the bowel has no investing sac. Note edema of the bowel wall and the dilated stomach adjacent to the umbilical cord. (Reproduced, with permission, from Albanese CT: Pediatric surgery. In: Norton JA. Surgery. New York, NY: Springer; 2000.)

abdominal defect, the bowel wall is edematous and has a very thick, shaggy membrane (“peel”) covering it. The loops of intestine are usually matted together, and the intestine appears to be abnormally short.

► Complications

Since the bowel has not been contained intra-abdominally, the abdominal cavity fails to enlarge, and it frequently cannot accommodate the protuberant bowel. Over 70% of infants with this disorder are premature, but associated anomalies occur in fewer than 10% of cases. Nonrotation of the midgut is present. Associated intestinal atresia occurs in approximately 7% because segments of intestine that have herniated through the defect become infarcted *in utero*.

► Treatment & Prognosis

Unlike omphalocele, urgent repair is necessary. Small defects may be closed primarily after manually stretching the abdominal cavity. A staged approach is frequently required using a silo as described above (under Omphalocele). As bowel wall edema subsides, the bowel will readily reduce into the abdominal cavity. Reduction is aided by having the infant paralyzed and receiving endotracheal ventilation to relax the abdominal wall and allow it to stretch and accommodate the bowel. When the bowel has been completely reduced (usually 5-7 days), the silo is removed and the abdominal wall is closed. Recently, the use of the umbilical remnant or a patch dressing has been described to allow primary closure without the need for operative intervention.

The death rate for infants with gastroschisis is less than 5%. Poor GI function and episodes of sepsis, presumably from compromised bowel, may occur. Prolonged postoperative ileus (> 2 weeks) is the rule, and total parenteral nutrition is necessary. Primary repair of an associated intestinal atresia is rarely safe and possible. Either a proximal stoma is created or the atretic ends are reduced and repaired 6 weeks later when the intra-abdominal inflammation has subsided.

CUTANEOUS VASCULAR ANOMALIES

Cutaneous vascular anomalies comprise a group of congenital and acquired vascular malformations of the skin. They are present in 2.6% of all newborns. These anomalies are broadly divided into two categories: hemangiomas and vascular malformations. They are most precisely classified by the biologic activity of the endothelium.

HEMANGIOMAS

Hemangiomas demonstrate endothelial hyperplasia and are seen in children and adults but behave differently at different ages. Hemangiomas are much more common than vascular malformations. In the neonatal period, hemangiomas can be subclassified according to their growth phase. A rapid proliferating phase is usually seen during the first few years of life followed by an involuting phase that may last several years.

► Clinical Findings

The clinical appearance depends on the depth of the lesion. Superficial dermal lesions (capillary hemangiomas, strawberry hemangiomas) are raised and profoundly erythematous, with an irregular texture; deep lesions (cavernous hemangiomas) are smooth and slightly raised, with a bluish hue or a faint telangiectatic pattern on the overlying skin. Mixed lesions are often noted (capillary-cavernous hemangiomas). Twenty percent of patients have multiple lesions. Complications from hemangiomas consist of ulceration (during the proliferative phase), bleeding, thrombocytopenia (Kasabach-Merritt syndrome), consumptive coagulopathy, high-output heart failure, visual field encroachment, airway obstruction, and minor skeletal distortions.

► Treatment

Fifty percent of hemangiomas will involute without treatment by age 5 years and 70% by 7 years. The remainder will slowly resolve by age 10-12 years. Steroid therapy hastens the rate of proliferation of hemangiomas by 30%-90% and is indicated for complicated lesions (ie, those causing severe physiologic or anatomic abnormalities).

CUTANEOUS VASCULAR MALFORMATIONS

Vascular malformations, in contrast to hemangiomas, have normal endothelial cell turnover and tend to grow proportionally with the child. These lesions are structural anomalies that are considered errors in vascular morphogenesis. They are usually visible at birth but may take years or even decades to become manifest. They are separated into low-flow and high-flow variants and further classified according to the type of vascular channel abnormality: capillary, venous, arterial, and mixed malformations. Capillary and venous malformations are low-flow variants; arterial and mixed arterial and venous ones are high-flow variants.

► Capillary Malformations

Capillary malformations are nevus flammeus (port-wine stain), nevus flammeus neonatorum (angel kiss), nevus flammeus nuchae (stork bite, salmon patch), angiokeratomas, and telangiectasias (spider, hereditary hemorrhagic telangiectasia [Rendu-Osler-Weber syndrome]). They are

prone to infection and are treated aggressively with intravenous antibiotics. A compression garment should be used if anatomically feasible. Some lesions can be excised or injected with a sclerosing solution.

► Venous Malformations

Venous malformations have a wide spectrum of appearances ranging from simple varicosities to complex lesions that may be located in deeper tissues (eg, bone, muscle, salivary gland). Pain is often related to thrombosis within the lesion. Radiographic imaging delineates the nature and extent of the lesion (angiogram, CT, MRI). Photocoagulation or Nd:YAG laser may be effective for superficial lesions. Resection is the definitive treatment since it can reduce bulk, improve contour and function, and control pain. It is limited by anatomic boundaries, and multiple, staged procedures may be required.

► Arterial Malformations

Arterial and arteriovenous malformations are associated with multiple small fistulas surrounded by abnormal tissues and can cause high-output cardiac failure. They are most common in the head and neck region (especially intracerebral). There is pain and overlying cutaneous necrosis. Adjacent osseous structures are often destroyed. Selective embolization is used either as palliation or presurgically to limit hemorrhage. Excision, when possible, is the treatment of choice.

► Combined Malformations

Combined vascular malformations and hypertrophy syndromes consist of Klippel-Trenaunay-Weber syndrome (combined capillary-lymphatic venous malformation associated with lower limb hypertrophy), Parkes-Weber syndrome (upper limb arteriovenous shunting), Maffucci syndrome (low-flow vascular malformations and multiple extremity enchondromas with hypoplastic long bones), and Sturge-Weber syndrome (upper facial port-wine stain and vascular anomalies of the choroid plexus and leptomeninges).

Fevurly RD, Fishman SJ: Vascular anomalies in pediatrics. *Surg Clin North Am* 2012 Jun;92(3):769-800.

TUMORS IN CHILDHOOD

NEUROBLASTOMA

Of all childhood neoplasms, neuroblastoma is exceeded in frequency only by leukemia and brain tumors. Approximately 60% of cases occur within the first 2 years of life and 97% within the first 20 years. This tumor is of neural crest origin and may originate anywhere along the distribution of the sympathetic chain. The most common site

for primary disease is in the abdomen (adrenal), followed by the thorax, pelvis, and occasionally the head and neck. Neuroblastomas originate in the retroperitoneal area in 75% of cases; 55% arise from the adrenal gland. They may reach massive size and violate tissue planes such that they envelop major blood vessels, their branches, and other important structures (eg, ureters), making initial primary resection potentially hazardous. The biologic behavior varies with the age of the patient, the site of primary origin, and the extent of the disease.

► Clinical Findings

A. Symptoms and Signs

Symptoms are site specific. The most common symptom is pain (from primary or metastatic disease). Nonspecific symptoms include growth retardation, malaise, fever, weight loss, and anorexia. Children frequently appear ill at the time of diagnosis. Constipation and urinary retention are signs of pelvic disease. Orbital metastases commonly present with periorbital ecchymoses and proptosis (“raccoon eyes”). Spinal canal involvement may present with acute paralysis due to compression. Opsomyoclonus syndrome is an acute cerebellar encephalopathy characterized by ataxia, opsoclonus (“dancing eyes”), myoclonus, and dementia. It occurs in association with approximately 3% of all neuroblastomas and is usually associated with a good prognosis, though the neurologic abnormalities tend to persist after successful treatment of the primary tumor. Interestingly, it is not due to CNS metastases of neuroblastoma and is believed to be immune mediated. Infants with stage IV-S disease (see below) may display cutaneous metastases (“blueberry muffin” lesions) or respiratory embarrassment secondary to massive hepatomegaly from tumor infiltration. Palpable lesions are often hard and fixed.

In infants, metastases confined to the liver or subcutaneous fat are frequent and cortical bone metastases unusual. In older children, metastases to lymph nodes and bone are found in over 70% of cases at diagnosis. Pain in areas of bony involvement and in joints with associated myalgia and fever mimics rheumatic fever. Eighty-five to 90% secrete high levels of the catecholamine metabolites vanillylmandelic acid and homovanillic acid. Hypertension and diarrhea may occur as a result of catecholamine and vasoactive intestinal peptide secretion.

B. Imaging Studies

Imaging is aimed at defining the extent of the tumor and determining the presence of metastases to distant sites (most commonly lymph nodes, bone, lung, and liver). Neuroblastoma is the most common abdominal tumor to demonstrate calcifications (50%) prior to chemotherapy. CT scan of the area of tumor involvement helps to identify

the relationship to surrounding structures and determine resectability. MRI is useful in assessing tumor within the spinal canal and spinal cord compression. MRI is as sensitive as CT scanning in terms of assessing tumor size and resectability but has the added advantage of being superior to CT in assessing vessel encasement, vessel patency, and spinal cord compression. MRI can also demonstrate bone marrow involvement in selected cases. Metaiodobenzylguanidine (MIBG) scintigraphy is very sensitive in detecting tumors that concentrate catecholamines and has been useful in the diagnosis of primary, residual, and metastatic disease in patients with neuroblastoma. For retroperitoneal tumors, an intravenous urogram may show displacement or compression of the adjacent kidney without distortion of the renal calices. Bone scans may be useful in detecting osseous metastases.

► Prognostic Factors

Favorable prognostic factors include diagnosis before age 18 months, a thoracic primary lesion, and low stage. In addition, several molecular and cellular characteristics of neuroblastic tumors are prognostically important. The most important is the high incidence of amplification of the proto-oncogene *N-myc*, seen in approximately 30% of tumors. Amplification of *N-myc* (> 10 copies) adversely correlates with prognosis independently of clinical stage. Using the histologic Shimada index, well-differentiated, stroma-rich tumors have a favorable prognosis. An elevated ratio of vanillylmandelic acid to homovanillic acid correlates with an improved outcome in patients with advanced disease. Other biochemical indicators of advanced disease include neuron-specific enolase, serum ferritin, and serum lactate dehydrogenase. Staging systems are surgically and anatomically based and have prognostic value. The most recent is the International Neuroblastoma Staging System (Table 43–6). Stage IV-s has favorable outcomes to older children with stage III and IV disease.

► Treatment

Diagnosis depends upon demonstration of immature neuroblastic tissue obtained by tissue or bone marrow aspirate and biopsy. Tissue is obtained by biopsy (either by laparotomy or laparoscopically), which allows accurate determination of resectability and ensures that adequate tissue (1 g or 1 cm³) is available for determination of tumor markers, cytologic studies, and the special stains required for accurate diagnosis and staging.

The spectrum of treatment for neuroblastoma is driven by risk stratification based on multiple factors beyond Stage. A localized neuroblastoma should be excised, and the local area of the tumor should be irradiated only when gross tumor remains. Unresectable neuroblastomas should be biopsied and treated initially by chemotherapy and radiation

Table 43–6. International neuroblastoma staging system.

I.	Localized tumor confined to area of origin; complete excision, with or without microscopic residual disease; ipsilateral and contralateral lymph nodes negative (nodes attached to primary tumor and removed en bloc when it may be positive)
IIa.	Unilateral tumor with incomplete gross excision; ipsilateral and contralateral lymph nodes negative
IIb.	Unilateral tumor with complete or incomplete excision; positive ipsilateral, nonadherent regional lymph nodes; contralateral lymph nodes negative
III.	Tumor infiltrating across the midline with or without lymph node involvement; or unilateral tumor with contralateral lymph node involvement; or midline tumor with bilateral lymph node involvement or bilateral infiltration (unresectable)
IV.	Dissemination of tumor to distant lymph nodes, bone, bone marrow, liver, or other organs
IVs.	Localized primary tumor as defined for stage I or II with dissemination limited to liver, skin, or bone marrow (limited to infants younger than 1 y)

therapy and then by surgical resection for residual tumor. Removal of all residual disease is the goal. Most neuroblastomas are radiosensitive and respond to radiation. Patients with disseminated disease should be treated with a combination of chemotherapeutic agents such as cyclophosphamide, vincristine, dacarbazine, doxorubicin, cisplatin, and teniposide. Patients with stage III or stage IV tumors who are at high risk by virtue of their age or of the stage and biologic characteristics of the tumor benefit from total body irradiation followed by either allogeneic or, more commonly, autologous bone marrow transplantation.

Davidoff AM: Neuroblastoma. *Semin Pediatr Surg* 2012 Feb;21(1):2-14.

WILMS TUMOR (NEPHROBLASTOMA)

Renal neoplasms account for about 10% of malignant tumors in children. Nephroblastoma (Wilms tumor), which accounts for 80% of these, consists of a variety of embryonic tissues such as abortive tubules and glomeruli, smooth and skeletal muscle fibers, spindle cells, cartilage, and bone. Seventy-five percent of children with nephroblastoma are under 5 years of age; the peak incidence is at 2-3 years. With current multimodality treatment, the survival rate exceeds 85%.

The left kidney is affected in 50% of cases of Wilms tumor and the right kidney in 45%. In 5% of cases, the tumors are bilateral; 60% are synchronous and 40% are metachronous. Associated anomalies and their incidence per 1000 cases are aniridia, 8.5; hypospadias, 18; hemihypertrophy, 25; and cryptorchidism, 28. Beckwith-Wiedemann syndrome and

neurofibromatosis occur together occasionally, and renal tumors may also occur in families. The constellation of Wilms tumor, aniridia, genitourinary anomalies, and mental retardation (WAGR syndrome) is associated with deletion of 11p13.

► Clinical Findings

A. Symptoms and Signs

In contrast to those with neuroblastoma, children are usually healthy appearing. Symptoms consist of abdominal enlargement in 60%; pain in 20%; hematuria in 15%; malaise, weakness, anorexia, and weight loss in 10%; and fever in 3%. Hypertension is noted in over half of patients. An abdominal mass, palpable in almost all cases, is usually very large, firm, and smooth, and it does not ordinarily extend across the midline.

B. Imaging Studies

Imaging is required to determine the extent of the mass; to assess for bilateral disease, venous invasion, and metastases; and to confirm contralateral renal function. This is accomplished with abdominal ultrasound (to assess venous invasion) and a CT scan of the chest and abdomen.

► Differential Diagnosis

Abdominal masses may also be caused by hydronephrotic, multicystic, or duplicated kidneys and by neuroblastoma, teratoma, hepatoma, and rhabdomyosarcoma. Ultrasonography and CT scanning can usually distinguish nephroblastoma from these other tumors. Calcification occurs in 10% of cases of nephroblastoma and tends to be more crescent-shaped, discrete, and peripherally situated than the calcifications of neuroblastoma, which are finely stippled.

► Treatment & Prognosis

Surgical excision is often accomplished without any preoperative treatment unless significant inferior vena caval thrombus is present. The aim of surgery is to completely remove the tumor (nephrectomy) and ureter without spill and to determine the tumor stage by virtue of its extent and the presence of lymph node involvement (Table 43-7). Stage I is tumor confined to a kidney that has been completely excised; stage II is tumor extending beyond the kidney (perirenal tissues, renal vein or vena cava, biopsy or local spill in the flank) and completely excised; stage III is residual, nonhematogenous tumor confined to the abdomen (lymph node metastases, preoperative or intraoperative diffuse peritoneal deposits, residual tumor at the surgical margins, or unresectable tumor); stage IV is hematogenous metastases (lung, liver, bone, and brain); and stage V is bilateral renal involvement.

Table 43-7. COG Wilms tumor staging system.

<p>Stage I: Tumor limited to kidney and completely excised. The surface of the renal capsule is intact and the tumor was not ruptured prior to removal. There is no residual tumor.</p> <p>Stage II: Tumor extends through the perirenal capsule but is completely excised. There may be local spillage of tumor confined to the flank, or the tumor may have been biopsied. Extrarenal vessels may contain tumor thrombus or be infiltrated by tumor.</p> <p>Stage III: Residual nonhematogenous tumor confined to the abdomen: lymph node involvement, diffuse peritoneal spillage, peritoneal implants, tumor beyond surgical margin either grossly or microscopically, or tumor not completely removed.</p> <p>Stage IV: Hematogenous metastases to lung, liver, bone, brain, etc</p> <p>Stage V: Bilateral renal involvement at diagnosis; each kidney should be staged separately.</p>

Irradiation of the tumor bed is indicated if the tumor has extended beyond the capsule of the kidney to involve adjacent organs or lymph nodes or if intraoperative tumor spillage has occurred. Very large tumors may be treated with radiation therapy and chemotherapy preoperatively to reduce their size. A significant reduction in size usually occurs in 7-10 days, after which nephrectomy can be readily performed. Nephrectomy is accomplished through a long transverse or thoracoabdominal incision.

Palpation of the renal veins and inferior vena cava is performed to detect tumor thrombus. Bilateral disease (6%) mandates “nephron-sparing” surgery. The treatment of bilateral disease is individualized with the goal of eradicating tumor while preserving the maximal amount of functional renal mass. It is a contraindication to primary nephrectomy. Suspicious lesions in the opposite kidney are biopsied. If the tumor is too large for safe resection, it is biopsied along with regional lymph nodes. Chemotherapy with or without radiation therapy will usually result in a significant reduction in tumor size and allow subsequent resection. Metastatic foci in the lung or liver may be resected or treated with radiation therapy. Any residual tumor following radiation therapy, including multiple lesions, should be resected.

Overall survival is 85%, and most patients are cured. Survival correlates with stage and histology. The 4-year survival with respect to stage and histology is shown in Table 43-8. Tumor rupture with gross spillage portends a sixfold increase in risk of local recurrence and requires the use of postoperative external beam radiation.

Hamilton TE, Shamberger RC: Wilms tumor: recent advances in clinical care and biology. *Semin Pediatr Surg* 2012 Feb;21(1): 15-20.

Table 43–8. Four-year survival for Wilms tumor.

Stage I/FH: 98%
Stage I-III/UH: 68%
Stage II/FH: 90%-95%
Stage III/FH: 85%-90%
Stage IV/FH: 78%-86%
Stage IV/UH: 52%-58%

FH, favorable histology; UH, unfavorable histology.

RHABDOMYOSARCOMA

Rhabdomyosarcoma is a childhood malignancy that arises from embryonic mesenchyme with the potential to differentiate into skeletal muscle. It is the most common pediatric soft tissue sarcoma and is the third most common solid malignancy. It accounts for 4%-8% of all malignancies and 5%-15% of all solid malignancies of childhood.

The age distribution is bimodal, the first peak is between 2 and 5 years, and the second peak is between 15 and 19 years. Fifty percent present before 5 years, and 6% present in infancy. There is an increased incidence in patients with neurofibromatosis, Beckwith-Wiedemann syndrome, and Li-Fraumeni cancer-family syndrome.

Rhabdomyosarcoma is divided into distinct histologic groups: favorable, intermediate, and unfavorable. Favorable types (5%) include the sarcoma botryoides and spindle cell variants. Botryoid tumors typically present in young children from within visceral cavities (eg, vagina), while spindle cell types have a predilection for paratesticular sites. Intermediate-prognosis tumors (50%) are of the embryonal type. Unfavorable-prognosis tumors (20%) include alveolar and undifferentiated tumors. Alveolar tumors arise from the extremities, trunk, and perineum. Undifferentiated tumors arise from the extremity and head and neck sites. Thirteen percent cannot be adequately characterized and are labeled “small, round cell sarcoma, type indeterminate.”

► Clinical Findings

The clinical presentation varies with the site of origin of the primary tumor, the patient’s age, and the presence or absence of metastatic disease. The majority of symptoms are secondary to the effects of compression by the tumor or by the presence of a mass. The most common site is the head and neck region (35%). These are subdivided into orbital (10%), parameningeal (15%), and nonparameningeal (10%) sites. They are usually embryonal and present as asymptomatic masses or functional deficits. Genitourinary rhabdomyosarcoma (26%) are divided into two groups: bladder and prostate (10%) and nonbladder and prostate, including paratesticular

sites, perineum, vulva, vagina, and uterus (16%). The most common histologic type is embryonal, though botryoid tumors and spindle cell tumors are seen more frequently here than in any other site. These tumors may be so massive as to make determination of the primary tumor site impossible. There is a propensity for early lymphatic spread in genitourinary primary tumors. Bladder and prostate tumors frequently present with urinary retention or hematuria, while vaginal and uterine tumors present with vaginal bleeding or discharge or with a mass exiting the vagina. Extremity rhabdomyosarcoma (1%) are more common in the lower than in the upper extremity. These are usually alveolar varieties with a high incidence of regional nodal involvement and distal metastases. “Other” sites account for 20%. The most common are the thorax, diaphragm, abdominal and pelvic walls, and intra-abdominal or intrapelvic organs.

Staging is determined by the histologic variant, the primary site, and the extent of disease since each has an important influence on the choice of treatment and on prognosis. CT scanning or MRI is essential to evaluate the primary tumor and its relationship to surrounding structures. A clinical grouping system was designed by the Intergroup Rhabdomyosarcoma Study Group to stratify different extents of disease in order to compare treatment and outcome results (Table 43–9). It is based on pretreatment and operative outcome and does not account for the biologic differences or the natural history of tumors arising from different primary sites.

► Treatment & Prognosis

The surgical management is site specific and includes complete wide excision of the primary tumor and surrounding

Table 43–9. Intergroup Rhabdomyosarcoma Study Clinical Group staging system.

Group I: Localized disease, completely removed
a. Confined to muscle or organ of origin
b. Infiltration outside organ or muscle of origin; regional nodes not involved
Group II: Total gross resection with evidence of regional spread
a. Grossly resected tumor with microscopic residual
b. Regional disease with involved nodes, completely resected with no microscopic residual
c. Regional disease with involved nodes, grossly resected, but with evidence of microscopic residual and/or histologic involvement of the most distal regional node in the dissection
Group III: Incomplete resection, or biopsy with presence of gross disease
Group IV: Distant metastases

Adapted, with permission, from Neville HL et al: Preoperative staging, prognostic factors, and outcome for extremity rhabdomyosarcoma: a preliminary report from the Intergroup Rhabdomyosarcoma Study IV (1991–1997). *J Pediatr Surg* 2000;35:317.

uninvolved tissue while preserving cosmetic appearance and function. Incomplete excision (beyond biopsy) or tumor debulking is not beneficial, and severely mutilating or debilitating procedures should not be performed. Tumors not amenable to primary excision should be amply biopsied and then treated with neoadjuvant agents; secondary excision is then performed and is associated with a better outcome than partial or incomplete excisions. Clinically suspicious lymph nodes should be excised or biopsied, while excision of clinically uninvolved nodes is site specific. Primary reexcision has been shown to improve outcome in patients where microscopic margins are positive, where the initial procedure was not a formal “cancer” resection, or where malignancy was not suspected preoperatively.

The 5-year survival for stage I tumors is 90%; for stage II, clinical group I or II, it is 77%; for stage II, clinical group III, it is 65%; and for stage III lesions (group I, II, or III), it is 55%. Stage IV tumors arising from favorable sites of origin are curable, while those from unfavorable sites have a very poor prognosis. The prognosis for recurrent disease is poor.

Paulino AC, Okeru MF: Rhabdomyosarcoma. *Curr Probl Cancer* 2008,32(1):7-34.

TERATOMA

Teratomas are embryonal neoplasms derived from pluripotent cells containing tissue from at least two of three germ layers (ectoderm, endoderm, mesoderm). Approximately 80% are found in females. They are typically midline or para-axial tumors and are distributed in the following regions: sacrococcygeal (57%), gonadal (29%), mediastinal (7%), retroperitoneal (4%), cervical (3%), and intracranial (3%). Other sites are rare. Nongonadal teratomas present in infancy; gonadal ones, in adolescence. Twenty-one percent are malignant.

The serum alpha-fetoprotein (AFP) level is elevated in tumors containing malignant endodermal sinus (yolk sac) elements. Serial AFP levels are markers for recurrence. Beta-human chorionic gonadotropin (β -hCG) is produced from those containing malignant choriocarcinoma tissue. Rarely, enough β -hCG is produced to cause precocious puberty. Elevated AFP and β -hCG levels in histologically benign tumors indicate an increased risk of recurrence and malignant transformation, particularly with “immature” benign teratomas.

► Sacrococcygeal Teratoma

The majority of sacrococcygeal teratomas present in the newborn period and can be detected by prenatal ultrasound. Females predominate; a history of twins is common. Pregnancy may be complicated by fetal high-output cardiac failure via arteriovenous shunting within the tumor, maternal polyhydramnios, and hydrops fetalis leading to

fetal demise. Fetal surgery has been utilized successfully in those with hydrops. The tumors are classified according to location: type I, predominantly external (46%); type II, external mass and presacral component (35%); type III, visible externally, but predominantly presacral (9%); and type IV, entirely presacral, not visible externally (10%).

Treatment is excision of the tumor and coccyx; type I and II lesions are resected from the perineal approach, and type III and IV lesions require a combined intra-abdominal and perineal resection. The majority (97%) of newborn sacrococcygeal teratomas are benign and do not require adjuvant therapy. Follow-up requires serial AFP levels and physical examinations, including digital rectal examination. Recurrent tumors are excised. The greatest risk factor for malignancy is age at diagnosis. The malignancy rate is approximately 50%-60% after 2 months of age. Malignant tumors are often treated with surgery and chemotherapy. The 5-year survival for malignant germ cell tumors arising from a sacrococcygeal teratoma is approximately 50%.

► Mediastinal Teratoma

Mediastinal teratomas account for approximately 20% of all pediatric mediastinal tumors. They usually arise in the anterior mediastinum, though intrapericardial and cardiac lesions have been reported. Symptoms include respiratory distress, chronic cough, chest pain, and wheezing. Males with β -hCG-producing tumors may display precocious puberty. Cardiac failure may develop from compression or pericardial effusion. The chest radiograph demonstrates a calcified anterior mediastinal mass in over one-third of cases. Ultrasonography delineates cystic and solid components. General anesthesia should not be induced until a CT scan evaluation of the airway has been obtained since the supine position coupled with a loss of airway tone from anesthetic agents may allow the anterior mass to obstruct the distal trachea, making rapid establishment of an airway all but impossible. If significant airway compression is present, an awake needle biopsy under local anesthesia followed by radiation therapy or chemotherapy is indicated. Complete resection is definitive treatment.

► Cervical Teratoma

Cervical teratomas are rare neonatal neck masses that by virtue of their large size frequently cause respiratory distress. Calcifications may be seen on a plain radiograph and a mixed cystic and solid appearance on ultrasound. These tumors are most commonly benign. The most common malignant type is the yolk sac tumor (endodermal sinus tumor). Serum AFP and β -hCG levels can be monitored to detect the presence of recurrent germ cell tumors. The rapid establishment of an endotracheal airway may be necessary. Tracheostomy is hazardous because of the distortion of landmarks by the large mass. Treatment is complete excision. Some malignant

tumors respond to radiation therapy. Regardless of the stage of disease, these tumors behave aggressively and should be treated adjunctively with a combination of cisplatin, vinblastine, and bleomycin or with dactinomycin, cyclophosphamide, and vincristine.

Amies Oelschläger AM, Sawin R: Teratomas and ovarian lesions in children. *Surg Clin North Am* 2012 Jun;92(3):599-613.

LIVER NEOPLASMS

Tumors of the liver are uncommon in childhood (2% of all pediatric malignancies). More than 70% of pediatric liver masses are malignant. The majority of hepatic malignancies are of epithelial origin, while most benign lesions are vascular in nature.

1. Hepatoblastoma

Hepatoblastomas account for nearly 50% of all liver masses in children and approximately two-thirds of malignant tumors. The majority are seen in children under 4 years of age, and two-thirds are noted prior to 2 years of age. Beckwith-Wiedemann syndrome, hemihypertrophy, familial adenomatous polyposis syndrome, fetal alcohol syndrome, and parenteral nutrition administration in infancy all increase the risk of hepatoblastoma.

► Clinical Findings

A. Symptoms and Signs

The most common finding is an asymptomatic abdominal mass or diffuse abdominal swelling in a healthy-appearing child. There may be obstructive GI symptoms secondary to compression of the stomach or duodenum or acute pain secondary to hemorrhage into the tumor. Physical examination reveals a nontender, firm mass in the right upper quadrant or midline that moves with respiration. Advanced tumors present with weight loss, ascites, and failure to thrive. Approximately 10% of males present with isosexual precocity secondary to tumor secretion of β -hCG.

B. Laboratory Findings

Laboratory studies reveal nonspecifically elevated liver function tests and a mild anemia. Thrombocytosis of unknown cause is occasionally seen. AFP is significantly elevated in 90-95%. This marker is also associated with other malignant lesions such as germ cell tumors, but levels are lower. Serial serum AFP measurements are used to monitor patients for tumor recurrence. Levels fall to normal after curative resection.

C. Imaging Studies

Abdominal ultrasound demonstrates a solid, usually unilobar (right lobe most common) lesion of the liver but lacks

sufficient detail to determine resectability. Abdominal CT scan using intravenous contrast is currently the imaging procedure of choice both for diagnosis and for planning therapy. The CT scan demonstrates the tumor's proximity to major vascular and hilar structures. The typical CT appearance is a solid solitary mass with lower attenuation levels than those of the surrounding liver. A novel technique, CT arteriography, holds promise as a reliable means of assessing vascular invasion along with gross tumor distribution. MRI has proved to be very useful in defining the patency of vascular structures.

► Differential Diagnosis

One major management problem is the inability to differentiate adenomas from hepatocellular carcinoma. Because of this, hepatic adenoma, despite being a benign lesion, is often excised. Focal nodular hyperplasia is a well-circumscribed, nonencapsulated nodular liver mass. Ultrasonography and CT scan demonstrate a solid mass, but one cannot differentiate it from adenoma or malignancy without a biopsy. If the diagnosis can be made by biopsy (percutaneous or open), no further treatment is needed. Mesenchymal hamartoma is an uncommon benign lesion presenting in the first year of life as an asymptomatic large solitary mass usually confined to the right lobe of the liver. CT scan demonstrates a well-defined tumor margin and minimal to no contrast enhancement. The treatment is surgical wedge resection; lobectomy is rarely required.

► Treatment

The definitive diagnosis of hepatoblastoma requires tissue biopsy. Although this can be performed percutaneously, there are reports of "seeding" of the biopsy tract. It is preferable to perform open biopsy of the lesion with assessment of resectability. If the lesion is not primarily resectable, vascular access is obtained during the same anesthetic interval for subsequent chemotherapy. Table 43-10 outlines the surgical staging system for childhood hepatic malignancies.

Complete surgical resection is the major objective of therapy and represents the only chance for cure. Approximately 60% of patients will have primarily resectable lesions. Lobectomy or extended lobectomy (trisegmentectomy) is usual, but segmental (nonanatomic) resection of small isolated tumors may be possible. Careful preoperative evaluation and planning have made liver resection in children

Table 43-10. Hepatic tumor staging.

Stage I: Tumor localized and completely resected
Stage II: Tumor resected with microscopic residual disease
Stage III: Unresectable tumor or gross residual disease
Stage IV: Metastatic disease

a safe procedure, with a mortality rate of less than 5%. Adequate exposure can be obtained via an extended subcostal or bilateral subcostal incision, although bulky lesions may require extension into the right hemithorax to gain adequate vascular control during dissection. Ascitic fluid is obtained for cytologic examination. If the lesion is deemed unresectable, the tumor is biopsied. If the lesion is made resectable following chemotherapy, lobectomy or trisegmentectomy is performed. Intraoperative cholangiography is helpful to verify the integrity of the remaining biliary tree.

Postoperative complications include bleeding, biliary fistula, subphrenic fluid collections or abscess, and inadvertent injury to the biliary tree. Hepatic regeneration occurs quickly, and hepatic insufficiency is rare if 25% or more of the liver parenchyma remains. Hepatic transplantation is used for unresectable disease when chemotherapy has failed to allow complete resection but no demonstrable metastases exist.

The overall survival for all children with hepatoblastoma is approximately 50%. The best survival (90%) is seen in patients with stage I tumors who receive adjunctive chemotherapy after complete excision. Survival decreases as the surgical stage increases, though long-term survival approaches 60%-70% in patients with unresectable disease who receive chemotherapy.

Meyers RL: Tumors of the liver in children. *Surg Oncology* 2007;16(3):195-203.

2. Hepatocellular Carcinoma

Hepatocellular carcinoma is less common than hepatoblastoma and typically presents in older children and adolescents (median age, 10 years). It is associated with preexisting chronic hepatitis, cirrhosis due to hepatitis B virus, and other causes of childhood cirrhosis (tyrosinemia, biliary cirrhosis, α_1 -antitrypsin deficiency, type 1 glycogen storage disease, and long-term parenteral nutrition). Signs and symptoms consist of an abdominal mass or diffuse swelling, abdominal pain, weight loss, anorexia, and jaundice. The serum AFP level is elevated in 50%, though the absolute levels are lower than in patients with hepatoblastoma. Diagnostic studies, staging, and treatment are somewhat the same as for hepatoblastoma. Because of multicentricity, bilobar involvement, portal vein invasion, and lymphatic metastases, only 15%-20% of hepatocellular carcinomas are resectable. Fibrolamellar hepatocellular carcinoma in younger patients is associated with a high rate of resectability and a better prognosis. The overall long-term survival is poor (15%), even for resectable disease. The role of liver transplantation is unclear.

3. Liver Hemangioma

This is the most common benign pediatric hepatic lesion. These tumors are solitary (cavernous hemangioma) or multiple (infantile hemangioendothelioma), involving the

bulk of the liver. Isolated cavernous hemangiomas are not often associated with cutaneous hemangiomas, whereas infantile hemangioendotheliomas are commonly associated with hemangiomas in other parts of the body or integument. Patients with a solitary hemangioma frequently have no symptoms or present with a mass. Infrequently there is intratumor hemorrhage or rupture resulting in abdominal pain. Infants with hemangioendothelioma commonly present with massive hepatomegaly and high-output cardiac failure from arteriovenous shunting. Approximately 40% develop Kasabach-Merritt syndrome (thrombocytopenic coagulopathy due to platelet sequestration within the tumor). The diagnosis is made by red blood cell-labeled radionuclide or dynamic abdominal CT scanning. CT scan demonstrates increased filling and a rapid venous phase from arteriovenous shunting. Angiography is unnecessary, and percutaneous biopsy is contraindicated.

Treatment is not necessary in an asymptomatic child. Patients with congestive heart failure or thrombocytopenia are treated with corticosteroids, digoxin, and diuretics. Refractory patients benefit from hepatic artery embolization. External beam radiation reduces hepatic size and controls symptoms. Their large size and diffuse involvement often preclude resection. Indications for surgery include ruptured lesions with hemorrhage, masses with uncertain diagnoses, symptomatic lesions, or disease limited to one lobe. Hemangioendotheliomas may undergo malignant degeneration into angiosarcoma.

Litten JB, Tomlinson GE: Liver tumors in children. *Oncologist* 2008 Jul;13(7):812-820.

PEDIATRIC TRAUMA

Accidental trauma is the leading cause of death among children 18 and younger. Patterns of injury vary by age, with a higher rate of isolated neurotrauma than adults. Mortality has been reduced in recent years due to a combination of factors including prevention, improved prehospital care and evolving management strategies. Pediatric trauma has a trimodal distribution of mortality. Early mortality is from massive injury to the CNS or central vasculature and can only be addressed by prevention. Mortality within hours from the time of injury is due to CNS mass lesions (brain bleeding or edema), solid organ injury with hemorrhage and pleural or pericardial compression. The rapid diagnosis and treatment of these conditions improves outcome and is the focus of advanced trauma life support courses. Late mortality seen days to weeks after injury is due to septic and inflammatory complications. This is less common in children than adults. Pediatric surgery has led the development of nonoperative management of spleen and liver laceration that has led to significant organ preservation.

NONACCIDENTAL TRAUMA

Child abuse is any nonaccidental injury inflicted by a parent, guardian, or other supervising adult. It may be passive, in the form of emotional or nutritional deprivation, but is most readily recognized in the active form, characterized as “battered, bruised, beaten, broken, and burned.” It is estimated that 1 million children per year in the United States suffer injuries that qualifying for reporting to the National Center on Child Abuse and Neglect. About 20%-50% of children are rebattered after the first diagnosis, resulting in death in 5% and permanent physical damage in 35% when the syndrome is not recognized.

The child abuser is usually a young, insecure, unstable person who had an unhappy childhood and who has unrealistic expectations of the child. Most of these individuals are of low socioeconomic status. The abuser may be a parent, guardian, babysitter, neighborhood child, or other close associate. Active traumatic abuse is usually perpetrated by the father, but passive neglect with failure to thrive from nutritional or emotional deprivation is usually attributable to the mother.

► Clinical Findings

In most cases, the battered child is under 3 years of age and is the product of a difficult pregnancy or premature labor, usually unwanted or born outside of a stable parental relationship. Many battered children have congenital anomalies or are hyperkinetic and colicky. In most cases there is a discrepancy between the history supplied and the magnitude of the injury—or else a reluctance to give a history. Contradictory histories or delay in bringing the child to medical attention—or taking the child to many different emergency room visits in different hospitals for unusual reasons—should be regarded with suspicion. A past injury in the child or sibling and almost any injury in an infant less than 1 year of age should trigger a consideration of child abuse. The parents may be evasive or hostile. They may have open guilt feelings or may be capable of complete concealment. The innocent spouse is usually more protective of the abuser than of the child.

The child is usually withdrawn, apathetic, whimpering, and fearful and shows signs of neglect or growth retardation. Multiple forms of injury may be noted at varying stages of healing. The child should be completely disrobed to enable the clinician to look for welts, bruises, lacerations, bite or belt wounds, stick or coat hanger marks on the head, trunk, buttocks, or extremities, and similar evidence of mistreatment. Cigarette, hot plate, match, or scalding burns may be evident. Subgaleal hematomas may be caused by pulled hair. Retinal hemorrhage or detachment may follow blows to the head. Abdominal injuries may produce laceration to the liver, spleen, or pancreas or bowel perforation. Sexual

abuse should be identified by determining whether the vaginal introitus or anus is bruised, lacerated, or enlarged and whether aspirated fluid contains sperm or prostatic acid phosphatase.

Even though no obvious fracture may be present, a skeletal radiographic survey should be performed. The bone most commonly fractured is the femur, followed by the humerus in the region of the diaphysis. Rib fractures and periosteal reactions in various stages of healing will be seen. Skull fractures are most commonly seen in infants less than 1 year old. Suture separation of the skull may indicate subdural hematoma. Neurologic injury may require a CT or MRI scan.

► Treatment

The child should be admitted to hospital to be protected until the home environment can be evaluated. Injuries should be documented radiographically and with photographs. The presence of sperm in the vagina or anal canal should be confirmed. Bleeding disorders should be evaluated by a platelet count, bleeding time, prothrombin time, and plasma thromboplastin test to make certain that multiple bruises are not due to coagulopathy. A serologic test for syphilis may be indicated as well as cultures (including pharyngeal) for gonorrhea.

Injuries should be treated. Consultation with ophthalmologists, neurologists, neurosurgeons, orthopedic surgeons, and plastic surgeons may be required.

It is required by law in every state for both the hospital and the physician to report child abuse (suspected as well as documented) to local child protection services, usually via the hospital's social work department. The physician is the protector of the child and a consultant to the parents and must not assume the role of prosecutor or judge. The most difficult task is to notify the parents without confrontation, accusation, or anger that battering or neglect is suspected. The physician must tell the parents that the law requires reporting injuries that are unexplained or inadequately explained in view of the nature of the injury. A written referral should then be made to other professionals, such as child welfare personnel, hospital social workers, or psychiatrists. The referral should describe the history of past injuries and the nature of current injuries, results of physical examination and laboratory and x-ray studies, and a statement about why nonaccidental trauma is suspected.

► Prognosis

The abuser may require careful evaluation for possible psychosis by a psychiatrist. Child welfare personnel and social workers will have to assess the home environment and work with the parents to prevent future abuse. It may be necessary to place the child in a foster home, but approximately 90% of families can be reunited.

MULTIPLE CHOICE QUESTIONS

1. What is the most appropriate diagnostic test for an otherwise healthy 2 month old with new-onset bilious emesis?
 - A. Ultrasound
 - B. Upper GI series
 - C. CT scan abdomen/pelvis
 - D. Contrast enema
 - E. Esophagram
2. Which of the following statements is not true concerning thyroglossal duct remnants?
 - A. Thyroglossal duct containing thyroid tissue has a higher risk of developing papillary carcinoma
 - B. Resection of the hyoid bone surrounding the duct is necessary to prevent recurrence
 - C. Thyroglossal ducts always occur in the midline of the neck
 - D. Resection when infected carries no higher risk of recurrence
 - E. Thyroglossal duct cysts can often be differentiated from other neck lesions on exam as they tend to move with swallowing
3. The management of congenital diaphragmatic hernia (CDH) includes which of the following?
 - A. A prosthetic patch should always be used to minimize tension in the repair of CDH
 - B. Extracorporeal membrane oxygenation (ECMO) is no longer needed to manage newborns with CDH due to advanced ventilator strategies
 - C. CT scan should be attained to determine the size of the hernia defect
 - D. CDH is a surgical emergency requiring quick reduction of the hernia contents to promote lung recovery
 - E. CDH mortality is related to the degree of pulmonary hypoplasia
4. In the delivery room, the pediatric team is unable to pass an orogastric tube beyond 12 cm in a term newborn who was being followed prenatally for polyhydramnios. Which of the following tests is not necessary prior to embarking on surgical repair?
 - A. Head ultrasound
 - B. Echocardiogram
 - C. Anorectal exam
 - D. Renal ultrasound
 - E. Chest and abdominal plain x-rays
5. Which of the following is an unfavorable prognostic indicator in neuroblastoma
 - A. Age less than 18 months
 - B. N-myc amplification
 - C. Well-differentiated, stroma rich tumor
 - D. Low serum lactate dehydrogenase (LDH)
 - E. Stage IV-S

44

Oncology

Michael S. Sabel, MD

Over 1.6 million individuals in the United States are diagnosed with invasive cancer each year. Currently, 23% of all deaths in the United States are due to cancer, ranking second only to heart disease as the leading cause of mortality in this country. Over the past 10 years, however, cancer death rates have decreased. Death rates have continued to decline for the four top cancer sites (lung, colorectum, breast, and prostate). This reduction in overall cancer death rates translates to the avoidance of over 1 million deaths from cancer.

The surgeon is intimately involved in the care of cancer patients, since the majority will require surgical therapy at some time. Surgeons are often the first specialists to see newly diagnosed cancer patients or are often called upon to make the diagnosis in patients suspected to have cancer. As such, they will be responsible for orchestrating the patient's care, including coordination with medical oncologists and radiation oncologists. It is imperative that they have an in-depth knowledge of the different types of cancer and the different modalities available for treatment.

TUMOR NOMENCLATURE

Neoplasms are defined as benign or malignant according to the clinical behavior of the tumor. Benign tumors have lost normal growth regulation but tend to be surrounded by a capsule and do not invade surrounding tissues or metastasize.

Benign tumors are generally designated by adding the suffix *-oma* to the name of the cell of origin. Examples include lipoma and adenoma. The term *cancer* normally refers to malignant tumors, which can invade surrounding tissues or metastasize to distant sites in the host. The nomenclature of malignant tumors is typically based on the cell's embryonic tissue origins. Malignant tumors derived from cells of mesenchymal origin are called *sarcomas*. These include cancers that derive from muscle, bone, tendon, fat, cartilage, lymphoid tissues, vessels, and connective tissue. Neoplasms of epithelial origin are called *carcinomas*. These may be further categorized according to the histologic

appearance of the cells. Tumor cells that have glandular growth patterns are called adenocarcinomas, and those that resemble squamous epithelial cells are called squamous cell carcinomas. Cancers composed of undifferentiated cells that bear no resemblance to any tissues are designated as "poorly differentiated" or "undifferentiated" carcinomas.

► Tumor Grade

Beyond the type of cancer, it is important to classify tumors by their behavior and prognosis in order to determine appropriate therapy as well as evaluate different treatment modalities. Grading of a tumor is a histologic determination and refers to the degree of cellular differentiation. Separate pathologic grading systems exist for each histologic type of cancer. Depending on the type of tumor, these systems are based on nuclear pleomorphism, cellularity, necrosis, cellular invasion, and the number of mitoses. Increasing grades generally denote increasing degrees of dedifferentiation. While the grade of the tumor typically has less prognostic value than its stage, tumor grade has great clinical significance in soft tissue sarcoma, astrocytoma, transitional cell cancers of the genitourinary tract, and Hodgkin and non-Hodgkin lymphoma.

► Tumor Stage

Tumor staging establishes the extent of disease and has important prognostic and therapeutic implications in most types of cancer. Clinical staging is based on the results of a noninvasive evaluation, including physical examination and various imaging studies. Pathologic staging is based on findings in surgical tumor specimens and biopsies and allows for the evaluation of microscopic disease undetectable by imaging techniques. Pathologic staging may reveal more extensive tumor spread than the clinical evaluation and is the more reliable information. Clinicians must be careful when attempting to compare clinically and pathologically

staged patients, as the two groups may have dramatically different outcomes.

As with grading, the staging systems vary with different tumor types. Two major staging systems are currently in use, one developed by the Union Internationale Contre le Cancer (UICC) and the other by the American Joint Committee on Cancer (AJCC). The UICC system is based on the TNM classification. *T* refers to the primary tumor and is based on the size of the tumor and invasion of surrounding structures. Tumors are characterized as T1 to T4 cancers, with the higher T stages for larger and more invasive tumors. *N* refers to regional lymph nodes, and classifications of N0 to N3 denote increasing degrees of lymph node involvement. Finally, *M* refers to distant metastatic disease, with M0 signifying no distant metastases and M1 and M2 indicating the presence of blood-borne metastatic disease. The AJCC system divides cancers into stages 0 to IV, with higher stages representing more widespread disease and a poorer prognosis. Regardless of the staging system or the tumor type, higher stages correlate with decreased survival.

► Cancer Epidemiology

Cancer epidemiology is the study of the distribution of cancer and its determinants among defined populations and is used to examine cancer etiology as well as the efficacy of prevention, detection, and treatment strategies. The most basic types of epidemiologic terms describe cancer rates or cancer deaths for specific populations over a certain period of time.

While absolute numbers of cancer cases may be useful for health care planning, they do not take into account the size or nature of the underlying population at risk. For this reason, the most commonly used population-based measures of cancer are incidence and mortality. **Cancer incidence rates** are defined as the number of new cancer cases diagnosed during a fixed time period divided by the total population at risk. **Cancer mortality rates** are defined similarly, with cancer deaths replacing new cancer cases. These rates are typically expressed as the number of events per 100,000 individuals per year.

Incidence and mortality rates are compared across populations or over time to identify causes as well as the effect of screening or treatment. However, other factors among populations may contribute to observed differences, and these must be taken into account. For most cancers, age is the strongest risk factor, and so comparison of cancer incidence between two populations must consider the age distributions of the two groups. Adjustment (or standardization) is the most common method used to account for such differences. Comparing age-adjusted cancer incidence rates ensures that any observed differences are not the results of differences in age distributions between the two populations. Incidence and mortality rates are often also adjusted for gender, race, or socioeconomic status.

Cancer incidence examines only those diagnosed with the disease during that time period; it does not include patients diagnosed earlier who are living with cancer. **Cancer prevalence** describes the number of people with the disease either at a single point in time (**point prevalence**) or within a defined period of time (**period prevalence**). Prevalence is more relevant to the public health burden of cancer because all prevalent cases involve accessing health care. The relationship among incidence, prevalence, and mortality is influenced by the fatality of the disease. If the disease is highly fatal and the interval between presentation and death is short, mortality rates will be similar to incidence rates. The number of deaths from cancer divided by the total number people diagnosed with the cancer is known as the **cancer fatality rate**, although this is somewhat of a misnomer because they are not technically rates (they do not include time as a parameter).

Examining the fatality of cancer is obviously important when comparing treatments meant to improve outcome. **Overall survival (OS)** is the most global endpoint and is defined as the proportion of people alive at a specified period after being diagnosed with the disease. Five years is conventionally used as the time period (ie, 5-year survival). However, overall survival may not always reflect the success of treatment. Over that period of time, some patients may die of disease, but others may die of other causes. In addition, some patients may have a local or regional recurrence that is successfully treated, while some may recur with distant metastases but not succumb to them. For this reason, survival rates in cancer are often qualified by the patient's disease status.

Disease-free survival refers to the proportion of patients alive and without disease over a specific period of time. A patient who developed metastases but is still alive would be included in the overall survival rate but not the disease-free survival rate. Disease-free survival and overall survival may provide different pictures of the success of treatment. A therapy that improves disease-free survival but not overall survival may still be important if quality of life is improved. In some cancers, local or regional recurrences can be readily treated with minimal impact on overall survival. In these cases, disease-free survival may present an overly pessimistic picture of outcome. Therefore, it may be more relevant to compare **distant disease-free survival**, which refers to the proportion of people alive and without distant metastases, regardless of local recurrence. In some cases, it is difficult to assess the efficacy of a treatment by looking at overall survival or disease-free survival if there are deaths from competing causes. It may be more helpful to compare **disease-specific survival**, which is the percentage of people who have survived a disease since diagnosis or treatment and does not count patients who died from other causes.

It is important for the surgeon to understand the different methods for describing cancer survival as well as the

differences between the definitions, because the appropriateness of the comparison will vary with the biology of the disease and the clinical question being asked.

ROLE OF THE SURGICAL ONCOLOGIST

The surgeon is often the first specialist to see a patient with suspected or newly diagnosed cancer and in many cases assumes responsibility for orchestrating the overall management of the cancer patient's care. The role of the surgeon involves not only the curative resection of the tumor but also obtaining tissue for diagnosis and staging, providing palliation for incurable patients, and preventing cancer by the prophylactic removal of organs. With improving imaging technologies, expanded use of neoadjuvant therapies, molecular staging, and increasing knowledge of the genetic predisposition to cancer, the role of the surgical oncologist is continuously evolving. It is therefore imperative for surgical oncologists to remain current on the newest approaches to cancer therapy and be prepared to adapt to the changing role of surgery.

► Diagnosis & Staging

A tissue diagnosis is critical to the care of all cancer patients. Depending on the type of tumor and its location, the method of biopsy will vary. Common diagnostic techniques include needle aspiration biopsy, core needle biopsies, incisional biopsy, and excisional biopsy.

Fine-needle aspiration biopsy (FNAB) is a rapid and minimally invasive technique for the biopsy of palpable superficial tumors. Deeper, nonpalpable lesions may also be sampled by this technique when FNAB is combined with various imaging modalities, such as ultrasonography or computed tomography (CT). FNAB involves aspiration of cells from a suspicious mass, followed by cytologic examination of the stained smear. FNAB is particularly useful in the diagnosis of enlarged lymph nodes, breast lumps, thyroid masses, and lung nodules.

Advantages to FNAB include the simplicity of the procedure and the low rate of complications. However, there are limitations. FNAB cytology requires an experienced cytopathologist for accurate interpretation. Because cytology does not demonstrate architecture, it does not allow the cytopathologist to accurately grade tumors or to differentiate between *in situ* and invasive disease. If this information is necessary, FNAB may be inadequate. Sampling errors can lead to false-negative results, so a negative FNAB should be interpreted cautiously. In addition, though rare, false-

positive results can occur, so confirmation may be needed before definitive surgical intervention. For example, a mastectomy should never be performed on the basis of an FNAB of a breast lump without confirming the diagnosis by either preoperative core biopsy or frozen section analysis at the time of surgery.

Core needle biopsy utilizes a needle that removes a sliver of tissue for analysis. This technique provides more histologic information than FNAB because it allows the pathologist to see the histologic architecture of the sample rather than just the cellular characteristics. False-positive results are extremely rare. Although less so than with FNAB, sampling errors may occur, and a negative result must be weighed against clinical judgment. Core biopsies are frequently used for prostate, breast, and liver masses. Again, ultrasound and radiographic imaging may enable the clinician to sample deep-seated or nonpalpable masses. The technique may also be used during surgery to biopsy suspicious masses encountered at operation.

When a larger tumor sample is necessary for accurate grading or staging, or a needle biopsy provided inadequate information, an incisional or excisional biopsy is required. **Excisional biopsy** is the surgical removal of an entire gross lesion, while **incisional biopsy** involves sampling a representative portion of a suspicious lesion. In general, excisional biopsy is recommended whenever it is possible to excise the entire lesion without damage to surrounding structures. Incisional biopsy should be considered whenever a core biopsy fails to make the diagnosis, but removing the tumor might compromise the subsequent operation (eg, a large [> 5 cm], deep soft tissue mass for which sarcoma is a possibility) or preclude delivery of neoadjuvant therapy.

Although biopsy techniques are usually simple, the surgeon must adhere to some specific principles when performing a biopsy for a suspected malignancy. The positioning of the needle tract or scar should be such that if further surgery is required, the biopsy site will be easily included in the excised specimen. Excisional biopsies of the breast should consider the possibility of a subsequent mastectomy, and the excision of skin or subcutaneous lesions on the extremities should be oriented in a way that allows for the following wide excision and lymphatic mapping if malignancy is discovered. Meticulous hemostasis is imperative, as the formation of a wound hematoma may make subsequent operation more difficult. The surgeon should carefully orient the pathologic specimen to allow the pathologist to evaluate margins in the context of the pre-resection anatomy, which may prove important in curative surgical procedures.

Once a diagnosis is made, the next step is typically to determine the extent of the cancer, or **staging**. This step begins with a complete history and physical examination, looking for signs or symptoms of advanced or metastatic disease. Laboratory or imaging studies may follow to determine not only the extent of the primary tumor but

the presence of regional or distant metastases. Patients with signs or symptoms of metastatic disease should undergo appropriate workup of their symptoms. For some tumor types, routine staging examinations are indicated. However, for many asymptomatic patients newly diagnosed with cancer, a full battery of staging studies is not necessary and not only will increase the cost of treatment but may lead to false-positive findings, unnecessary biopsies, and inappropriate changes in therapy.

Surgeons are often called upon to perform operations that provide staging information for various types of cancer. Such procedures are necessary when the clinical extent of the disease has a direct bearing on the choice of treatment modalities. Examples include laparoscopy for gastric or pancreatic cancer, a staging laparotomy for ovarian cancer, or mediastinoscopy for lung and esophageal cancer. Staging procedures can often help to avert highly morbid procedures in cases where there is little chance for cure.

► Curative Surgery

Surgical resections with curative intent can be divided into three categories: resection of a primary lesion, resection of isolated metastases, and resection of metastatic deposits. In each case, the clinician must strive to reach a balance between the chance for cure and the morbidity of the procedure. Each situation must be evaluated individually, and the patient's wishes must be paramount.

The guiding principle of cancer surgery is to remove the entire tumor with adequate margins so as to prevent local recurrence and potentially distant recurrence. What constitutes an adequate margin varies among tumor types. Various tumors require different disease-free margins in order to achieve optimal chances for a cure. For a tumor that appears adherent or fixed to adjacent structures, **en bloc resection** is mandatory, and any attachment should be considered malignant in nature. Appropriate preoperative imaging of the tumor is often necessary to be prepared in the operating room for the possible resection of small or large bowel, bladder, or other adjacent organs.

It is important that the surgeon have knowledge of other modalities that may be integrated into the management plan to allow for a less extensive surgical procedure. Radiation and chemotherapy are commonly used in combination with surgery and are referred to as adjuvant therapies if used after complete resection with no demonstrable local or systemic disease. While their use has in some cases diminished the extent of resection necessary for local control (breast, sarcoma, head, and neck), it is important to note that these modalities do not compensate for inadequate margins in controlling local disease. Every attempt should be made to achieve widely negative margins surgically, even if it requires a second operation, rather than assuming radiation will "clean up" residual disease.

If these modalities are used in the preoperative setting, they are called neoadjuvant therapies. In many cases, neoadjuvant therapy has dramatically improved outcomes, as with pediatric rhabdomyosarcoma or locally advanced or inflammatory breast cancer. In some cases, neoadjuvant therapy can convert an unresectable tumor to resectable, while in other cases, it can decrease the extent of surgery necessary to obtain control or decrease the likelihood of positive margins. Neoadjuvant therapy is commonly used in the treatment of esophageal cancer, rectal cancer, pancreatic cancer, breast cancer, and sarcoma. It is important the surgeon consider the possibility of neoadjuvant therapy when performing a biopsy, staging the patient, or planning surgery.

The regional lymph nodes represent the most prevalent site of metastases for solid tumors, and in most cases involvement of the regional nodes represents the most important prognostic factor. Removal of the regional lymph nodes not only provides important prognostic information that may help guide adjuvant therapy, but provides regional control, preventing regional recurrence and the associated complications. For this reason, the removal of the regional lymph nodes is often performed at the time of resection of the primary cancer. More controversial is whether the removal of regional lymph nodes can improve survival. These controversies concern both the extent and the timing of the procedure. For example, the extent of lymphadenectomy at the time of gastrectomy for stomach cancer has been hypothesized to have an impact on improving overall survival. This has not, however, been borne out in prospective randomized trials. It may be that extended lymphadenectomy results in more accurate staging of patients at a cost of increased morbidity and minimal effect, if any, on overall survival. The relative benefit of nodal dissection may also vary with the efficacy of adjuvant therapies, such as chemotherapy or radiation therapy. How extensive a lymph node dissection to perform at the time of definitive resection varies with tumor type and in many cases remains controversial.

For many nonvisceral solid tumors, such as melanoma or breast cancer, elective node dissections were performed in clinically node negative patients at the time of their primary tumor resection. Unfortunately, this exposed many node-negative patients to the morbidity of a node dissection, and a clear survival benefit could not be demonstrated in prospective randomized studies. This practice has been replaced with lymphatic mapping and sentinel lymph node biopsy. Mapping agents (a radioactive tracer or a blue dye) are injected around the site of the tumor prior to surgery. These travel to the lymph nodes that first receive drainage from the site of the primary, and thus are the most likely to harbor cancer. Only the sentinel nodes (those nodes that are blue or radioactive) are removed, and carefully examined for micrometastases. This has dramatically improved our ability to stage the regional lymph nodes, helping to guide adjuvant therapies, while minimizing morbidity. Classically,

node negative patients could safely avoid further surgery, while node positive patients underwent a completion lymph node dissection. This approach has also changed recently. In breast cancer, the American College of Surgeons Oncology Group (ACoSOG) Z0011 trial, demonstrated that a subset of breast cancer patients with positive sentinel lymph nodes did not benefit from completion lymph node dissection. A similar trial, the Multicenter Selective Lymphadenectomy Trial II (MSLT-II), is examining a similar question among sentinel lymph node positive melanoma patients.

The surgeon plays a much more limited role when the patient has metastatic disease; nonetheless, the resection of “isolated” metastases in patients with solid malignancies is sometimes a consideration when technically feasible. The selection of candidate patients for surgical resection requires a thorough evaluation of the extent of known disease, likelihood of additional metastatic disease, length of time between the primary and the distant recurrence (disease-free interval), medical status of the patient, and feasibility of resecting the metastatic site with a negative margin. Ultimately, this process identifies a small subset of patients who would be surgical candidates. Although there are no prospective randomized trials documenting the survival benefit of surgical resection of metastatic disease, there is considerable retrospective evidence indicating that this approach can result in long-term benefit. The resection of lung metastases in patients with osteogenic or soft tissue sarcomas has been associated with an approximately 20%-25% overall survival rate greater than 5 years. There is also a large body of retrospective evidence documenting the benefit of resecting colorectal metastases to the liver, resulting in a 25%-40% overall 5-year survival rate, depending on the extent of liver involvement. A similar benefit has been demonstrated in an aggressive surgical approach to metastatic melanoma. Another question in stage IV disease is when to resect the primary tumor. Typically, resection of the primary cancer when the patient already has metastatic disease was only done for palliation, or to prevent future complications. This approach is changing, however. For some cancers, such as colon cancer, resection of the primary tumor in the face of metastatic disease to prevent obstruction or bleeding, is less necessary due to the improved efficacy of systemic agents. Conversely, in some cancers, such as renal cell carcinoma and possibly breast cancer, there is evidence that resection of the primary tumor improves may improve outcome in stage IV patients. One of the roles of the surgical oncologist is to know when it is appropriate to offer this option.

► Palliation

Surgical intervention is sometimes required in the patient with unresectable advanced cancer for palliative indications such as pain, bleeding, obstruction, malnutrition, or infection. The decision to operate must balance several factors,

including the likelihood of adding significantly to the quality of life of the patient, the expected survival of the individual, the potential morbidity of the procedure, and whether there are alternative methods of palliation.

Malnutrition is a common problem in the cancer patient, especially one with advanced, unresectable disease. Commonly, the surgeon is involved in placement of vascular access for hyperalimentation, or if the gastrointestinal tract is functional, the placement of gastrostomy or jejunostomy tubes for enteral nutrition. Occasionally, the surgeon is involved in palliating pain due to a metastatic lesion compressing upon an organ or adjacent nerves. Examples include cutaneous or subcutaneous melanoma metastases, a large ulcerating breast cancer, or a recurrent intra-abdominal sarcoma mass. The surgeon must assess the relative risk-to-benefit ratio in resecting a symptomatic mass knowing that it will not impact the overall survival of the patient. If the quality of life of the individual can be improved at an acceptable operative risk, then the surgical intervention is warranted.

Finally, the surgeon may be called upon to manage oncologic emergencies. Acute hemorrhage and obstruction of a hollow viscus represent the most common potential oncologic emergencies. In these cases, surgeons may have to emergently intervene in the care of a cancer patient, or in some instances, use nonsurgical approaches (such as stents or angiography).

► Prophylaxis

With our improved understanding of inherited genetic mutations and the identification of patients who are predisposed to cancer, surgical therapy has expanded beyond the therapy of established tumors and into the prevention of cancer. Prophylaxis is not a new concept in surgical oncology. Patients with chronic inflammatory diseases are known to be at high risk of subsequent malignant transformation. This typically prompts close surveillance and surgical resection at the first identification of premalignant changes. One of the earliest examples of this is the recommendation for total proctocolectomy for subsets of patients with chronic ulcerative colitis.

The ability to perform genetic screening for relevant mutations has allowed for prophylactic surgery to be implemented prior to the onset of symptoms or histologic changes. Familial adenomatous polyposis (FAP) syndrome, defined by the diffuse involvement of the colon and rectum with adenomatous polyps, almost always predisposes to colorectal cancer if the large intestine is left in place. With the identification of the gene responsible for FAP, the adenomatous polyposis coli (APC) gene, members of families in which an APC mutation has been identified can have genetic testing prior to polyps becoming evident and be considered for prophylactic proctocolectomy. Medullary

thyroid cancer (MTC) is a well-established component of multiple endocrine neoplasia syndrome type 2A (MEN2A) or type 2B (MEN2B). Mutations in the *RET* protooncogene are present in almost all cases of MEN2A and 2B. Family members of MEN patients can be screened for the presence of a *RET* mutation, and those with the mutation should undergo total thyroidectomy at a young age (6 years for MEN2A, infancy for MEN2B). The role of prophylactic mastectomies has been greatly expanded with the identification of *BRCA1* and *BRCA2*, which can be associated with a lifetime probability of breast cancer of between 40% and 85%. Other prophylactic operations are listed in Table 44–1. However, potential benefits of prophylactic surgeries must be weighed against quality-of-life issues and the morbidity of the surgery. A detailed discussion must be held with each patient considering prophylactic surgery regarding the risks and benefits, so today's surgical oncologist needs a clear understanding of genetics and inherited risk.

CYTOTOXIC CHEMOTHERAPY

The goal of chemotherapeutic regimens is to deliver pharmacologic agents systemically to eradicate all tumor cells. The ideal tumor drug would kill cancer cells without harming normal tissues. No such agent exists, and most drugs

affect normal cells to some extent. The success of chemotherapy relies on the normal cell's greater capacity for repair and survival relative to tumor cells.

Even a single cancer cell can potentially reproduce to form a lethal tumor. For this reason, the goal of curative chemotherapy must be the complete eradication of all tumor cells. Tumor burden is important in chemotherapy. A large cancer may harbor more than 10^9 tumor cells. If a tolerable dose of an effective drug killed 99.99% of these cells, the tumor burden would still be 10^5 cells. The remaining cells, while clinically undetectable, are likely to continue to grow and lead to a clinical recurrence of cancer. For this reason, most chemotherapy protocols rely on repeated administrations of drugs in order to achieve maximal cell killing. Tumor cells may avoid the cell-killing effects of a particular drug because of their stage in the cell cycle, residence in an area protected from the drug (central nervous system), or an inherent resistance to the drug.

Drug resistance plays a large role in chemotherapy failures. Several mechanisms of tumor resistance are known. The multidrug resistance (*MDR*) gene encodes a protein that actively pumps drugs out of tumor cells. This gene confers resistance on a variety of antitumor drugs, including the antibiotics and plant-derived compounds. Other tumor mechanisms of resistance include the alteration of target enzymes, increased production of a target enzyme to overwhelm the drug, and an increased capability for DNA repair. Tumor resistance to a given chemotherapeutic agent can often be overcome by the administration of multiple drugs.

Table 44–1. Prophylactic operations in surgical oncology.

Prophylactic Surgery	Potential Indications
Bilateral mastectomy	<i>BRCA1</i> or <i>BRCA2</i> mutation Atypical hyperplasia or lobular carcinoma <i>in situ</i> Familial breast cancer
Bilateral oophorectomy	<i>BRCA1</i> mutation Familial ovarian cancer Hereditary nonpolyposis colorectal cancer Hysterectomy for endometrial cancer Colon resection for colon cancer
Thyroidectomy	<i>RET</i> protooncogene mutation Multiple endocrine neoplasia type 2A (MEN2A) Multiple endocrine neoplasia type 2B (MEN2B) Familial non-MEN medullary thyroid carcinoma (FMTC)
Total proctocolectomy	Familial adenomatous polyposis (FAP) or antigen-presenting cell (APC) mutation Ulcerative colitis Hereditary nonpolyposis colorectal cancer (HNPCC) germ-line mutation

Principles of Chemotherapy Use

A. Curative Chemotherapy

Hematologic malignancies are typically treated by chemotherapy, radiation, or both, with surgery used primarily for diagnosis and staging. On the other hand, surgery is the primary treatment for nonhematologic malignancies, although there are some exceptions. Anal cancer is cured in approximately 80% of patients with the Nigro protocol—5-FU/mitomycin-C and radiation therapy—as first-line treatment. Testicular cancer, even when metastatic, is curable with bleomycin/etoposide/cisplatin in approximately 85% of patients.

B. Adjuvant Treatment

Although all visible tumor may be removed at the time of surgery, microscopic tumor deposits may still be present locally or may have spread to distant locations. Chemotherapy is most effective against very small tumors and microscopic tumor deposits. Therefore, adjuvant chemotherapy is often given to improve the likelihood of cure after surgical resection.

The benefit gained from adjuvant chemotherapy can be thought of in terms of absolute benefit or relative benefit

▲ **Figure 44–1.** Benefits of adjuvant chemotherapy. For 100 patients treated with adjuvant chemotherapy, some will be cured by surgery alone (dark red bar), some will die of other causes (gray bar), and some will die of their cancer (light red bar). Adjuvant therapy will prevent a cancer death in a portion of those patients (medium red bar). Adjuvant chemotherapy will result in a relative benefit of 50% for both patient A and patient B, meaning treatment will reduce the likelihood of dying of cancer by 50%. However, the absolute benefit is different for both patients. For patient A, who has a high likelihood of dying of disease, the absolute benefit is 24%. For patient B, who has a good prognosis, the absolute benefit is only 9%.

(Figure 44–1). For example, after colectomy for stage III colon cancer, the chance of cure is approximately 50%. This can be increased to approximately 70% by adjuvant 5-FU/leucovorin. This represents a 40% relative benefit (40% more patients are cured with chemotherapy than without chemotherapy) but a 20% absolute benefit (20% of the patients who take the chemotherapy will have altered their outcome). Another way to look at this is that with a 20% absolute benefit, 80% of patients experience the inconvenience and side effects of chemotherapy without gaining any improvement themselves. The decision to receive adjuvant chemotherapy is a balance between the expected benefit of treatment, the patient's comorbid conditions and general health, and the patient's wishes.

C. Neoadjuvant Treatment

Neoadjuvant chemotherapy is usually given to facilitate surgical resection by shrinking the primary tumor, or it may convert an unresectable tumor into a resectable tumor. In some cases, this treatment has been shown to prolong survival. Another advantage to neoadjuvant chemotherapy is that it allows the oncologist to observe the primary tumor to determine if it is sensitive to a particular chemotherapeutic regimen. During the course of cancer treatment, it is important to define the progress and outcomes resulting from therapy. The terms complete and partial response are often used as endpoints to evaluate the efficacy of a particular therapeutic regimen. A **complete response** is defined as the absence of demonstrable cancer. A **partial response** refers to

a reduction of tumor mass by greater than 50%. The patient's response to neoadjuvant chemotherapy can be an important predictor of outcome.

D. Chemotherapy for Metastatic Disease

The majority of patients who are receiving chemotherapy have metastatic disease that is not curable. For these patients, treatment with chemotherapy is intended to prolong survival, improve quality of life, or both. Response rates range from 20% to 75% depending on the tumor type and chemotherapy regimen. However, even a complete remission is rarely durable. Most partial or complete remissions last only months.

As with all therapies, the decision to use chemotherapy must balance the potential benefits with the risks, toxicities, and the patient's general health and condition. There is little to be gained by treating an asymptomatic patient if no prolongation of survival is expected. A detailed discussion must be held with each individual patient; some patients are more willing than others to tolerate the side effects of chemotherapy. Since the disease is not curable, treatment with single agents, which are less toxic than combination chemotherapy, are often considered, with more willingness to reduce doses for toxicity.

► Classes of Chemotherapeutic Agents

With all forms of curative chemotherapy, the goal is elimination of all tumor stem cells. Cells that are incapable of further

division cannot cause progression of a tumor, and the sterilization of a tumor cell is as good as a kill. Chemotherapeutic drugs are generally classified as cell cycle-specific (CCS) drugs, which are toxic to actively proliferating cells, or cell cycle-nonspecific (CCNS) drugs, which are capable of killing cells that are not dividing during drug exposure. These two classifications are not absolute, and many drugs may overlap between the two categories.

In order to achieve maximal cell killing, most therapeutic protocols use combination chemotherapy. Agents with differing mechanisms of action and different toxic side effects are used, allowing for relatively high doses of multiple agents. This method of combining agents helps to combat tumor cell resistance and increase the tumor cell killing while avoiding the compounding of toxic effects.

A. Alkylating Agents

These agents exert their effects by the transfer of alkyl groups to various cellular components, most importantly by the alkylation of DNA. Alkylators can cause DNA strand breaks, cross-linking of DNA strands, or miscoding of DNA during replication. The alkylating agents are considered cell cycle-nonspecific agents but tend to have their greatest effect on proliferating cells. Normal cells are able to avoid many of the lethal affects of alkylating agents because of their ability to repair DNA. The alkylating agents are effective in treatment of the hematologic malignancies and in a variety of solid tumors such as breast, melanoma, lung, and endometrial cancers. Included in this class are the nitrosoureas (eg, carmustine, semustine, lomustine), cyclophosphamide, chlorambucil, mechlorethamine, dacarbazine, and procarbazine.

B. Platinum Analogues

The platinum analogs are similar to the alkylating agents. They bind DNA to form interstrand and intrastrand cross-links, leading to inhibition of DNA synthesis and transcription. The mechanisms of cancer cell resistance are also similar to those of alkylating agents: decreased cellular uptake of the drugs, increased activity of DNA repair enzymes, and increased thiol-containing proteins. In addition, resistance to both cisplatin and carboplatin has been associated with a deficiency of mismatch repair (MMR) genes. It is not known why this mechanism of resistance appears to be specific to cisplatin and carboplatin, but the efficacy of the newest platinum analog, oxaliplatin, is not affected by MMR gene deficiency.

C. Antimetabolites

Rapidly dividing cells require increased synthesis of nucleic acid precursors. This increased synthesis can be exploited pharmacologically by the antimetabolites. These drugs are analogs of nucleic acids or nucleic acid precursors. The

antimetabolites may be incorporated into the nucleic acids of a cell and serve as a false messenger. Antimetabolites can shut down the cellular synthetic machinery by binding to and inhibiting enzymes important in the production of nucleic acids. Since this class of drugs affects all rapidly proliferating cells, they are relatively toxic to normal tissues that have a high rate of cell turnover. Antimetabolites are most effective in the hematologic malignancies but are also used in the treatment of solid tumors such as breast and gastrointestinal cancers. They include methotrexate, mercaptopurine, thioguanine, fluorouracil, and cytarabine.

D. Antimicrotubule Agents

A variety of antitumor drugs are derived from natural plants (and are also known as plant alkaloids). Vincristine, vinblastine, docetaxel, and paclitaxel work by binding tubulin and poisoning the assembly of microtubules in the mitotic spindle. This leads to mitotic arrest in metaphase, and these compounds are effective only on rapidly dividing cell populations. The plant alkaloids are most useful for hematologic malignancies and breast, renal, testicular, and head and neck cancers.

E. Topoisomerase Inhibitors

These plant derivatives exert their antitumor effects by binding to and inhibiting various forms of the enzyme topoisomerase. Topoisomerases are responsible for the maintenance of DNA structure and are also important in the cleavage and religation of DNA strands. Inhibition of these enzymes leads to DNA strand breakage and structural damage. The topoisomerase inhibitors are also cell cycle-specific agents and have their greatest activity against rapidly proliferating cells. Examples include etoposide, teniposide, and topotecan. These drugs are used in the treatment of hematologic malignancies and lung, bladder, prostate, and testicular cancers.

F. Antibiotics

Most of the drugs in this class are derived from the soil fungus *Streptomyces*. All the antibiotics exert their antitumor effects by interference with the synthesis of nucleic acids. Most of the drugs in this class intercalate in DNA, blocking DNA synthesis and inducing strand breakages. The antibiotics are considered cell cycle-nonspecific, and they have antitumor activity against a wide variety of solid tumors. Included in this class of drugs are doxorubicin, dactinomycin, plicamycin, mitomycin, and bleomycin.

► Side Effects of Chemotherapy

Most side effects from chemotherapeutic regimens are the result of toxicities to rapidly dividing normal cell populations—particularly bone marrow and epithelial cells. Bone marrow suppression is an adverse effect of many of these

drugs, resulting in neutropenia, thrombocytopenia, and even anemia. Mucosal ulcerations and alopecia also occur in patients treated with cell cycle–specific agents. Intractable nausea and vomiting is another common side effect that can severely affect quality of life. Testicular or ovarian failure can result from chemotherapy, leading to sterility. Many of these drugs also are powerful teratogens and should be avoided in pregnant patients. Finally, many of the alkylating agents have been implicated in the development of secondary cancers, especially hematologic malignancies.

REGIONAL THERAPY

Systemic chemotherapy is limited by toxicity to the host. Regional delivery of chemotherapeutic agents via arterial cannulation allows for high levels of drugs in the region of the primary tumor while decreasing systemic toxicity.

Isolated limb perfusion (ILP) is a technique for the delivery of chemotherapeutic agents to an extremity with locally advanced cancer and is of benefit primarily in the treatment of extremity melanoma and sarcoma. In this approach, a tourniquet is applied to the extremity to occlude venous outflow. The major artery perfusing the limb is then isolated, cannulated, and perfused with hyperthermic chemotherapeutic agents using a pump oxygenator as for cardiopulmonary bypass. The perfusion is done in the operating room and lasts for approximately 1 hour. The cannula is then removed. Most protocols involve only a single treatment. Melphalan, an alkylating agent, is the most common agent used today in the treatment of both sarcomas and melanomas. In patients with extensive in-transit melanoma confined to an extremity, isolated limb perfusion can provide regional control and palliation. In patients with unresectable extremity sarcomas, preoperative limb perfusion may shrink the tumor and allow for a limb-sparing resection. While improving regional control, this therapy has yet to show a definitive survival benefit. An alternate approach is isolated limb infusion (ILI), which involves using minimally invasive techniques to access the vessels along with a tourniquet to minimize systemic uptake.

Another approach is isolated hepatic artery infusion for the treatment of colorectal cancer metastatic to the liver. Metastatic tumors derive nearly all of their blood supply from the hepatic artery, while the normal liver parenchyma derives more than two-thirds of its blood supply from the portal system. This permits the delivery of higher doses of chemotherapeutic agents to the tumor relative to the normal hepatocytes. The drug most commonly used in this protocol is floxuridine, which is almost completely extracted on its first pass through the liver, resulting in relatively low systemic toxicity. Hepatic artery infusion requires the surgical placement of a catheter into the hepatic artery, which is connected to an implanted or external infusion pump for continuous treatment. Hepatic artery infusion has been used

for unresectable colorectal metastases as well as an adjuvant to hepatic resection. While there are clearly improved tumor responses in comparison to systemic therapy, the data is less clear on overall survival benefits. Some studies, however, have suggested an improved survival and have stimulated further investigation.

TARGETED THERAPIES

An expanding knowledge of molecular biology is revolutionizing the field of oncology, truly personalizing care for each individual patient with cancer. Molecular diagnostics is increasingly allowing us to customize the selection and dosing of traditional agents to maximize benefit and minimize toxicity. Molecular oncology is changing the way we approach drug discovery and development, leading to the development of targeted therapies. One definition of targeted therapy is any drug in which there is a specific diagnostic test that must be performed before the patient can be considered eligible to receive the drug. An example is measuring Her-2/neu overexpression on breast cancer to determine if a patient is eligible for trastuzumab (Herceptin). A more oncologic definition is any drug with a focused mechanism that specifically acts on a well-defined target or biologic pathway. Inactivation of this target/pathway results in regression or destruction of the malignant cell. Targeted therapies are often considered “magic bullets.”

Several targeted therapies have been FDA approved and are in clinical use; many others are being developed. The ideal target is one that is expressed (and can be measured) on cancer cells but not significantly expressed in vital organs and tissues. It is preferably crucial to the malignant phenotype, and its inhibition results in a clinical response in patients whose tumor expresses the target. Several methods for very specific targeting are being examined. The ability of therapeutic antibodies to bind with high affinity makes them excellent candidates for targeted therapy. While antibodies may induce an immune-mediated destruction of cancer cells (and be considered immunotherapy [see section on Immunotherapy]), they can also be used to target specific cell surface receptors to interrupt that pathway. For this latter function, it is important that the target, when bound by the antibody, is internalized by endocytosis to facilitate the intracellular mechanism of pathway inhibition and cell death.

Trastuzumab is an IgG antibody that binds to the juxtamembrane portion of the extracellular domain of the Her-2/neu receptor and has become an important option for patients with Her-2/neu–positive breast cancer. Her-2/neu is an epidermal growth factor receptor (EGFR) that has a functional intracellular tyrosine kinase and when overexpressed can lead to increased proliferation, increased metastatic potential, and resistance to therapeutic agents. While the binding of trastuzumab to the Her-2/neu protein may lead to antibody-dependent cell-mediated cytotoxicity,

the more important function appears to be the disruption of the downstream signaling through the intracellular tyrosine kinase.

Another way to target cancer cells is through the use of small molecules. The development of **imatinib mesylate** is the classic example of a small-molecule targeted therapy. Imatinib is an adenosine triphosphate-binding selective inhibitor of *bcr-abl*, and its use has been associated with durable, complete responses in the treatment of Philadelphia chromosome-positive chronic myelogenous leukemia as well as the treatment of gastrointestinal stromal tumors. The latter characteristically express an activating mutation in the c-kit receptor tyrosine kinase (*RTK*) gene.

Perhaps the most noteworthy example of the impact of targeted therapies is in the treatment of melanoma. It was discovered that 40%-60% of melanoma patients harbor a specific mutation in the *BRAF* gene, and 90% of these mutations involve a substitution of glutamic acid for valine at amino acid 600 (the V600E mutation). This gene codes for the protein kinase BRAF, a component of the mitogen-activated protein (MAPK) kinase pathway. **Vemurafenib** (Zelboraf) selectively inhibits the kinase activity of this mutated BRAF. Vemurafenib is FDA approved for the treatment of unresectable or metastatic melanoma that tests positive for the BRAF V600E mutation based on prospective randomized studies that demonstrated a dramatic improvement in progression free and overall survival. **Dabrafenib** also specifically targets the BRAF V600E mutation and has very promising clinical trial data. Another promising drug for melanoma patients with the BRAF mutation is **trametinib**, which blocks MEK, an alternate protein in the MAP kinase pathway.

Multiple other targeted therapies, both monoclonal antibodies and small molecule inhibitors, are in clinical use. **Cetuximab** (Erbix) binds to the EGFR with high affinity, blocking the subsequent signal transduction events leading to cell proliferation. It enhances the antitumor effects of chemotherapy by inhibiting cell proliferation and angiogenesis and promoting apoptosis. Cetuximab has been approved for use in combination with CPT-11 for the treatment of advanced colorectal cancer. **Bevacizumab** (Avastin) targets the vascular endothelial growth factor (VEGF), which regulates vascular proliferation and permeability and promotes angiogenesis. Other targeted therapies in use in cancer are listed in Table 44-2.

HORMONAL THERAPY

Hormones are normally involved in the differentiation, stimulation, and control of certain tissues, including but not limited to lymphoid tissue, the uterus, the prostate, and the mammary glands. Tumors arising from these tissues may also be stimulated or inhibited by hormones, and so manipulation of the hormonal balance can be beneficial in the

systemic therapy of these cancers. In some cases, hormones themselves are used as cancer therapies. For example, the administration of estrogen to a man ultimately suppresses the production of testosterone, which is a useful effect in the treatment of prostate cancer. Corticosteroids, particularly the glucocorticoids, have a powerful suppressive effect on lymphoid cells, making them useful in the treatment of acute leukemias, lymphomas, myeloma, and other myeloproliferative disorders. In most cases, however, hormonal therapy involves blocking the effects of hormones that stimulate proliferation.

► Estrogen and Androgen Inhibitors

One approach to hormonal therapy is to block the hormone receptor on the cell. Selective estrogen receptor modulators (SERMs) are medications that mimic the structure of estrogen. Because the estrogen-receptor complex varies among tissue types, SERMs can have different effects on different tissues, sometimes inhibiting the actions of estrogen and sometimes behaving like estrogen. The most well-known SERM is tamoxifen (Nolvadex), which is used not only to treat estrogen-sensitive breast cancer but also to prevent breast cancer in high-risk individuals. Because it also has some proestrogen properties, side effects of tamoxifen can include an increased risk of uterine cancer and deep vein thrombosis. Raloxifene (Evista) is a newer SERM that has been approved for prevention and treatment of postmenopausal osteoporosis and is used in the chemoprevention of breast cancer for postmenopausal women.

Flutamide (Eulexin) is a testosterone antagonist used in the treatment of prostate cancer. It works by blocking translocation of the androgen receptor to the nucleus. Although hormonal therapy for prostate cancer is palliative, it can be quite effective in slowing the progression of disease. Hormonal therapy can add several years to the life expectancy of patients with unresectable or metastatic disease. Flutamide is most effective when used in combination with surgical or pharmacologic castration.

► Gonadotropin-Releasing Hormone Analogues

The most definitive way to block the production of testosterone and estrogen is by surgical castration. The pharmacologic equivalent of castration can be accomplished with leuprolide, an analog of gonadotropin-releasing hormone (GnRH). Normally, GnRH leads to the production of luteinizing hormone and follicle-stimulating hormone, the physiologic stimulators of sex hormone production. Constant stimulation with leuprolide actually inhibits luteinizing hormone and follicle-stimulating hormone release and leads to decreased synthesis of the sex steroids. Leuprolide (Lupron) is commonly used to decrease testosterone levels in the treatment of unresectable prostate cancer. In premenopausal

Table 44–2. Targeted therapeutic agents for cancer.

Drug Name	Brand Name	Target	Used in the Treatment of
Imatinib mesylate	Gleevec	Bcr-abl, c-kit, PDGFR	GIST, DFSP, ALL, CML
Dasatinib	Sprycel	SRC-family protein kinases	CML, ALL
Nilotinib	Tasigna	Bcr-abl, c-kit, PDGFR	CML
Trastuzumab	Herceptin	Her-2/neu	Breast cancer, gastric adenocarcinoma
Pertuzumab	Perjeta	Her-2/neu	Breast cancer
Lapatinib	Tykerb	EGFR, ErbB2, Erk-1&2 AKT kinases	Breast cancer
Gefitinib	Iressa	EGFR	Non–small-cell lung cancer
Erlotinib	Tarceva	EGFR	Non–small-cell lung cancer, pancreatic cancer
Cetuximab	Erbix	EGFR	SCCA of the head and neck, colorectal cancer
Panitumumab	Vectibix	EGFR	Colorectal cancer
Temsirolimus	Torisel	mTOR	Renal cell carcinoma
Everolimus	Afinitor	Immunophilin FK–binding protein-12	Renal cell carcinoma, astrocytoma, breast cancer, pancreatic neuroendocrine tumors
Vandetanib	Caprelsa	EGFR, VEGFR2	Medullary thyroid
Vemurafenib	Zelboraf	BRAF V600E	Melanoma (BRAF V600E mutation)
Crizotinib	Xalkori	EML4-ALK	Non–small-cell lung cancer
Vorinostat	Zolinza	Histone deacetylases (HDACs)	CTCL
Romidepsin	Istodax	HDACs	CTCL
Bexarotene	Targretin	Retinoid X receptors	CTCL
Alitretinoin	Panretin	Retinoic acid receptors, retinoid X receptors	Kaposi sarcoma
Tretinoin	Vesanoid	Retinoic acid receptors	Acute promyelocytic leukemia
Bortezomib	Velcade	Proteasome	Multiple myeloma, mantle cell lymphoma
Carfilzomib	Kyprolis	Proteasome	Multiple myeloma
Bevacizumab	Avastin	VEGF	Glioblastoma, non–small-cell lung cancer, colorectal cancer, renal cell carcinoma
Sorafenib	Nexavar		Renal cell carcinoma, hepatocellular carcinoma
Sunitinib	Sutent		Renal cell carcinoma, GIST, pancreatic neuroendocrine tumors
Paxopanib	Votrient	VEGF, c-kit, PDGFR	Renal cell carcinoma, soft tissue sarcoma
Rituximab	Rituxan	CD20	B-cell non-Hodgkin lymphoma, CLL
Alemtuzumab	Campath	CD52	B-cell CLL
Ofatumumab	Arzerra	CD20	B-cell CLL

ALL, acute lymphoblastic leukemia; DFSP, dermatofibrosarcoma protuberans; CLL, chronic lymphocytic leukemia; CML, chronic myelogenous leukemia; CTCL, cutaneous T-cell lymphoma; GIST, gastrointestinal stromal tumor; PDGFR, platelet-derived growth factor receptor.

women, estrogen levels fall to postmenopausal values with leuprolide administration. For this reason, the drug can be useful in the treatment of estrogen receptor-positive breast cancers in premenopausal women.

► Aromatase Inhibitors

Postmenopausal women have functionally inactive ovaries; however, estrogens are still produced to a lesser extent in

extragonadal tissues, primarily the conversion of adrenal steroids in fat cells by the enzyme aromatase. Aromatase inhibitors, such as anastrozole (Arimidex), exemestane (Aromasin), and letrozole (Femara), eliminate functional estrogen in this population of women and are an effective hormonal treatment of breast cancer. A number of studies have demonstrated the benefit of aromatase inhibitors in postmenopausal women with hormone receptor positive breast cancer, either as first-line therapy or after the use of tamoxifen.

RADIATION THERAPY

Radiation therapy may be used alone or in combination with surgery and chemotherapy and may be given with curative or palliative intent. Some tumors, such as head and neck cancers, prostate cancer, and Hodgkin disease, can often be cured by irradiation alone, eliminating the need for surgical resection or chemotherapy. More commonly, locoregional control of tumors involves surgical resection combined with localized radiation. The theoretical advantage of combining these two therapies is based on the mechanisms by which they fail to achieve their purpose. Surgical failures occur at the margins of tumors, while radiation therapy fails in the center of tumors, where the malignant cells are numerous and hypoxic conditions exist. Radiation failures are rare at the periphery of tumors, where cell numbers are low and oxygenation is high. Depending on tumor histology and location, radiation therapy can be used as a surgical adjunct either preoperatively or postoperatively. Preoperative radiation can shrink tumors and increase the chances for complete surgical resection in cancers such as sarcomas, rectal cancers, and superior sulcus lung cancers.

► Principles of Radiation Therapy

Ionizing radiation is defined as energy with sufficient strength to cause the ejection of an orbital electron from an atom when the radiation is absorbed. Ionizing radiation can take either an electromagnetic form, as high-energy photons, or particulate forms, such as electrons, protons, neutrons, alpha particles, or other particles. Most radiation therapies utilize either photons or electrons. Electrons interact directly with tissue, causing ionization, in contrast to photons, which affect tissues by the electrons that they eject. Electron beams deliver a high skin dose and exhibit a rapid fall-off after only a few centimeters and are therefore commonly used to treat superficial targets such as skin cancers or lymph nodes within a few centimeters of the surface of the body. More commonly, electromagnetic radiation (high-energy photons) is used to treat cancer. This consists of either gamma rays (photons created from the decay of radioactive nuclei) or x-rays (photons created by interaction of accelerated electrons with electrons and nuclei of atoms in an x-ray tube target).

To quantify the interaction of radiation on tissues, one must first measure the ionization produced in air by the beam

of radiation. This quantity is known as **exposure** and is measured in Roentgens (R). One can then correct for the presence of soft tissue and calculate the **absorbed dose**: the amount of energy absorbed per unit mass. This quantity was previously measured in rads but today is typically measured as joules per kilogram, or gray (Gy) units: 100 rad = 100 cGy = 1 Gy. As photons enter tissue, the dose increases at first and then begins to fall off because radiation falls off with the square of the distance from the source (a law of physics known as the inverse-square law).

The effect on biological tissues when they encounter ionizing radiation comes from ejected electrons interacting either directly with target molecules within the cell or indirectly with water to produce free radicals (such as hydroxyl radicals) that subsequently interact with target molecules. During their brief life span, electrons and free radicals interact with molecules in a random fashion. If they interact with molecules that are not crucial to cell survival, the effect of the radiation will be harmless. If they react with biologically important molecules, the effect will be detrimental. Molecular oxygen prolongs the life of reactive radicals, increasing the likelihood that it will have a detrimental effect. This is why tumor hypoxia tends to increase resistance to radiation.

While ionizing radiation may damage many molecules with the cell, the most critical injury with respect to cell death appears to be DNA damage in the form of single-strand or double-strand breaks. Cells have relatively efficient repair mechanisms for single-strand breaks in DNA, but double-strand breaks in DNA are much more difficult for cells to repair, although not impossible. Therefore, the ability of ionizing radiation to kill cells is dependent not only on the generation of enough DNA double-strand breaks to overwhelm repair pathways but also on the time the cell has to repair those breaks prior to the next mitotic cell division.

This phenomenon is known as **sublethal damage repair** in which increased cell survival is observed if a dose of radiation is divided into two fractions separated by a time interval. As the time interval between the fractions increases, the surviving fraction of the cells also increases as the cells are able to repair double-strand DNA breaks. Of course, in clinical radiation therapy, the goal is to kill the cancer cells but spare the normal cells. Delivering a single large dose of radiation will have a high rate of tumor cell killing, but the concordant killing of the normal tissue cells may limit the clinical utility due to normal tissue toxicity. This has led to the development of multifraction regimens commonly used today, typically delivering daily fractions of 1.8-2.5 Gy. *Fractionation* of radiation dose spares normal tissues because of their greater ability to repair sublethal damage between dose fractions and repopulate with cells if the overall time is sufficiently long.

► Modes of Delivery

A. Teletherapy

Radiation is administered by two methods: an external machine (teletherapy) or the implantation of radioactive sources in or around the tumor (brachytherapy). In the past, teletherapy radiation was delivered using cobalt 60, a radioisotope produced in nuclear reactors. Although cobalt machines were very reliable, their usefulness is restricted by limited penetration to deep tumors without significant skin toxicity and difficulty in confining the dose to normal tissues. Today, external radiation is most often administered using a linear accelerator capable of producing higher energy photons without the geometric disadvantages associated with cobalt 60 units.

No matter the source, the beam of radiation needs to be modified to get optimal delivery of the desired dose to the tumor while minimizing dose to the normal tissues. Typically, the beam of radiation is rectangular. Collimators are thick shielding devices made from materials with a high atomic number. Primary collimators at the head of the machine create a rectangular beam, and additional devices such as wedges, compensators, blocks, or multileaf collimators are used to further modify the beam to desired specifications. Wedges or compensators can optimize the dose distribution if the treatment surface is curved or irregular in shape. The beam can also be shaped using individually fashioned blocks custom-made for each patient's anatomy and tumor size and shape. In modern linear accelerators, multileaf collimators have replaced handmade blocks and allow automated and precise field shaping without the use of cumbersome handmade blocks.

B. Brachytherapy

Brachytherapy involves the placement of radioactive sources into or next to the target tissue. It takes advantage of the inverse-square law, which states that the intensity of electromagnetic radiation dissipates as the inverse square of the distance from the source. Thus, if radioactive sources can be placed so that the tumor is within a centimeter of the sources, the dose received by normal tissues just 2 cm distant from the source and 1 cm distant from the tumor would be one fourth of the dose received by the tumor. This can allow delivery of a high dose to the tumor with only a modest dose to normal tissue.

There are many implantation techniques for brachytherapy. The surgical approach to the target volume may be interstitial (such as prostate seed implantation), intracavitary (such as gynecologic applicators), transluminal (such as endoscopic applications), or surface mold techniques (such as eye plaques for ocular melanoma). The implants may be permanent or temporary, and the dose may be delivered using low-, medium-, or high-dose rates. Many modern

applications use afterloading techniques that place treatment applicators and subsequently load radioactive sources to reduce radiation exposure for therapy personnel.

► Complications of Radiation Therapy

A. Acute Radiation Effects

Acute radiation effects are those toxicities that occur within a few weeks to months of radiation therapy. They occur mainly in self-renewing tissues that are characterized by actively proliferating stem cells producing progeny that divide and differentiate into mature functioning cells. This includes bone marrow, skin and its appendages, and mucosal surfaces of the oropharynx, esophagus, stomach, intestines, rectum, bladder, and vagina. Once the normal life span of the mature cells expires, the normal turnover and replacement with new cells does not occur because of radiation killing of the dividing stem cells. Acute toxicity is influenced by both fraction size and the time interval between fractions. The more rapidly a given dose is delivered during the overall treatment period, the more severe the acute effects will be. A decrease in fraction size or prolongation of the interval between fractions allows the cell populations to repair and repopulate, decreasing the severity of acute toxicity.

Head and neck irradiation is among the most toxic in the acute period due to significant mucositis of the oral cavity, oropharynx, larynx, and cervical esophagus. Skin and the salivary glands are also affected. Mucositis, yeast superinfection, desquamation, pain, xerostomia, odynophagia, dysphagia, dehydration, and malnutrition are all common clinical scenarios that radiation oncologists manage when delivering head and neck radiotherapy. Other common acute effects observed during radiation therapy directed at other anatomic sites include dysphagia and cough from thoracic radiation, nausea, vomiting, and diarrhea from abdominal radiation, and dysuria, proctitis, and perineal desquamation and pain from pelvic radiation.

B. Late Radiation Effects

Late effects are those toxicities that occur months to years after radiotherapy and are more commonly permanent. Mitotically inactive tissues without the capacity for self-renewal are commonly involved. The mechanism causing late effects may include direct damage to the parenchymal cells within an organ or indirect effects due to microvascular damage. Each organ is characterized by a **tolerance dose**, a radiation dose above which the risk of organ complications increases rapidly. These normal tissue tolerances are the true dose-limiting factors in clinical radiation therapy, because late complications can be permanent and in some cases life threatening.

The types of late complications induced by radiation can vary. For the brain, late toxicity may mean necrosis of

the brain tissue, while in the kidney it may mean nephrotic syndrome and organ failure. The tolerance doses for different organs vary over a large range, from a few Gy for sterility from testicular irradiation to over 100 Gy for necrosis or perforation of the uterus. Late complications may include fibrosis, necrosis, ulceration and bleeding, chronic edema, telangiectasias and pigmentation changes, cataract formation, nerve damage, lung pneumonitis and fibrosis, pericarditis, myocardial damage, bone fracture, liver or kidney failure, sterility, intestinal obstruction, and fistula and stricture formation.

IMMUNOTHERAPY

► Principles of Antitumor Immune Responses

Immunotherapy refers to treatments designed to kill tumor cells through immune mechanisms. There are two broad types of antitumor immune responses: one involving the humoral arm of the immune system and the other involving the cellular arm. Humoral immunity involves antibody production by mature B lymphocytes. Cell-mediated immunity involves stimulation of cytotoxic (CD8+) T cells through a major histocompatibility complex (MHC) class I-restricted process and stimulation of helper (CD4+) T cells through an MHC class II-restricted process. The humoral and cell-mediated immune responses overlap in that the activation of a B-cell response usually requires the presence of helper T cells. Whether a humoral or a cell-mediated immune response is more important in generating antitumor immunity is still debated; however, patients who exhibit both responses appear to fare better than those who demonstrate only one type of response or no response.

Essential to the generation of an immune response through either arm of the immune system is the ability of antigen-presenting cells (APCs), such as monocytes, macrophages, B cells, and dendritic cells, to process and present tumor-related peptide antigens. Proteins are phagocytosed by APCs and partially digested into smaller polypeptides. These small peptide antigens are then bound to MHC molecules on the cell surface. These unique antigen:MHC complexes can then be recognized by naïve T lymphocytes through the T-cell receptor. When a naïve helper (CD4+) T cell recognizes the antigen being expressed on the MHC class II molecule and also recognizes costimulatory molecules present on the APC, it becomes activated, resulting in proliferation and differentiation. There are two types of helper T cells. The Th1 helper T cells produce cytokines to promote a cellular response (interleukin [IL]-2, interferon

[IFN]- γ , tumor necrosis factor α , granulocyte-macrophage colony-stimulating factor). In the presence of these cytokines, naïve cytotoxic (CD8+) T cells that recognize antigen being presented on MHC class I molecules on the surface of an APC become activated. Once activated, cytolytic T cells destroy tumor cells via T-cell receptor recognition of tumor-specific antigen presented on MHC class I molecules at the tumor cell surface. Antigen-specific T cells bind to the MHC I receptor–tumor antigen complex and destroy the tumor cell via the release of granules containing granzyme B and perforin and via induction of the Fas/Fas ligand apoptosis. Cytotoxic T cells can only recognize antigen expressed on the tumor surface in the context of the MHC class I molecule.

The second type of helper T cell (Th2) secretes B-cell stimulatory cytokines (IL-4, IL-5, IL-10), which results in the proliferation and differentiation of plasma cells. As opposed to a cellular response, for an antibody response, the antigens do not have to be presented on class I MHC receptors. Tumor cells can then be killed by a variety of methods. Antibody-dependent cell-mediated cytotoxicity involves the attachment of tumor-specific antibodies to tumor cells and the subsequent destruction of the tumor cell by the natural killer (NK) cell. Complement-dependent cell-mediated cytotoxicity involves the recognition and attachment of complement-fixing antibodies to tumor-specific surface antigens followed by complement activation. A third mechanism of tumor destruction, opsonization, results when tumor-specific antibodies attach to their target antigens on tumor cell surfaces, thus marking them for engulfment by macrophages.

There are several methods by which the immune system may be incorporated into cancer therapy. Immunotherapy can be categorized as either active or passive. With passive immunotherapy, the host need not mount an immune response; the therapeutic agent will directly or indirectly mediate tumor killing. Examples of passive immunotherapy include the use of monoclonal antibodies or adoptive (cellular) immunotherapy. Active immunotherapy, on the other hand, is the delivery of materials designed to elicit an immune response by the host. This can further be broken down to nonspecific and specific active immunotherapies. Nonspecific agents are those that stimulate the immune system globally but do not recruit tumor-specific effector cells. Active specific immunotherapy is designed to elicit an immune response to one or more tumor antigens, the prime example being the use of vaccines.

► Passive Immunotherapy (Monoclonal Antibodies)

The development of monoclonal antibodies with unique specificity to tumor antigens has allowed for multiple attempts to utilize them as cancer therapy. In addition to their relative

selectivity and minimal toxicity, they are easily mass produced for widespread application. In some cases, monoclonal antibodies work primarily through the immune system (antibody-dependent cell-mediated cytotoxicity), while in other cases, they behave more as targeted therapies (see earlier section on Targeted Therapies). Examples of monoclonal antibodies that are primarily immunotherapies include rituximab and alemtuzumab. Rituximab (Rituxan) is an anti-CD20 monoclonal antibody that is approved for the treatment of relapsed or refractory low-grade or follicular non-Hodgkin lymphoma (NHL). Alemtuzumab (Campath) targets CD52, which is present on both B and T cells, and is used in the treatment of B-cell chronic lymphocytic leukemia (B-CLL).

► Adoptive Immunotherapy

Adoptive immunotherapy is the passive administration of cells with antitumor activity to the tumor-bearing host. Tumor-infiltrating lymphocytes are lymphocytes that infiltrate growing tumors and can be isolated by growing single-cell suspensions from the tumor in the presence of IL-2. They have been isolated from virtually all types of tumors and can recognize tumor-associated antigens. These cells can also be manipulated *ex vivo* to increase their recognition of tumor antigen or cytolytic potential. Adoptive immunotherapy is presently under active investigation.

► Nonspecific Active Immunotherapy

A. Immunostimulants

Before the mechanism by which the immune system can eradicate tumor cells was fully understood, early attempts at immunotherapy involved nonspecific stimulation of the immune system. The idea was that any increase in immune reactivity would be associated with a concomitant increase in the antitumor immune response. Probably the most widely embraced immunostimulant investigated has been the use of bacille Calmette-Guérin (BCG), a modified form of the tubercle bacillus. Initial trials suggested a possible benefit, but multiple prospective, randomized trials in various malignancies have failed to substantiate a survival benefit of BCG, either alone or in combination with other therapeutics. Local therapy with BCG in the bladder eliminates superficial bladder cancers and prevents tumor recurrences. It is one of several standard therapies for patients with bladder cancer. It is also being studied as an adjuvant to other immunotherapies, such as vaccines. Levamisole is an antihelminthic drug that was reported to have several immunomodulatory properties. Although the exact mechanism of action is unknown, it has been effective in the adjuvant therapy of colorectal cancer.

B. Cytokines

Cytokines are naturally occurring soluble proteins produced by mononuclear cells of the immune system that can affect

the growth and function of cells through interaction with specific cell-surface receptors. There have been over 50 cytokines isolated to date, and several have subsequently been approved by the FDA for clinical use, including interferon- α and IL-2.

The interferons (IFN- α , IFN- β , IFN- γ) were originally described as proteins produced by virally infected cells that serve to protect against further viral infection through a variety of effects. These include the increased antigen presentation via increased expression of MHC and antigens, enhancement of NK cell function, and the enhancement of antibody-dependent cell-mediated cytotoxicity. In addition, the interferons exert direct antiangiogenic, cytotoxic, and cytostatic effects. While the anticancer effects of IFN- β and IFN- γ have been disappointing, several hematologic and solid tumors have proved responsive to IFN- α , including chronic myelogenous leukemia, cutaneous T-cell lymphoma, hairy cell leukemia, melanoma, and Kaposi sarcoma.

IL-2 was originally described as the “T-cell growth factor” because it is required for the differentiation and proliferation of activated T cells. As such, it seems like an ideal choice for immunotherapy. The major drawback of IL-2 is the significant dose-related toxicity. IL-2 leads to significant interstitial edema and vascular depletion and lymphoid infiltration into vital organs, possibly resulting in severe hypotension and ischemic damage to the heart, liver, kidneys, and bowel, which limits the use of IL-2 to patients with excellent performance status, normal pulmonary and cardiac function, and no active infections. Despite these limitations, IL-2 has proved to be an effective therapy in patients with metastatic melanoma and metastatic renal cell carcinoma.

► Specific Active Immunotherapy (Vaccines)

The goal of cancer vaccines is to generate a host immune response to known or unknown tumor-associated antigens. Many different vaccine strategies are under investigation, each with advantages and disadvantages in regard to clinical feasibility, cost, the number of antigens available, and the mechanism of response (cellular, humoral, or both). Some vaccine strategies use specific peptide antigens. These are highly purified and therefore are easy to standardize, distribute, and administer. Unfortunately, immunizing a patient against a single antigen has several drawbacks that limit the potential clinical benefit. If a peptide vaccine does stimulate a response, it may not be the “right” peptide for many patients. Even commonly expressed tumor antigens are not present on all patients’ tumors, or they may be present in varying degrees. In addition, the T-cell recognition of an antigen depends on the presentation of that antigen on a specific MHC molecule. Only certain human lymphocyte antigen (HLA) phenotypes can present any given peptide to induce an immune response, so they will function only on a limited subset of patients. A classic example is that of the MART-1/Melan-A

antigen in melanoma. The antigen is expressed by 80% of melanomas, but the peptide only binds to HLA-A2. Because only about 45% of Caucasians have HLA-A2, only 36% (80% of 45%) of melanoma patients given a MART-1/Melan-A vaccine would see a benefit. Finally, a cancer can escape immune recognition rather simply if a population of cells stops expressing that antigen or the MHC molecule.

For many cancers, only a few tumor-associated antigens have been defined; these may not be present on a large percentage of patients. Using the patient's cancer as the vaccine precludes the need to identify specific antigens. Autologous tumor cell vaccines are created from cancer cells harvested from the patient, altered to be more immunogenic, and irradiated, before being returned to the patient to stimulate a tumor-specific immune response. This approach is limited to individuals with sufficient tumor to prepare a vaccine. Trials are restricted to patients with bulky nodal or accessible distant metastatic disease who have a poor overall prognosis to begin with. Furthermore, the technical complexities inherent in procuring tumor and preparing a vaccine have made it difficult to conduct multi-institutional trials to test the efficacy of these vaccines.

Since many tumor-associated antigens are shared among a large number of patients, it is possible that one could create a vaccine from cultured cell lines that would stimulate an antitumor immune response in any patient who shared some of those antigens. This is the principle behind allogeneic tumor cell vaccines. This approach offers several advantages over autologous vaccines: Allogeneic vaccines are readily available, even for patients who lack sufficient tumor to produce an autologous tumor cell vaccine, and can be standardized, preserved, and distributed in a manner akin to any other therapeutic agent.

► Tumor-Induced Immunosuppression

It is becoming increasingly apparent that in addition to mechanisms to generate and propagate an immune response, the immune system has several mechanisms to limit an immune response. This immune regulatory function is necessary to prevent lymphoproliferative disorders and autoimmune diseases. Neoplasms, however, may take advantage of this, creating an immunosuppressive network within the tumor microenvironment that protects the tumor from immune attack and minimizes the efficacy of immunotherapy.

Several components of the immune system function to regulate or limit an immune response. While it was initially thought that dendritic cells were exclusively immunogenic, recent evidence suggests that they possess dual functions, and some subsets of dendritic cells possess a regulatory function. Myeloid-derived suppressor cells can also suppress the antitumor response to cancer by blocking the effects of cytotoxic T cells in the tumor microenvironment.

In addition to cytotoxic and helper T cells, another T-cell population is the regulatory T cell, which also functionally suppresses immune responses. Immunosuppressive cytokines within the tumor microenvironment (IL-6, IL-10, TFG- β) may function to intensify these immunosuppressive components, augmenting tumor escape from immune recognition. It is also possible that many immunotherapies fail by augmenting not only immune stimulation but immune suppression, canceling out the effect. In some cases, these therapies may tilt the response toward immune suppression, for a detrimental effect. Newer immunotherapeutic strategies are focusing on not only increasing immune recognition of the tumor but blocking the suppressive mechanisms. These include pretreatment depletion of regulatory T cells, blocking suppressive pathways or neutralizing immunosuppressive cytokines.

Activated T lymphocytes express the molecule CTLA-4 (cytotoxic T lymphocyte-associated antigen 4), which exerts a suppressive effect on the induction of immune response through its interactions with the B7 molecules on antigen-presenting cells. Blocking the binding of CTLA-4, through the use of monoclonal antibodies, can therefore enhance antitumor T-cell responses. Ipilimumab (Yervoy), a monoclonal antibody to CTLA-4, has been shown to cause tumor regression and improve survival in patients with metastatic melanoma. PD-L1 is often expressed on tumor cells, and when it binds to PD-1 on T cells, can prevent T-cell function and lead to anergy. The use of an anti-PD-1 monoclonal antibody in patients with a variety of advanced cancers showed promising tumor responses, and may provide a new immunotherapy for patients with PD-L1 expressing tumors.

SPECIFIC TYPES OF MALIGNANT NEOPLASMS

SOFT TISSUE SARCOMA

Soft tissue sarcomas account for approximately 1% of all new cancer diagnoses. Almost half of all patients diagnosed with the disease eventually die as a result of the cancer. Soft tissue sarcomas can occur anywhere in the body, but most originate in an extremity (41%), the trunk (10%), the retroperitoneum

(16%), visceral sites (21%), or the head and neck (12%). Soft tissue sarcomas originate from a wide variety of mesenchymal cell types and include malignant fibrous histiocytoma, liposarcoma, rhabdomyosarcoma, leiomyosarcoma, and desmoid tumors. While the histopathology of these tumors is highly variable, with some exceptions they tend to behave in a fashion dictated by tumor grade rather than the cell of origin.

Most soft tissue sarcomas arise de novo, and rarely do they result from malignant degeneration of a benign lesion. There are several familial syndromes in which patients are genetically predisposed to the formation of soft tissue sarcomas, including Li-Fraumeni syndrome, Recklinghausen disease, and Gardner syndrome. Other proven risk factors exist that may increase the chances of sarcoma formation. External radiation therapy can increase the incidence of sarcomas by 8-fold to 50-fold. Chronic extremity lymphedema also increases the risk for lymphangiosarcoma. A classic example is the development of upper extremity lymphangiosarcomas in the lymphedematous arm of women treated for breast cancer (Stewart-Treves syndrome). Other less clear associations link chronic tissue trauma and occupational chemical exposures with an increased risk for sarcoma formation.

The major features of the staging system for soft tissue sarcomas are the grade of the tumor, its size, and the presence of metastatic disease (Table 44–3). Although the site of the tumor is not considered in staging, patients with retroperitoneal tumors tend to have a worse prognosis. Sarcomas generally metastasize by the hematogenous route, and the metastatic sites of sarcomas are related to the location of the primary tumor. The vast majority of metastases from extremity sarcomas are to the lung, while the majority of retroperitoneal tumors metastasize to the liver. Lymph node involvement is rare with most soft tissue sarcomas, although it may occur with epithelioid sarcoma, clear cell sarcoma, angiosarcoma, rhabdomyosarcoma, or synovial sarcoma.

The most important prognostic variables for patients with soft tissue sarcoma are the size and grade of the primary tumor. Since grading is based on the cellular architecture and invasive nature of the tumor, FNAB is not a typically useful biopsy technique for the initial diagnosis of a sarcoma. If a tumor is small (< 3 cm) and superficial, excisional biopsy should be performed. All extremity biopsy incisions should be oriented longitudinally, as the biopsy incision scar should be excised in a subsequent definitive resection of the tumor. Core needle biopsies may be performed for large, palpable superficial tumors. For large, deep tumors or those adjacent to vital structures, where core needle biopsy is not advised or failed, incisional biopsy should be considered. The incision should be centered over the mass, tissue flaps should not be raised, and meticulous hemostasis should be ensured, all to prevent the dissemination of tumor cells into adjacent tissue planes.

► Treatment of Extremity Sarcomas

MRI is the imaging modality of choice for any suspected extremity sarcoma because it is most accurate in defining the extent of the tumor and invasion of surrounding structures. MRI is also used for follow-up imaging to assess response in patients undergoing therapy, as well as for local and regional recurrence. A chest x-ray or chest CT should be obtained in order to evaluate for pulmonary metastases in patients with high-grade tumors.

Surgery remains the primary therapy for localized extremity sarcomas, but multimodality therapy is recommended to minimize the likelihood of recurrence or the need for amputation. Historically, amputation was the only form of curative surgical therapy for large extremity sarcomas, but multimodality therapy has allowed for a high rate of limb preservation. Today, fewer than 5% of patients with extremity soft tissue sarcoma require amputation, generally reserved for patients whose tumors do not respond to preoperative

therapy and cannot be resected adequately, have no evidence of metastatic disease, and have a good prognosis for rehabilitation.

A pseudocapsule composed of tumor cells surrounds sarcomas, and local invasion along fascial planes and neurovascular structures is common. It is important not to dissect along the pseudocapsule, which is associated with high local recurrence rates, but rather obtain a wide (2-cm) margin of normal tissue. This may need to be compromised in the immediate vicinity of functionally important neurovascular structures. If the tumor involves these structures, nerve grafts and arterial reconstruction with autologous or prosthetic conduits may be required. Large soft tissue defects often require the construction of myocutaneous flaps to improve function and cosmesis. Soft tissue sarcomas rarely invade bone or skin, and wide resections of these structures are infrequently necessary.

Following wide local excision, metal clips should be placed at all margins of the resection in order to guide subsequent radiotherapy. For patients with T1 tumors located superficially in an area where it is not difficult to obtain widely negative margins, postoperative radiation therapy may not be necessary. For most other lesions, postoperative radiation is almost always recommended, with either external beam radiation or brachytherapy. Radiation should be started 4-8 weeks after surgery, as delay can result in a lower local control rate. Preoperative radiotherapy may have some advantages in patients with large tumors. Lower doses can be delivered to an undisturbed tumor bed, which may also have better oxygenation, and larger tumors may decrease in size, allowing for limb-sparing procedures. Preoperative radiation is associated with an increase in short-term wound complications but a decrease in long-term tissue fibrosis and edema. The optimal mode and sequence for treatment has yet to be defined and often requires a multidisciplinary approach.

Adjuvant chemotherapy remains controversial. Chemotherapy can be given either preoperatively or postoperatively. The three drugs most effective in sarcoma are doxorubicin, dacarbazine, and ifosfamide. Preoperative chemotherapy is sometimes recommended because in addition to the early treatment of micrometastatic disease, it allows for assessment of tumor response, which helps avoid prolonged therapy in patients not responding. However, while disease-free survival may be improved, there are conflicting data on overall survival. A recent meta-analysis of randomized trials suggested there may be a small survival benefit for extremity sarcomas, and so its use has increased.

The vast majority of localized recurrences in soft tissue sarcomas occur in the first 2 years after resection, necessitating close follow-up during that period. A local recurrence is not indicative of systemic disease and, in the absence of evidence of metastases, should be treated aggressively in the same manner as a primary tumor. The resection of pulmonary

metastases should be considered in patients who have fewer than four radiographically detectable lesions and who have achieved apparent local control following resection of the primary tumor. In such circumstances, disease-free survival can approach 25%-35%.

► Treatment of Retroperitoneal Sarcomas

Retroperitoneal sarcomas comprise approximately 15% of all soft tissue sarcomas, with liposarcoma, malignant fibrous histiocytoma, and leiomyosarcoma the three most common types. They usually present as a large abdominal mass. Nearly half are over 20 cm in size at diagnosis. Once they compress or invade contiguous structures, they can cause symptoms such as abdominal pain or nausea and vomiting. Workup should include CT of the abdomen and pelvis to evaluate the mass as well as CT of the lung and liver to look for metastases. CT-guided core biopsy is the sampling technique of choice, with open or laparoscopic incisional biopsy reserved for inconclusive core biopsies.

As with extremity sarcomas, surgery represents the primary treatment, with the goal being en bloc resection with a rim of normal tissue. Although retroperitoneal tumors are generally large at presentation and often invade vital structures, the majority of these tumors are resectable. Retroperitoneal sarcomas rarely invade surrounding organs, but an intense desmoplastic reaction makes it difficult to assess the extent of tumor, so often these organs need to be resected rather than risk positive margins. The kidney, colon, pancreas, and spleen are the most commonly resected organs.

While adjuvant radiation therapy is standard in extremity sarcoma, evidence supporting its use in retroperitoneal sarcoma is less convincing. Because of the low tolerance to radiation of the abdominal and retroperitoneal organs, delivery of adequate radiotherapy is often difficult. There is encouraging evidence for intraoperative radiation therapy to the tumor bed, but this technique is still considered investigational and can be performed only in select centers. Although complex, preoperative radiation may be beneficial because it uses lower radiation doses, is less injurious to the small bowel, and can increase respectability by shrinking the tumor and creating a thickened capsular structure around the lesion.

MELANOMA

The incidence of melanoma is unfortunately rising. The reasons for this rise are not clear but are most likely related

Table 44-4. Clinical characteristics of melanoma (ABCDs).

A- Asymmetry: Asymmetric shape, color, or contour
B- Borders: Irregular or ill-defined borders
C- Color: Color variation within the lesion
D- Difference: Any lesion that has changed in size, shape, or color

to an increased exposure to ultraviolet radiation from sunlight. Individuals whose first sunburn occurred at an early age, or have had three or more sunburns before age 21 have an increased incidence of melanoma, as do individuals who use tanning beds. Other risk factors include freckles, a fair complexion, reddish or blond hair, blue eyes, a first-degree relative with melanoma, and the presence of multiple or dysplastic nevi.

The best approach to melanoma is to prevent it from occurring, through sun avoidance and sun protection with sunscreens with a sun protection factor (SPF) of 30 or higher. Second to prevention, the most significant impact on melanoma comes from early recognition and diagnosis. The prognosis of melanoma is inversely and dramatically related to the depth of invasion at diagnosis (Breslow thickness), emphasizing the importance of early diagnosis of this disease. Lesions that are suspicious for melanoma can be identified by their clinical characteristics, often referred to as the ABCDs of melanoma (Table 44-4). Diagnosed early, well over 90% of primary melanomas can be cured with surgical excision alone. Patients presenting with thicker lesions or regional nodal metastases have a significantly poorer prognosis. The AJCC staging system is presented in Table 44-5.

There are several distinct categories of melanoma; the four most common are superficial spreading, nodular, lentigo maligna, and acral lentiginous melanoma.

Superficial spreading melanoma is the most common presentation, accounting for nearly 70% of all melanomas. These usually occur in sun-exposed areas of the body or in individuals with multiple dysplastic nevi. They generally arise in preexisting nevi and can occur at any age after puberty. The superficial spreading subtype tends to grow in a radial pattern during the earlier stages and converts to a vertical growth pattern during the later stages of development.

Nodular melanomas account for between 15% and 25% of all melanomas. These tend to occur in older individuals and are more common in men. Nodular melanomas generally develop de novo, not in a preexisting nevus. They usually are dome shaped with distinct borders and often resemble a blood blister. Nodular melanomas occur most commonly on the head, neck, and trunk. They lack a significant horizontal growth phase and tend to be deep at the time of diagnosis.

Lentigo maligna melanoma has less propensity to metastasize and thus has a more favorable prognosis relative to the other subtypes. However, it can be locally aggressive, with high recurrence rates after excision. These lesions

Table 44-5. AJCC staging system for melanoma.

TNM Classification		
T1a	≤1 mm	without ulceration and mitoses < 1/mm ²
T1b	≤1 mm	with ulceration or mitoses ≥ 1/mm ²
T2a	1.01-2.0 mm	without ulceration
T2b	1.01-2.0 mm	with ulceration
T3a	2.01-4.0 mm	without ulceration
T3b	2.01-4.0 mm	with ulceration
T4a	> 4.0 mm	without ulceration
T4b	> 4.0 mm	with ulceration
N0	No regional metastases detected	
N1a	Micrometastasis in 1 node	
N1b	Macrometastasis in 1 node	
N2a	Micrometastasis in 2-3 nodes	
N2b	Macrometastasis in 2-3 nodes	
N2c	In-transit met(s)/satellite(s) without metastatic nodes	
N3	≥ 4 metastatic nodes, or matted nodes, or in-transit met(s)/satellite(s) with metastatic nodes	
M0	No detectable evidence of distant metastases	
M1a	Metastases to skin, subcutaneous, or distant lymph nodes with normal serum LDH	
M1b	Metastases to lung with normal serum LDH	
M1c	Metastases to all other visceral sites or any distant metastases with an elevated serum LDH	
Stage Groupings		
IA	T1a N0 M0	
IB	T1b N0 M0, T2a N0 M0

IIC	T4b N0 M0	
IIIA	T1-4a, N1a or N2a, M0	
IIIB	T1-4b, N1a or N2a, M0 T1-4a, N1b, N2b or N2c, M0	
IIIC	T1-4b, N1b, N2b or N2c, M0 Any T, N3, M0	
IV	Any T, Any N, M1	

account for 4%-10% of melanomas and occur in an older population. Lentigo maligna lesions almost always develop in sun-exposed areas. They have a long horizontal growth phase and often have very convoluted borders.

Acral lentiginous melanomas account for between 2% and 8% of melanomas in Caucasians but for 30%-60% of melanomas in blacks, Asians, and Hispanics. These lesions do not occur in sun-exposed areas; instead, they occur on the sole of the foot, the palm, beneath the nail beds, and in the perineal region. Acral lentiginous melanomas are often large, with an average diameter of 3 cm at the time of diagnosis. They develop relatively rapidly over the course of months to several years and tend to behave very aggressively. The clinical characteristics of these melanomas are often unmistakable, with variegations in color and convoluted borders. Ulceration of these lesions is common.

► Treatment of Primary Melanoma

Any suspected melanoma should be removed by punch or excisional biopsy. Given the importance of Breslow thickness, shave or curette biopsies are contraindicated. If the biopsy specimen reveals melanoma, a formal excision with adequate margins is required. Because microscopic tumor cells frequently surround primary melanomas, excision with narrow margins is associated with an unacceptably high rate of local recurrence. The current standard for lesions less than 1 mm in depth is excision with 1-cm margins. Melanomas between 1 and 2 mm in thickness should be excised with 2-cm margins, but a smaller margin (10-15 mm) may be acceptable in areas where it is difficult to get 2 cm without the need for a skin graft or exceptionally tight closure. Melanomas deeper than 2 mm should be excised with a 2-cm margin. The resection should be carried down to the underlying fascia, although the fascia need not be excised.

Melanomas generally metastasize by the lymphatic route in a predictable and orderly fashion. Any palpable nodes must be considered suspicious for metastatic involvement, easily verified with an FNAB. About 5%-10% of patients have clinical evidence of nodal metastases upon initial presentation and should undergo a therapeutic lymph node dissection at the time of their wide excision. Many patients will have microscopic disease in the lymph nodes that will not be apparent on physical examination. In the past, substantial controversy surrounded elective lymph node dissection of the draining nodal basin for melanoma. The practice gained dramatic acceptance, however, with the advent of the sentinel lymph node biopsy, which is based on the anatomic concept that lymphatic fluid from defined regions of skin drains specifically to an initial node or nodes ("sentinel nodes") prior to disseminating to other nodes in the same or nearby basins. Sentinel node biopsy allows for a more detailed histologic examination of the sentinel lymph nodes and helps avoid the morbidity of lymph node dissection

in patients who are pathologically node negative. Patients with a negative sentinel node are over six times more likely to survive than those with a positive sentinel lymph node, making the predictive impact of sentinel node status much greater than any other prognostic factor. Evidence also suggests that early removal of micrometastatic disease from the lymph nodes, as compared with waiting for regional recurrence to perform a lymph node dissection, may improve survival.

The sentinel lymph node biopsy has become the standard of care in the staging and treatment of melanoma and should be performed at the time of the wide excision for primary melanomas thicker than 1.0 mm. It should be selectively applied for tumors between 0.75 and 1.0 mm when other worrisome features are present, such as ulceration, angiolymphatic invasion or a mitotic rate >1 . Melanomas less than 0.75 mm are very unlikely to have regional metastases and do not require sentinel lymph node biopsy. The dominant drainage basins can be identified by lymphoscintigraphy, which involves intradermal injection of technetium-99m (^{99m}Tc) sulfur colloid in the area around the tumor and a gamma camera to image the sites of lymph node drainage. In the operating room, blue dye (isosulfan or methylene) is injected in a similar fashion. Any lymph nodes that have evidence of ^{99m}Tc uptake on a handheld gamma probe, have evidence of blue dye, or are clinically suspicious should be excised. After removal of the nodes, they are analyzed by serial thin-sectioning, routine H&E staining, and immunohistochemical staining. Using these methods of analysis, the pathologist is able to detect even minute numbers of metastatic melanoma cells in the sentinel node. Patients with a positive sentinel lymph node biopsy should undergo formal lymph node dissection of the entire drainage basin, although the benefit of this is being examined in the prospective randomized Multicenter Selective Lymphadenectomy Trial-II (MSLT-II).

Traditional chemotherapy regimens have proved largely ineffective in the treatment of melanoma; however, the cytokine IFN alpha-2b (Intron A) has been shown to improve disease-free and overall survival in high-risk patients with no evidence of systemic metastases. This treatment is not without controversy, however, as the duration of therapy is long (12 months), the toxicities are substantial, and some of the data regarding the overall survival benefit are conflicting. An alternate approach to high-dose IFN alpha-2b is pegylated interferon alpha-2b. This has a longer half-life and can be administered subcutaneously with fewer side effects, albeit for a longer period of time (5 years). Finally, another consideration for adjuvant therapy is biochemotherapy, which combines IL-2, IFN alpha-2b, cisplatin, vinblastine, and DTIC. This regimen has significant toxicity but is shorter (9 weeks) and was shown in a prospective randomized trial to improve relapse-free survival compared with high-dose interferon, although there was no improvement in overall survival. All

patients with high-risk melanoma (node-positive melanoma or thick, ulcerated, node-negative melanoma) should have a balanced discussion of the potential risks and benefits of adjuvant therapy. While melanoma is relatively radioresistant, there may be some benefit to regional control after node dissection with radiation in patients with gross extracapsular extension or multiple involved lymph nodes.

► Local Recurrence & In-transit Metastasis

Although rare with appropriate surgery, an isolated local recurrence can be treated with a repeat wide excision with 2-cm margins. Approximately 2%-3% of melanoma patients will develop in-transit metastasis, which is the appearance of metastasis along the path from the primary tumor to its regional nodal basin, and is lymphatic in nature. The management of in-transit metastasis is dictated by the number and the size of the lesions. If few in number, surgical excision with a margin of surrounding normal cutaneous and subcutaneous tissue is appropriate; however, this becomes unlikely with multiple lesions. Intralesional therapy with granulocyte-macrophage colony-stimulating factor can result in significant regression of melanoma deposits but requires multiple injections and is not always effective. Although melanoma is relatively radiation resistant, this therapy can provide palliation in unresectable lesions in many cases. Radiation therapy should be considered in those patients with a smaller volume of cutaneous or subcutaneous metastases.

Hyperthermic isolated limb perfusion (HILP) is a way of isolating the blood circuit to the extremity and administering chemotherapeutic agents regionally at a concentration 15-25 times higher without resulting in systemic side effects. Melphalan has been used as a standard drug for hyperthermic isolated limb perfusion secondary to its efficacy and low regional toxicity. While this has not been shown to improve survival, the use of hyperthermic isolated limb perfusion provides a significant palliation of locoregional symptoms when other options are not available. Less complicated, but also effective, is isolated limb infusion (ILI). This involves using minimally invasive techniques to access the vessels along with a tourniquet to minimize systemic uptake.

Regional and systemic recurrence of melanoma can be latent, and recurrence 10 years after the original diagnosis is not uncommon. This fact necessitates close lifelong follow-up of these patients. Patients with a past history of melanoma have a dramatically increased risk of developing a second primary lesion and require diligent screening for other lesions.

LYMPHOMA

Lymphomas are malignant neoplasms that originate from the lymphoid tissues. Two distinct categories of lymphoma exist: Hodgkin and non-Hodgkin. The two types not only have different morphologic characteristics but differ also in their clinical behavior and their response to various therapeutic regimens. It is not possible to differentiate Hodgkin and non-Hodgkin lymphoma on clinical grounds; surgical biopsy is necessary. In the diagnosis of a suspected lymphoma, excisional biopsy of the entire lymph node or nodes is imperative, as the architecture has a bearing on the diagnosis and the subsequent treatment of the tumor.

1. Hodgkin Lymphoma

Hodgkin lymphoma may occur at any age but is generally a disease of young adults. Prevalence in women peaks in the third decade and then falls, while it remains fairly constant in men after this time. The diagnosis of Hodgkin lymphoma is based on the finding of Reed-Sternberg cells in an appropriate cellular background of reactive leukocytes and fibrosis. It is the pattern of the lymphocytic infiltrate that determines the classic subtypes of Hodgkin disease (see Table 44-6). All subtypes of classical Hodgkin lymphoma are presently treated in the same way, and modern therapy has allowed for cure of over 70% of patients with this malignancy.

The cause of Hodgkin disease is not well understood; however, epidemiologic studies have revealed certain patterns of disease clustering. The incidence appears to be higher with a lower number of siblings, early birth order, siblings with Hodgkin disease, a decreased number of playmates, certain HLAs, single-family dwellings, and patients who have undergone tonsillectomy. The incidence is increased also in persons with immunodeficiencies and autoimmune disorders. This pattern suggests that an oncogenic virus may cause Hodgkin disease. Nuclear proteins of the Epstein-Barr virus have been

Table 44-6. Classic subtypes of Hodgkin lymphoma.

Subtype	Characteristics
Lymphocyte-predominant	Uncommon (6% of Hodgkin lymphomas), diffuse lymphocytic infiltrate with few Reed-Sternberg cells, excellent prognosis
Lymphocyte-depleted	Rare (2% of Hodgkin lymphoma), abundant Reed-Sternberg cells, paucity of lymphocytes, occurs in older males, aggressive clinically
Mixed cellularity	Common (20%-25% of Hodgkin lymphoma), histologically intermediate between above two forms, often presents with disseminated disease
Nodular sclerosis	Most common form (70% of Hodgkin lymphoma), fibrosis with Reed-Sternberg and lymphoid cells, more common in young women, presents with cervical or mediastinal disease

detected in about 40% of classical Hodgkin lymphoma, and alternative lymphotropic viruses may be involved in the pathogenesis of cases negative for Epstein-Barr virus.

Most patients present with enlarged but painless lymph nodes, typically in the lower neck or supraclavicular region. On occasion, mediastinal masses are associated with cough or dyspnea or discovered on routine chest x-ray. About 25% of patients will have systemic symptoms, called B symptoms, including weight loss, pruritus, fever, and drenching night sweats.

► Staging

With regard to therapy, the most important prognostic factor in Hodgkin lymphoma is the disease stage. The AJCC staging system for Hodgkin and non-Hodgkin lymphoma is shown in Table 44-7. The Ann Arbor staging system is also commonly used, which further subclassifies the stages into A and B categories: B for those with weight loss, fever, night sweats, or other constitutional symptoms, and A for those without such symptoms.

Table 44-7. AJCC staging system for Hodgkin and Non-Hodgkin lymphoma.

Stage	Prognostic Groups
I	Involvement of a single lymphatic site (ie, nodal region, Waldeyer ring, thymus, or spleen) (I).
	OR
	Localized involvement of a single extralymphatic organ or site in the absence of any lymph node involvement (IE) (rare in Hodgkin lymphoma)
II	Involvement of two or more lymph node regions on the same side of the diaphragm (II)
	OR
	Localized involvement of a single extralymphatic organ or site in association with regional lymph node involvement with or without involvement of other lymph node regions on the same side of the diaphragm (IIE). The number of regions involved may be indicated by a subscript Arabic numeral, for example, II ₃
III	Involvement of lymph node regions on both sides of the diaphragm (III), which also may be accompanied by extralymphatic extension in association with adjacent lymph node involvement (IIIE) or by involvement of the spleen (IIIS) or both (IIIE, IIIS). Splenic involvement is designated by the letter S
IV	Diffuse or disseminated involvement of one or more extralymphatic organs, with or without associated lymph node involvement
	OR
	Isolated extralymphatic organ involvement in the absence of adjacent regional lymph node involvement, but in conjunction with disease in distant site(s). Stage IV includes any involvement of the liver or bone marrow, lungs (other than by direct extension from another site), or cerebrospinal fluid

As discussed earlier, excisional lymph node biopsy is essential to the diagnosis of Hodgkin lymphoma. Once the diagnosis is made, disease staging begins with a detailed history and physical examination, with attention to all lymph node beds, B symptoms, and symptoms related to extranodal involvement. CT of the chest, abdomen, and pelvis is the major means of staging intrathoracic and intra-abdominal disease. Bone marrow biopsy is also part of the staging evaluation of patients with bony symptoms or cytopenias. Fluorodeoxyglucose F 18 (FDG-PET) scan significantly adds to the staging of Hodgkin lymphoma and has become a standard staging tool both before treatment and at completion. In the past, a staging laparotomy (splenectomy, wedge liver biopsy, and dissection of the para-aortic, iliac, splenic hilar, and hepatic portal lymph nodes) was used to determine the extent of disease in the abdomen. Given the improved imaging studies and the inclusion of chemotherapy for patients even with favorable stage I disease, staging laparotomies are rarely, if ever, performed.

► Treatment

Hodgkin lymphoma has changed from a uniformly fatal disease to one that is curable in almost three-quarters of patients. Treatment is guided by both the stage of disease as well as stratification into favorable and unfavorable prognosis. This has allowed for less intensive therapy in patients with a favorable prognosis, with no compromise in outcome. The definition of favorable disease differs with different groups, but takes into account stage and extent of disease, age, ESR, and symptoms. For patients with favorable prognosis stage I-II disease, treatment typically involves a combination of ABVD chemotherapy (doxorubicin, bleomycin, vinblastine, dacarbazine) in combination with involved field irradiation. For patients at risk of long-term complications from radiation, 4 to 6 cycles of ABVD without radiation can be considered, although there are higher recurrence rates compared with combined modality therapy. Patients with unfavorable stage I-II disease are treated with more cycles of AVBD in combination with irradiation.

While ABVD remains the standard regimen for stage III-IV Hodgkin lymphoma (advanced stage), newer regimens include escalated BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone) and Stanford V (doxorubicin, vinblastine, mechlorethamine, vincristine bleomycin, etoposide and prednisone). Consolidation radiotherapy may be considered with ABVD or BEACOPP, but is an essential component of the Stanford V protocol. The response rates, toxicity and patient comorbidities must be weighed when deciding on a regimen.

Approximately 5%-10% of patients are refractory to initial therapy, and 10%-30% will relapse after complete remission. In this case, salvage therapy typically involves an alternate chemotherapy regimen. High-dose chemotherapy and autologous hematopoietic cell transplantation (HCT)

should be considered for patients with early relapse (within 12 months), second relapse or a generalized systemic relapse, even after 12 months. For patients who fail this approach or are not candidates for high-dose chemotherapy with HCT, there are unfortunately few good treatment options.

2. Non-Hodgkin Lymphoma

Non-Hodgkin lymphoma encompasses a wide spectrum of lymphoid-derived tumors. This heterogeneous group of diseases includes more than 10 distinct tumor subtypes with variable biologic behavior and responses to treatment. As opposed to Hodgkin lymphoma, the prevalence of non-Hodgkin lymphoma rises with age. The incidence has been rising steadily over the past 20 years by about 3%-5% per year, for unknown reasons. Several risk factors have been identified that predispose patients to the development of disease. Patients with congenital disorders such as ataxia-telangiectasia, Wiskott-Aldrich syndrome, and celiac disease have an increased incidence of lymphoma. Certain acquired conditions also predispose patients to lymphoma, including prior chemotherapy or radiotherapy, immunosuppressive therapy, Epstein-Barr infection, HIV infection, human T-cell lymphoma virus [HTLV]-1 infection, *Helicobacter pylori* gastritis, Hashimoto thyroiditis, and Sjögren syndrome.

Non-Hodgkin lymphoma may originate from B cells, T cells, or histiocytes. Morphologically, the tumors may appear as nodular clusters or diffuse sheets of lymphoid cells.

Classically, non-Hodgkin lymphoma presents as non-tender enlargement of lymph nodes, but nearly one-third of all cases originate outside the lymph nodes. These extranodal malignancies develop in organs that normally have nests of lymphoid tissue (mucosal surfaces, bone marrow, and skin).

► Staging & Classification

The goal of the staging evaluation is to distinguish patients who have localized disease from those with disseminated disease. After pathologic diagnosis, the staging evaluation for non-Hodgkin lymphoma consists of a detailed history and physical examination, routine laboratory tests, a bone marrow biopsy, and a CT scan of the neck, chest, abdomen, and pelvis. Evaluation of the cerebrospinal fluid should be considered in patients with diffuse large-cell non-Hodgkin lymphoma with bone marrow involvement, a high lactate dehydrogenase (LDH) level, or multiple extranodal sites of disease. It should also be considered in patients with high-grade lymphomas, HIV-related lymphomas, primary central nervous system lymphomas, and posttransplantation lymphoproliferative disorders. Finally, FDG-PET scans provide whole-body images that allow a comprehensive assessment of disease extent and, in conjunction with CT, provides complementary staging information. A pretreatment PET scan is often obtained so that PET can be used for monitoring of response to treatment. Normal PET at the end of therapy correlates with a highly

favorable prognosis, while persistent abnormalities mandate close follow-up or biopsy to rule out residual disease.

The staging system for Hodgkin lymphoma is also used in non-Hodgkin lymphoma. Although helpful in assessing the anatomic extent of disease, the Ann Arbor system is of minimal clinical value in non-Hodgkin lymphoma. The international prognostic index (IPI) uses patient age, Ann Arbor stage, LDH level, number of extranodal sites, and ECOG performance status to categorize aggressive non-Hodgkin lymphoma. However, this system does not clearly stratify indolent lymphomas, so another prognostic factor model was devised for follicular lymphoma. The follicular lymphoma international prognostic index uses patient age, Ann Arbor stage, hemoglobin level, number of nodal areas, and serum LDH level to stage patients.

Scientists have made countless attempts to develop a universal, clinically relevant classification system for the subtypes of non-Hodgkin lymphoma, and the merits of the various classifications are an area of hot debate. The most widely accepted classification system is the Revised European-American Lymphoma/World Health Organization (REAL/WHO) classification (Table 44-8).

In determining the therapeutic approach to patients with non-Hodgkin lymphoma, a simpler classification system can be utilized. For treatment purposes, these lymphomas can be functionally divided into two groups: indolent (low-grade) and aggressive (high-grade) lymphomas. Smaller, differentiated cells characterize the indolent lymphomas, and this class tends to have a follicular architecture. Although the course of these lymphomas is not very aggressive and they have a long median survival, they are not usually curable in advanced clinical stages. The natural history of indolent lymphomas often involves progression of the tumor cells to a more aggressive subtype. This progression is sometimes heralded by the onset of B symptoms and portends a dismal prognosis.

The aggressive lymphomas behave differently from the indolent ones and demand a different therapeutic approach. Histologically, the aggressive lymphomas spread more diffusely throughout the lymph nodes and consist of larger, less differentiated cell types. This class of lymphomas demonstrates a very rapid growth rate and an increased rate of early mortality. Despite this malignant behavior, this class of non-Hodgkin lymphoma is more often curable. The extranodal lymphomas develop outside of the lymph nodes and are not amenable to conventional classifications, so they are generally regarded as a separate entity. They can involve any organ but most commonly affect the oropharynx, paranasal sinuses, thyroid, gastrointestinal tract, liver, testicles, skin, and bone marrow.

► Treatment

A. Indolent Lymphoma

Patients with localized disease, although this is the minority, can be treated with radiation therapy only with curative

Table 44–8. Revised European-American lymphoma/World Health Organization (REAL/WHO) classification of lymphoma.

B-cell neoplasms	
I. Precursor B-cell neoplasm	Precursor B-lymphoblastic leukemia/lymphoma (B-ALL/LBL)
II. Mature (peripheral) B-cell neoplasms	B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma B-cell prolymphocytic leukemia Lymphoplasmacytic lymphoma Splenic marginal zone lymphoma (+/– villous lymphocytes) Hairy cell leukemia Plasma cell myeloma/plasmacytoma Extranodal marginal zone B-cell lymphoma of MALT type Mantle cell lymphoma Follicular lymphoma Nodal marginal zone B-cell lymphoma (+/– monocytoid B cells) Diffuse large B-cell lymphoma Burkitt lymphoma
T-cell and NK-cell neoplasms	
I. Precursor T-cell neoplasm	Precursor T-lymphoblastic lymphoma/leukemia
II. Mature (peripheral) T-cell neoplasms	T-cell prolymphocytic leukemia T-cell granular lymphocytic leukemia Aggressive NK-cell leukemia Adult T-cell lymphoma/leukemia (HTLV1+) Extranodal NK/T-cell lymphoma, nasal type Enteropathy-type T-cell lymphoma Hepatosplenic gamma/delta T-cell lymphoma Subcutaneous panniculitis-like T-cell lymphoma Mycosis fungoides/Sézary syndrome Anaplastic large cell lymphoma, primary cutaneous type Peripheral T-cell lymphoma, unspecified Angioimmunoblastic T-cell lymphoma Anaplastic large cell lymphoma, primary systemic type
Hodgkin disease/lymphoma

II. Nodular sclerosis	
III. Mixed cellularity	
IV. Lymphocyte depletion	
V. Lymphocyte-rich classic Hodgkin disease	

intent. Most patients have disseminated disease, which tends to be chronic relapsing and remitting. The current therapies for systemic indolent lymphomas are rarely curative, and the goal of treatment is generally directed at palliation of symptoms. At present, a “watch and wait” approach to treatment is recommended for asymptomatic patients. After diagnosis, asymptomatic patients are followed up clinically until they progress to more aggressive disease, major symptoms, or organ dysfunction. Withholding chemother-

apy does not reduce survival in patients with non-Hodgkin lymphoma, and it probably improves quality of life.

For patients who have symptoms, a combination of rituximab and alkylator chemotherapy has high response rates and can alleviate symptoms. Rituximab is a monoclonal antibody that binds to the B-cell surface antigen CD20. CD20 is a cell-surface protein involved in the development and differentiation of normal B cells. It is found on the vast majority of B-cell lymphomas. Rituximab is well tolerated and has remission rates of 40%-50% when used as single-agent therapy for relapsed indolent lymphoma. In younger patients with systemic indolent disease, or patients who had a short response to first-line treatment, high-dose chemotherapy with HCT may be considered, although the chance of cure should be balanced against the mortality of treatment, which can approach 10%.

B. Aggressive Lymphomas

Despite their aggressive nature, these lymphomas have a better chance for cure than their more indolent counterparts. The treatment is typically guided by the prognostic factors (IPI score). Patients with low-risk lymphoma respond well to CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) chemotherapy plus rituximab. Radiotherapy may be used after chemotherapy for areas of bulky disease. Patients with high-risk lymphoma benefit from more intensive regimens of chemotherapy and rituximab and potentially high-dose therapy with HCT. This approach should also be considered for patients who relapse or fail to enter remission after induction chemotherapy. A promising immunotherapy is tositumomab, an anti-CD20 monoclonal antibody bound to ¹³¹I (Bexxar). It can kill cells by antibody-mediated cellular cytotoxicity, activation of complement-mediated tumor cell lysis, and the tumor-specific delivery of radiation. Bexxar is currently indicated for the treatment of patients with CD20 antigen-expressing relapsed or refractory non-Hodgkin lymphoma.

C. Nonlymphoid Disease

There is no consensus about the proper management of localized nonlymphoid lymphomas because large-scale studies of therapy for this disease have not been conducted. With few exceptions, nonlymphoid disease is managed somewhat in the same way as systemic aggressive lymphomas, using combination CHOP therapy.

The CHOP regimen has the disadvantage of poor penetration of the blood-brain barrier and is thus ineffective in the treatment of primary central nervous system lymphomas. These lymphomas rarely metastasize, remaining localized to the central nervous system. Current regimens utilize steroids and whole-brain radiation with some form of adjuvant chemotherapy. Methotrexate is the most common adjuvant treatment in this patient population, and it can be effective when delivered either systemically or intrathecally. This can be combined with whole brain radiation

therapy. Central nervous system lymphomas have a poor prognosis, with approximately 20% 5-year survival rates in treated patients. The combined modalities, while providing modest survival benefits, have significant neurotoxicities, and as many as 50% of patients develop severe dementia. Given this morbidity, clinicians often use chemotherapy as the sole modality in the treatment of patients with primary central nervous system lymphomas. Extranodal lymphomas that have a predilection for metastases to the central nervous system, such as testicular, paranasal, and AIDS-related lymphomas, require systemic CHOP therapy combined with prophylactic intrathecal methotrexate treatments.

The treatment of gastric lymphomas has been controversial. Mucosa-associated lymphoid tissue-type gastric lymphomas (MALT-type gastric lymphomas) typically have an indolent behavior, and the most widely accepted initial therapy is the eradication of *H. pylori* using regimens combining antibiotics and proton pump inhibitors. For patients with MALT-type gastric lymphoma who are *H. pylori* negative or do not respond to antibiotic/proton pump inhibitor therapy, radiation therapy to the stomach and perigastric lymph nodes obtains high complete response rates and excellent long-term survival. While surgery had previously been used in the treatment of gastric lymphomas, there is now sufficient data to suggest nonoperative management permits a better quality of life with no impact on overall survival. When the disease has spread, the use of chemotherapy is similar to that used for other indolent, advanced lymphomas.

High-grade gastric lymphoma is treated with aggressive polychemotherapy, usually combined with rituximab. Again, surgery used to play a more prominent role but has greatly diminished. It was assumed that the increased risk of perforation and bleeding with chemotherapy could be prevented by pretreatment gastric resection, but modern series have failed to demonstrate that benefit and actually show a high degree of postsurgical complications that may delay the start of chemotherapy. Surgery is limited to patients who have complications or who cannot be managed by standard regimens.

Splenectomy in patients with lymphomatous splenic involvement has not demonstrated therapeutic benefit and should be reserved for patients with symptomatic splenomegaly, pain from recurrent splenic infarctions, and hematologic depression from hypersplenism.

MULTIPLE CHOICE QUESTIONS

- Which of the following is true?
 - Cancer incidence rate is usually expressed as events per 100,000 people over their lifetime
 - Overall survival is the inverse of the likelihood that a person will die of disease
 - Tumor stage is determined on histologic examination
 - Cancer point prevalence describes the number of people with cancer at a given time
 - Epithelial malignancy can also be called sarcoma
- Biopsy to evaluate a lesion for malignancy
 - Can include image guidance for needle, incisional or excisional biopsies
 - Should always remove the entire lesion for analysis
 - Can yield a sliver of tissue removed with a core needle biopsy
 - Both A and C
 - None of the above
- Adjuvant chemotherapy for cancer
 - Is typically administered prior to resection
 - Can be described according to its absolute or relative benefit
 - Is necessary for most patients who are treated for cancer who never have recurrence
 - Is most effective in patients who have gross disease remaining after surgery
 - Uses different agents than are typically used for metastatic disease of the same type
- Soft tissue sarcomas
 - Have tumor size and tumor grade as the most important prognostic variables
 - Often metastasize to regional lymph nodes
 - Can usually be diagnosed by FNA biopsy
 - Usually spread to liver as the first site of distant metastasis
 - All of the above
- Melanoma
 - Incidence is decreasing in the United States
 - Most commonly presents as the nodular subtype
 - Is best biopsied using a shave technique
 - Should be excised with a 2-cm skin margin if greater than 2 mm thick
 - Rarely spreads to lymph nodes

Organ Transplantation

Satish N. Nadig, MD, PhD
Jeffrey D. Punch, MD

45

The ability to transplant human organs successfully has developed in the span of a single generation of physicians and surgeons. This remarkable achievement is an excellent example of how animal models may be used to understand and develop treatments for human disease. Organ transplantation is now the preferred treatment modality for a variety of different types of organ failure. Transplantation offers not only improved long-term survival but also improved quality of life for many patients afflicted by renal, hepatic, cardiac, and pulmonary failure.

Enormous effort is currently being expended to develop methods of artificially replacing vital organ functions. Despite these efforts, the ability to replace organ function with mechanical or biomechanical devices remains elusive. While hemodialysis can replace renal function effectively, it offers neither a normal quality of life nor a normal life span. Despite major advances in artificial heart technology, current systems have not reached the point where they can be used routinely to restore normal cardiac function. To date, there are no effective replacements for hepatic or pulmonary function that are suitable for long-term use. Organ transplantation is frequently the only treatment modality that offers a normal lifestyle for patients with advanced organ failure. Recently, successful composite tissue allografts of limbs, face, and larynx have been reported. While these grafts are not lifesaving, it can be argued that for selected patients they reduce misery. This chapter discusses the indications for organ transplantation as well as the limitations to the current state of the art.

KIDNEY TRANSPLANTATION

With the exception of organs from a genetically identical twin (**isografts**), all organs from genetically dissimilar individuals (**allografts**) will naturally be subjected to immunologic rejection. This fundamental biologic limitation has largely been overcome by the development of targeted

immunosuppression therapies. These therapies are able to suppress the immunological reactivity that produces graft rejection while leaving intact sufficient immune competency to allow recovery from most infectious diseases. The same degree of success has not been reached when transplanting organs between species (**xenografts**).

Once it was realized that allografts failed due to an active immunologic attack of the recipient's immune system on the donor organ, methods of suppressing the immune system were investigated. Early attempts at immunosuppression with substances such as nitrogen mustard and total lymphoid irradiation were unsuccessful because of the toxicity of the therapy. The first practical immunosuppressant was azathioprine, an antimetabolite inhibitor of DNA synthesis. When used in combination with corticosteroids, the first successful combination of immunosuppressants was born and the first boom in the number of transplants occurred. This combination remained the state of the art until it was realized that the cell type that exerts primary control over allograft rejection is the T lymphocyte. This led to the later development of agents able to specifically inhibit activation and proliferation of T cells. The result was immunosuppressants that were both more effective and much less toxic than the azathioprine/corticosteroids combination. These agents ushered in a further acceleration in the number of transplants occurring, because now it was possible to transplant organs between individuals who did not share human leukocyte antigens.

Almost all renal diseases responsible for renal failure can be treated by transplantation. Diabetes is the most common cause of chronic renal failure in adults and accounts for 45% of all renal failure in the United States. The second most common cause is hypertensive nephropathy (27%), followed by chronic glomerulonephritis (11%). The causes of renal failure in children are somewhat different, with congenital causes, including both nonobstructive and obstructive uropathies, predominating.

IMMUNOLOGIC RESPONSES

▶ HLA Histocompatibility Antigens

The **major histocompatibility (MHC)** antigens are the most antigenic proteins on donor organs, meaning that they cause the most intense immune responses when the donor and recipient do not share the same antigens. The MHC genes are coded by a single chromosomal complex of closely linked genes on the short arm of the sixth chromosome. This complex consists of at least seven loci that code for genes involved with histocompatibility: human lymphocyte antigen (HLA)-A, HLA-B, HLA-C, HLA-D, HLA-DR, HLA-DQ, and HLA-DP. Each HLA gene locus is highly polymorphic, so that as many as 50 or more discrete antigens are controlled by each locus. The collection of HLA genes in an MHC complex is termed a **haplotype**.

Histocompatibility antigens are grouped into class I (A, B, C) and class II (DR, DQ, DP) antigens. Class I antigens are composed of a 45-kDa heavy chain with three globular extracellular domains (α_1 , α_2 , α_3) that confers HLA specificity, a transmembrane portion, and an intracellular domain. Class I antigens are stabilized by β_2 -microglobulin, a 12-kDa protein that is not encoded in the MHC complex. Class I antigens are expressed on all nucleated cells and interact primarily with CD8+ T cells. Class II antigens are composed of two noncovalently linked chains: a 33-kDa α chain and a 28-kDa β chain. Each chain has two extracellular domains that confer HLA specificities. Class II antigens are only constitutively expressed on B cells and antigen-presenting cells (macrophages, monocytes, dendritic cells) but can be induced on activated T cells and endothelial cells. Class II antigens interact primarily with CD4+ T cells. The three most important antigens clinically in solid organ transplantation are A, B, and DR. Since each person has two MHC complexes, one on each copy of chromosome 6, everyone has a total of six HLA antigens that are of primary importance to organ transplantation.

The 3D structures of both class I and II molecules are similar. The extracellular domains form a β -pleated sheet with two looping α -helices that creates a groove facing away from the cell. Following ribosomal synthesis, during assembly of the HLA antigens, peptides are added to this groove. Intracellularly derived peptides are added to class I antigens in the endoplasmic reticulum, while extracellularly derived proteins are added to class II antigens. The end of the groove on class II antigens is open, allowing class II antigens to accommodate longer peptides. Antigenic determinants are found predominantly on the α_1 and α_2 chains of the class I molecule and on the β chain of the class II molecule. Some antigenic determinants are shared by many different HLA allotypes. These common determinants are called **public specificities**. Antigenic

determinants that are only found on a unique HLA antigen are termed **private specificities**.

Lymphocytes are categorized as either B or T cells. B cells are responsible for antibody production. T cells are categorized into two functional subsets: helper cells that are CD4+ and cytotoxic T cells that are CD8+. Helper T cells preferentially recognize peptides displayed in the groove of class II antigens, while cytotoxic T cells preferentially recognize peptides displayed by class I antigens. A third type of T cell, called regulatory T cells, is now well-established and may be either CD4+ or CD8+. Helper T cells direct both the formation of cytotoxic T cells, which are able to cause graft destruction directly, and the maturation of B cells. Helper T cells can be further subdivided based on their cytokine secretion profile into type 1 and type 2 cells. Type 1 helper T cells secrete interleukin (IL)-2, interferon (IFN)- γ , IL-12, and TNF- α . These cytokines stimulate delayed-type hypersensitivity, cytolytic activity, and the development of complement-fixing IgG antibodies. Type 2 helper T cells secrete IL-4, IL-5, IL-10, and IL-13. These cytokines activate eosinophils and cause the production of IgE antibodies. Additionally, Th17 cells are a distinct subset of helper T cells that produce the proinflammatory cytokine IL-17 and are implicated in diseases of autoimmunity and inflammatory states.

Allograft rejection begins when foreign antigen is taken up by an antigen-presenting cell, processed, and presented to helper T cells. The T cell is activated in response to properly presented antigen and secretes cytokines that in turn recruit and activate additional lymphocytes and cause them to begin to clonally proliferate. Cytokines released in the allograft milieu by other cells, including macrophages, contribute to the generation of the immune response as well. Helper T cells also stimulate the differentiation and proliferation of cytotoxic T cells and B cells.

B-cell activation induces the production of specific antibodies directed against donor antigens. This response is important, especially for class I antigens. Recipients who develop a primary immunological response to a particular antigen and produce cytotoxic antibodies directed against the donor HLA will often retain memory B cells and maintain the ability to produce antibodies that are directed against that particular HLA allotype. Upon reexposure to the same antigens, an immediate destructive reaction to the graft—called hyperacute rejection—occurs. Antibody directed against the donor vascular endothelium triggers fixation of complement, direct cellular damage, and the formation of platelet and fibrin plugs, leading to microvascular thrombosis and ischemic necrosis of the organ. Transplantation in the presence of cytotoxic anti-HLA antibody directed against a donor organ is prevented in practice by performing a complement-mediated cytotoxic cross-match with pretransplant recipient sera against lymphocytes from the potential donor.

► **Histocompatibility Testing, Crossmatching, & Blood Group Compatibility**

Grafts between identical twins are rare but very successful because immunosuppressive therapy is not required when there is no antigenic difference between the donor and recipient. Grafts between HLA-identical siblings who share two HLA haplotypes give the next best results. One-fourth of any given sibling pair will share both HLA haplotypes and thus share all of the same HLA antigens. Despite sharing HLA, immunosuppression is still required because of incompatibilities at minor histocompatibility loci. Parents, offspring, and half of siblings share one HLA haplotype. One-fourth of siblings will not share an HLA haplotype and will therefore share antigens only by chance. The same is true for genetically unrelated donor/recipient pairs such as spouses and friends. At one time, HLA compatibility was considered to be crucial because there were large differences between graft survivals depending on the degree of histocompatibility. Transplants between individuals who shared many HLA antigens were much more likely to avoid graft loss compared to donor/recipient pairs who did not share HLA antigens. This has changed due to the ability of modern immunosuppression to provide for excellent immunological outcome even in the setting of complete HLA mismatch. HLA testing is now of much lesser value than it once was. HLA histocompatibility testing is now primarily of value in determining which of several donors has the best histologic match to the intended recipient. Kidney allocation from deceased donors was once heavily influenced by HLA matching. This has now changed because of the realization that the degree of HLA match has a relatively unimportant effect on the odds of successful outcome. The newest allocation strategy relies more on waiting time and less on the degree of HLA match. Kidneys from donors who share all six HLA antigens with a recipient on the waiting list are still allocated first to any recipient who happens to be a “perfect match.” This situation is uncommon, affecting fewer than 10% of the kidneys from deceased donors.

Regardless of the results of tissue typing and antigen matching, it is essential to determine whether a recipient has preformed antibodies against donor antigens, since their presence would result in a hyperacute rejection of the graft as described previously. Preexisting antibodies may develop because of prior exposure to foreign histocompatibility antigens in the form of blood transfusion, pregnancy, or previous organ transplants.

These antibodies are identified by performing a crossmatch between the patient’s serum against the donor’s lymphocytes. Multiple methods of performing the crossmatch are available with varying degrees of sensitivity and specificity. It is difficult to find an appropriate donor with a negative crossmatch for patients who have antibodies directed against multiple HLA specificities. Some of these patients can be

treated with desensitization strategies to reduce their burden of circulating antibodies. Methods currently utilized include plasmapheresis, infusion of random intravenous donor immune globulin, and anti-B-cell monoclonal antibodies. Experience is accumulating with desensitization protocols suggesting that donor/recipient pairs with positive crossmatches can sometimes be successfully transplanted. The long-term outcome for these kidneys is unclear.

The ABO blood group antigens behave as strong histocompatibility antigens for kidney transplantation; therefore, ABO-incompatible kidney transplants have generally been considered an absolute impossibility. It is certainly true that ABO-incompatible kidneys will fail rapidly if nothing is done to reduce the amount of antibody directed against the incompatible antigen in the recipient’s serum. Success is now being reported for ABO-incompatible kidney transplants using combinations of anti-B-cell therapy and plasmapheresis.

► **Immunosuppressive Drug Therapy**

Multiple immunosuppressive strategies are effective at preventing acute allograft rejection. Most strategies involve the use of more than one agent. Conceptually, using multiple immunosuppressive agents has the effect of blocking multiple targets in the immune response cascade, which allows relatively low doses of each drug to be used, thus avoiding toxicity associated with high doses of these powerful drugs. Thus, many patients are treated with “triple therapy” using corticosteroids, a calcineurin inhibitor, and either an anti-metabolite or a mammalian target of rapamycin (mTOR) inhibitor. A variant of this strategy, termed “quadruple therapy,” involves the initial use of a very potent antilymphocyte agent and chronic administration of the same drugs used for triple therapy. The antibody treatment has two effects: it decreases the likelihood of rejection in the critical first few months after the transplant, and it allows there to be a delay before the introduction of the calcineurin inhibitor. This is advantageous because of the associated nephrotoxicity of calcineurin inhibitors. Since the risk of rejection is highest immediately after the transplant, it is typical to begin with relatively high doses of each agent and gradually taper down to a maintenance level over several weeks to months.

Rejection is diagnosed by biopsy. Patients are followed up with serial measurements of renal function in the form of serum creatinine. When a transplanted kidney begins to function, the serum creatinine will fall gradually over several

days to reach a nadir level that becomes a new baseline for the patient. Any significant elevation above the baseline should prompt evaluation as to the cause, and once obstruction, dehydration, and infection have been ruled out, it is usually appropriate to biopsy the kidney graft. Rejection may be treated with high-dose “pulse” corticosteroid therapy over several days or with antilymphocyte antibodies. Rejection therapy is effective in more than 90% of cases.

Many drugs are available today for immunosuppression. All of these drugs share the common side effect of increasing susceptibility to infectious diseases. This is an intrinsic feature of currently available therapy, which aims to suppress natural immune responses against all foreign antigens. When the transplant recipient develops an infection, it is vital that a physician with experience prescribing immunosuppression is involved with the patient’s care. In many cases, it is appropriate to temporarily reduce the degree of immunosuppression in order to allow recovery from the infection. Precisely, how this is accomplished varies widely among practitioners, but it generally involves lowering the dosage or withholding one or more of the agents being used for maintenance immunosuppression. When the infection has resolved, immunosuppression is restored to an acceptable maintenance regimen. It is appropriate to individualize therapy because different individuals have different propensities to develop both rejection and infection.

Many long-term immunosuppressive therapies are associated with the development of malignancy, especially skin cancer and lymphomas. Patients receiving chronic immunosuppression should pay particular attention to minimizing direct exposure to ultraviolet radiation. Since many skin cancers are treatable with simple resection, it is also important that transplant physicians are careful to monitor for and treat skin lesions that develop in transplant recipients.

In the future, it may be possible either to modify the graft so that it is not viewed as foreign to the recipient’s immune system or to modify the recipient’s immune system so that it will not reject the graft without altering the immune response to other foreign antigens.

A. Antimetabolites

The antimetabolite drugs include azathioprine, cyclophosphamide, mycophenolate, and leflunomide. These drugs inhibit nucleic acid synthesis, which in turn limits the ability of activated lymphocytes to rapidly clonally expand. In general, these drugs are used to prevent rejection but are not effective at reversing active acute rejection.

Azathioprine, a purine analog, is the original member of this family. The effects of this drug are not specific to lymphocytes; therefore, the drug also frequently causes decreased levels of circulating neutrophils and platelets. This side effect is dose dependent. This drug is of only historical importance currently.

Cyclophosphamide is an alkylating agent that is a common component of chemotherapy protocols. It is an effective immunosuppressant when given in high doses, but it has been used only very infrequently in clinical transplantation.

Mycophenolate is an inhibitor of inosine monophosphate dehydrogenase, a critical enzyme in the de novo synthesis pathway of purines. Lymphocytes uniquely depend on the de novo pathway to synthesize purines, while other cells are able to utilize a salvage pathway for synthesis. Mycophenolate is therefore more specific for lymphocytes than the other antimetabolites. It has largely replaced azathioprine for use in combination with a calcineurin inhibitor and corticosteroids since well-designed studies have shown it to have a superior ability to prevent rejection. Side effects are primarily gastrointestinal in nature. Enterically coated formulations are available for patients who are unable to tolerate mycophenolate mofetil.

Leflunomide is a selective inhibitor of de novo pyrimidine synthesis. It is thought to work by inhibiting the enzyme dihydroorotate dehydrogenase. It is used widely for treatment of rheumatoid arthritis. Clinical trials have demonstrated it to be efficacious in terms of preventing rejection, but it is difficult to use clinically because of its long half-life (15-18 days).

B. Corticosteroids

Corticosteroids used in combination with azathioprine was the first combination of immunosuppressants with the ability to prevent the development of allograft rejection, and high doses of corticosteroids was the first practical and effective means of reversing established rejection. Hence, over the past 40 years, corticosteroids have been a component of most successful immunosuppressive protocols. Typically, a high dose of intravenous corticosteroids is given at the time of engraftment, and the dose is tapered over weeks to months down to a maintenance dosage of 0.1-0.2 mg/kg of oral prednisone. In the recent past, there has been strong interest in discontinuation of corticosteroids—and even more recently, in developing protocols that do not require the administration of any corticosteroids. The evidence is accumulating that this treatment is appropriate and effective for some low-risk renal transplant recipients, but the use of corticosteroid-free protocols for higher-risk candidates—including those with known sensitization to HLA and patients undergoing second renal transplants—is more controversial.

Corticosteroid therapy is associated with many different side effects, including infection, weight gain, cushingoid features, hypertension, increased bruisability, hyperlipidemia, hyperglycemia, and acne. Daily corticosteroid therapy in children may inhibit somatic growth. This may be circumvented to some degree by alternate-day treatment, administering the drug once in the morning every other day.

Corticosteroids are standard therapy for a rejection episode, typically consisting of three or more daily doses of between 100 and 500 mg of intravenous methylprednisolone ("steroid pulses"). Depending on the severity of the rejection, steroid pulses will resolve 50%-80% of allograft rejection episodes.

C. Calcineurin Inhibitors

Transplantation was revolutionized by the introduction of the first calcineurin inhibitor, cyclosporine, into clinical practice in the early 1980s. Cyclosporine is a cyclic undecapeptide isolated from a fungus. It is a potent immunosuppressant and the first compound identified that can inhibit immunocompetent lymphocytes specifically and reversibly. Cyclosporine was followed by the introduction of tacrolimus, another compound derived from a fungus that also inhibits calcineurin. The primary mechanism of these agents appears to be inhibition of the production and release of IL-2 by helper T cells. They also interfere with the release of IL-1 by macrophages as well as with proliferation of B lymphocytes. Blood levels must be carefully monitored because both drugs are nephrotoxic and neurotoxic at higher levels. They also both have chronic effects on renal function and lead to significant long-term renal dysfunction in many patients who take them chronically. Both cyclosporine and tacrolimus are also associated with an increased incidence of neoplasms, particularly lymphomas.

D. Inhibitors of Mammalian Target of Rapamycin

Sirolimus is a macrocyclic triene antibiotic produced by a species of *Streptomyces*. It was originally developed as an antifungal and antitumor agent but was found to have significant immunosuppressive properties. The effect of sirolimus is believed to relate to inhibition of lymphocyte transduction pathways through binding to the mTOR. It functions as an antiproliferative and prevents not only expansion of lymphocyte clones but also smooth muscle proliferation. It is known to effectively prevent rejection in combination with a calcineurin inhibitor. The major advantages of this drug are that it does not cause renal dysfunction and its antiproliferative properties suggest that it will not be associated with the same risk of developing long-term malignancy. Side effects, in addition to the infections associated with immunosuppression, include oral ulcerations, wound healing problems associated with its ability to inhibit smooth muscle proliferation, and significant hyperlipidemias. An association with hepatic artery thrombosis has also been noted in patients receiving sirolimus therapy as part of their initial immunosuppression regimen following liver transplantation.

Everolimus is a derivative of sirolimus that also acts as an mTOR inhibitor. It has a side-effect profile similar to that of sirolimus but a shorter serum half-life.

E. Polyclonal Antithymoblast or Antilymphocyte Globulin and Antithymocyte Globulin

Antilymphoblast globulin and antithymocyte globulin are polyclonal antibody preparations derived by immunizing animals against human lymphocytes and collecting and purifying the antibodies that animals develop in response to the foreign antigenic proteins. They are potent drugs that deplete circulating lymphocytes, an effect that can be measured and followed by flow cytometry or by simply following the complete blood count with differential. Because they are polyclonal, they not only are effective against T cells but also may have important effects against circulating B cells and natural killer cells.

These agents are particularly effective in induction of immunosuppressive therapy and in the treatment of established rejection that is either severe or resistant to pulse corticosteroid therapy. Therapy is typically given daily for 5-7 days. The effect of these agents is profound immunosuppression that lasts for weeks to months. They are associated with increased incidence of viral infections because of their effects on cellular immunity and also with a higher lifetime risk of developing malignancy, particularly B-cell lymphoma.

Side effects are many and include fevers and chills, neutropenia, and thrombocytopenia. Fever, chills, and malaise occur because of mediator release by T cells and circulating mononuclear cells, especially TNF- α , IL-1, and IL-6, that occurs when the antibody is bound to certain cell surface receptors. The symptoms are very similar to those associated with an acute viral infection. These effects are usually transient, often lasting less than 12 hours. They occur primarily following the first or second dose of the treatment and can be attenuated markedly by pretreatment with corticosteroids, acetaminophen, and diphenhydramine. Neutropenia and thrombocytopenia occur because of direct antibody binding to these cell types, causing depletion. This effect is also transient and tends to resolve in 24-48 hours. It is necessary to monitor neutrophil and platelet counts during therapy and withhold doses of the treatment if the counts drop to dangerously low levels.

F. Monoclonal Antibody Therapy

The knowledge that the T cell is central to the development of allograft rejection led to the development of agents that selectively inhibit or deplete T cells, or both. The first example of such an agent is the monoclonal antibody OKT3 (muromonab-CD3), which is secreted by a hybridoma in culture. This agent may have some advantages over antilymphoblast globulin and antithymocyte globulin preparations in management of rejection because it specifically blocks T-cell generation and function. Because it is a monoclonal antibody and reacts with a defined antigen, it can be consistently produced with a defined activity and without unwanted reactivities against other cells like neutrophils and

platelets. OKT3 is most effective in the treatment of steroid-resistant rejection, where more than 90% of rejection episodes are reversed, thus obviating further high-dose steroids. The downside of this antibody treatment is that since it is a murine monoclonal antibody, it may induce recipient antibody directed against the murine antibody molecule. This effect occurs in 5%-10% of patients treated with OKT3 and may decrease the efficacy of the treatment if given a second or third time. Like the polyclonal antilymphocyte preparations, treatment is usually given daily for 5-7 days. Side effects due to cytokine release are typically more severe than those seen with polyclonal agents but may also be attenuated with appropriate pretreatment. Since the antibody does not bind to epitopes other than the CD3 molecule, which is found only on T cells, it does not cause cytopenias.

The success of OKT3 led to the development of a new generation of monoclonal antibodies that are “humanized.” The monoclonal antibody molecule has been modified by genetic engineering to avoid the side effects seen with OKT3. The genetic code directing the production of the antibody molecule by the hybridoma has been altered by replacing most of the murine portion of the sequence with human antibody sequence. The antibody is thus chimeric, or “humanized” since only the highly variable portion of the antibody that binds to the antigenic epitope is foreign to the human recipient. Cytokine release therefore does not occur when the antibody is administered, nor is it likely that the recipient will develop neutralizing antibodies against the monoclonal preparation. Because the antibodies so closely resemble human immunoglobulin, they also have a long circulating half-life.

The first of these agents, daclizumab and basiliximab, binds to CD25, the high-affinity subunit of the T-cell receptor for IL-2. Since IL-2 is necessary for T-cell activation and proliferation, these agents have the ability to selectively inhibit the expansion of T-cell clones that are activated at the time of transplantation, without affecting existing T-cell immunity to other antigens. Existing cellular immunity to viruses, for example, is left intact. Induction treatment with anti-CD25 antibodies at the time of engraftment has been shown to reduce the incidence of future rejection episodes.

A more recent agent, alemtuzumab (Campath-1H), is a depleting humanized monoclonal antibody that binds to CD52, an antigen found on all peripheral blood mononuclear cells. Alemtuzumab administration causes a profound and sustained depletion of T cells from peripheral blood that lasts for many months. It similarly depletes B cells, natural killer cells, and monocyte, but to a lesser degree. Alemtuzumab is currently approved for treatment of patients with some forms of chronic lymphocytic leukemia. It is being used by some transplant centers for initial induction immunosuppression and for treatment of rejection.

G. Costimulation Blockade

Another emerging avenue for immunosuppression is that of signal two costimulation blockade. Once the T-cell receptor is engaged (signal 1), lipid rafts carry costimulation molecules to the immunologic synapse and allow for second messenger signaling to carry messages to the cell nucleus. Cytotoxic T lymphocyte antigen 4—immunoglobulin (CTLA4-Ig) or belatacept is a second-generation intravenous fusion protein designed to bind CD80/86 (B7 molecules) on antigen-presenting cells with high avidity, thereby inhibiting B7-CD28 complexes and T-cell activation. When compared to CNIs, phase II and III clinical trials have revealed that belatacept portends superior renal function and exhibits similar patient and graft survival with a decrease in the side-effect profile of renal toxicity and donor specific antibody formation. It has been recently approved for use as maintenance therapy. Due to an increased risk of patients developing posttransplant lymphoproliferative disorder, its use is restricted to Epstein-Barr virus (EBV) + recipients. Further studies attempting to design more selective targeting of alloreactive lymphocytes are ongoing. Specifically, pathways involving CD40/40L, LFA-1/ICAM, and CD2/LFA-3 are targets of newer, more potent monoclonal antibodies and fusion proteins.

SOURCES OF DONOR KIDNEYS

The two sources of kidneys for renal transplantation are living donors and deceased donors. Approximately one-third of patients who are acceptable candidates for transplantation will have a willing and medically suitable living donor. ABO-compatible donors are not absolutely required today because of the availability of treatments that can reduce the amount of antidonor antibody in the recipient. However, ABO-compatible donors are greatly preferred, because antibody reduction treatments are expensive and associated with infectious risk due to the depletion of protective antibodies.

At one time, only related living donors were acceptable because it was necessary to have closely matched HLA antigens between the donor and recipient in order to achieve acceptable graft survival rates. The graft survival rate for donor/recipient pairs who do not share any HLA antigens

is now greater than 90%, leading transplant programs to accept increasing numbers of donors who are not genetically related to the recipients. It is now common practice to accept volunteer donors who are spouses, in-laws, friends, coworkers, and even members of the same community who may be only acquaintances. More controversial is a recent trend for patients and donors to meet through Internet web sites. Despite initial hesitancy to condone this method of finding a living donor, it has been difficult for the transplant community to make value judgments about the relationship between living donors and recipients as long as both parties are fully informed and committed.

Recently, programs have begun arranging transplants between two or more pairs of living donors and recipients who participate in a paired exchange. Recipients with willing but incompatible donors are paired with another donor/recipient pair who have the same problem. The outcome from paired donation transplants has been similar to that seen with other living donor transplants.

Living donors should be in good health both physically and psychologically. Above all, the living donor should be a volunteer and must clearly understand the nature of the procedure so that informed consent to the operation can be given. Donors should generally be of legal age, but reasonable exceptions have been made in extenuating circumstances, particularly when an identical twin donor is available. In these circumstances, it is wise for the program to assign to the donor an outside advocate who has no relationship with either the recipient or the remainder of the family to ensure that the minor is not coerced into proceeding.

► Living Donors

Live kidney donors are now as common as deceased donors, although since each deceased donor can donate two kidneys, the total number of kidneys from deceased donors still far exceeds that obtained from living donors. Because of the biological ability of the body to compensate for the loss of one kidney, renal function tends to stabilize at approximately 75%-80% of the original renal function a few months following donation. Follow-up studies on donors show that they have good renal function and do not appear to suffer ill effects from the procedure, either physically or psychologically. Women with one kidney do not have an increased incidence of urinary infections during pregnancy.

There are at least two methods of performing donor nephrectomy in common practice: open nephrectomy and laparoscopic nephrectomy. Open nephrectomy, long the standard method, involves a flank incision about 15 cm long below the 12th rib. The peritoneum is retracted medially, and the kidney is removed along with its vessels and ureter without disturbing the intra-abdominal contents. More recently, laparoscopic techniques have been developed to allow the removal of a kidney for transplantation. The

donor is placed under general anesthesia, and the abdomen is insufflated with carbon dioxide to allow visualization of the abdominal structures. Some surgeons use a large port in the midline, just above the umbilicus, to insert their hand into the abdomen. The kidney is then withdrawn through the hand port once it has been dissected free from surrounding tissues and the vessels and ureter have been divided. It is also possible to remove the kidney using purely laparoscopic techniques without inserting a hand port. The kidney is removed by placing it in a bag inside the abdomen and withdrawing the bag through a low transverse incision. Laparoscopic nephrectomy tends to take longer than a nephrectomy through an open approach, but it is associated with somewhat less postoperative pain and a briefer period of convalescence. Prospective donors should be informed about the options for nephrectomy and the advantages and disadvantages of each technique as well as the associated risk and the known complications.

The main risk to a donor is the anesthesia and the operation itself. The mortality rate is estimated to be 0.03%, and most deaths are not judged to be preventable but appear to be intrinsic risks of having a major operation. The most common significant complications following nephrectomy are wound related, including infection and hernia formation. These complications occur in less than 1%-3% of cases. Wound infections typically respond to dressing changes, and hernias require operative repair.

The evaluation of a living donor must be thorough and complete. It is first necessary to make sure that the donor is truly a volunteer and is not being coerced or unfairly influenced by the recipient or other family members. This often involves a careful evaluation by an individual with excellent understanding of the transplant process as well as excellent communication skills. It is advisable that this portion of the interview be conducted in private so that donors can be honest about their feelings. Transplant social workers, psychologists, and psychiatrists are typically involved with this aspect of donor selection. Once it is clear that the donor is genuinely seeking to donate of his or her own accord, a detailed history is taken, and a physical examination is performed. Factors that may affect operative risk as well as future risk of renal failure are carefully sought out. The routine workup includes chest x-ray, electrocardiography, urinalysis, complete blood count, fasting blood glucose, serum bilirubin, hepatic transaminases, serum creatinine, and blood urea nitrogen. If these are normal, the kidneys are imaged radiographically to make sure that two kidneys are present, to rule out intrinsic or structural renal disease, and to evaluate the vasculature of the kidneys. Angiography, CT, and MRI are all methods that can be used. Kidneys with multiple renal arteries may be transplanted, but care must be taken in the anastomosis of small accessory vessels, particularly when they come from the lower pole and may therefore provide the sole vascular supply to the ureter. When there are multiple

renal veins, the smaller veins can often be ligated, since there is free communication of the veins within the kidney.

► Deceased Donors

Two-thirds of eligible kidney recipients do not have a suitable living donor. These patients are placed on a waiting list for a kidney from a deceased donor. Since more patients are added to the list each year, the number of patients waiting for a kidney from a deceased donor grows longer each year.

Kidneys can be successfully transplanted from donors who are declared dead on the basis of brain death or from donors who die of cessation of spontaneous cardiovascular activity.

Brain death is now widely accepted, in principle, in the United States, and all hospitals have protocols to be followed to ensure that the diagnosis of brain death is confirmed without any doubt.

Consent for donation should always be obtained by individuals with training in how to approach the family of the donors. In this way, the family can be given time to grieve and express the inevitable sorrow and anger that accompanies the death of a loved one. Individuals who are not part of the team caring for the patient are best able to provide the emotional support that families need during this time. The discussion regarding donation can then occur separate from the discussion in which the family learns that their loved one has died.

Kidneys from brain-dead donors are removed operatively. The excision of the kidneys occurs operatively following *in situ* cold perfusion and exsanguination of the kidneys, often in concert with the removal of other transplantable abdominal and thoracic organs. The kidneys are perfused with specially designed preservative solutions and kept cold. Successful transplantation has been reported following cold storage of more than 72 hours, but optimal results are achieved if the kidney is transplanted as soon as possible following removal from the donor, preferable within 24 hours.

Kidneys may also be transplanted from deceased donors following cardiopulmonary death, a practice termed “donation following cardiac death.” The most common circumstance under which this occurs in the United States is when medical therapy that is judged to be futile is withdrawn from an individual. Typically, patients have suffered profound, irreversible brain injury and have essentially no conscious awareness and no potential for meaningful recovery. Standard medical practice in this circumstance is to recommend withdrawal of life-sustaining support such as mechanical respiration and intravenous infusions, since the vast majority of people state that they would not want to be kept alive in such a hopeless state. Withdrawal of support always occurs with the consent and understanding of the family. The decision to donate organs should be made separate from the decision to withdraw medical therapy. Once consent is obtained and preparation for donation is completed, support is withdrawn by the primary care team.

When cardiopulmonary activity ceases, the primary physician team declares death, and the organs are then excised as with brain-dead donors.

SELECTION OF RECIPIENTS

Patients with chronic renal failure should be considered for transplantation. Acute renal failure on the basis of acute tubular necrosis can usually be managed with temporary dialysis, and therefore kidney transplantation is not appropriate in this setting. It is not necessary for patients to be on dialysis at the time of transplantation. In fact, results for patients who receive kidney transplants prior to beginning dialysis have the best chance of graft survival, while patients who had long-term dialysis prior to transplantation have poorer success rates. It is therefore important to begin consideration for renal transplantation as soon as dialysis appears to be inevitable and imminent within the next year.

During the early years of renal transplantation, most of the patients accepted for transplantation were between 15 and 45 years old. In recent years, the age range has been extended in both directions—children younger than age 1 and adults who are over 70 years old have received transplants. For many years, the success rates for transplanting in young children was inferior to that achieved with adults, but this problem has now been corrected. Even children younger than 1 year of age at the time of transplantation can be expected to have an excellent chance of graft survival.

Historically, there has been reluctance to perform renal transplants in the elderly. However, as the practice of renal transplantation continues to improve, with less toxic and more effective immunosuppression and more effective methods of preventing posttransplant infections, this unwillingness appears less justified. Elderly individuals naturally have a shorter life span, but to date, patients over 60 years old who receive transplants appear to enjoy approximately the same degree of improvement in life expectancy as do younger patients.

This benefit has been quantified by comparing the mortality rate of suitable candidates awaiting kidney transplantation with the mortality rate following transplantation. Life expectancy appears to be approximately doubled by kidney transplantation in all age ranges that have been studied to date. The improved life expectancy following kidney transplantation is particularly dramatic for diabetic patients. Today, patients tend to be judged on the basis of their physiologic functional status rather than on their chronological age. It is nevertheless true that elderly patients are more commonly found to be poor candidates for transplantation because of either coexisting disease or poor functional status.

Candidates must be free of active infections at the time of transplantation. Chronically infected tissues such as chronic pyelonephritis or chronic osteomyelitis should be definitively treated prior to consideration for transplantation. Patients with active viral or bacterial infection at the

time, an organ is available for transplantation should usually be deferred until the infection has resolved. This is because it is unwise to initiate immunosuppression during an active infection, particularly given that the highest doses of immunosuppression are given around the time of the procedure.

Recipients with almost all types of primary renal disease have been successfully transplanted: glomerulonephritis, hypertensive nephropathy, chronic pyelonephritis, polycystic kidney disease, reflux pyelonephritis, Goodpasture syndrome, congenital renal hypoplasia, renal cortical necrosis, Fabry syndrome, and Alport syndrome. Successful transplants have been achieved in patients with certain systemic diseases in which the kidney is one of the end organs affected (cystinosis, systemic lupus erythematosus, and diabetic nephropathy). Renal transplantation is generally inadvisable in patients with oxalosis if high serum levels of oxalate are present because the disease recurs in the transplant quickly. However, liver transplantation corrects the enzymatic defect that leads to excessive oxalate accumulation. Therefore, combined liver-kidney transplantation may be an acceptable treatment option for these patients.

Patients who do not have normal bladder function may be acceptable kidney transplant candidates, but a plan for ureteral drainage should be made before transplantation occurs. Many patients with long-term defunctionalized bladders can still undergo ureteral reimplantation and then be treated with intermittent catheterization if necessary posttransplant. If the bladder is congenitally or surgically absent, a defunctionalized loop of small bowel can be created, brought out as a stoma, and used for a urinary conduit. Care must be taken in planning the positioning of the conduit so that the ureter from a transplanted kidney will reach it.

Transplant patients must be compliant with posttransplant care to achieve successful outcome. Patients with a history of poor compliance may be candidates for transplantation if they are regretful of past behavior and have established a compliant pattern. In some cases, especially in the adolescent age group, it is wise for the patient to experience dialysis prior to receiving a kidney transplant in order to foster a complete understanding of the differences in lifestyle that are afforded by a successful kidney transplant. It is also necessary that patients have a support network to help them manage following the transplant. They will need a way to reliably obtain immunosuppressive therapy as well as transportation to and from the transplant center that is continuously and reliably available. Fortunately, support services are often available to patients who lack social support, and it is rare to deny transplantation solely on the basis of inadequate social support.

In the early years of kidney transplantation, it was common to perform bilateral nephrectomy prior to transplantation, but this has recently become very uncommon. Most patients who have native nephrectomy have polycystic kidney disease with profound pain, recurrent infections, or

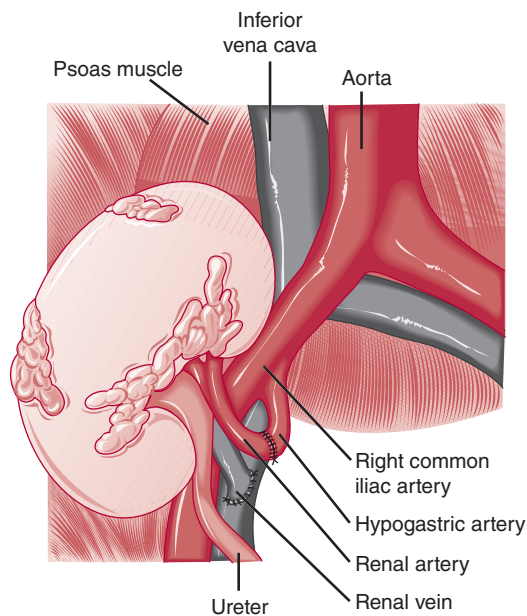

recurrent hemorrhage. Other indications for native nephrectomy include recurrent infection, especially when associated with ureteral reflux, and occasionally profound hypertension attributable to an ischemic native kidney.

OPERATIVE TECHNIQUES

The surgical technique of renal transplantation involves anastomoses of the renal artery and vein and ureter (Figure 45-1). The transplant kidney is placed in the iliac fossa through an oblique lower abdominal incision. The dissection is carried out by retracting the peritoneum medially so the kidney will lie in an extraperitoneal position. The iliac arteries and veins are mobilized as indicated for the proposed specific anastomoses. An end-to-side anastomosis is performed between renal vein and iliac vein; an end-to-side anastomosis is then performed between the renal artery and the external iliac artery. An alternative technique is to connect the renal artery end-to-end to the internal iliac artery, but this technique is more difficult in most patients. When multiple arteries are present, there are several options. If the artery is very small (< 2 mm), it can often be ligated, especially if it is an upper

▲ Figure 45-1. Technique of renal transplantation.

pole branch. If the kidney is from a deceased donor, it is often possible to use a large Carrell patch of donor aorta that encompasses all of the arteries. Other options include reimplanting multiple renal arteries into the iliac artery using multiple anastomoses; reimplanting a smaller artery into the side of the dominant renal artery and then using the larger artery for anastomoses to the iliac; and spatulating the ends of the two arteries together to form a single lumen for anastomosis.

In small children and infants, the kidney transplant can be performed either through a midline abdominal incision or by making a very large flank-type incision extending from the pubic symphysis to the costal margin and exposing the aorta and vena cava by reflecting the peritoneal contents medially and superiorly. End-to-side anastomoses of the renal vessels may be made to the iliac vessels if they are large enough, but often it is necessary to use the infrarenal vena cava and aorta for the anastomotic site.

Kidneys from small pediatric deceased kidneys function poorly when transplanted into small pediatric recipients. However, many pediatric kidneys have often been transplanted en bloc with the donor aorta and vena cava anastomosed to the recipient's iliac vessels along with double ureteral anastomoses. The exact age at which it is best to transplant kidneys as a single unit is unclear, but certainly kidneys from children as young as 6 will function well and last a long time when transplanted into adults.

Urinary tract continuity can be established by pyeloureterostomy, ureteroureterostomy, or ureteroneocystostomy. The most common technique is ureteroneocystostomy. This technique can be performed by bringing the ureter into the bladder through a submucosal tunnel and suturing the mucosa of the ureter to the mucosa of the bladder from the inside of the bladder through a large cystotomy (Politano-Leadbetter method). Other techniques include an external neocystostomy, which avoids the need for a large cystotomy and is more common, and the "one stitch" technique, whereby the mucosa of the ureter is not directly sutured to the bladder mucosa, but rather the ureter is fixed into place in the interior of the bladder with a suture that traverses the full thickness of the bladder wall. A ureteral stent may be placed with any of the techniques discussed above. A 6Fr pediatric ureteral stent with a J shape at each end fits nicely across the anastomosis and goes from the interior of the renal pelvis into the bladder or other urinary conduit. The stent should be removed in the first month or two following the transplant to prevent stone formation and bladder infection.

POSTOPERATIVE MANAGEMENT & COMPLICATIONS

Recipients who have received a kidney transplant usually produce urine immediately, and the serum creatinine falls over the next 3-7 days. The magnitude of urine output is related

to how hydrated the patient was before transplantation and to how much fluid is administered during the procedure. It is important that the patient is fully hydrated at the time the kidney is revascularized in order to achieve the best chance of immediate transplant kidney function. Transplanted kidneys frequently will have an obligate diuresis for a period of hours to days after they begin to function. During this phase, it may be necessary to replace urinary output in order to prevent the development of hypovolemia as a result of excess urinary output. Once this phase has passed, intravenous fluid can be discontinued. However, patients are encouraged to maintain generous fluid intake to prevent dehydration in the future, as transplanted kidneys appear to have a greater susceptibility to hypovolemia than native kidneys. Patients are usually able to eat the morning following the transplant procedure and should be encouraged to get out of bed with assistance. The urinary catheter can be removed as early as 2 days following the procedure, depending on the technique used for ureteral anastomosis. Some programs prefer to leave the urinary catheter in place for a longer period of time to allow sufficient healing of the anastomosis. Most recipients are able to be discharged from the hospital on the second or third postoperative day if there are no complications in their postoperative course once they are able to maintain oral hydration, have learned how to properly take their medications, and have received training about what to do, what not to do, and what to watch out for in the next few weeks.

Kidney transplantation can be followed by a variety of postoperative complications that must be recognized and treated early for optimal results. The most frequent complications are infection and rejection, reflecting the natural tension between too much and too little immunosuppression. Urinary infection is one of the most common complications and usually responds to antibiotic therapy. Bacterial pneumonia is the most common pulmonary complication and may be very serious if not promptly diagnosed and treated. Current immunosuppression protocols that focus on the T lymphocyte are associated with unusual, opportunistic types of infections including herpesviruses, the parasite *Pneumocystis carinii*, and fungal infections. These infections are seen much less often than previously because it is standard to prescribe prophylactic anti-infective therapy aimed at preventing the common types of infection. In particular, the availability of agents that are effective against cytomegalovirus (CMV) infection has almost eliminated clinical CMV infections. At one time, CMV infections were a frequent, expensive, and exceedingly unpleasant occurrence after many transplants.

In approximately 20% of kidney transplants from deceased donors, the kidney will fail to function immediately. This complication is termed delayed graft function and is due to acute tubular necrosis of the kidney. In some cases, there is a modest urinary output, but the serum creatinine does not fall. In other cases, there is profound oliguria. Delayed graft function can also occur following living donor transplantation,

but it is much less common (< 3%). Delayed graft function is associated with older donors and donors who had a rising creatinine at the time of donation. Long ischemic times are also known to increase the chance of delayed graft function. In most cases, the acute tubular necrosis will resolve and the renal function will recover. Most recovery happens within a week, but in some cases, the kidney will require several weeks before renal function is sufficient to support the patient without dialysis. Treatment is supportive with dialysis as necessary. If recovery takes more than a week, it may be wise to biopsy the kidney to rule out silent rejection.

Vascular complications of kidney transplants are uncommon, affecting 1%-2% of renal transplants. Either renal artery or venous thrombosis of the kidney is devastating and almost uniformly results in graft loss. The incidence of acute graft thrombosis is higher in patients with high levels of circulating anti-HLA antibodies, suggesting that some of these cases are related to accelerated acute rejection. The incidence of graft thrombosis is also higher in patients with factor V Leiden and other physiologic derangements that cause a hypercoagulable state. Patients should be screened for factor V Leiden if they have a history of unusual thrombotic events and receive anticoagulation perioperatively when it or other known hypercoagulable states are known. Renal artery stenosis, which may be associated with rejection involving the renal artery, is also a rare complication. It can present with severe hypertension. It may be treated surgically or in some cases by percutaneous transluminal balloon angioplasty.

Urologic complications occur in about 4% of patients, most often urinary extravasation from the cystotomy closure or ureteral obstruction. These complications can almost always be managed with percutaneous placement of a nephrostomy tube by an interventional radiologist and are not associated with a higher risk of graft loss.

A complication relatively unique to kidney transplantation is formation of a pelvic lymphocele in the transplant bed. Lymphatic fluid may come from either lymphatics in the hilum of the kidney or from lymphatics disrupted during exposure of the iliac vessels. Careful ligation of the adjacent lymphatics during preparation of the recipient blood vessels may decrease the incidence of this complication. Large lymphoceles may obstruct the ureter or the vasculature of the transplanted kidney, and they occasionally become infected. Sterile lymphoceles may be drained into the peritoneal cavity, while infected lymphoceles need to be drained externally.

Gastrointestinal complications may affect all levels of the intestine, but upper gastrointestinal symptoms, including nausea and abdominal pain, are most common. In many cases, the culprit is the large number of medications that the patient must take. Peptic ulceration was once a major problem for transplant recipients, but this complication has virtually disappeared because of routine use of medications like H₂-blockers and proton pump inhibitors to inhibit the production of gastric acid.

GRAFT REJECTION

Despite advances in immunosuppressive management, rejection is still a major hazard for the postoperative allograft recipient. Most episodes of rejection occur within the first 3 months. There are three basic kinds of rejection:

1. **Hyperacute rejection** is due to preformed cytotoxic antibodies against donor antigens. Pretransplant cross-match testing is designed to prevent this type of rejection. This reaction begins soon after completion of the anastomosis, and complete graft destruction occurs in 24-48 hours. Initially, the graft is pink and firm, but it then becomes blue and soft, with evidence of diminished blood flow. There is often no effective method of treating hyperacute rejection, but treatment with plasmapheresis and immunoglobulin infusion may be effective if the diagnosis is made immediately.
2. **Acute rejection** is the most common type of rejection episode during the first 3 months after transplantation. It is primarily an immune cellular reaction against foreign antigens. The reaction may be predominantly cellular, or there may be a component of antibody-mediated inflammation. Typically, the patient is asymptomatic and the diagnosis of rejection is suspected on the basis of serial measurement of serum creatinine levels. In severe cases, symptoms may include oliguria, weight gain, and worsened hypertension. Fever and tenderness and enlargement of the graft are uncommon with modern immunosuppressive protocols but used to be seen when only azathioprine and corticosteroids were available. This type of rejection process is usually treated with pulse steroid therapy. If this is unsuccessful, or in very severe cases of acute rejection, either a polyclonal or monoclonal depleting antilymphocyte preparation is used. The vast majority of acute rejection episodes are successfully reversed. Currently, grafts are only lost to rejection when patients are noncompliant or when rejection occurs together with a life-threatening infection, since it is unsafe to enhance the degree of immunosuppression in this setting.
3. **Chronic rejection** is a late cause of renal deterioration. It is unclear precisely what causes chronic rejection, but the absence of cellular elements on biopsy and the association of antidonor antibodies with chronic graft loss have led to the assumption that it is mediated by humoral factors. It is most often diagnosed on the basis of slowly decreasing renal function in association with proteinuria and hypertension. Chronic rejection is resistant to all known methods of therapy and graft loss will eventually occur, though perhaps not for several years after renal function begins to deteriorate. It is unclear what the relationship is between this pathologic process and the damage produced by chronic calcineu-

rin inhibitor use, which is seen in nonrenal transplant recipients as well. It has recently been uncovered that chronic graft loss is accelerated in patients who experienced rejection in the first year after a transplant, in patients who had delayed graft function, and in patients who received kidneys from marginal donors.

▶ **Differential Diagnosis of Renal Allograft Dysfunction**

An unexpected elevation in serum creatinine above baseline levels in a renal transplant recipient has a broad differential diagnosis list. Dehydration should be ruled out by history and physical examination. The medication the patient is taking should be reviewed, paying attention to over-the-counter medications, especially nonsteroidal anti-inflammatory drugs and herbal remedies. These drugs can cause renal dysfunction or can alter the metabolism of immunosuppressant medications and result in blood levels that are either too high or too low. Urinary infection should be ruled out with a urinalysis. If these simple evaluations do not disclose the cause of renal dysfunction, the next step is usually a renal ultrasound to rule out ureteral obstruction, followed by a renal allograft biopsy. This last step is crucial to arriving at the correct diagnosis. A biopsy may disclose acute rejection, or it may show calcineurin inhibitor toxicity. Since the treatment for these conditions is opposite, a biopsy is very important to guide appropriate therapy.

HEART TRANSPLANTATION

The first successful human heart allograft was performed in 1967 by Christiaan Barnard. At that time, however, the only available immunosuppressive therapy was azathioprine and steroids. This regimen was inadequate to safely prevent rejection in these patients. As a result, the procedure remained experimental and was limited to a small number of institutions worldwide. The introduction of cyclosporine in 1981 resulted in dramatically improved survival. As a result, heart transplantation was federally designated as no longer experimental in 1985. In 2003, there were about 2000 heart transplants performed in the United States at more than 100 centers. The 1-year survival rate is now over 85%, and the 3-year survival rate is over 75%.

SELECTION OF DONORS

At one time, deceased donors were considered suitable for cardiac donation only if they were men aged 40 years or younger or women 45 or younger. The large waiting list and the increasing number of patients who die on the waiting list has led surgeons to accept hearts from donors as old as 60, and more than one-third of current donors are older than 40. Cardiac donors must be ABO-compatible with the recipient and should be within 20% of the recipient's ideal body weight. Ideally, there should be no history of preexistent

or intercurrent cardiac disease. It is routine to obtain echocardiography to determine cardiac function, even in young donors. At many programs, it is routine to obtain cardiac catheterization in older donors to rule out silent coronary artery disease. Ideally, there should be no history of cardiac arrest, but if cardiac function is good, this factor alone does not usually rule out a cardiac donor. The donor should be receiving only moderate doses of pressor drugs.

At the donor operation, the chest is opened and the heart is inspected for evidence of contusion and observed to determine its overall function. If the heart is suitable, this information is relayed to the recipient operating team so that the timing of the recipient operation can be carefully coordinated. The heart is removed following cross-clamping of the aorta and infusion of cold cardioplegia, which results in cessation of electrical and mechanical cardiac activity. The heart is typically removed first, prior to the excision of kidney, liver, or pancreas. It is flushed with a preservative solution and stored aseptically at 4°C. Optimal function is obtained when the heart is implanted within 4 hours of procurement. For recipients who have previously had cardiac procedures through a sternotomy, it is sometimes necessary to delay the procurement of the donor heart to make sure that the recipient will be ready to receive the heart when it arrives back at the transplant hospital. The same is true when recipients have left ventricular assist devices implanted and extra time is necessary to prepare the recipient to receive the donor heart.

SELECTION OF RECIPIENTS

Patients for cardiac transplantation should have end-stage cardiac disease for which there is no other surgical option and should have received maximal medical treatment. Most heart transplant candidates have idiopathic dilated cardiomyopathy or ischemic cardiomyopathy. Most patients are younger than 55 years of age, but successful transplantation has been reported on more elderly patients. Patients should not have systemic disease that will be worsened by the immunosuppressive regimen (infection, type 1 diabetes, severe peripheral vascular disease, poorly controlled hypertension), nor should they have underlying renal insufficiency that cannot be attributed to low cardiac output.

Patients should have pulmonary vascular resistance of less than 5 Wood units, since levels above this or a pulmonary artery systolic pressure of greater than 50 mm Hg or a transpulmonary gradient (mean pulmonary artery pressure–pulmonary capillary wedge pressure) of greater than 15 mm Hg are associated with inadequate donor heart function. As with other organs, a history of compliance with a complex medical regimen and a strong social support system are necessary for long-term success.

If the recipient has circulating antibodies directed against HLA antigens, it is necessary to perform a crossmatch between the recipient's serum and the donor lymphocytes to

make sure that hyperacute rejection of the cardiac graft does not occur. Patients who have left ventricular assist devices in place may be particularly difficult to obtain hearts for because of the sensitizing effect that the device has on the immune system.

OPERATIVE TECHNIQUE

The operative technique originally developed by Lower and Shumway continues to be used and is shown in Figure 45–2. A median sternotomy is performed and the patient is placed on cardiopulmonary bypass. The recipient heart is removed, and the atrial cuffs trimmed. The left atrial anastomosis is performed first and then the right, each with one continuous suture. Before the left atrium is closed, it is filled with saline to avoid air embolism. The aortic and then pulmonary artery anastomoses are then performed. Topical cooling may be continued, and the addition of blood cardioplegia after the atrial anastomoses may be done in order to improve graft function. The implant time is generally 45–60 minutes. It is frequently necessary to provide chronotropic support for the denervated heart in the form of atrial pacing or isoproterenol.

IMMUNOSUPPRESSION

Triple immunosuppression with a calcineurin inhibitor, antimetabolite, and corticosteroids is typical of the standard immunosuppressive protocol at most heart transplant programs. Perioperative induction immunosuppressive therapy with either polyclonal or monoclonal antibody therapy directed at lymphocytes is sometimes used in order to avoid the renal toxicity associated with early high-dose calcineurin inhibition and to reduce the risk of later rejection. Rejection is diagnosed on endomyocardial biopsy, which is performed regularly, since rejection may occur in the absence of clinical symptoms. Rejection is treated with 3 days of pulse steroids and resistant rejection with antilymphocyte therapy.

FOLLOW-UP CARE

Transplant recipients must be carefully monitored for infection and rejection. Protocols for endomyocardial biopsies vary by center but are typically performed every other month for the first year, then every 3 months. The incidence of rejection episodes is 0.5–1.5 per patient for the first year. The major infection rate is 1.5 episodes per patient for the first year and then declines. Accelerated coronary atherosclerosis, believed to be a manifestation of chronic graft rejection, occurs in 30%–40% of patients within 5 years after transplantation. There is no effective therapy for this condition except for retransplantation in highly selected, usually younger, patients. Progressive renal dysfunction may occur over time due to the cumulative effect of calcineurin inhibitor therapy.

COMBINED HEART-LUNG TRANSPLANTATION

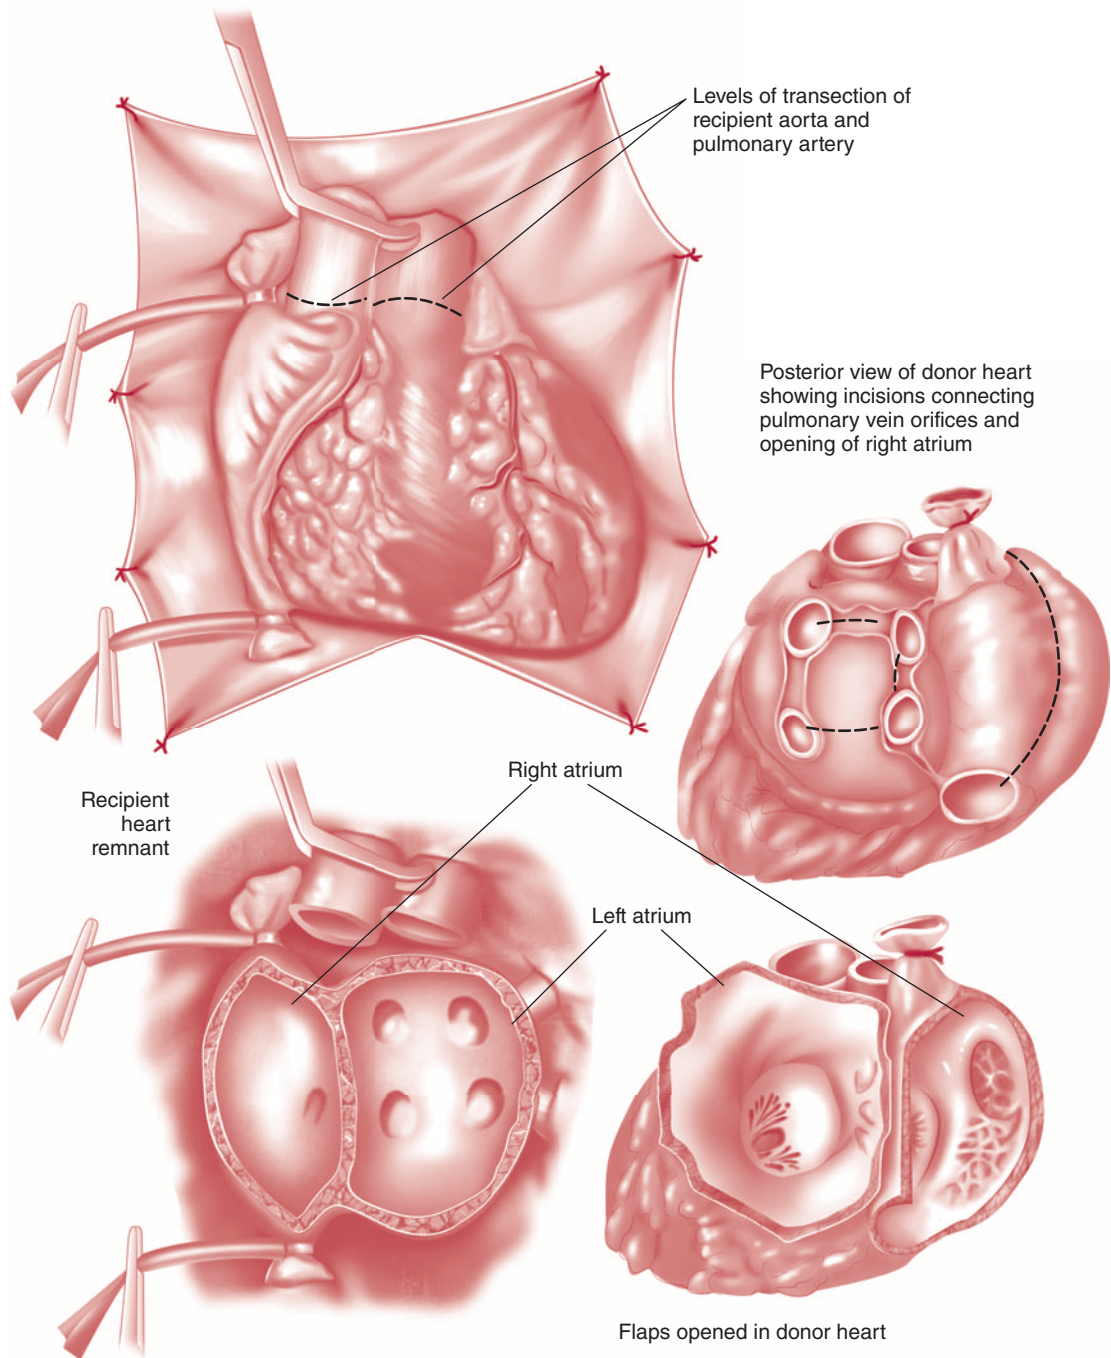

Combined heart-lung transplantation was first performed in 1981. Initially, it was felt that rejection of both organs would be evident in the myocardial biopsy. However, experience has shown that rejection is dissimilar in the two organs, with heart rejection occurring infrequently and lung rejection, evidenced by obliterative bronchiolitis and arteritis, being a more severe problem. Heart-lung transplantation is currently performed with gradually decreasing frequency. In 1994, there were 71 heart-lung transplants in the United States. This number had declined to 28 in 2003. The main indication for heart-lung transplantation is end-stage disease in both organs or end-stage disease in one with poor function in the other prohibiting single-organ transplantation. Examples are primary pulmonary hypertension, congenital heart disease with Eisenmenger physiology, fibrotic lung disease and cor pulmonale, and cystic fibrosis.

The operation consists of en bloc heart-lung transplantation with anastomosis of the trachea, right atrium, and aorta of the donor.

Immunosuppression parallels that of heart transplantation with the exception that steroids are avoided initially in order to promote tracheal wound healing. Heart-lung transplantation currently results in a 70% 1-year survival rate.

LUNG TRANSPLANTATION

Single-lung transplantation became clinically successful through a systematic approach by the Toronto Lung Transplant Group to the problem of bronchial disruption, which had made previous attempts unsuccessful. The addition of an omental wrap to the bronchial anastomosis and the avoidance of steroids during the first 3 weeks allowed bronchial healing and clinical success. Lung transplantation is currently performed for a myriad of indications, including emphysema, cystic fibrosis, idiopathic pulmonary fibrosis, α_1 -antitrypsin deficiency, primary pulmonary hypertension, and congenital diseases. Candidates for lung transplantation have irreversible end-stage disease for which there is no other therapy, are oxygen dependent, and are likely to die of their disease within 12–18 months. Lung donors are scarce, but the use of one lung for transplantation does not preclude using the heart for another recipient. Long-distance procurement of lungs has been possible since institution of a regimen consisting of pulmonary artery flush with cold

▲ **Figure 45-2.** *Top left:* Recipient heart showing levels of transection across aorta and pulmonary artery. *Lower left:* Implantation site with recipient heart removed. *Top right:* Posterior view of donor heart showing lines of incision connecting pulmonary vein orifices and opening the right atrium in preparation for implantation. *Lower right:* Flaps opened in donor heart in preparation for implantation.

preservative solution following alprostadil (PGE₁) via the central venous line to promote pulmonary vasodilatation.

Patients with bilateral pulmonary sepsis, such as cystic fibrosis or bronchiectasis, or patients with emphysema and normal heart function may sometimes be eligible for double-lung transplantation. The advantage is that the patient does not have the potential complications of heart transplant and rejection. Another innovative approach to the lung transplant patient with a normal heart is the operation whereby a heart-lung block is placed in a patient with end-stage lung disease and a normal heart, and the recipient's heart is extracted and donated to a patient in need of an isolated heart transplantation.

Immunosuppressive management of lung transplant recipients is very similar to that of heart recipients in that the cornerstone of therapy is a calcineurin inhibitor. The major difference is that steroids are omitted for several weeks in order to promote healing of the bronchial anastomosis. Postoperative management focuses on prevention of sepsis and detection and treatment of rejection. Bronchoscopy is performed liberally and transbronchial lung biopsy is used to diagnose lung transplant rejection. Acute rejection may be effectively treated with corticosteroid pulse therapy, or by enhancing the existing immunosuppressive regimen. The major long-term complication in lung transplant recipients is the development of bronchiolitis obliterans syndrome (BOS). BOS is felt to be the lung manifestation of chronic rejection. Episodes of acute rejection are risk factors for the development of BOS in the future. There is currently no effective therapy for BOS. A promising development that is currently experimental is aerosolized delivery of immunosuppression. It is hoped that directing immunosuppression preferentially to the lung itself may allow enhanced protection from rejection without increasing the risk of infection.

LIVER TRANSPLANTATION

After many years of experimental effort, Dr Thomas Starzl performed the first successful human liver transplantation in 1967. Over the next decade and a half, the procedure was done only in low volumes, and outcomes were generally poor. As with other organs, the introduction of cyclosporine in the 1980s resulted in marked improvement in survival rates. Today, more than 5000 liver transplants are performed annually in the United States, and 1-year patient survival rates are more than 85%.

Since the introduction of clinical liver transplantation, the list of indications has rapidly expanded and the list of

contraindications has diminished. The most common indication for liver transplantation is currently cirrhosis due to chronic hepatitis C infection. Other diseases for which liver transplant is indicated include cirrhosis due to hepatitis B, alcoholic cirrhosis, primary biliary cirrhosis, sclerosing cholangitis, autoimmune hepatitis, and cirrhosis secondary to nonalcoholic fatty liver disease. Less common indications are Wilson disease, α_1 -antitrypsin deficiency, Budd-Chiari syndrome, and hemochromatosis. In children, the most common indication is biliary atresia. Other common diagnoses include α_1 -antitrypsin deficiency, tyrosinemia, and other inborn errors of metabolism.

Alcoholic cirrhosis was once a subject of considerable controversy because of the self-induced nature of the disease. The world community rejected the notion that lifesaving therapy should be withheld from patients who could benefit from it merely because their disease is self-induced. It was pointed out that many, if not most, diseases are to some degree self-induced, whether it is diabetes and high blood pressure due to obesity or cancer and heart disease due to smoking. It is now recognized that alcoholic cirrhosis is an accepted indication for liver transplant if the patient has demonstrated the ability to abstain from alcohol and is clearly committed to continued abstinence. Overall results in alcoholic recipients have shown that patients transplanted for alcoholic cirrhosis fare at least as well as patients transplanted for most other diagnoses.

Chronic active hepatitis B was formerly considered to be a controversial indication for liver transplantation because recurrence was quite frequent and tended to result in rapid graft failure. This changed when effective strategies to prevent recurrence of hepatitis B using high-dose hepatitis B hyperimmune globulin infusions posttransplant were reported. Now hepatitis B is considered to be a standard indication, and results are equal to those obtained for other diagnoses. In contrast, the outcome for patients transplanted for hepatitis C was once considered to be equal to that of other diagnoses. Recent data, however, suggest that recurrence of hepatitis C in the new liver graft is virtually universal following transplantation, and 25% of patients will have developed cirrhosis in the graft within 5 years. It is not surprising that longer-term data are now appearing showing that the 10-year survival for patients transplanted for hepatitis C is significantly worse than for other diagnoses.

As with transplantation for hepatitis B and C, the consensus opinion has gone back and forth in recent years regarding whether liver transplantation should be used for the treatment of hepatocellular carcinoma in adults. Patients with cirrhosis are at risk for development of primary hepatocellular cancer. Since these patients usually die of liver failure, unlike patients with other forms of malignancy who usually succumb to widespread metastatic disease, it was reasoned that transplantation would be a curative therapy. Unfortunately, the initial results with transplantation for hepatoma were

disappointing due to a high rate of tumor recurrence. These poor results prompted many programs to stop doing transplants for hepatoma. The group from Barcelona, Spain, then reported that survival rates are good if the tumor is small (< 5 cm in diameter) but poor if the tumor is large or shows evidence of large vessel invasion. Numerous reports have confirmed this finding, and currently liver transplantation is considered to be a standard treatment for patients with small hepatomas. Results for liver transplantation for other malignancies remain poor, with the exception of several encouraging reports of reasonable survival rates for highly selected patients with cholangiocarcinoma who receive adjuvant radiation and chemotherapy.

Current contraindications are few and are primarily related to evidence of cardiopulmonary disease that prohibits safe liver transplantation. Examples are significant, uncorrected coronary artery disease; pulmonary hypertension with pulmonary artery systolic pressures greater than 70 mm Hg; and FEV₁ of less than 1 L on pulmonary function testing. Active substance abuse is also an absolute contraindication to transplantation. Diabetes increases the risks associated with transplantation and the incidence of post-transplant complications, but it is not an absolute contraindication to liver transplantation. Even infection with HIV, long considered a contraindication to transplantation, is no longer an absolute contraindication at some centers that are reporting good results in small numbers of carefully selected HIV-positive patients. Portal vein thrombosis, which at one time was a contraindication to transplant, is now managed by performing thrombectomy on the portal vein, by using vein grafts to bypass thrombosed vessels, or by using the infrahepatic cava for portal inflow.

► Donor Selection

The number of patients listed for liver transplantation increases each year. This has led to a gradual increase in the number of patients who die while waiting and consequently to a relaxation of past standards for liver graft suitability. Livers are currently being transplanted from donors more than 80 years old with acceptable outcomes. It is important that the liver is a rough size match for the donor, but there is much leeway in this regard. Blood-type compatibility is preferred but not an absolute requirement. Matching of tissue antigens does not appear to be relevant for liver transplantation, and a positive crossmatch is not a contraindication to proceeding with transplantation because it is not associated with a worse outcome posttransplant.

The technique of preserving the liver grafts after removal from the donor is based on decreasing metabolic requirements by keeping the graft cold. Blood is flushed from the organ to prevent vascular occlusion; preservation solution is infused; and the organ is kept on ice at 4°C. Multiple preservative solutions are in common use worldwide. Most contain

inert high-molecular-weight molecules that do not diffuse into the cell to prevent cellular swelling. Also, free oxygen radical scavengers, which are thought to prevent injury upon reperfusion of the graft, are frequently included. The introduction of Viaspan solution in the late 1980s revolutionized liver transplantation by extending the period of safe *in vitro* liver preservation from 10 hours to more than 24 hours. Despite this advance, it is clear that prolonged cold ischemia is bad for the liver graft, particularly if the graft contains a large amount of intracellular fat or is from an older donor. Transplant programs therefore continue to strive to minimize the cold ischemic time to whatever degree is feasible.

► Operative Technique

In general, liver transplantation is an orthotopic procedure: The host liver is removed and the donor organ placed in an orthotopic position. The operation is performed in three phases: the dissection phase, during which the attachments of the diseased liver are dissected and the vascular structures are prepared for resection; the anhepatic phase, which extends from the time the host liver is removed until the time the donor liver is revascularized; and the reperfusion phase, during which blood is circulating through the new organ and the biliary tree is reconstructed.

Several techniques are available for handling the retrohepatic vena cava. Historically, the liver was removed en bloc with the vena cava and hemodynamic instability was avoided by using venovenous bypass to overcome decreased venous return when vena caval and portal vein flow was interrupted. The new liver was then sutured into place using a bicaval technique with end-to-end caval anastomoses being performed from donor to recipient both above and below the new liver. With careful anesthetic technique and preloading with fluid, venovenous bypass may be avoided in many cases. An alternative method of handling the retrohepatic cava is to dissect the liver off the cava and sequentially ligate the hepatic venous branches that enter the cava directly from the right and caudate lobes. This allows the liver to be removed by clamping the main hepatic veins without occluding the vena cava. The new liver is then sutured into place by connecting the suprahepatic cava of the donor to a common orifice created by connecting the right, middle, and left hepatic veins. This technique is called the piggyback technique because the donor cava sits directly on top of the recipient cava. The infrahepatic cava of the donor is occluded with either sutures or a vascular stapler. This method may preclude the need for venovenous bypass because caval flow is usually not completely interrupted. A third option for caval reconstruction is to connect the donor cava to the recipient cava using a side-to-side technique by making longitudinal incisions from the hepatic veins caudally, creating a very wide anastomosis. This technique is difficult when the donor liver is large relative to the size of the recipient's hepatic fossa.

The current methods of biliary reconstruction include primary choledochocholedochostomy (when the recipient duct is intact) or Roux-en-Y choledochojejunostomy if the recipient bile duct is not intact or if anatomically the donor and recipient duct cannot be approximated without creating tension on the anastomosis. It was once standard to place a T tube or another type of biliary stent across the biliary anastomosis, but many programs have now discontinued this practice because it is not clear that the presence of a stent influences the rate of biliary complications.

Although the liver can function normally with only portal venous flow, the bile duct is dependent on hepatic arterial flow. For this reason, the hepatic arterial anastomosis is crucial to postoperative graft survival. The arterial supply of the liver is quite variable, with nearly half of the patients having some form of aberrant circulation. The most common aberrancies are replacement of the right hepatic artery to the superior mesenteric artery and the presence of an accessory left hepatic artery that derives from the left gastric artery. When aberrant arterial vessels are identified on a deceased donor, it is important that they are carefully preserved so that reconstruction can occur when the liver has been perfused and cooled and is sitting in sterile ice slush. Multiple methods of reconstruction of aberrant vessels are available and, if necessary, a conduit of donor iliac artery may be used in the reconstruction.

► Living Donor Liver Transplantation & Split Liver Transplantation

The shortage of organs for small children in the late 1980s prompted the development of techniques to reduce the size of an adult liver graft by performing an anatomic resection of one or more lobes and transplanting the reduced graft. In this way, it was possible to transplant the left lobe or the left lateral segment from an adult liver into a child. This technique was successful and rapidly became a standard method of obtaining grafts for small children. The natural evolution of this technique was to apply the method used to reduce the size of a deceased donor liver graft to adult living donors. Broelsch at the University of Chicago popularized the transplantation of the left lateral segment from an adult into a child and showed that this technique could be at least as effective as using full-sized grafts from small children. It was hoped that living-related liver transplantation would offer an immunologic advantage as it does with kidney transplantation, but this did not turn out to be the case. The major advantage of living donor liver transplantation appears to be the ability to allow transplant to occur prior to the deterioration of the recipient's condition into a poor state of health that is associated with a higher risk for transplantation.

The success of living donor liver transplantation from adult donors into children, together with the shortage of

suitable adult donors, led to the development by Marcos and Tanaka of techniques to utilize the right lobe from a living donor to transplant into another adult. The donor operation is a major undertaking and is associated with appreciable morbidity as well as a mortality rate of approximately 0.5%. Nevertheless, living donor liver transplants have become a standard option when timely deceased donor liver transplantation is not possible.

By applying the living donor technique to deceased donors, two transplants can be obtained from a single adult liver from a deceased donor. This has been termed a split liver transplant. Typically, the lateral segment of the left lobe is used for a child or very small adult, while the remainder of the liver consisting of the right lobe plus the medial segment of the left lobe is used for an adult. Less commonly, the liver from an adult deceased donor can also be split into a right lobe graft and a left lobe graft and used for two adults. In fact, improvements in operative technique in the last decade have allowed for an increased use of living donor left lobe grafts in adults with improvements in outcomes.

► Immunosuppressive Therapy

The mainstay of immunosuppression for liver transplant recipients is a calcineurin inhibitor. An antimetabolite or corticosteroids, or both, may also be included but are not absolutely necessary. Induction therapy with antilymphocyte preparations was once considered standard but has now been abandoned by many liver transplant programs because it appears unnecessary.

Despite being one of the largest organs transplanted in terms of mass, the liver seems to require less immunosuppression for maintenance therapy compared to other organs. Corticosteroids can frequently be safely discontinued. Typically, monotherapy with a low dose of a calcineurin inhibitor is all that is required to suppress rejection long term. Spontaneous tolerance with normal graft function despite complete discontinuation of all immunosuppressants occurs in approximately 10%-20% of liver transplant recipients. The liver is unique in this regard, since rejection is almost universal if immunosuppression is discontinued in recipients of renal, cardiac, pulmonary, and pancreatic grafts.

► Complications

Complications following liver transplantation are common, but most can be treated effectively. Coagulopathy is routinely present during liver transplant procedures, particularly during the anhepatic phase. For this reason, bleeding is common following the procedure, and 5%-10% of liver transplant recipients will require reoperation because of continued bleeding following the procedure.

One of the most devastating complications is primary nonfunction of the liver. Primary nonfunction is a condition in which the new liver does not function and death

results unless a second transplant is performed. Patients with primary nonfunction typically have profoundly elevated serum transaminases together with severe coagulopathy and acidosis. The incidence of this complication is between 5% and 10%. The cause of primary nonfunction is poorly understood, but multiple donor factors are known to be associated. Long cold ischemic times, poor perfusion of the graft with preservative solution, severe hepatic steatosis, and elevation of the donor serum sodium level above 165 mEq/L are all known risk factors for primary nonfunction.

Vascular complications occur in 5%-10% of transplant recipients. The hepatic artery is particularly prone to thrombosis, especially in children. If this is detected early, it is frequently possible to perform thrombectomy and restore hepatic arterial flow. If flow cannot be reestablished, necrosis of the intrahepatic and extrahepatic biliary tree usually occurs, resulting in death from sepsis if retransplantation is not performed.

The bile duct has been called the Achilles heel of the liver transplant because it is so prone to anastomotic leakage or stricture. Fortunately, while as many as 20% of liver transplant recipients will experience a bile duct complication, it is uncommon for this complication to be lethal. Leaks tend to occur early and can often be managed by placing a biliary stent using endoscopic retrograde cholangiopancreatography (ERCP). If a large collection of bile develops because of a bile leak, it is usually necessary to drain the area either operatively or by placing a percutaneous suction drain. Biliary stenosis can occur early or late. Unlike the native liver, the transplanted liver will not always develop intrahepatic biliary dilatation when the bile duct is obstructed. It is therefore necessary to have a high index of suspicion. Patients with elevated bilirubin or elevated serum alkaline phosphatase levels (or both) should be evaluated with either ERCP or magnetic resonance cholangiography. Strictures can often be managed noninvasively with biliary stents and balloon cholangioplasty, but in some cases, operative correction is required. Patients who develop multiple intrahepatic strictures usually require retransplantation.

Rejection is a frequent complication of liver transplantation—it occurs in about 20%-50% of patients. Rejection should be suspected whenever serum transaminases or bilirubin levels, or both, worsen or fail to gradually normalize following a liver transplant. The diagnosis of rejection is made histologically by the finding of a mixed portal cellular infiltrate together with injury to bile duct epithelium and inflammation of the central vein endothelium (endotheliitis). When the condition is diagnosed early and treated aggressively, rejection rarely culminates in a need for retransplantation. Because the principal rejection target is the bile duct epithelium, severe, unrelenting rejection is often manifested by destruction and disappearance of bile ducts (vanishing bile duct syndrome). The treatment for rejection depends on its severity. Mild rejection is treated either with corticosteroid pulse therapy or by increasing

the dosage of maintenance immunosuppressive therapy. Rejection that does not respond to these measures may require treatment with an antilymphocyte preparation.

CMV is a member of the herpes family of viruses. Prior to the availability of prophylaxis against this virus, as many as half of liver transplant recipients developed clinical CMV infection. Symptoms of this infection typically include fever, leukopenia, and malaise, but a more serious clinical syndrome with pneumonitis or hepatitis is possible. Patients at greatest risk for severe CMV disease are those without previous CMV exposure who receive a liver from a CMV-positive donor, but reactivation of CMV infection is possible in any patient with prior exposure to the virus. In order to prevent CMV infection, most liver transplant programs prescribe either ganciclovir or valganciclovir for a period of months following liver transplantation to all patients at risk for CMV infection.

EBV is another common viral pathogen in these patients. Although the systemic illness with Epstein-Barr virus infection is usually mild, it may be associated with development of a lymphoproliferative disorder known as posttransplant lymphoma. This disorder can progress to frank malignancy, and the mortality rate is high. In many cases, the lymphoproliferation resolves merely by reducing immunosuppression. If the lymphoproliferative tissue expresses CD20, treatment with the monoclonal antibody rituximab may be helpful. Patients with lymphoproliferation that does not respond to these measures may require chemotherapy.

Immunosuppression predisposes to fungal infections, especially esophageal *Candida albicans* (“thrush”). The incidence of this infection is reduced by the use of prophylactic nystatin to decrease gastrointestinal fungal colonization.

PANCREAS TRANSPLANTATION

Although pancreatic transplantation involves transplantation of a nonessential organ as compared with the liver, heart, or kidney, it has enormous potential in the management of patients with insulin-dependent diabetes. In many patients with type 1 diabetes—even though insulin and diet are carefully controlled—the complications of the disease progress relentlessly. Many patients develop severe retinopathy at an early age, leading to blindness and renal disease as well as

severe neuropathy and peripheral vascular disease that ultimately results in limb loss. The goal of pancreas transplantation is primarily to prevent or delay end-organ damage by the complications of diabetes. Another important indication for pancreas transplantation is hypoglycemic unawareness. Diabetic nephropathy can cause loss of the autonomic nervous pathways that allow patients to sense hypoglycemia. These patients can lapse into a coma at any moment. For patients with severe hypoglycemic unawareness, pancreas transplantation can truly be a lifesaving procedure.

Currently, most pancreas transplants are whole-organ grafts from deceased donors. The pancreas is procured along with a cuff of the first, second, and third portion of the duodenum attached. The graft can be placed into the pelvis with the iliac artery supplying arterial supply to the pancreas and the iliac vein used for portal venous drainage of the graft. Alternatively, the graft can be placed in the mid-abdomen and connected to the infrarenal aorta and the superior mesenteric vein. This allows insulin secreted by the pancreas to enter the portal circulation rather than the systemic circulation, which is more physiologic. The pancreatic exocrine secretions may be managed by anastomosing the duodenum to the bladder or to a loop of small bowel.

If the pancreas graft is successful, the patient will quickly become normoglycemic. As long as the graft functions normally, the patient will no longer require exogenous insulin because the pancreas graft responds normally by secreting insulin in response to rising blood glucose levels that occur following eating and ceasing insulin secretion when blood glucose levels fall to normal.

Much research has dealt with the transplantation of isolated pancreatic islet cells, which make up only about 2% of the pancreatic mass. This procedure is intuitively very attractive because it does not require an abdominal incision or general anesthesia. A team from Edmonton has reported successful transplantation of islets into the liver using a transhepatic injection into the portal vein. The patients in the original report all achieved insulin independence, although this often required more than one infusion of islets from more than one deceased donor pancreas. Immunosuppression consisted of rapamycin, tacrolimus, and induction treatment basiliximab, an inhibitor of IL-2R. The success at Edmonton has led to increased enthusiasm worldwide for islet transplantation, but to date, no other center has achieved the same degree of success. The critical factor appears to be the isolation procedure of the islets themselves. Nevertheless, it seems likely that in the long run, islet transplantation will eventually replace whole-organ pancreas transplantation.

MULTIPLE CHOICE QUESTIONS

- Which of the following cytokines is most often implicated in the delayed type hypersensitivity?
 - IL-10
 - IL-17
 - IFN- γ
 - IL-6
 - IL-13
- Lymphoma after transplant is most commonly of which cellular origin?
 - T-cell
 - B-cell
 - Delta Cell
 - Gamma Cell
 - Macrophage
- Life expectancy in patients who have undergone kidney transplantation is increased compared with chronic dialysis by a factor of
 - Two
 - One-half
 - Four
 - Three
 - Unchanged
- Chronic transplant dysfunction (CTD) is the leading cause of graft failure in the long term. Which of the following organs is affected by CTD?
 - Kidney
 - Heart
 - Liver
 - Lung
 - All of the above
- Which of the following conditions are not currently indications for liver transplantation?
 - Hepatocellular carcinoma
 - Hepatitis C infection with liver failure
 - Steatohepatitis with liver failure
 - Metastatic colon cancer
 - Alcoholic cirrhosis with liver failure

Appendix: Answers to Multiple Choice Questions

CHAPTER 2

- 1A. Beneficence and nonmaleficence are synonyms
- 2E. Both A and C are true
- 3C. Technical skills
- 4D. Are separate organizations that credential surgeons, and educate surgeons, respectively, as primary parts of their missions
- 5E. A, B, and C

CHAPTER 3

- 1A. Is an approach to categorizing patients preoperatively to assess their risk for an operative procedure
- 2D. Should include a pain assessment to aid in the management of postoperative pain
- 3C. Can be modified by risk-based interventions
- 4E. Both A and C are true
- 5C. Can have frailty measured by a variety of means that predict the risk of complications

CHAPTER 4

- 1E. Hypocalcemia
- 2D. Discharge the patient with a prescription for pain medication and a plan for follow-up in 2 weeks
- 3C. Cancel the operation with the plan for improved preoperative preparation
- 4E. All of the above except for D
- 5D. Evaluation of the patient, intubation for protection of airway, transfer to a higher level of care, transfusion with 2 units of FFP and 2 units of matched packed RBCs,

antibiotic administration, and computed tomography of the abdomen

CHAPTER 5

- 1A. They are common after chest procedures, but rare after abdominal operations.
- 2C. Her initial management can include intravenous hydration and nasogastric suction.
- 3C. High ileostomy output with inadequate postoperative replacement
- 4D. Bladder pressure measurement may be useful to determine the likelihood of abdominal compartment syndrome.
- 5A. Classified by the Centers for Disease Control into: (1) wound only, (2) organ space, and (3) involving organ parenchyma

CHAPTER 6

- 1B. Inflammation. An acute wound is defined by its ability to normally progress, in a predictable and timely manner, through all of the phases of wound healing; coagulation, inflammation, fibroplasia, angiogenesis, and remodeling. A protracted inflammatory phase is the usual mechanism for the formation of a chronic wound. All clinical efforts should be made to reduce chronic wound inflammation in an effort to support healing.
- 2C. Macrophage. The macrophage is the most important source of growth factor signals for wound healing. Experimental studies show that wound healing is most impaired in the absence of macrophages. Although fibroblasts are the main source of collagen synthesis and endothelial cells are required for revascularization, they are dependent on macrophage signaling to stimulate and direct tissue repair. A platelet is not a cell.

3E. TcO₂ less than 30 mm Hg. Wounds will not heal when the tissue concentration of oxygen falls below 30 mm Hg. It is the most powerful predictive measure of delayed or impaired wound healing. Vitamin C deficiency may result in impaired collagen cross linking (scurvy) and weak scars. Low serum albumin predicts increased wound complications, like wound infection. The microangiopathy of radiated tissue indirectly reduces perfusion and therefore, TcO₂ levels. Finally, smoking impairs wound healing through the vasoconstrictive effects of chronic nicotine and relative hypoxia as well.

4C. A moist wound environment. A moist or even wet wound environment is critical to normal wound healing. The cellular and molecular biological activity within a wound requires hydration to proceed. Clinical use of dry dressings to support wound debridement, for example, should be limited. Similarly, poor dressing resulting in repeated trauma and mechanical instability to the wound is often overlooked as a source for wound healing failure. Wound infection is the most clinically important, and expensive, impediment to surgical wound healing. Foreign bodies in the wound, such as synthetic surgical meshes, also delay normal wound healing. Finally, experimental and clinical data support that obesity contributes to abnormal wound healing, primarily through a metabolic pathway, and secondarily by increasing the risk of wound infection.

5D. Early fascial dehiscence and wound failure. Pollock and Evans showed in a classic clinical study that 94% of incisional hernias were the result of 1.2 cm fascial dehiscence before POD 30. The majority of the time, these were clinically occult wound closure failures, progressing to incisional hernias over the subsequent 3 years. It is no longer believed that many incisional hernias are the result of abnormal scar formation or suture breaking, stretching or even pulling through the fascia. Poor technique certainly will contribute to incisional hernia formation, but the fundamental mechanism is early fascial dehiscence.

CHAPTER 7

1B. In bipolar electrosurgery, the current flows from the handpiece to the return electrode.

2B. Depends upon the presence of an oxygen source, an ignition source and fuel

CHAPTER 8

1E. All of A, B, and C

2E. Both A and C are true

3C. Can be improved by the use of alcohol-containing skin preparation solutions

4E. Both A and C

5A. NSSSIs are generally self-limited and non-threatening

CHAPTER 9

1C. Anion gap metabolic acidosis with appropriate respiratory compensation. As above, values from an arterial blood gas are typically reported in this order: pH, pCO₂, pO₂, HCO₃⁻.

This patient's pH is normal, but near-acidotic. HCO₃⁻ and pCO₂ are both low. Decreased HCO₃⁻ will cause acidosis, while decreased pCO₂ will cause alkalosis, thus the patient's primary disorder is metabolic. His calculated anion gap is 22. pCO₂ is within the 36-40 mm Hg range of appropriate compensation predicted by Winter's formula, thus no concurrent respiratory disorder exists. Therefore, this patient has an anion gap metabolic acidosis with appropriate respiratory compensation. Respiratory compensation for metabolic disorders is rapid (note his hyperventilation), hence the normal pH.

If respiratory compensation were inappropriate, one would need to consider another, simultaneous process, in addition to alkalosis, eg, the respiratory acidosis which occurs in the later stages of salicylate poisoning, when central respiratory drive has been suppressed.

Note the patient's $\Delta\Delta = 2.5$. Considering this finding in isolation, one would conclude that the patient has a mixed anion-gap metabolic acidosis and metabolic alkalosis. This underscores the need to take into account all of the patient's data when making determinations of acid-base status. There is no additional evidence of a metabolic alkalosis, thus this additional disturbance is unlikely.

2A. Hypophosphatemia. Refeeding syndrome occurs when a malnourished patient (eg, an elderly or alcohol-dependent patient, or a patient who has experienced recent weight loss) begins to consume calories or begins to receive intravenous glucose administration. Insulin levels rise, causing electrolytes which have shifted to the extracellular space during a period of starvation to shift back to the intracellular space for use in the construction of new proteins and cells. Refeeding also leads to increased intracellular requirements for PO₄³⁻ and Mg²⁺ due to increased ATP production and glucose metabolism, decreasing serum levels of these electrolytes even further. This all leads to hypokalemia, hypomagnesemia, and hypophosphatemia, any one of which may be fatal. For these reasons, electrolytes must be closely monitored and aggressively repleted in patients at risk for refeeding syndrome.

3C. FENa < 1%. In oliguric patients, FENa < 1% is indicative of pre-renal azotemia and intravascular volume depletion. BUN:Cr ratio > 20 is indicative of hypovolemia. FENa > 1% is indicative of intrinsic renal causes of oliguria, and should prompt workup including microscopic urine analysis and renal ultrasonography. Post-renal obstruction should be investigated if clinically suspected (eg, caused by benign prostatic hypertrophy in this 70-year-old male).

FENa is unreliable in patients taking diuretics. In such cases, FEUN should be calculated:

$$\text{FEUN} = 100 \times \frac{(\text{UN}_U * \text{Cr}_P)}{(\text{Cr}_U * \text{BUN})}$$

where U: urine, P: plasma, UN: urea nitrogen, BUN: blood urea nitrogen, Cr: creatinine.

Table 9-5. Common laboratory values distinguishing between oliguric pre-renal and intrinsic renal failure.

Test	Pre-renal value	Intrinsic renal value	Post-renal value
FENa	< 1%	≥ 1%	
FEUN	< 35%	≥ 35%	
BUN:Cr ratio	> 20	< 10	10-20

4D. All of the above. Stored blood products are anticoagulated with trisodium citrate, which chelates Ca^{2+} from stored blood, disrupting the clotting cascade. In the setting of massive transfusion, such as this patient has undergone, normal hepatic metabolism of trisodium citrate may be overwhelmed, and Ca^{2+} (along with Mg^{2+}) may be chelated from the blood, leading to hypocoagulability, hypocalcemia, and hypomagnesemia. Furthermore, stored pRBCs contain high levels of K^+ , the result of lysis of red blood cells. This is especially true of the older pRBCs often utilized in massive transfusion situations. For these reasons, serum electrolytes must be closely monitored and controlled in the setting of massive transfusion.

5B. Mixed metabolic alkalosis and AG metabolic acidosis. The patient is acidotic, with a normal pCO_2 , low-normal HCO_3^- , and high anion gap. Therefore, this patient has an anion-gap metabolic acidosis. Given the clinical circumstances, the most likely etiology of her metabolic acidosis is lactic acidosis caused by septic shock.

Note that the patient's pH is significantly below the lower limit of normal, despite the normal pCO_2 and low-normal HCO_3^- . This should prompt concern for a mixed acid-base disorder. Her $\Delta\Delta = 2$, indicating a coexistent metabolic alkalosis. The several days of gastric suctioning provides a ready explanation for this component of her mixed acid-base disorder.

CHAPTER 10

1C. Bactericidal activity of enteral nutrition components. Multiple mechanisms have been proposed for the morphological and functional differences observed in the intestinal epithelium with parenteral nutrition (PN) when compared to enteral nutrition. It has repeatedly been demonstrated

that small bowel mucosal mass is lost with only PN. Yang and colleagues demonstrated that the administration of 25% enteral nutrition reversed the abnormal IL-10, IL-4, and IL-6 messenger RNA (mRNA) expression that had resulted from only PN support in animal models. This is of particular significance as these changes in cytokine expression were associated with epithelial leak and an increased rate of enterocyte apoptosis.

It has also been shown that the type and route of nutrition affect pIgR expression in an organ-specific manner; pIgR represents the exclusive transport pathway for IgA to move from the lamina propria, through the epithelia, into the lumen of the gut where it acts as a key component in the gut's defense. Enteral nutrition components are not bactericidal and actually help preserve normal flora.

2D. Burns. Energy requirements above basal needs are approximately 10% for elective operations, 10%-30% for trauma, 50%-80% for sepsis, and 100%-200% for burns. Burns covering more than 40% total body surface area (TBSA) are typically followed by a period of severe stress, characterized by an exaggerated catabolic state. Increases in catecholamine, glucocorticoid, glucagon, and dopamine secretion are thought to initiate the cascade of events leading to the acute hypermetabolic response with its ensuing catabolic state. Appropriate nutrient delivery can be accomplished by feeding 1.2-1.4 times the measured resting energy expenditures (REEs).

3C. The recommended amino acid dose ranges from 0.8 to 1 g/kg. The recommendation for the amino acid dose ranges from 1.2 to 1.5 g/kg/d for most patients with normal renal and hepatic function, although some sources recommend higher doses. TPN via a central line is indicated for patients who cannot obtain adequate nourishment via the gastrointestinal tract for a minimum duration of treatment of 7-10 days. The use of postoperative TPN for only 2 or 3 days is highly discouraged, as the risks outweigh the benefits incurred over this short period of time. A reasonable initial guideline is to provide 60%-70% of nonamino acid calories as dextrose and 30%-40% of nonamino acid calories as fat emulsion. The placement of central line catheters always carries risks; the overall complication rate related to this access is greater than 15%. Femoral vein access carries the highest risk of infection and should be avoided if possible.

4C. Gastric bypass patients are prone to deficiencies of the fat-soluble vitamins, calcium, iron, vitamin B12, and folate. Gastric bypass procedures intentionally limit the amount of oral intake and decrease the amount of small bowel that takes part in absorption. This renders the population of patients prone to deficiencies of the fat-soluble vitamins (A, D, E, and K), calcium, iron, vitamin B12, and folate.

Careful attention should be paid to ensuring that these deficiencies are countered with supplementation. Technical complications occur in about 5% of enterally fed patients and include clogging of the tube; esophageal, tracheal, bronchial, or duodenal perforation; and tracheobronchial intubation with tube feeding aspiration. Lactose intolerance is least common in European Caucasians, present within only 5%-10% of this population. Although recommendations differ depending on source, enteral feeds are not typically held until gastric residuals of greater than 200 cc are encountered.

5B. The NRI is an excellent tool for tracking the adequacy of nutritional support. The NRI is an index that has been prospectively crossvalidated against other nutritional indices with good results, but is not a good tool for tracking the adequacy of nutritional support, since supplemental nutrition often fails to improve serum albumin levels. The index successfully stratifies perioperative morbidity and mortality using serum albumin and weight loss as predictors of malnutrition.

CHAPTER 11

1D. Stop all over-the-counter herbal remedies. Although the use of herbal medications has been around for many years, none have been approved by the FDA. Many times the pharmacology of these remedies is unknown and the remedies may not contain the correct amounts of active ingredients stated on the label. It is estimated that up to 12% of patients are using these herbal drugs.

2B. The initial assessment should be done at a minimum the day before surgery for patients undergoing procedures of high surgical invasiveness. The timing of the preoperative evaluation by an anesthesiologist depends primarily on the planned degree of the surgery. Even healthy patients undergoing a surgical procedure that involves a high degree of surgical invasiveness that may include the risks of a high volume of blood loss, prolonged surgical time, special positioning requirements, etc, should be seen at least a day before the planned procedure. Patients with significant comorbidities should be seen in a PAC at least the day before surgery no matter the degree of surgical invasiveness as it is necessary to ascertain the degree of control of the comorbidities.

3D. Surgery should be delayed for up to 1 year. The risk of stent thrombosis makes it necessary to place patients who have had a drug-eluting stent placed on antiplatelet agents such as clopidogrel and aspirin. Stopping these drugs prematurely to allow for the performance of an elective surgical procedure requires careful consideration of the risk of bleeding as well as the risk of stent thrombosis if the antiplatelet agents are both stopped. At a minimum aspirin should be continued. Emergent procedures that involve a high risk of

bleeding require that the clopidogrel be stopped, but continuing the low-dose aspirin is recommended.

4D. None of the above. There is no way to be 100% of preventing intraoperative awareness. Anesthesiologists performing strict equipment check before beginning an anesthetic to ensure that vaporizers have sufficient agent levels, that there is an agent concentration monitor as part of the anesthesia monitoring system, and frequent observation that IV lines are patent and intact when intravenous medications are used is one way to eliminate the preventable components. Stable vital signs throughout a case are not always a reliable sign that a patient may not suffer from intraoperative awareness. Finally the processed EEG BIS monitor has been shown to be no more effective in preventing awareness than careful monitoring of end-tidal agent concentration.

5C. Obesity. The RCRI factors of (1) ischemic heart disease, (2) heart failure, (3) high-risk surgery, (4) diabetes mellitus, (5) renal insufficiency, and (6) cerebral vascular diseases are a validated set of independent predictors of cardiac risk for patients. There RCRI factors were derived from a single-center prospective group of patients undergoing elective major noncardiac surgery. The anesthesiologist in a pre-op clinic will screen for these factors and recommend further studies based on the presence or absence of RCRI factors. Patients with no RCRI factors had a very low (0.4%) cardiac risk while patients with three or more risk factors have a 5.4% risk of an adverse cardiac event and warrant further testing or optimization of the factor(s).

CHAPTER 12

1E. All of A, B, and C

2B. Can contribute to coagulopathy

3E. All of A, B, and C

4A. Can be related to products of coagulation and inflammation that are washed out from the damaged tissues

5B. PSV includes a set inspiratory time

CHAPTER 13

1C. Should have an initial assessment including airway, breathing and circulation

2D. Should bypass the trauma room and go directly to the operating room

3E. A, B, and C are all correct

4E. From gunshot wounds below the nipple line typically require laparotomy for evaluation and management

5E. All are correct

CHAPTER 14

- 1C. Death of others in same incident
- 2A. Can contribute to coagulopathy
- 3D. Primary management with bismuth-containing antimicrobial topical agents
- 4A. Benefits from early consideration with functional position splinting and active motion
- 5B. Inhalational injury

CHAPTER 15

1B. Take her to the operating room immediately for an emergent biopsy. Invasive fungal sinusitis is usually seen in immunocompromised patients, such as the patient described here. It is caused by uncontrolled infiltrative growth of usually nonpathogenic fungal organisms such as *Rhizopus* or *Aspergillus* species. Even with prompt diagnosis, aggressive surgical therapy, and modern antifungal agents, the disease still carries a significant mortality rate (up to 30%). The index of suspicion for invasive fungal sinusitis must be high for any immunocompromised patient, as the symptoms can be subtle and the disease rapidly progressive. If invasive fungal sinusitis is suspected, biopsies should be taken of the suspicious areas and sent for immediate pathologic examination. Note that this can often involve calling a pathologist in from home in the middle of the night or on a weekend, if they are not in-house. In the case presented here, the likelihood of the child cooperating with an examination and biopsy is low, thus an emergent posting to the operating room is the most prudent action.

2E. All of the above. Acute angioedema is characterized by localized swelling of subcutaneous and submucosal tissue of the head and neck. The swelling usually begins with mild facial involvement but may progress to involve the oral cavity, tongue, pharynx, and larynx. The underlying pathophysiology of angioedema involves vasoactive mediators such as bradykinin and histamine, causing interstitial edema through endothelial-mediated vasodilation of arterioles with subsequent capillary and venule leakage. Drug-induced angioedema has classically been associated with the use of angiotensin-converting enzyme inhibitors (ACE inhibitors), although many other medications can also cause this phenomenon. Other drugs known to be associated with angioedema include rituximab, alteplase, fluoxetine, laronidase, lepirudin, angiotensin II receptor blockers (ARBs), and tacrolimus.

3A. Immediately superior to the cricoid cartilage. The patient described has Ludwig's Angina, an uncommon life-threatening condition characterized by cellulitis involving the submental, sublingual, and submandibular spaces. The source of the infection is odontogenic and spreads rapidly. The infection is usually polymicrobial with aerobic and anaerobic gram-positive cocci and gram-negative

rods. Airway compromise in these patients is common, and should be of primary concern. A cricothyroidotomy is performed through the cricothyroid membrane which spans the midline area between the cricoid cartilage inferiorly and the thyroid cartilage superiorly. It can be easily palpated just inferior to the thyroid cartilage in greater than 90% of individuals, and has no major blood vessels or structures. While an emergency tracheotomy can be performed through the second or third intertracheal ring space, this often involves either going through or dissecting part of the thyroid gland off the tracheal wall. As the thyroid's blood supply is quite robust, the bleeding encountered can be quite significant. Therefore, in an emergency situation the cricothyroid space is almost universally preferred.

4C. Left posterior cricoarytenoid muscle. Innervation to the larynx is provided by the vagus nerve (cranial nerve X). The recurrent laryngeal nerves branch from the vagus nerve and provide motor innervation to all of the intrinsic muscles of the larynx except the cricothyroid muscle. All of the intrinsic muscles of the larynx serve to tense the vocal folds or adduct the vocal folds except one—the paired posterior cricoarytenoid muscles. Current understanding of peripheral nerve injury and regeneration presents the following scenario when the nerve supply to the larynx is injured. After nerve injury, neuronal axon regrowth results in reinnervation of the target muscles but in a random pattern. Since only one of the muscles abducts the vocal folds, reinnervation is unlikely to result in a tonically abducted vocal fold. Instead, the vocal fold usually assumes a paramedian position, accompanied by loss of muscle bulk and atrophy due to loss of innervation. This can lead to hoarseness and vocal fatigue when one side is injured, but often causes airway obstruction if both sides are injured.

5D. 25-year old man with 12 pack-year tobacco history and chronic severe gastroesophageal reflux. Presents with throat pain and dysphagia (trouble swallowing). On fiberoptic endoscopy is found to have a 3 cm ulcerated hypopharyngeal mass. No palpable neck adenopathy is present. Assuming appropriate treatment, outcomes for patients with oral cavity cancer are generally good with 5-year survival rates of 72% for stage I-II, 44% for stage III-IVb, and 35% for stage IVc. Outcomes for patients with laryngeal cancer can be excellent. For early stage I glottis carcinoma (tumor limited to the true vocal folds), 5-year overall survival rates of 90% can be expected. Overall, laryngeal cancer carries a 5-year survival for stage I-II disease of 79%. Survival for oropharyngeal cancer is somewhat worse: stage I-II oropharyngeal cancer 5-year survival average is 58% and stage III-IVb 41%. The hypopharynx is invested with an abundant lymphatic drainage network, and patients with hypopharyngeal cancer typically present with advanced stage disease. Hypopharyngeal cancer carries the worst prognosis of any head and neck subsite. Five-year survival for stage I-II hypopharyngeal cancer is 47%, stage III-IVb is 30%, and stage IVc only 16%.

CHAPTER 16

- 1D. TSH
- 2D. Both A and C
- 3B. Is less likely to spread to lymph nodes than is papillary thyroid cancer
- 4A. Vitamin A toxicity
- 5D. Osteoporosis with a T-score of -2.8

CHAPTER 17

- 1C. Caused at least in part by estrogen stimulation of breast tissue
- 2D. A personal history of breast cancer
- 3B. Identifies cancer without node involvement in about 80% of detected cases
- 4A. A painless mass identified by the patient
- 5D. Can be reliably detected by sentinel lymph node biopsy in women with clinically uninvolved axillary lymph nodes

CHAPTER 18

- 1C. Mostly arise from bone or cartilage
- 2D. Iodine deficiency
- 3B. Ureteral obstruction with transdiaphragmatic urine leak
- 4A. Spontaneous bacterial mediastinitis of sarcoidosis
- 5D. Effectively cured by double lung transplantation with a 10-year graft survival exceeding 85%

CHAPTER 19A

- 1C. Atherosclerosis tends to occur diffusely in small coronary vessels. Myocardial tissue extracts 70%-80% of arterial blood oxygen at rest, unlike other organs which can extract additional oxygen during periods of increased demand. The myocardium recruits additional blood flow by vasodilation and recruitment of an extensive capillary bed via a feedback mechanism from adenosine diphosphate and other byproducts of metabolism, increasing oxygen delivery to match consumption. Atherosclerosis, or the formation of intra-arterial cholesterol plaques, tends to occur in the more proximal and larger epicardial vessels, leaving the distal vasculature relatively unobstructed. This allows revascularization by either percutaneous or surgical techniques.
- 2D. Typical symptoms are exertional dyspnea, angina or syncope. Senile calcific aortic stenosis occurs in the eighth decade of life in patients with tricuspid (normal) aortic valves. While dilation of the ascending aorta is a normal part of the aging process, aneurysms of the ascending aorta are associated with bicuspid aortic valves, related to abnormalities in elastin fiber formation. Rheumatic heart disease

affects the mitral valve most commonly. It is unusual for a patient with rheumatic heart disease to present with isolated aortic stenosis but not mitral valve disease, whereas the opposite is fairly common. Indications for surgery in aortic stenosis are the presence of symptoms, which are exercise intolerance, angina, syncope, and dyspnea.

3C. Asymptomatic with a prolapsed anterior mitral leaflet. Indications for surgery in patients with mitral regurgitation include heart failure symptoms, left ventricular dilation and reduced left ventricular systolic function. In asymptomatic patients without symptoms and normal ventricular function and size, surgery could be recommended if the likelihood of durable repair is high. Repair of posterior leaflet prolapse is much more common than in prolapse of the anterior leaflet. Mitral replacement would entail either a bioprosthetic with limited durability, or a mechanical valve and a lifelong requirement for anticoagulation. Moderate mitral regurgitation is typically addressed incidentally at the time of other cardiac surgery, including coronary bypass grafting or aortic valve replacement.

4D. Malperfusion of the abdominal viscera can occur with either Stanford type A or type B aortic dissections. Due to gradual and progressive breakdown of elastin fibers, the ascending aorta dilates as part of the natural aging process. Indications for replacement of the ascending aorta include size of 5-5.5 cm in asymptomatic patients, 4.5 cm in patients with known Marfan syndrome, interval growth of 1 cm in 1 year, or 4.5 cm when incidental to other cardiac surgery including aortic valve replacement or coronary bypass grafting. Stanford type A dissections involve the ascending aorta, which can cause sudden death from intrapericardial rupture and tamponade, aortic valve insufficiency from prolapse, or coronary malperfusion and myocardial infarction. Stanford type B dissections are distal to the ascending aorta and thus not within the pericardial space and not directly adjacent to the aortic valve or coronary ostia. Malperfusion from an aortic dissection occurs when the intimal flap occludes any branch of the aorta causing ischemia. Both Stanford type A and B can cause malperfusion of the abdominal viscera, depending on the extent and geometry of the dissection.

5A. Beta-blockers improve survival in patients with advanced heart failure from a variety of proposed mechanisms, including up-regulation of beta-receptors in the myocardium. Heart failure incidence is increasing related to aging population and the rising incidence of diabetes as well as obesity. Deaths from coronary artery disease and myocardial infarctions are decreasing from improved medical care. Temporary mechanical circulatory support increases a heart transplant candidate to status 1A, while implantable mechanical circulatory support results in status 1B. Patients with chronic heart failure on oral medical treatment are status 2. Following heart transplantation, right ventricular dysfunction is the most frequent complication, as the donor's

untrained right ventricle is required to maintain circulation in a recipient with pulmonary hypertension, which is often present from long standing heart failure.

CHAPTER 19B

1B. Left-to-right shunting through a VSD causes a volume load on the right ventricle. Ventricular septal defects are classified by their location in the ventricular septum. The most common type is perimembranous. Left-to-right shunting through a VSD causes a volume load on the left ventricle as blood returns from the lungs. The right ventricle does not experience a volume load, but is pressure loaded. Certainly, as PVR decreases after birth, congestive heart failure may develop in a previously asymptomatic patient with a large VSD as left-to-right shunting increases. Knowledge of the expected location of the conduction system is paramount in the surgical repair of a VSD. The AV node is an atrial structure that lies at the apex of an anatomic triangle (known as the triangle of Koch) formed by the coronary sinus, the tendon of Todaro, and the septal attachment of the tricuspid valve. The node then gives rise to the bundle of His, which penetrates the AV junction beneath the membranous septum. The bundle of His then bifurcates into right and left bundle branches, which pass along either side of the muscular ventricular septum. In the presence of a perimembranous VSD, the bundle of His passes along the posterior and inferior rim of the defect, generally on the left ventricular side. The bundle of His tends to run along the posterior and inferior margin of inlet VSDs as well. The conduction tissue is usually remote from outlet and trabecular VSDs.

2A. Neonate with prenatal diagnosis of aortic coarctation who develops acidosis, oliguria, and diminished pedal pulses 8 hours after birth. In scenario A, the neonate described has inadequate systemic perfusion as demonstrated by oliguria and acidosis. With a prenatal diagnosis of aortic coarctation, one must be suspicious at 8 hours after birth that ductal closure has caused a critical narrowing of the aortic isthmus as it involutes. This patient will benefit by reopening the ductus arteriosus with PGE1. The patient described in option B is likely experiencing pulmonary overcirculation with congestive heart failure. Initiating PGE1 would be expected to exacerbate this problem. In option C, a 6-week-old child's ductus would not be expected to reopen with prostaglandins. Also, the etiology of the heart failure symptoms described is due to myocardial ischemia and surgical correction of the coronary anomaly is required. PGE is not appropriate. In option D, the vascular ring described is likely causing a mechanical airway obstruction. Again, surgical intervention is required. PGE therapy has no role in this situation.

3C. Balloon atrial septostomy. d-transposition of the great arteries typically requires two or more levels of mixing in order to maintain adequate saturations. This may involve mixing at the atrial level (via an ASD), ventricular level

(via a VSD), or at the level of the great arteries (via a PDA). In the situation described, the infant requires an additional level of mixing. This may be due to the absence of additional (intracardiac) shunts, or they may be too small if present. Emergent balloon atrial septostomy in the catheterization laboratory is indicated. The other options are not appropriate at this time.

4C. Coronary AV fistula. Coronary AV fistula is the most common major coronary anomaly. The second most common is ALCAPA.

5B. Isolated pulmonary stenosis in a neonate. Isolated aortic coarctation in a neonate is well managed with a primary extended end-to-end anastomosis and is almost always primarily approached surgically. Isolated pulmonary stenosis is typically primarily treated with balloon pulmonary valvuloplasty. This approach has been highly successful. The patient in option C is best managed with a trial of Indocin, followed by bedside surgical ligation if the ductus fails to close with medical management. Larger patients with PDAs requiring closure are frequently treated with catheter-based closure with excellent results. Perimembranous VSDs are best closed surgically. Device closure of VSDs in this location is associated with prohibitively high rates of complete heart block along with the risk of impairing the function of the aortic and/or tricuspid valve.

CHAPTER 20

1A. Absence of esophageal peristalsis. Esophageal manometry is the gold standard for establishing the diagnosis of esophageal achalasia. The classic manometric findings are: (1) absence of esophageal peristalsis and (2) hypertensive LES (in about 50% of patients) that relaxes only partially in response to swallowing. Dysphagia for both solid and liquid food is the most common symptom, experienced by virtually every patient. Heartburn is present in about 40% of patients. As the low intraluminal pH, it is not due to GER, but rather to stasis and fermentation of undigested food in the distal esophagus.

2D. The surgical treatment consists of LES myotomy, resection of the diverticulum or its suspension. Although rare, Zenker diverticulum is more common than the epiphrenic diverticulum. It is a protrusion of pharyngeal mucosa through a weak zone in the Killian's triangle, secondary to abnormalities of the UES sphincter. Dysphagia occurs very frequently. As the pouch enlarges, its contents can be inhaled into the respiratory tree causing chronic cough and pneumonia. Finally, the established treatment consists of eliminating the functional obstruction performing a UES myotomy, associated with resection or suspension of the diverticulum.

3A. Esophageal manometry, 24-hour pH monitoring and upper endoscopy. Heartburn, along with regurgitation and dysphagia is considered a typical symptom of gastroesophageal reflux (GERD). However, a clinical diagnosis of GERD based on these symptoms is correct in only 70%

of patients (when compared with the results of pH monitoring). Heartburn can also be caused by nonesophageal disorders such as biliary disease, irritable bowel syndrome, coronary artery disease, and psychiatric diseases. Esophageal manometry is mandatory to evaluate the function of both the esophageal body and LES. In addition, manometry is essential for proper placement of the pH probe for ambulatory pH monitoring. Twenty-four-hour pH monitoring measures reflux of acid from the stomach into the esophagus and correlate it to the symptoms. Upper endoscopy visualizes the mucosal surface of the esophagus, determines the presence and degree of esophagitis and allows biopsies.

4B. Is linked to duodeno-gastro-esophageal reflux. Barrett esophagus is defined as a change in the esophageal mucosa with replacement of the squamous epithelium by columnar epithelium. It is classified into short segment if less than 3 cm in length or long segment if 3 cm or longer. Barrett esophagus represents an adaptation of the esophageal mucosa to the acid and duodenal juice from the stomach. The diagnosis is confirmed by pathologic examination of the esophageal mucosa and requires the identification of goblet cells, typical for intestinal epithelium. Patients with BE have typically a long history of GERD. Nevertheless, they may become asymptomatic over time due to the decreased sensitivity of the metaplastic epithelium.

5D. All of the above. In patients with early esophageal cancer (pT1a), an esophagectomy can be avoided, because of the very low risk of lymph nodes metastasis (0%-3%), and EMR and RFA are very effective. Unlike intramucosal cancer (T1a), T1b cancer has a high risk of lymph node metastases (20%-30% vs. 0%-3%), and therefore esophageal resection is the treatment of choice. In case of locally advanced esophageal cancer (T3-4N0-3, T2N1-3), chemo-radiation is the best treatment, followed by surgery. It seems that the combination of neo-adjuvant therapy followed by surgery offers the best survival benefit. This is particularly true in the subgroup of patients (about 20%) who have a "complete pathologic response" (no tumor found in the specimen). In patients with distant metastases, survival is very poor and treatment modalities focus on the palliation of symptoms. Endoscopic stenting is one of the most successful options in the treatment of dysphagia.

CHAPTER 21

1C. Appendicitis. Both the patient's age and gender play an important role in forming the differential diagnosis. As patients age there is a distinct shift in causes of abdominal pain and an increase in surgically treatable etiologies. This has been best documented in the OMGE's (World Organization of Gastroenterology) survey of worldwide causes of abdominal pain. This survey gathered data on more than 10,000 patients in 17 countries presenting with acute abdominal pain. When the data is segregated by age

comparing those less than 50 years of age to those older than 50 years of age there are clear differences. Appendicitis is by far the most common etiology of a surgical abdomen in patients younger than 50. In the older population group cholecystitis is the most common cause with good representation from bowel obstruction, appendicitis, pancreatitis and diverticulitis. In older patients hernias are a more common problem, with up to a third of bowel obstructions being related to hernias. Cancer, vascular disease, and mesenteric ischemia are also more common as we age. While it is more common for a patient in their twenties to present with abdominal pain, a large proportion will have the diagnosis of nonspecific abdominal pain. Patients older than 50 years of age have both a higher likelihood of an operative etiology for their acute abdomen as well as an increased mortality related to their presentation. This mortality is higher still for patients older than 70 years of age.

2B. They are most useful when intestinal obstruction is part of the differential diagnosis. Before the advent of the CT scan the acute abdominal series played an important role in the diagnosis of the acute abdomen as diagnostic tools were limited. There are long lists of radiologic findings that may correlate with a wide variety of intra-abdominal pathology. A small percentage of renal and biliary stones may be seen on plain radiograph. In our current practice environment there is a much more limited role for plain films of the abdomen. They can be helpful in locating foreign bodies within the GI tract and they may assist in the diagnosis and evaluation of bowel obstructions. Ultrasound is a more sensitive test for biliary stones. CT scans have increased sensitivity and specificity in almost all causes of intra-abdominal pathology when compared with abdominal plain films. For this reason, in stable patients who are going to undergo CT scan there is little added value in obtaining plain films. Upright chest radiograph is the most sensitive test for intra-abdominal free air from a perforated viscus. It should be obtained as part of the evaluation of the acute abdomen both for identifying free air as well as ruling out a variety of cardiac and pulmonary pathologies.

3E. ABG and Lactate. Given the severity of the patient's pain and its abrupt presentation it would not be prudent to solely admit this patient without further evaluation. This patient presents with severe acute abdominal pain and a relatively benign abdominal examination, concerning for mesenteric ischemia. Etiologies include arterial or venous occlusion as well as nonocclusive low-flow states such as in critically ill with hypotension. This patient has an irregular heart rate from atrial fibrillation, which puts the patient at risk for an arterial embolic event. The classic presentation of mesenteric ischemia is severe pain out of proportion to physical examination findings. Helpful laboratory data include an arterial blood gas with lactate. An elevated lactate suggests tissue hypoxemia. Ischemic bowel as a result of

diminished blood flow will convert to anaerobic metabolism on a cellular level producing lactate. Although not specific to mesenteric ischemia, it can be a helpful laboratory value to predict severity of illness when elevated. A normal lactate does not exclude mesenteric ischemia. If clinically suspected, workup should proceed despite a normal lactate. Radiographic imaging of choice is CT angiography to assess mesenteric vessels. These patients should be kept strict NPO and if mesenteric ischemia is diagnosed, patient should proceed emergently to the operating room for exploratory laparotomy to minimize further bowel ischemia. Amylase is helpful in ruling out other diagnostic possibilities such as pancreatitis. As mentioned earlier plain abdominal films are rarely indicated in evaluation of the acute abdomen.

4C. MRI abdomen/pelvis. Pregnancy presents a diagnostic dilemma when encountering abdominal pain. Ultrasound is the first line imaging modality in pregnant women as it is noninvasive and does not involve radiation; however, ultrasound often will be equivocal or indeterminate in diagnosing appendicitis. If ultrasound is nondiagnostic, MRI is preferred to CT scan for the evaluation of acute appendicitis in pregnancy. MRI avoids ionizing radiation, making it a safer imaging modality for the fetus. Both laparotomy and laparoscopy are considered safe in pregnancy. Early operative intervention in appendicitis during any trimester is warranted as ruptured appendicitis is associated with higher rates of fetal mortality, maternal mortality, and preterm delivery. Given the operative risks of the procedure (fetal loss, early labor) and the risks of delayed diagnosis (ruptured appendicitis, fetal loss) when possible confirmation of diagnosis is preferred before proceeding to the OR and patients are rarely simply observed.

5D. A 65-year-old man with 1 day of mild abdominal pain and reports of bright red blood per rectum. Normotensive, but hematocrit on admission 24% (baseline Hct 42%). There are several pathways in the management of patients with an acute abdomen. There is a subset of patients who require immediate operative intervention including ruptured abdominal aortic or visceral aneurysms, splenic or hepatic adenoma rupture, ruptured ectopic pregnancy, and major abdominal trauma. These patients may be recognized by their hemodynamic instability. Another cohort of patients will present with urgent operative indications. In this group there is often enough time for diagnostic testing to confirm the diagnosis, but once confirmed the patient should proceed expeditiously to the operating room. Conditions requiring urgent intervention include perforated hollow viscus, acute appendicitis, diverticulitis (perforated), mesenteric ischemia, and strangulated hernias. A third group of patients include those who will need operative intervention on the same admission (12-48 hours) but not urgently. Early intervention would be for patients with uncomplicated cholecystitis, or incarcerated hernias. Several diagnoses should be observed on surgical services but may not require operative

intervention. This group includes patients with uncomplicated bowel obstructions, uncomplicated diverticulitis, and symptomatic cholelithiasis. These patients may require operative intervention if they fail to improve with nonoperative management. Lastly diseases such as pancreatitis, inflammatory bowel disease, peptic ulcer disease, endometriosis, and gastritis may cause significant abdominal pain but usually respond to nonoperative therapies and usually do not require operative intervention. The lower GI bleeding is preferentially treated with colonoscopy and resuscitation. It rarely requires urgent operative intervention and only in those patients with hemodynamic instability who have failed conservative management. When the cause of abdominal pain is uncertain despite diagnostic testing a judgment must be made as to whether the patient merits inpatient monitoring or can be further evaluated as an outpatient.

CHAPTER 22

- 1D. Is divided anatomically into parietal and visceral components
- 2D. Is most frequently associated with cirrhosis and ascites
- 3B. That often originates from gastrointestinal sources

CHAPTER 23

- 1D. May include a posterior gastric artery that is typically a branch of the splenic artery
- 2D. It is the site of the assembly of micelles for nutrient absorption
- 3B. Cannot be done by Billroth I reconstruction after total gastrectomy
- 4A. Can impair the appropriate relaxation of the pylorus
- 5C. Initially includes gastric decompression and acid suppression

CHAPTER 24

- 1D. A replaced right hepatic artery typically arises from the inferior mesenteric artery and courses posteriorly and to the right of the common bile duct within the porta hepatis
- 2D. Serum sodium
- 3B. With a laceration 4-cm deep but not affecting the major vasculature is a Grade III lesion
- 4A. In the United States, is most often caused by cirrhosis
- 5C. Should include controlling hemorrhage as expeditiously and simply as possible

CHAPTER 25

- 1D. Oral cholecystography
- 2D. Intestine

- 3B. Are nearly always present in people with chronic cholecystitis
- 4A. Diverticulitis
- 5C. Should usually include draining the biliary tree

CHAPTER 26

- 1D. The uncinate process lies anterior to the superior mesenteric artery
- 2D. Parotid gland
- 3B. Can be complicated by pancreatic abscess
- 4A. Is unresectable at the time of diagnosis in most people
- 5C. Should usually include resection of the primary tumor

CHAPTER 27

- 1D. The gastrosplenic ligament carries the short gastric vessels.
- 2D. Both A and C
- 3B. Is at greatest risk in young children

CHAPTER 28

- 1D. The appendix is fixed retroceally in 65% of adults
- 2D. A, B and C
- 3B. Are most commonly neuroendocrine (carcinoid) tumors

CHAPTER 29

- 1A. Intra-abdominal adhesions. Sixty percent to 75% of cases of mechanical SBO are secondary to adhesions, related to prior abdominal surgery. Lower abdominal and pelvic surgery appears to be associated with a higher incidence of adhesions than the upper abdominal surgery. Congenital bands are rarely seen in children.
- 2D. All of the above. A nasogastric tube should be inserted early in order to relieve symptoms, avoid aspiration, and monitor the fluid and electrolyte losses. Depending on the level and duration of obstruction, fluid and electrolyte deficit vary. The exact volume of fluid and electrolytes must be calculated individually for each patient. In some cases, in which there is preoperative evidence of free space in the abdomen for the trocar placement, laparoscopy finds a good indication. Laparoscopic adhesiolysis reduces the risk of further adhesions thanks to the reduced peritoneal trauma.
- 3C. Deep venous thrombosis can be a cause. Acute mesenteric ischemia is characterized by severe and diffuse abdominal pain that is often unresponsive to narcotics. Mesenteric arterial embolism accounts for about 50% of cases. The main cause is atrial fibrillation. Venous thrombosis can be a consequence of venous stasis (as in portal hypertension) or hypercoagulability (congenital disorders, oral contraceptives).

Deep venous thrombosis may cause pulmonary embolism but not mesenteric thrombosis.

4D. Carcinoid syndrome develops in the presence of liver metastases. *Adenomas* are the most common benign tumors of the small intestine. The duodenum is the most common site of involvement, and the lesion most commonly noted is the villous adenoma. These lesions tend to involve the region of the ampulla of Vater. Malignant tumors tend to increase in frequency from proximal to distal, with the exception of adenocarcinomas which are most frequent in the duodenum. Adenocarcinoma is the most common histologic type (45%), followed by carcinoids (30%), lymphomas (15%), sarcomas, and GISTs (10%). Peutz–Jeghers syndrome is characterized by diffuse gastrointestinal hamartomas and mucocutaneous pigmentation. The malignant potential of this polyposis is very small.

Carcinoid tumors produce symptoms secondary to hormone production, including hot flashes, bronchospasms and arrhythmias. This constellation of symptoms, called carcinoid syndrome, occurs when the liver is not able to metabolize the active substances produced by the carcinoid tumor.

5A. Ileosigmoid fistula is a common complication of perforating CD of the terminal ileum. Typically, the inflamed terminal ileum adheres to the sigmoid colon that is otherwise healthy. Ileovesical fistulae occur in approximately 5% of CD patients. Although hematuria and fecaluria are virtually diagnostic of ileovesical fistula, these symptoms are absent in almost 30% of cases. Enterovaginal and ECF are rare fistulas caused by perforating small bowel disease draining through the vaginal stump in a female who has previously undergone a hysterectomy or through the abdominal wall, usually at the site of a previous scar.

CHAPTER 30

- 1D. Inferior hypogastric plexus near Denonvillier fascia
- 2C. Bowel rest, intravenous fluids, broad spectrum antibiotics, and percutaneous drainage
- 3D. Exploratory laparotomy
- 4D. Right hemicolectomy
- 5C. Dehydration

CHAPTER 31

- 1D. Infravator
- 2D. Anal fissure
- 3B. Is an intussusception of the rectum
- 4A. Are typically treated with a regimen of chemotherapy and radiation therapy after diagnosis
- 5C. Can include palliation of macroscopic lesions my operation

CHAPTER 32

1D. A tension free repair. A tension free repair is the key factor in successful repair of all groin hernias. Although a tension-free repair can be accomplished by using a relaxing incision in the traditional tissue repairs, the use of mesh for either an open or laparoscopic repair obviates the need for a relaxing incision. Although decreasing the size of the internal ring will help prevent recurrence of an indirect inguinal hernia, it is not sufficient to prevent a recurrence through the transversalis fascia if a strong, tension-free repair is not accomplished.

2E. The use of the inguinal ligament in the repair. Keys to successful repair of a femoral hernia include the knowledge that the femoral canal lies beneath the inguinal ligament. For this reason, the repair must be performed to Cooper's ligament or the iliopubic tract, which lie deep to the inguinal ligament. The repair must result in obliteration of the hernial defect, whose medial border is the stiff lacunar ligament, superior border is the inguinal ligament, and lateral border is the femoral vein; these structures do not lend themselves to primary repair with sutures. After the contents of the hernia sac are reduced and the sac excised, either mesh or tissue is used to cover the defect in a tension-free manner. If a tissue repair is used, a vertical relaxing incision in the anterior rectus sheath is necessary to prevent tension on the repair. If a laparoscopic or open mesh repair is elected, the defect in the transversalis fascia must be covered completely.

3A. Equivalent recurrence rate of open and laparoscopic hernia repairs with mesh in the hands of experienced surgeons. Although early trials of open and laparoscopic mesh hernia repairs showed higher recurrence with laparoscopic repairs, more recent randomized trials involving surgeons with greater laparoscopic experience show equivalent recurrence rates for mesh repair performed open or laparoscopically. Perioperative complications are higher with extraperitoneal laparoscopic procedures than other repairs, as are recurrence rates, compared to laparoscopic transabdominal or open techniques. Laparoscopic repairs are generally associated with less pain and numbness long-term than open repairs.

4C. Develop a wound infection. Several comorbidities have been demonstrated to increase the risk of incisional hernia formation after an abdominal operation: poor surgical technique, advanced age, obesity, pulmonary disease, smoking, diabetes, previous radiation, blood loss greater than 1000 mL, poor nutrition, steroid use, and immunocompromise. The greatest risk of incisional hernia, as high as 80%, is found in patients who develop a wound infection.

5E. Underlay of biologic mesh with primary tissue brought to midline. For all but the very smallest (< 2 cm) hernias, primary repair carries an unacceptable recurrence rate. Similar poor results are seen with inlay mesh repair, whether synthetic or biologic mesh is used. Synthetic mesh has high infection risk when bowel must be resected and should not be

used under these circumstances. The best results in a contaminated field are seen with an underlay of biologic mesh with the patient's primary tissue brought together in the midline.

CHAPTER 33

1A. Laparoscopy. Laparoscopic adrenalectomy is safe for small adrenal tumors. Large incisions are not necessary for most adrenal tumors and are associated with more morbidity.

2A. Plasma-free metanephrines. Plasma-free metanephrines or 24-hour urinary fractionated metanephrines are the most sensitive and specific test for diagnosis of pheochromocytoma/paraganglioma.

3C. Fine-needle biopsy of the adrenal tumor. Fine-needle biopsy of an adrenal tumor is almost never necessary, is associated with significant false positive and false negative results, can be dangerous (for pheochromocytoma) and risks seeding of tumor (adrenocortical cancer).

4B. A feminizing tumor. Feminizing adrenal tumors are rare, large, and almost always adrenal cortical cancer. Laparoscopic resection would be both difficult and risk local recurrence and seeding of the cancer. In contrast, metastatic cancer to the adrenal gland can usually be resected safely by laparoscopy.

5E. 5-HIAA. Adrenal tumors do not secrete 5-HIAA as do some carcinoid tumors.

CHAPTER 34

1D. Typically occurs with at least a 50% reduction in arterial diameter, which correlates with a 75% narrowing of cross-sectional area

2D. Pain occurs at rest

3B. Can be caused by a major arterial dissection

4A. Cannot be performed when the carotid artery is completely occluded

5C. Is defined as a localized dilation of an artery to at least 1.5 times its normal diameter

CHAPTER 35

1C. Thermal ablation is an effective approach to the treatment of saphenous veins. The 2011 consensus opinion recommends thermal ablation to surgical or chemical ablation for GSVs. Selective treatment of incompetent perforating veins is not recommended in patients with simple varicose veins, though is an option for pathologic perforating veins. Vein absorption occurs over the course of months.

2D. Three months' anticoagulation is similarly recommended in patients with (i) PE/proximal DVT of the leg provoked by a nonsurgical transient risk factor, (ii) in patients with PE/an isolated distal DVT of the leg provoked

by surgery or by a nonsurgical transient risk factor. This is recommended over a longer or shorter duration of anticoagulation. Not all patients with DVT require anticoagulation for this period of time.

3D. Upper extremity venous duplex ultrasound. Upper extremity venous duplex ultrasound is both sensitive and reliable in the diagnosis of axillary-subclavian vein thrombosis. A chest x-ray is obtained to exclude the presence of cervical ribs which can contribute to the compression of the subclavian vein, but cannot be used solely in diagnosis. A CT venogram is not an appropriate initial evaluation modality. A CT angiogram will not properly image the subclavian vein.

4B. Up to 40% of presentations have associated acute DVT. Less than 10% and up to 40% of patients with superficial thrombophlebitis have been reported to have associated acute DVT. Generalized edema is present only if the deep veins are involved. Ambulation is encouraged along with NSAIDs, local heat, elevation, and support stockings. Most episodes of septic thrombophlebitis respond to conservative management and do not require operative treatment.

5C. Venous duplex scans aid in ruling out venous insufficiency and venous obstruction. The distribution of edema from lymphedema is centered around the ankle and is most pronounced on the dorsum of the foot. It often involves the toes, a characteristic not seen in venous stasis disease. Venous duplex scans are helpful in ruling out venous causes of edema, especially in patients with unilateral edema. Due to its minimal risk and ability to provide information on lymph transport and reflux, lymphoscintigraphy is the gold standard for evaluation of lymphatic function. Diuretics are not effective in the long-term treatment of lymphedema, though may be useful for acute exacerbations.

CHAPTER 36

1D. Is normally maintained at a stable level by displacement of CSF

2D. Trendelenburg position

3B. Is accompanied by initial hyporeflexia

4A. Occurs with axonal regeneration after wallerian degeneration at a rate of 1 mm per day

5C. Can cause symptoms related to the compression of the pituitary stalk causing increased prolactin levels

CHAPTER 37

1C. Medically manage the patient's pain and nausea and arrange an urgent ophthalmology consult. Sudden onset of severe unilateral eye pain with decreased visual acuity, a dilated, unreactive pupil, hazy cornea, and elevated intraocular pressure is the classic presentation of acute angle-closure glaucoma. This is a vision threatening condition that must

be managed urgently. It is necessary to treat the patient's pain and nausea and lower the patient's intraocular pressure with topical, oral, and IV medications; however, definitive treatment consists of performing a peripheral iridotomy.

2C. Obtain a maxillofacial CT scan and start on IV antibiotics. Acute onset of eyelid swelling with the additional signs of eyelid warmth and redness is highly suggestive of an infectious process. Double vision and limitation of extraocular movement on the affected side indicates that there is orbital involvement. Imaging is indicated to rule out abscess formation and IV antibiotics should be initiated. Oral antibiotics would be appropriate for a preseptal cellulitis; however, there are signs of orbital involvement in this case. Thyroid ophthalmopathy is a common cause of chronic, progressive unilateral proptosis and herpes zoster ophthalmicus can present with eyelid swelling and a vesicular rash.

3D. HSV keratitis classically presents with a dendritic corneal lesion. Ocular HSV infection is most commonly caused by HSV-1 and presents with eye irritation, reduced vision, and a dendritic corneal lesion on fluorescein staining. Herpes zoster virus (HZV) infection typically presents differently from HSV, often with vesicular skin lesions around the eye. If a vesicular lesion is found on the tip of the nose (Hutchinson sign) this is suggestive of intraocular involvement with HZV. Postherpetic neuralgia can be a painful sequela of HZV—not HSV.

4C. Nonexudative “dry” macular degeneration. VEGF targeting agents are used to treat a variety of ophthalmic conditions including diabetic macular edema, exudative macular degeneration, and other diseases in which neovascularization occurs such as neovascular glaucoma. VEGF-targeting agents are not used in nonexudative or “dry” macular degeneration.

5C. Instill tetracaine 0.5% and irrigate with ~2 liters of saline (or any other immediately available fluid) immediately. Ocular burns with the alkali ammonia are serious because of rapid penetration of ocular tissue and the significant tissue damage caused. Immediate steps should be taken to make the patient comfortable and irrigate the eye with large volumes of saline. Ophthalmology can be consulted while the patient is being irrigated and eventually, after the pH has normalized, topical dilating drops and antibiotic ointments may be instilled.

CHAPTER 38

1A. Prenephros

2A. Just outside the external ring

3D. Have a history of urinary tract infections

4A. Hyperoxaluria

5C. Transurethral prostatectomy

CHAPTER 39

- 1D. Luteal cyst
- 2D. Carcinoma occurs most frequently in women between the ages of 20 and 30 years
- 3B. Consists of radiation therapy and chemotherapy for advanced disease
- 4A. Are present in 20-30% of women of reproductive age
- 5D. A, B, and C

CHAPTER 40

- 1C. An open fracture is defined as an osseous disruption with a break in the overlying skin and soft tissues resulting in communication between the fracture and the external environment. Open fractures can be classified using the Gustillo and Anderson classification: Grade 1, clean skin opening less than 1.0 cm, Grade 2, traumatic wound greater than 1.0 cm but less than 10 cm in size, and Grade 3, extensive soft tissue injury requiring flap and/or vascular repair. Antibiotic treatment, tetanus prophylaxis and urgent irrigation and debridement in the operation is necessary. Fractures should be stabilized with internal or external fixation and/or splinting to minimize additional soft tissue injury.
- 2C. The clinical findings in spinal cord injury depend on the level, mechanism and severity of injury. Injuries are classified as complete or incomplete. A complete spinal cord injury refers to lack of motor or sensory function below the level of the lesion. Incomplete spinal cord injuries may demonstrate a variable pattern of sensory and motor preservation. The American Spinal Injury Association published a scale to classify the severity of SCI: ASIA A – complete, ASIA B- sensory incomplete, ASIA C- motor incomplete, ASIA D- motor incomplete, more than half muscles below lesion have > grade 3 strength, ASIA E – normal. Spinal shock is a spinal cord dysfunction due to physiologic disruption, resulting in hypotonia, areflexia and paralysis. Resolution usually occurs within 24 hours and the bulbocavernosus reflex is the first to come back.
- 3D. Pelvic fractures are among the most serious orthopaedic injuries, resulting in life-threatening hemorrhage, neurologic and genitourinary injury. Hemodynamically unstable patients have a mortality of 40-50%. Immediate care of the patient with a pelvic fracture must address the retroperitoneal hemorrhage, pelvic ring stability and injuries to the GU system. General resuscitation principles are applied and active bleeding from the pelvic can be controlled by wrapping a pelvic binder or sheet circumferentially around the pelvis to close down the pelvic volume.

4A. Traumatic knee dislocations can be limb-threatening because of disruption to the popliteal vasculature. If the knee remains dislocated at presentation, immediate reduction should be performed. Postreduction neurologic and vascular exam is critical. If there is any indication of abnormal arterial inflow (ABI < 0.9, diminished or absent pulses, delayed capillary refill) then arteriography is indication. If the limb is frankly ischemic, emergent vascular exploration is indicated.

5C. Supracondylar humerus fractures are among the most common injuries in children ages 4-8 years. The typical mechanism is a hyperextension injury after a fall onto an outstretched arm. If displaced, supracondylar fractures require urgent reduction and stabilization in the operating room. The anterior interosseous nerve is the most commonly injured with extension type fractures. Most nerve injuries represent neuropraxias that resolve with observation over the subsequent 3-6 months.

CHAPTER 41

- 1C. Full-thickness skin grafts are indicated for multiple reconstructive procedures. Long term, they have less of a contracture rate than split-thickness grafts. Due to the fact that it is full thickness, the number of skin appendages is actually increased. This allows for improved graft incorporation. This also makes them more resilient to trauma in both the immediate and long-term recovery. The aesthetics of a FTSG are generally better than a STSG due to the factors noted.
- 2B. A random pattern flap does not have a truly dedicated vascular pedicle to keep it alive. Therefore, due to its random pattern the length to width ratio is crucial for its survival. For example, if a 3-cm-long flap is required, the width should not be less than 2 cm, meaning a 1.5:1 ratio.
- 3B. The ischial pressure sore is a commonly encountered problem for the plastic surgeon. Adequate tissue coverage is mandatory, meaning skin graft and primary closure is not adequate. The rectus femoris would not be best suited to reach the ischium. The gracilis flap is a versatile flap that has been thoroughly described for pressure sore management.
- 4C. An AVM develops from arterial and venous misconnections. Over time this can lead to significant health consequences. Glut-1 is associated with hemangiomas. AVMs usually grow in proportion with the patient and do not usually express a rapid growth phase. In most cases, AVMs do not undergo involution on their own.
- 5E. the TRAM flap has been shown to be extremely versatile and provides the best aesthetic breast reconstruction for those patients with radiation therapy. When radiation therapy is involved, implants in general have been shown to cause more complications and less than desirable results.

CHAPTER 42

- 1D. The hand should be in the position of rest
- 2D. Zigzagged across lines of tension
- 3B. Can include camptodactyly
- 4A. Can be treated by local injections of corticosteroid
- 5C. Should usually incision of the transverse carpal ligament, which forms the roof of the tunnel

CHAPTER 43

1B. Bilious emesis is indicative of a proximal bowel obstruction. In a 2 month old who has been thriving, the abnormality that must be ruled out is a midgut volvulus. This typically occurs in the setting of malrotation with a narrow-based mesentery that is susceptible to clockwise rotation and strangulation of the mesenteric vessels. While Ultrasound has been used in the diagnosis of malrotation based on the relationship of the superior mesenteric vessels, it is not currently the test of choice with acute obstruction. CT scan can make the diagnosis, but it is unnecessarily costly and time consuming. Contrast enema can be indicative of malrotation, but will not confirm midgut volvulus. Esophagram will show neither malrotation nor midgut volvulus. Upper GI series is the current test of choice. The study classically shows a “corkscrew” sign with twisting of the small intestine near the ligament of Treitz, which may be displaced medially in the setting of malrotation.

2D. Thyroglossal duct remnants are the most common midline cervical congenital anomaly. Complete excision is indicated because of the risk of infection and the possibility of the development of papillary carcinoma later in life. Acute infection in thyroglossal tracts should be treated with antibiotics. Abscesses should be incised and drained. After complete subsidence of the inflammatory reaction (approximately 6 weeks), a thyroglossal cyst and its epithelial tract should be excised. The mid portion of the hyoid bone should be removed en bloc with the thyroglossal tract to the base of the tongue (Sistrunk procedure). Recurrences occur when the hyoid is not removed and when the cyst was previously infected or drained. Lymph nodes, dermoid cysts, and enlarged Delphian nodes containing tumor metastases may be confused with thyroglossal remnants in the midline of the neck. However unlike thyroglossal duct cysts, they do not move with swallowing.

3E. CDH is a physiological emergency, not a surgical emergency. Newborns should be stabilized and pulmonary hypertension managed prior to repair. ECMO is still used to manage severe respiratory failure and pulmonary hypertension, although its use is less common with advanced ventilator strategies and inhaled nitric oxide. CT scan can be used to differentiate CDH from cystic lung disease if there is a question, but the diaphragmatic defect cannot be visualized. Small defect are amenable to primary repair and mortality is determined by the degree of pulmonary hypoplasia.

4A. Tracheoesophageal fistula is associated with other congenital anomalies in 50% of cases and with the VACTERL association (vertebral, anorectal, cardiac, tracheoesophageal, renal, and limb anomalies) in 25% of cases. Workup of associated anomalies should be undertaken prior to surgery. Cerebral anomalies are not part of the association, thus screening head ultrasound is not necessary.

5B. N-myc amplification is a predictor of poor prognosis independent of stage. Young age, differentiation, and low LDH are all positive predictors. Stage IVs have favorable outcomes to older children with stage III and IV.

CHAPTER 44

1D. Cancer point prevalence describes the number of people with cancer at a given time

2D. Both A and C

3B. Can be described according to its absolute or relative benefit

4A. Have tumor size and tumor grade as the most important prognostic variables

5D. Should be excised with a 2 cm skin margin if greater than 2 mm thick

CHAPTER 45

1C. IFN- γ

2B. B-cell

3A. Two

4E. All of the above

5D. Metastatic colon cancer
