Preface

All practitioners, doctors and nurses, who care for newborn babies have an enormous responsibility. They are entrusted with the care of approximately 130 million children who are born each year worldwide, about 20 million of whom are of low birth weight. Because they are born light and early, these children are at high risk of dying during the perinatal period, have reduced survival during infancy and are at risk of survival with cognitive impairment. Their health later in life may be adversely affected and even the next generation may suffer. Some babies become sick because they are born small, others because of inherited diseases, which often provide diagnostic and therapeutic challenges. Still others, about one in every thousand, have thrived during the pregnancy but are subjected to severe and potentially damaging hypoxic ischaemia at full-term. We firmly believe that good care can help improve the survival of these small vulnerable patients and this book was produced with the aim of providing healthcare practitioners in neonatology with an up-to-date, readily available and comprehensive source of practical advice for the expert management of their patients and their diverse illnesses.

Neonatology is a science in rapid evolution and all the contributors to this new textbook are experts in their fields, clinically active and committed to developing the best possible care for their patients. This book brings together their expertise in a clear and easy-to-follow manner. Although some may feel that in the age of the internet such a textbook is an anachronism, we feel passionately that those caring for newborn babies will be helped by the accessibility of the information, written by experts, in this single volume. Our intention is that healthcare practitioners with responsibility for babies will be helped by the knowledge of the contributors to this book and their collective experience acquired over many years. The evidence base for practice has been set out where available, but there are gaps in the research-based evidence and sick babies still deserve to be given first-class care. We firmly believe that this textbook will enable the better delivery of such high quality care by making widely available the personal expertise of the contributors, who have been selected because of their international reputations and renown. We hope this textbook finds a place in the library of every neonatal unit and on the bookshelf of every practitioner committed to the care of newborn babies.

The book has been organized in a logical manner. In the first section, relevant epidemiology and fetal medicine are considered. Here consideration is given to epigenetic mechanisms and well as more traditional risk factors. Intrauterine growth restriction is considered from obstetric, neonatal and therapeutic aspects. There are chapters devoted to the difficult ethical problems in this area of care, how to make decisions, and how to measure the quality of the care that our small patients receive. The vital issue of follow up outcomes is considered, as well as the complexities of cerebral plasticity and functional reorganization in children with congenital brain lesions.

The second section deals with therapeutic issues, including the organization of perinatal care, transport services, resuscitation and oxygen toxicity, home care after discharge from hospital and the training of specialist doctors and nurses. Here legal issues are also considered. The third section on nutrition begins with a consideration of the

physiology of the gastrointestinal tract and of the developing endocrine milieu. Nutrition of the baby in hospital is considered in its various aspects, as is post-discharge nutrition, calcium and phosphorous homeostasis and micronutrients and vitamins. Section IV provides a detailed consideration of the problems due to drugs taken during pregnancy and there is an expert review of developmental pharmacology and therapeutics. Issues relating to infants born to mothers with diabetes are also considered here. Section V deals with the respiratory system in all its complexity, ranging from its development and physiology, through a consideration of the control of breathing and the molecular structure of surfactant and rare lung disorders, to practical therapeutic considerations. The following sections deal with the cardiovascular system, hyperbilirubinemia and liver diseases. Section VIII deals with surgery, including the treatment of orofacial malformations and necrotizing enterocolitis, and pre- and post- natal management. Subsequent sections deal with hematology, immunology and inflammation, and the rare but important topic of neonatal malignancies. Sections on infection and endocrine and metabolic disease follow. Finally there are sections on neurology, including brain development, injury, electrophysiology and imaging, and relevant ophthalmology, orthopedics and dermatology.

This book is comprehensive and provides an easily accessible single reference point. It is intended for all involved in the care of newborn babies – pediatricians, neonatal nurses, nurse practitioners, midwives, pediatric surgeons, anesthesiologists, neonatologists and those training in these various areas.

Acknowledgements
The Editors are grateful to the Europe Against Infant Brain Injury (EURAIBI - Onlus) Foundation for its most generous support. Particular thanks to Barbara Marzocchi, who gave so much energy contacting contributors and getting back manuscripts, and to Marco Martorelli for his unfailing help in copy editing. Last, but no means least, we are very grateful to our trainees and residents, Sara Bertrando, Sara Cornacchione, Tei Monica, and Gemma Stazzoni, who carefully checked the index.

Epidemiology: Mortality and Morbidity

Marcello Orzalesi and Carlo Corchia

1.1 Introduction

During the past 20 years the most important indicators of maternal and child health have improved considerably in many parts of the world, with the notable exception of countries affected by the HIV/AIDS epidemic. Nevertheless, it is estimated that out of 130 million babies that are born alive every year, almost 8 million die in their first year of life and more than 4 million die in the first 4 weeks after birth; furthermore, every year over 3,3 million fetuses are stillborn and one third of fetuses die during delivery [1].

The rates of neonatal, infant and child mortality as well as those of stillbirths and perinatal mortality vary considerably among different nations, with a persistent large gap between developed and developing countries [1]. The reasons for these variations are many and complex, including socio-economic, educational, organizational, technological, ethnic, historical as well as being dependent on other characteristics of the different countries. This description focuses on the situation in developed countries: Europe, North America, Japan, Australia and New Zealand. Those who are interested in a description of maternal and child health in the rest of the world are referred to the recent report of the World Health Organization (WHO) [1].

1.2 Definitions

When comparing data from different countries, regions or single centers, discrepancies arise because of differences in the definitions of the variables used for comparison. For this reason, the WHO has recommended using definitions from the tenth revision of the international classification of diseases (CD) as adopted by the World Health Assembly [2] (see § 1.7).

M. Orzalesi (✉)
Maruzza Lefebvre D'Ovidio Foundation
Rome, Italy

In spite of these WHO recommendations, substantial differences in international criteria for measuring perinatal and neonatal mortality persist [3]. The issue has also been somewhat confused by two other factors: a recent trend towards increasing survival of infants of gestational age (GA) below 26 completed weeks or birth weight below 800 grams [4, 5], and variability in attitudes concerning resuscitation of these infants, which depends on different personal or institutional ethical approaches [6, 7]. These factors have made it difficult to compare stillbirth and neonatal death rates between single centers or geographically defined areas.

1.3 Sources of Data

The data for the evaluation of perinatal and neonatal health are derived from two main sources: center-based, i.e., data from single or multiple centers; and area-based, i.e., data from a geographically defined area, such as a region or a whole country.

The first type of data is more easily obtainable and therefore common in the literature. Such data are useful for monitoring the performance of a single center over time, for comparisons and bench-marking between different centers, for the study of specific risk factors and for the evaluation of new procedures or therapeutic approaches. However, they are subject to selection biases and, since they are usually provided by centers of excellence, the results are generally better than those obtained from area-based studies and do not provide a true picture of the overall situation in a given region or country [8].

The second type of data is less easily obtained, since it requires considerable organizational and financial efforts, and such data are therefore less common in the literature. They are, however, extremely useful since they provide a more complete picture of the situation in a given region or country, including highlighting important socio-economic and organizational aspects that are often not apparent from center-based studies.

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

1.4 Neonatal Mortality Rates

Over the past decades, the neonatal mortality rate (NMR, within 28 days of birth) has decreased steadily in most parts of the world. However, the gap between developed and developing countries persists [9], and in some cases has widened (Table 1.1). Significant differences have also been reported between the most developed countries (Table 1.2) [9] and between different geographical areas of the same country [10, 11]. Once again, the reasons for these differences are many and often not entirely clear: socio-economic, demographic and organizational issues play their parts, as do different attitudes towards the more or less aggressive management of infants of very low GA at the limits of viability. However, these factors do not entirely explain the variability.

The contribution of neonatal mortality to infant mortality rate (IMR, within the first year of life) and to child mortality rate (CMR, within the first 5 years of life) also varies greatly between countries, and neonatal mortality continues to be a major cause of death in infancy and early childhood all over the world (Tables 1.1 and 1.2).

The causes of neonatal deaths vary between countries (Table 1.3) [9]. In developed countries four main causes account for more than 75% of all neonatal deaths: disorders related to prematurity or low birth weight (LBW), congenital anomalies, neonatal infections, birth asphyxia and birth trauma [9]. The proportion to which each one of these causes contributes to neonatal mortality varies from country to country but prematurity and LBW are always predominant.

1.5 Prematurity and Low Birth Weight

Prematurity (GA <37 weeks) and LBW (<2500 g) are the leading causes of neonatal and infant death among babies born in developed countries [9, 12]. Neonatal and infant mortality for moderately LBW infants (BW 1500–2499 g) is five times higher than for infants of normal birthweight: the mortality of LBW infants is almost completely concentrated in infants of very low birth weight (VLBWI <1500 g) who are 100 times more likely to die than their normal birth weight counterpart [13].

The contribution of prematurity and LBW to the total neonatal mortality appears to be greater when the NMR is lower [9], and this is particularly true for VLBW infants who contribute to more than half the neonatal and infant deaths in developed countries with a low NMR [13]. For these reasons, neonatologists have concentrated their attention on VLBW infants, and particularly on those of extremely low birth weight (ELBWI, <1000 g). The prevalence of VLBW infants is around 1–2% of all live births but varies considerably between countries, and this can significantly affect the neonatal mortality rates [14]. The neonatal mortality rate also varies between centers and geographically defined areas; part of this variation is due to differences in the management of these infants in NICU, but a great part can also be attributed to selection biases [15] and differences in reporting [14].

Neonatal mortality increases progressively with a lowering of GA and BW. The inverse proportion between neonatal mortality and GA is well depicted in a recent study from England and Wales [16]. In general, for any given GA, the lower the BW, the higher the mortality; and for any given BW, the lower the GA, the higher the mortality [12]. The prognosis is therefore usually worst in small for gestational age infants (SGA, BW <10th percentile for GA).

Many other factors affect the survival of preterm and LBW infants. These include gender, ethnicity, multiple pregnancy, maternal health and complications of pregnancy, mode and place of delivery, prenatal administration of corticosteroids, condition at birth and clinical problems after birth

Table 1.1 Number of births/year (2007), neonatal mortality rates (NMR, 2004), infant mortality rates (IMR, 2007) and child mortality rates under 5 years (CMR, 2007) in different parts of the world (decimals are omitted and numbers are rounded to the nearest unit)

[12]. The frequency and severity of clinical problems tend to be related more to GA than BW [12].

The mortality rate of LBW infants has declined progressively during the past decades. Improvements in the care of preterm fetuses and newborns have contributed substantially to this decline [12]. Regionalization of perinatal care, with increased numbers of infants delivered in third level hospitals with intensive care units [12, 17], has also contributed significantly. Efforts to prevent prematurity and LBW have not been equally successful. This is because the causes and risk factors associated with preterm and LBW births are numerous and by and large unknown or not completely understood [12, 17, 18]. They are usually grouped into three major categories: spontaneous preterm labor and rupture of membranes, maternal and fetal complications, and multiple pregnancy and assisted reproduction [18]. In many developed countries, there has been a slight increase in preterm births mainly due to increasing rates of multiple births, greater use of assisted reproduction techniques, and more obstetric interventions [12, 18, 19].

Premature and LBW infants contribute to more than half of all neurodevelopmental, cognitive, sensory and other disabilities in infancy, childhood and adolescence [12]. The incidence and severity of such long-term sequelae, as reported by single or multicenter studies, varies according to the case mix, the obstetric and neonatal management, the age and methods of evaluation and other variables [18–20]. In general, the incidence and severity are inversely correlated with GA and BW and are particularly high in infants of extremely low GA (<26 weeks) (see Chapter 129).

There has been some concern that the increased survival of these high risk and delicate infants would result in an increased number of infants with long-term severe disabilities. This appeared indeed to be the trend until the early 1990s; however, the trend seems to have reversed and recent data indicate that improved survival may be associated with a concomitant decrease in cerebral palsy and other disabling conditions [21–23].

Recent technological advances in neonatal intensive care have pushed back the lower limits of gestation at which survival is possible and many centers have reported significant survival in infants of 23 and even 22 weeks' gestation. However, as shown by the few area-based studies where follow-up has been carried out to around school age, the short and long-term prognosis of these infants at the limits of viability (GA <25 weeks) remains very poor [24–26].

1.6 Conclusions

Perinatal, neonatal and infant mortality rates have decreased in the past decade in many parts of the world but remain high in most developing countries. Neonatal mortality contributes significantly to infant and child mortality and morbidity, particularly in developed countries.

In developing countries some of the causes of intrapartum and neonatal deaths, such as birth asphyxia and birth trauma, neonatal infections, tetanus and diarrheal diseases, are largely preventable by adequate social, organizational, hygienic, obstetric and neonatal interventions.

In developed countries, the challenge concerns mainly premature infants of very low gestation. Their numbers seem to have increased because of more widespread use of assisted reproduction techniques and because of more aggressive obstetric and neonatologic approaches.

It is unlikely that the mortality rates of these infants can be further significantly decreased by new therapies or technological advances. However, it should be possible to decrease the incidence and severity of long-term sequelae.

Hopes for a significant improvement in neonatal mortality depend mainly on the prevention of prematurity and low birth weight, although this seems to be a goal difficult to achieve.

Careful standardized collection and reporting of area based data relating to maternal, perinatal, neonatal and infant mortality and morbidity, such as those published in the European Perinatal Health Report [27], is highly recommended and may help identify the areas and types of interventions that might be reasonably expected to improve maternal and child health.

1.7 Appendix

Extracted from the International statistical classification of diseases and related health problems, 10th revision (ICD-10) [2]

Definitions

The following definitions have been adopted by the World Health Assembly in relation both to statistics amenable to international comparison and to reporting requirements for the data from which they are derived.

- *Live birth*. Live birth is the complete expulsion or extraction from its mother of a product of conception, irrespective of the duration of the pregnancy, which, after such separation, breathes or shows any other evidence of life, such as beating of the heart, pulsation of the umbilical cord, or definite movement of voluntary muscles, whether or not the umbilical cord has been cut or the placenta is attached; each product of such a birth is considered liveborn.
- *Stillbirth or fetal death (deadborn fetus)*. Fetal death is death prior to the complete expulsion or extraction from its mother of a product of conception, irrespective of the duration of pregnancy; the death is indicated by the fact that after such separation the fetus does not breathe or show any other evidence of life, such as

beating of the heart, pulsation of the umbilical cord, or definite movement of voluntary muscles.

- *Birth weight*. The first weight of the fetus or newborn obtained after birth. For live births, birth weight should preferably be measured within the first hour of life before significant postnatal weight loss has occurred. While statistical tabulations include 500 g groupings for birth weight, weights should not be recorded in those groupings. The actual weight should be recorded to the degree of accuracy to which it is measured.
- *Low birth weight*. Less than 2500 g (up to and including 2499 g).
- *Very low birth weight*. Less than 1500 g (up to and including 1499 g).
- *Extremely low birth weight*. Less than 1000 g (up to and including 999 g).
- *Gestational age*. The duration of gestation is measured from the first day of the last normal menstrual period. Gestational age is expressed in completed days or completed weeks (e.g., events occurring 280–286 completed days after the onset of the last normal menstrual period are considered to have occurred at 40 weeks of gestation). Gestational age is frequently a source of confusion, when calculations are based on menstrual dates. For the purposes of calculation of gestational age from the date of the first day of the last normal menstrual period and the date of delivery, the first day is day zero and not day one; therefore days 0–6 correspond to "completed week zero"; days 7–13 to "completed week one"; and the 40th week of actual gestation is synonymous with "completed week 39". Where the date of the last normal menstrual period is not available, gestational age should be based on the best clinical estimate. In order to avoid misunderstanding, tabulations should indicate both weeks and days.
- *Preterm*. Less than 37 completed weeks (less than 259 days) of gestation.
- *Term*. From 37 completed weeks to less than 42 completed weeks (259–293 days) of gestation.
- *Post-term*. 42 completed weeks or more (294 days or more) of gestation.
- *Perinatal period*. The perinatal period commences at 22 completed weeks (154 days) of gestation (the time when birth weight is normally 500 g), and ends seven completed days after birth.
- *Neonatal period*. The neonatal period commences at birth and ends 28 completed days after birth. Neonatal deaths (deaths among live births during the first 28 completed days of life) may be subdivided into early neonatal deaths, occurring during the first seven days of life, and late neonatal deaths, occurring after the seventh day but before 28 completed days of life.

Neonatal and Perinatal Mortality Rates

Published rates should always specify the denominator, i.e., live births or total births (live births plus fetal deaths). Countries are encouraged to provide the rates listed below, or as many of them as their data collection systems permit.

- *Fetal death rate*. Fetal deaths/1000 total births.
- *Early neonatal mortality rate*. Early neonatal deaths/1000 live births.
- *Perinatal mortality rate*. Fetal deaths and early neonatal deaths/1000 total births. The perinatal mortality rate is the number of deaths of fetuses weighing at least 500 g (or, when birth weight is unavailable, after 22 completed weeks of gestation or with a crown-heel length of 25 cm or more), plus the number of early neonatal deaths, per 1000 total births. Because of the different denominators in each component, this is not necessarily equal to the sum of the fetal death rate and the early neonatal mortality rate.
- *Neonatal mortality rate*. Neonatal deaths/1000 live births. It can be subdivided into early mortality rate (first week of life) or late mortality rate (8–28 days of life).
- *Infant mortality rate*. Deaths under one year of age/1000 live births.

Presentation of Causes of Perinatal Mortality

For statistics of perinatal mortality derived from the certificate recommended for this purpose, full-scale multiple-cause analysis of all conditions reported are of greatest benefit. Where such analysis is impracticable, analysis of the main disease or condition in the fetus or infant and of the main maternal condition affecting the fetus or infant, with cross-tabulation of groups of these two conditions should be regarded as the minimum. Where it is necessary to select only one condition (for example, when early neonatal deaths must be incorporated into single-cause tables of deaths at all ages), the main disease or condition in the fetus or infant should be selected.

Reporting Criteria

The legal requirements for the registration of fetal deaths and live births vary from country to country and even within countries. If possible, all fetuses and infants weighing at least 500 g at birth, whether alive or dead, should be included in the statistics. When information on birth weight is unavailable, the corresponding criteria for gestational age (22 completed weeks) or body length (25 cm crown-heel) should be used. The criteria for deciding whether an event has taken place within the perinatal period should be applied in the order: (1) birth weight, (2) gestational age, (3) crown–heel length. The inclusion of fetuses and infants weighing between 500 g and 999 g in national statistics is recommended both

because of its inherent value and because it improves the coverage of reporting at 1000 g and over.

Statistics for International Comparison

In statistics for international comparison, inclusion of the extremely low birth weight group disrupts the validity of comparisons and is not recommended. Countries should arrange registration and reporting procedures so that the events and the criteria for their inclusion in the statistics can be easily identified. Less mature fetuses and infants not corresponding to these criteria (i.e., weighing less than 1000 g) should be excluded from perinatal statistics unless there are legal or other valid reasons to the contrary, in which case their inclusion must be explicitly stated. Where birth weight, gestational age and crown-heel length are not known, the event should be included in, rather than excluded from, mortality statistics of the perinatal period. Countries should also present statistics in which both the numerator and the denominator of all rates are restricted to fetuses and infants weighing 1000 g or more (weight-specific rates). Where information on birth weight is not available, the corresponding gestational age (28 completed weeks) or body length (35 cm crown–heel) should be used. In reporting fetal, perinatal, neonatal and infant mortality statistics the number of deaths due to malformations should whenever possible be identified for live births and fetal deaths and in relation to birth weights of 500–999 g and 1000 g or more. Neonatal deaths due to malformations should be subdivided into early and late neonatal deaths. This information enables perinatal and neonatal mortality statistics to be reported with or without the deaths from malformations.

The Development from Fetus to Newborn

Domenico Arduini and Marianne Vendola

2.1 The Fetus at Term

The stages of development of the human, from embryo to fetus and finally to newborn baby, are shown in Table 2.1.

Table 2.1 The stages of development of the human fetus, from embryo to newborn

Fetus at term

3. Diagnosis of fetal well-being
4. Fetal injuries
5. Fetal response to injuries
6. Postnatal development

2.2 Developmental Phases of the Fetus

The embryonic phase is a critical stage of development, when systems undergo important basic development.

The third week after conception marks the beginning of the embryonic period. It ends at the end of the tenth week, when the embryo comprises three layers from which all organs will develop.

The second fetal phase begins after the tenth week and continues until the end of pregnancy. During this phase, organs (liver, kidneys) begin to function.

From the 16th to 20th weeks, the fetus undergoes a rapid growth spurt. Fat develops under a thin skin. Cardiac output increases. Meconium accumulates in the bowel. The fetus hiccups and spends time awake and asleep.

Fetal development slows down between the 21st and 24th weeks. By the 24th week, the fetus weighs approximately 1,3 pounds (0,6 kg).

Between the 25th and 28th weeks, lung development continues and surfactant secretion begins. By the 28th week, 90% of fetuses will survive *ex utero* with appropriate support.

From the 29th to the 40th weeks, the amount of body fat rapidly increases. Thalamic brain connections, which mediate sensory input, form. Bones are fully developed. Most of the major systems and organs are complete. The immune system develops.

By weeks 35–40, the fetus is sufficiently developed for life outside the uterus without any more support than that which would be required by any newborn baby delivered at term. At 37 weeks, the fetus will continue to add approximately one ounce (28 g) per day to its body weight and it will be 48–53 cm (19–21 inches) in length at birth.

2.3 Fetal Constitutional Characteristics

2.3.1 The Central Nervous System (CNS)

The CNS is formed by four subdivisions of the neural tube that develop into distinct regions of the central nervous system.

The neural tube is initially open both cranially and caudally. These openings close during the fourth week. Failure of closure of these neuropores can result in neural tube defects such as anencephaly or spina bifida.

The dorsal part of the neural tube comprises the alar plate, which is primarily associated with sensation. The ventral part of the neural tube comprises the basal plate, which is primarily associated with motor control.

The spinal cord is a long, thin, tubular bundle of nervous tissue and support cells that extend from the brain. The brain and spinal cord together make up the central nervous system. The spinal cord functions primarily for the transmission of neural signals between the brain and the rest of the body, but also contains neural circuits that independently control numerous reflexes and central pattern generators.

2.3.2 The Fetal Circulation

The essential difference between the circulatory system of a fetus and that of the baby after birth is that the lungs are not in use: the fetus obtains oxygen and nutrients from the mother through the placenta and the umbilical cord. Blood from the placenta is carried to the fetus by the umbilical vein. A large proportion enters the fetal ductus venosus and passes to the inferior vena cava, while the remainder enters the liver from vessels on its inferior border. The branch of the umbilical vein that supplies the right lobe of the liver joins the portal vein and blood then passes to the right atrium. In the fetus, there is an opening between the right and left atria (the foramen ovale), and most of the blood flows from the right into the left atrium, thus bypassing pulmonary circulation. The majority of blood flow is then into the left ventricle from where it is pumped through the aorta to supply the various organs. Blood then flows from the aorta through the internal iliac arteries to the umbilical arteries, and re-enters the placenta, where carbon dioxide and other waste products from the fetus are taken up and enter the maternal circulation. A small proportion (about 4%) of the blood from the right atrium does not enter the left atrium, but enters the right ventricle and is pumped into the pulmonary artery. In the fetus, a connection between the pulmonary artery and the aorta, called the ductus arteriosus, directs most of the blood away from the lungs (which are not being used for respiration at this point as the fetus is suspended in amniotic fluid).

An important concept of the fetal circulation is that fetal hemoglobin has a higher affinity for oxygen than adult hemoglobin, which facilitates diffusion of oxygen from the maternal circulation to the fetus. The circulatory system of the mother is not directly connected to that of the fetus, so gas exchange takes place at the placenta. Oxygen diffuses from the placenta to the chorionic villus, an alveolus-like structure, from which it is then carried to the umbilical vein. Fetal hemoglobin enhances the fetal ability to draw oxygen from the placenta because the oxygen dissociation curve is shifted to the left, which has the effect of oxygen being taken up at a lower concentration than by adult hemoglobin. This enables fetal hemoglobin to take up oxygen from adult hemoglobin in the placenta, which has a lower partial pressure of oxygen than at the lungs after birth.

A developing fetus is highly susceptible to anomalies of growth and metabolism, increasing the risk of birth defects.

2.3.3 Fetal Metabolism

A continuous placental supply of glucose provides the substrate for energy metabolism to the fetus, and this converts after birth to intermittent feeding. While the fetus is dependent on maternal glucose as the main source of energy, it can also use lactate, free-fatty acids, and ketone bodies under some conditions (e.g. starvation or hypoxia). Fetal glucose utilization is augmented by insulin produced by the developing fetal pancreas in increasing amounts as gestation proceeds; this enhances glucose utilization in insulin-sensitive tissues (skeletal muscle, liver, heart, adipose tissue), which increase in mass and thus glucose requirement during late gestation. Glucose-stimulated insulin secretion increases with gestation. Glycogen stores are maximal at term, but even the term fetus only has sufficient glycogen available to meet energy needs for 8–10 hours, and this store can be depleted even more quickly if demand is high. At 27 weeks' gestation, only 1% of a fetus's body weight is fat; this increases to 16% at 40 weeks. Inadequate glucose substrate can lead to hypoglycemia and fetal growth restriction. In cases of intrauterine growth restriction, fetal weight-specific tissue glucose uptake rates and glucose transporters are maintained or increased, while synthesis of amino acids into protein and corresponding insulin-like growth factor (IGF) signal transduction proteins are decreased. These observations demonstrate the mixed phenotype of the intrauterine growth restriction (IUGR) fetus that has an enhanced capacity for glucose utilization, but a diminished capacity for protein synthesis and growth. Excess substrate can also lead to problems, as with infants of diabetic mothers (IDM). Thus, the normal fetus has a considerable capacity to adapt to changes in glucose supply [1].

2.3.4 Regulation of Fetal Growth

Fetal growth depends on many different aspects, mostly influenced by maternal and uteroplacental factors.

2.3.4.1 Role of the Mother in Fetal Growth Regulation

Fetal growth and development are influenced by genetic as well as environmental factors. Maternal genes have an important specific influence on fetal growth; for example, maternal height is a major determinant of fetal size, representing uterine capacity and the potential for growth. Although the birth weights of siblings are similar and correlate, environmental influences are also important in determining growth. Maternal constraint refers to the limited capacity of the uterus to support fetal growth and is important in limiting fetal overgrowth and subsequent dystocia, to ensure the mother's capacity for future successful pregnancies [2].

Maternal Nutrient Intake

The mother is the supplier of oxygen and essential nutrients to the fetus via the placenta. Maternal diet, caloric intake, and metabolic function have an important role in supplying nutrients to the fetus. Increased caloric intake is necessary during the second and third trimesters to allow for fetal and

placental growth [3]. A Cochrane systematic review of six randomized controlled trials found that balanced protein-energy supplementation reduced the risk of small for gestational age (SGA) neonates by approximately 30% [4]. Glucose is an important nutrient in the control of fetal growth. Studies of diabetic women have shown that low blood glucose levels during pregnancy as a result of excessively tight glycemic control lead to a greater incidence of SGA neonates, whereas high blood glucose levels increase the likelihood of macrosomia [5].

Maternal Uterine Artery Blood Flow

Increased uterine blood flow is essential to meet the metabolic demands of the growing uterus as well those of the placenta and fetus [6]. Uterine artery blood flow increases by more than three-fold during pregnancy, partly influenced by an increased artery diameter and reduced resistance to flow. In addition to increased uterine blood flow during normal pregnancy, new blood vessels develop in the uterus, promoted by the placental hormones human chorionic gonadotropin (hCG) [7] and IGF-II [8]. Using Doppler assessment of uterine arterial flow at 23 weeks' gestation, Albaiges et al [9] found that that increased uterine artery blood flow resistance was associated with an increased risk of an SGA baby.

Maternal Smoking and Drug Use

Maternal cigarette smoking is associated with reduced birth weight. Early reports suggested a doubling of the rate of low birth weight in babies of smokers compared with those of non-smokers and a dose-dependent effect with increasing number of cigarettes smoked. More recent studies demonstrated a 3.5-fold increased risk of SGA infants in women who smoked during pregnancy [10], with a greater effect on low birth weight with increasing maternal age [11]. Growth restriction is usually symmetrical with reduced weight, head circumference, and abdominal circumference. The use of drugs, such as cocaine and marijuana, also has significant negative effects on fetal growth. Cocaine use contributes to an increased rate of low birth weight and a reduction in mean birth weight of at least 100 g.

Maternal Hypoxia

Maternal hypoxia influences fetal growth. Its effect is independent of socioeconomic status, prematurity, maternal smoking, pregnancy-induced hypertension, and parity. The combination of hypoxia and pregnancy appears to be important in altering maternal physiology, including changes in immune pathways [12]. Maternal hypoxia affects placental and uterine blood flow, which contribute to reduced nutrient transport to the fetus [13].

Maternal Inflammatory Diseases

The presence of maternal inflammatory disease may contribute to reduced fetal growth. Several inflammatory diseases are associated with reduced fetal growth, including rheumatoid arthritis [14], inflammatory bowel disease, systemic lupus erythematosus, and periodontal disease [15]. Women with active inflammatory arthritis during pregnancy have smaller babies compared with healthy women or women whose disease is in remission [16], suggesting that active inflammation during pregnancy may contribute to reduced fetal growth. Maternal health influences the maternal state during pregnancy with implications for fetal growth. In addition to inflammatory diseases, many other maternal factors, including preeclampsia [17], anemia [18], infections and alcohol consumption, influence fetal growth via changes in placental function.

2.3.4.2 Role of the Placenta in Fetal Growth Regulation

The placenta receives and transmits endocrine signals between the mother and fetus and is the site of nutrient and waste exchange. Adequate placental growth is essential for adequate fetal growth. Several aspects of placental function are critical for human fetal growth and development, including adequate trophoblast invasion, an increase in uteroplacental blood flow during gestation, transport of nutrients such as glucose and amino acids from mother to fetus, and the production and transfer of growth-regulating hormones. Increased blood flow during pregnancy increases the flow of nutrients from mother to fetus, and uteroplacental blood flow has been shown to be reduced by up to 50% in women with preeclampsia [19]. Doppler velocimetry is used to detect increased vascular resistance in the uterine arteries, which occurs as a result of abnormal trophoblast invasion of the spiral arteries. In addition, examination of the fetal circulation, particularly umbilical artery waveforms, may reflect placental insufficiency [20]. Umbilical vein blood flow, measured by Doppler ultrasound, is decreased in IUGR fetuses, representing reduced perfusion of the fetal tissues.

Placental Hormone Production

During human pregnancy, the placenta is an important endocrine organ. It produces hormones, including estrogens and progesterone, hCG, human growth hormone (GH) variant, and human placental lactogen. Some of these play a role in the regulation of fetal growth. Fetal insulin promotes growth of the fetus, acting as a signal of nutrient availability [20]. Insulin deficiency results in reduced fetal growth, as the fetal tissues decrease their uptake and utilization of nutrients. There is also a relationship between increased insulin production and increased fetal growth. It has been proposed that the fetus increases its own production of insulin in response to maternal hyperglycemia, and that this increase in fetal insulin

is responsible for the increased growth and macrosomia observed in diabetic pregnancies.

2.4 Diagnosis of Fetal Well-being

During pregnancy, women are generally offered non-invasive screening tests, such as blood tests, ultrasound and cardiotocography (CTG) (to detect the fetal heartbeat and uterine contractions, usually monitored during the third trimester), to evaluate the baby's health. Alternatively, more invasive tests, such as chorionic villous sampling or amniocentesis, may be performed.

Obstetric ultrasound is usually used to:

- diagnose pregnancy;
- assess possible risks to the mother (miscarriage or molar pregnancy);
- check for fetal malformation;
- determine intrauterine growth restriction;
- note the development of fetal body parts;
- check the amniotic fluid and the umbilical cord.

Generally an ultrasound examination is ordered whenever an abnormality is suspected or following a schedule similar to that outlined below:

- *7 weeks* Confirm pregnancy, determine expected date of delivery;
- *11–13 weeks* Evaluate the possibility of Down syndrome;
- *20–22 weeks* Perform a scan to assess anatomic integrity;
- *32 weeks* To evaluate fetal growth, verify the position of the placenta and perform the Doppler study to establish fetal well-being.

Fig. 2.1 Reconstructed 3-D imaging of the eyes, palate and mandible from the fetal profile

Three- dimensional (3-D) and four- dimensional (4-D) ultrasound techniques are used to provide additional imaging of fetal structures. Today 3-D ultrasound is most commonly performed for the visualization of the baby's face. However, it has the potential to become part of routine care and many hospitals use the 3-D ultrasound to detect fetal anomalies, especially of the heart and of the CNS (Fig. 2.1).

2.5 Fetal Injuries

It is important during fetal development to maintain good fetal oxygen delivery to avoid irreversible fetal compromise. Fetal hypoxia from any cause leads to conversion from aerobic to anaerobic metabolism, which produces less energy and more acid. If the oxygen supply is not restored, the fetus dies. Hypoxia may be:

1. *Hypoxemic hypoxia*: reduced placental perfusion with maternal blood and consequent decrease in fetal arterial blood oxygen content due to low pO_2.
2. *Anemic hypoxia*: reduced arterial blood oxygen content due to low fetal hemoglobin concentration.
3. *Ischemic hypoxia*: reduced blood flow to the fetal tissues.

Making this diagnose can be difficult, and some episodes of hypoxia before and during birth may pass unnoticed at the time, but may affect the central nervous system and not become evident until much later in life.

2.5.1 Causes of Hypoxia

Two major categories of neurological injury can be observed in the full-term infant: (1) hypoxic-ischemic encephalopathy (HIE) and (2) intracranial hemorrhage (ICH). Brain hypoxia and ischemia due to systemic hypoxemia, reduced cerebral blood flow (CBF), or both are the primary pathophysiological processes that lead to an hypoxic-ischemic encephalopathy.

The first compensatory adjustment to an hypoxic-ischemic (asphyxic) event is an increase in CBF due to hypoxia and hypercapnia. This is associated with a redistribution of cardiac output so that the brain receives an increased proportion of the cardiac output. This is followed by a slight increase in systemic blood pressure (BP) due to increased release of epinephrine. In the fetus suffering from acute asphyxia (hypoxic ischemia), if early compensatory adjustments fail, cerebral blood flow (CBF) may become pressure-passive and brain perfusion becomes dependent on systemic BP. As BP falls, CBF falls below critical levels, and a diminished blood supply in the brain leads to insufficient oxygen to meet its needs and intracellular energy failure.

Neuronal injury in hypoxic ischemia is an evolving process. During the early phases of brain injury, brain temperature drops, and there is local release of neurotransmitters, such as γ-aminobutyric acid transaminase (GABA). The magnitude

of the final neuronal damage depends on both the severity of the initial insult and damage due to energy failure, injury during reperfusion, and apoptosis. The extent, nature, severity, and duration of the primary injury are all important in determining the magnitude of the residual neurological damage.

Intracranial hemorrhage in the full-term infant can be intraventricular, subarachnoid, subdural, or intracerebellar. There is often ventilatory disturbance and hypoxia because of varying neurological depression. Intraventricular hemorrhage (IVH), which is unusual in term infants, may be associated with evidence of intrapartum asphyxia, but may also be clinically silent and underdiagnosed, causing later deficits or hydrocephalus [21].

Approximately 20% of neonatal HIE is primarily related to antepartum events that lead to hypoxic ischemia. Maternal conditions such as hypotension, placental vasculopathy, and insulin-dependent diabetes mellitus may predispose the fetus to intrapartum hypoxic ischemia because there is little reserve to compensate for the stresses of labour [22]. Intrapartum events such as prolapsed cord, abruptio placentae, and traumatic delivery have been linked to 35% of cases of HIE. Because of the limitations in determining the actual timing of the insult, it may be difficult to identify the antepartum contribution separately from the intrapartum. Other events besides intrapartum hypoxia may be responsible for HIE or CP, as less than 25% of these infants have symptoms of hypoxic ischemia at birth [23].

The true incidence of intracranial hemorrhage (ICH) in utero has not been determined. Significant subarachnoid hemorrhage can occur with intrapartum hypoxia, or may result from trauma at delivery. It can be isolated or associated with subdural bleeding and cerebral contusion. The presentation is variable but generally includes CNS depression, irritability, and seizures. When subarachnoid hemorrhage is associated with other signs of physical injury and is caused by a difficult delivery, outcome is frequently poor.

In fetal hypoxemia, there is a redistribution of blood flow. This results in an increased blood supply to the brain, myocardium, adrenal glands and reduced perfusion of the kidneys, gastrointestinal tract and the lower extremities. There is preferential delivery of nutrients and oxygen to vital organs, compensating for a diminished placental supply [24]. This compensation is manifest as cerebral vasodilatation and there is an increase in the pulsatility index (PI) in cerebral vessels. The PI index is an arterial blood-flow velocity waveform index designed to quantify the pulsatility or oscillations of the waveform. It is calculated by the formula PI = (Vmax – Vmin)/Vmax mean, where Vmax is the peak systolic velocity, Vmin is the minimum forward diastolic velocity in unidirectional flow, or the maximum negative velocity in diastolic flow reversal, and Vmax mean is the maximum velocity averaged over one cardiac cycle (Figs. 2.2 and 2.3). Cerebral vasodilatation produces a decrease in left ventricular afterload, while increased placental and systemic resistance result in an increased right ventricular afterload. In severe

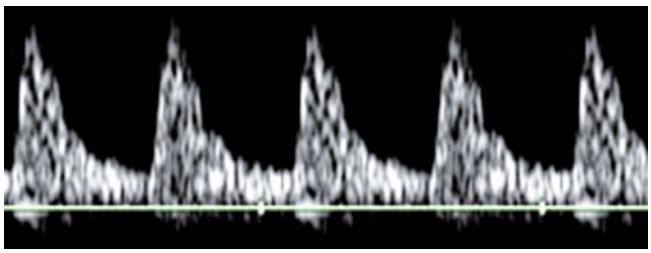

Fig. 2.2 Flow velocity waveforms from the middle cerebral artery in a normal fetus

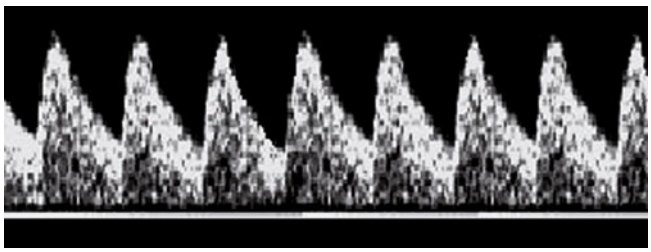

Fig. 2.3 Flow velocity waveforms from the middle cerebral artery in a growth-restricted fetus

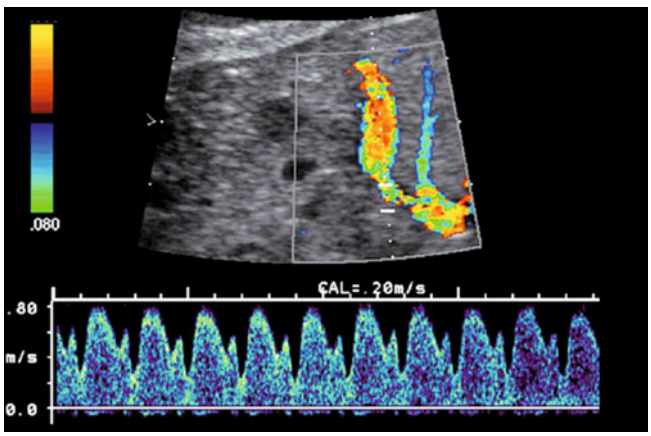

Fig. 2.4 Color Doppler examination of the ductus venosus with normal flow velocity waveforms

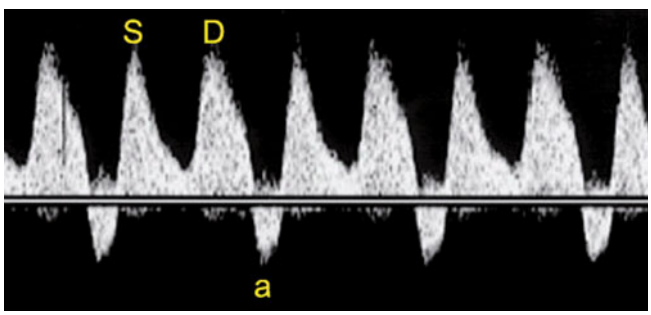

Fig. 2.5 Abnormal DV wave form with reversal of flow during atrial contraction and markedly increased pulsatility systole (*S*), diastole (*D*), atrial contraction (*a*)

hypoxemia, there is also redistribution of umbilical venous blood towards the ductus venosus (Figs. 2.4 and 2.5). Consequently, blood flow in the umbilical vein, which contributes to the fetal cardiac output, is increased. In contrast, a reduced afterload is associated with an increase in peak diastolic forward flow, indicating that fetal systemic vascular resistance has a major influence on venous return and filling patterns of the right heart. Increased placental resistance and peripheral vasoconstriction cause an increase in right ventricular afterload, and thus ventricular end-diastolic pressure increases. This may result in highly pulsatile venous blood flow waveforms and umbilical venous pulsations due to the transmission of atrial pressure waves through the ductus venosus.

2.6 Fetal Response to Injury

During normal development, cardiovascular and circulatory functions progress from fetal life, which is characterized by low PaO_2 (20–24 mmHg; 2.66–3.19 kPa) through transition at birth, to normoxemia after birth (PaO_2 70–80 mmHg; 9.31–10.64 kPa); the fetus and newborn are clearly able to thrive despite their "hypoxic" environment. Adaptive responses by the cardiovascular, metabolic and endocrine systems, allow fairly severe intrauterine hypoxic stress to be tolerated, with the fetus having relatively normal growth and development. However, severe acute or chronic intrauterine hypoxic stress in utero can cause compromised circulation, organ dysfunction, and threaten survival or intact survival. At the time of transition to extrauterine life, signs of a depressed circulatory system because of intrauterine hypoxia may become apparent because of the increased metabolic demands at birth, and loss of placental gas exchange [25]. Acute hypoxemia produces various circulatory adaptations in the fetus that enhance fetal survival, including the development of tachycardia, hypertension, redistribution of blood flow toward the brain, myocardium and adrenals, and depression of fetal breathing and skeletal muscle activity. The fetal heart also has a greater capacity for anaerobic metabolism than the adult heart [26].

The neonatal brain is more resistant to acute hypoxia than the brain of an older child or adult. Nevertheless, hypoxia affecting the fetus or newborn is a major cause of mortality and chronic neurologic disability. The outcome for infants sustaining cerebral hypoxia and ischemia is influenced by many factors, including the duration and severity of the event, and associated infectious, traumatic, or metabolic (especially hypoglycaemic) derangements [27]. Repetitive episodes of severe hypoxia may cause global neuronal, cortical, midbrain, and cerebellar damage, even if there has been initial "sparing" of the CNS.

Damage may cause cerebral palsy and developmental disabilities in later life. The fetus of a high-risk pregnancy may experience such damage before birth, with recovery of biochemical markers of distress, such as metabolic acidosis so that these are not apparent after birth [27]. If myocardial contractility is impaired following severe or sustained hypoxia, the resultant reduction in cardiac output may further compromise cerebral blood flow and other organ perfusion. Again, depending on the degree of insult, this can be associated with acute myocardial dilatation and consequent tricuspid regurgitation, myocardial ischemia, and hypotension.

Renal impairment is commonly reported following a generalised hypoxic-ischemic insult at birth. The degree of insult varies in effect from oliguria with minor electrolyte abnormality and minimally elevated creatinine, to complete renal failure requiring dialysis.

An elevated blood concentration of liver enzymes, as a marker of hepatocellular injury due to perinatal hypoxia, is also common after acute hypoxia, but irreversible liver damage is rare.

Fetal cardiovascular and endocrine responses may be altered, both in acute and in chronic hypoxia. Recurrence of mild hypoxia may occur in pregnancies where the blood flow to placenta, uterus, and fetus is repeatedly compromised by physiological and environmental influences. In chronic hypoxia, fetal growth restriction is not uncommon, and depression of growth factors during hypoxia has an important protective effect in conserving fetal substrate for energy as opposed to growth needs [28, 29]. The full-term infant, while more likely to survive a severe hypoxic-ischemic insult at birth than a preterm infant (approximately 70% *vs* 30%), is also more likely to have significant long-term morbidity [30].

2.7 Postnatal Development

2.7.1 Adaptation to Extrauterine Life

With the first breath after birth, changes in the cardiopulmonary system occur. The first challenge for a newborn is the provision of oxygen by independent breathing instead of utilizing placental oxygen. With the first breaths, there is a fall in pulmonary vascular resistance, and an increase in the surface area available for gas exchange. As the pulmonary vascular resistance falls, there is a corresponding increase in systemic vascular resistance due to loss of the low-resistance placental circulation. These two changes result in a rapid redistribution of blood flow to the pulmonary vascular bed from approximately 4% to 100% of the cardiac output, with an increase in blood oxygen delivery. The consequent increase in pulmonary venous return results in the left atrial pressure being slightly higher than the right atrial pressure, which closes the foramen ovale. This changed flow pattern results in decreased blood flow across the ductus arteriosus and the higher blood oxygen content stimulates the constriction and ultimately the closure of this fetal circulatory shunt. The umbilical vein and the ductus venosus close off within two to five days after birth, leaving behind the ligamentum teres and the ligamentum venosus of the liver, respectively.

These cardiovascular system changes result in a transition from fetal to adult circulation pattern. During this transition, some types of congenital heart disease that were not symptomatic in utero when there was a fetal circulation will present with cyanosis or respiratory signs (see Chapters 75 and 76).

2.7.2 The Preterm Fetus

In Europe and many developed countries, the preterm birth rate is generally 5–9%, and in the USA it has risen to 12–13% in the last decades. There are three categories of preterm birth: (1) spontaneous preterm births are the 40–45% preterm births that follow preterm labour of spontaneous (i.e. idiopathic) onset; (2) 25–30% preterm births occur after premature rupture of the membranes; (3) the remaining 30–35% are preterm births that are induced for obstetric reasons. Full-term pregnancy is from 37 to 41 completed weeks and babies born just a few weeks earlier usually do not experience any problems related to their slight prematurity. However, the more premature these infants are, the more serious are the complications.

The term intrauterine growth restriction (IUGR) describes a condition in which the fetus is smaller than expected for the number of weeks of pregnancy. Newborn babies with IUGR are often described as small for gestational age (SGA). A fetus with IUGR often has an estimated fetal weight below the tenth percentile and may be born at term (after 37 weeks of pregnancy) or prematurely (before 37 weeks). IUGR refers to a condition in which a fetus is unable to achieve its genetically determined potential size. This functional definition seeks to identify a population of fetuses at risk of poor outcome. The clinician's challenge is to identify IUGR fetuses whose health is endangered in utero because of a hostile intrauterine environment and to monitor and intervene appropriately. Increasingly, data support the notion that long-term consequences of IUGR last well into adulthood. These individuals are predisposed to the development of a metabolic syndrome later in life, manifesting as obesity, hypertension, hypercholesterolemia, cardiovascular disease, and type 2 diabetes. Several hypotheses suggest that intrauterine malnutrition results in insulin resistance, loss of pancreatic beta-cell mass, and an adult predisposition to type 2 diabetes. Although the causative pathophysiology is uncertain, the risk of a metabolic syndrome in adulthood is increased among individuals who were IUGR at birth [31]. In addition to an increased risk for physical sequelae, mental health problems have been found more commonly in children with growth restriction.

2.7.3 Diagnosis

Fetal arterial Doppler studies are useful in the differential diagnosis of SGA fetuses. In normal pregnancies, umbilical artery (UA) resistance shows a continuous decline as the pregnancy progresses; but this does not occur in fetuses with uteroplacental insufficiency.

The most commonly used measure of gestational age-specific UA resistance is the systolic-to-diastolic ratio of flow, the Pulsatility Index (PI), which increases with worsening disease. As the insufficiency progresses, end-diastolic velocity is lost and eventually reversed. The status of UA blood flow supports the diagnosis of IUGR and provides early evidence of circulatory abnormalities in the fetus, helping clinicians to identify these high-risk fetuses. UA Doppler measurements may help the clinician decide whether a small fetus is truly growth restricted and to identify a small fetus at risk of chronic hypoxemia. In hypoxemic fetuses with impaired placental perfusion, the PI in the umbilical artery is increased and the fetal middle cerebral artery PI is decreased; consequently, the PI ratio of the umbilical artery to middle cerebral artery (UA/MCA) is increased. However, the UA/MCA ratio does not appear to correlate significantly with outcome after 34 weeks.

Investigations of the venous vascular system have become increasingly important in the assessment of fetal myocardial function, and different indices are used to evaluate the blood flow velocity during the different phases of the cardiac cycle in the ductus venosus. Reference values for ductus venosus flow velocities are represented by ventricular systole (S wave) and diastole (D wave), the lowest forward velocity during atrial contraction (A wave). Different indices are calculated, e.g., the S/A ratio. The most important parameter which represents the final stage of disease is the abnormal reversal of blood flow velocities in the ductus venosus, inducing an increase in the S/A ratio, mainly due to a reduced A component of the velocity waveforms. Reference values should be used for ductus venosus flow velocities during ventricular systole (S wave) and diastole (D wave), the lowest forward velocity during atrial contraction (A wave) and different calculated indices as the S/A.

In the inferior vena cava, there is an increase of reverse flow during atrial contraction with progressive fetal deterioration, suggesting a higher pressure gradient in the right atrium. (Figs. 2.6 and 2.7). A high venous pressure induces a reduced velocity at end-diastole in the umbilical vein, causing typical

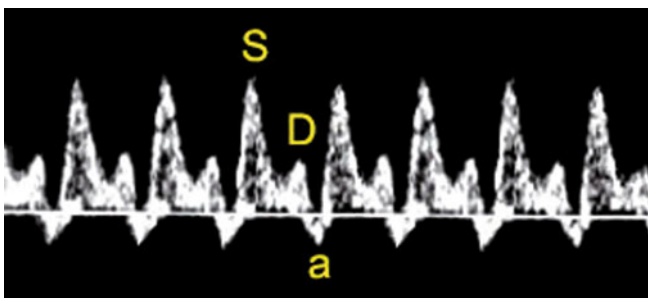

Fig. 2.6 Doppler examination of the inferior vena cava with normal flow velocity waveforms

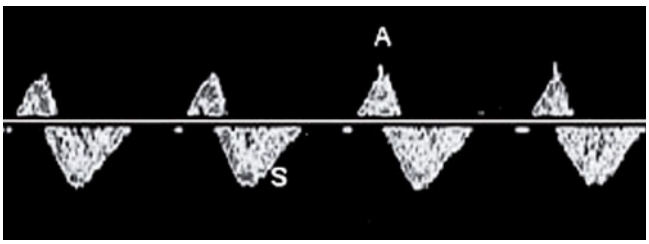

Fig. 2.7 Abnormal waveform with increase in reversed flow during atrial contraction in a growth-restricted fetus

end-diastolic pulsations. The development of these pulsations is close to the onset of abnormal fetal heart rate patterns and is frequently associated with acidemia and fetal endocrine changes. At this stage, there may be an increased coronary blood flow velocity compared with that seen in normally grown third-trimester fetuses and, if the affected fetus is not delivered, intrauterine death may occur within a few days.

2.7.4 Fetal Hemodynamic Aspects

Although the usual definition of preterm birth is birth before 37 weeks' gestation, a useful pragmatic definition for a "premature" infant is one who has not yet reached the level of fetal development that generally allows life outside the womb. In the normal human fetus, several organ systems mature between 34 and 37 weeks, and the fetus reaches adequate maturity by the end of this period. One of the main organs greatly affected by premature birth is the lung.

In umbilical venous blood, mild hypoxemia may be manifest through an absence of hypercapnia or acidemia. In severe uteroplacental insufficiency, the fetus cannot compensate hemodynamically, and hypercapnia and acidemia increase exponentially [32]. Hypoxemic growth-restricted fetuses also demonstrate a range of hematological and metabolic abnormalities, including erythroblastosis, thrombocytopenia, hypoglycemia, deficiency in essential amino acids, hypertriglyceridemia, hypoinsulinemia and hypothyroidism. Low birth weight increases the risk for perinatal mortality (death shortly after birth), asphyxia, hypothermia, polycythemia, hypocalcemia, immune dysfunction, neurologic abnormalities, and other long-term health problems [33].

2.7.5 Timing of Delivery and Management

In August 2004, *The Lancet* published data on brain development in survivors of the multicenter Growth Restriction Intervention Trial (GRIT) [34]. The aim of this study was to identify compromised fetuses between 24 and 36 weeks' gestation and answer the question of whether it was safer to deliver them immediately or to delay until there was no clinical doubt that delivery was necessary. Five-hundred and eighty-eight such fetuses were identified in 69 hospitals in 13 European countries. In the GRIT study, the 24 week gestation babies were very different from those at 36 weeks. In the absence of severe congenital abnormalities, the current infant mortality after 32 weeks' gestation is low: the causes of this rare event include asphyxia, necrotising enterocolitis and infection; respiratory distress syndrome is rare in this group. By contrast, before 32 weeks, and particularly in the extreme preterm fetus, there is a much higher mortality, and the levels of morbidity were recently emphasised by the EPICure Study, in which 49% of surviving infants born at less than 26 weeks' gestation had some disability at 30 months of age and 19% were severely disabled [35]. The EPICure study reached some important conclusions. It demonstrated that 44% of infants born at 25 weeks' gestation survived to discharge, whereas delivery at 22 weeks almost invariably resulted in neonatal death.

Neonatologists, obstetricians and parents must increasingly recognise that infants born less than 25 weeks' gestation who survive are at risk of disability at school age. In the EPICure study, only 20% were totally free of disability at school age and so the prognosis must be guarded. Disability was classified as follows:

1. *Severe*: the child was likely to be highly dependent on care-givers, e.g., non-ambulant cerebral palsy, profound hearing loss or blindness.
2. *Moderate*: children who were likely to be reasonably independent, e.g., ambulant cerebral palsy, some hearing loss, some visual impairment.
3. *Mild*: children with neurological signs with minimal functional consequences.

In the EPICure study, over half of the survivors had moderate disability or no disability at school age. In addition, some of the 24% with moderate disability were improved with spectacles and hearing aids.

There is uncertainty about whether iatrogenic delivery of the very preterm (before 33 weeks of gestation) growth restricted fetus should be undertaken before the development of signs of severe hypoxemia, with a consequent risk of prematurity-related neonatal complications, or whether delivery should be delayed, incurring risks of prolonged exposure to hypoxia and malnutrition imposed by the hostile intrauterine environment [36]. With every week that passes, there is a decreasing risk of complications including intraventricular hemorrhage, retinopathy of prematurity and sepsis. However, delay may expose the growth-restricted fetus to ischemic injury of the brain, resulting in asphyxia, periventricular leukomalacia and intraventricular hemorrhage, as well as a significant risk of intrauterine death. It is important to weigh the risks and benefits of early interventions. This is a dynamic process, in which advancements in both fetal and neonatal medicine are of crucial importance for the appropriate counselling of parents and the management of these pregnancies.

The GRIT study showed a small increase in fetal death if the obstetrician delayed delivery, and a small increase in

Table 2.2 Suggested management of the preterm fetus

What to do	Perform parental counselling Share any type of decisions with the neonatologist, the anesthesiologist and the couple, personalizing the specific situation Fill the informed consent as much detailed as it is possible
Considering	Short-term consequences: RDS, NEC, IVH, PVL, pulmonary dysplasia, sepsis Long-term consequences: cerebral palsy, mental impairment, attention disorders Pregnancy age and prognosis age Etiology of the preterm labour (maternal causes, fetal causes) Maternal mortality related to the type of delivery Fetal presentation Obstetric anamnesis of the patient Combination of the multiple factors
When	Better after 26 weeks Using corticosteroids between 48 hours and 7 days before delivery
Where	Any hospital with NICU
How	Trying to reduce the effects of the hypoxia Balance maternal and fetal morbidity Preterm delivery is not itself an indication of cesarean section unless associated with maternal or fetal consequences

neonatal death if early delivery was chosen. Thus the monitoring of fetal health is particularly important if there is growth restriction. Such fetuses have few metabolic reserves, and sudden death during pregnancy may occur. Labor is an intermittently hypoxic event, and anaerobic metabolism may not be an option when there are inadequate stores of fat and glycogen.

In recent years, placental and fetal arterial Doppler flow-velocity waveforms have guided the timing of delivery. Doppler has been particularly effective in assessing the growth-restricted pregnancy and has been a useful adjunct for the assessment of the very preterm fetus, when cardiotocographical monitoring is unhelpful. However, in the growth-restricted hypoxemic fetus, redistribution of well-oxygenated blood to vital organs, such as the brain, heart and adrenals, represents a compensatory mechanism to prevent fetal damage, and when the reserve capacities of the circulatory redistribution reach their limits, fetal deterioration may occur rapidly. In clinical practice, serial Doppler investigations estimate the duration and degree of fetal blood flow redistribution. The onset of an abnormal venous Doppler recording indicates deterioration in the fetal condition and iatrogenic delivery should be considered.

In conclusion, the goal in the management of the preterm fetus is to deliver the most mature fetus possible, at least at 32–34 weeks, in the best condition possible while minimizing the risk to the mother (Table 2.2). There is lack of a firm evidence base and IUGR fetuses remain a challenging problem for clinicians. Most cases of IUGR occur in pregnancies in which no risk factors are present and the clinician must therefore be alert to the possibility of growth disturbance in all pregnancies. No single measurement secures the diagnosis and a complex strategy for diagnosis and assessment is therefore necessary. The current therapeutic goals are to optimize the timing of delivery to minimize hypoxemia and maximize gestational age and maternal outcome.

General Characteristics of Preterm and Term Newborn

Stefano Parmigiani, Daniela Gianotti and Giulio Bevilacqua

The aim of both parents and healthcare professionals is to achieve a normal healthy infant. This chapter deals with some general principles.

3.1 History

A full family history is essential. This should include a full medical and social history. Note should be taken of alcohol ingestion and of any drugs (prescribed or recreational). It should enquire about the possibility of consanguinity – the question, "Are your families related?" to both parents is one way of approaching this often delicate subject. Enquiry should be made about the presence of possible transmissible and inheritable diseases in the families of both parents. Tall or short stature can generate a search for specific undiagnosed diseases in the parents (e.g., Marfan syndrome, gluten intolerance, achondroplasia). Anemia in the parents can be a marker of a hematological defect (e.g., thalassemia), as well as the place of origin and ethnicity of the parents (e.g., G6PD deficiency).

3.2 History of the Pregnancy and Delivery

A baby's well-being is determined by periconceptional events. The mother's medical history is important, including the possibility of maternal diabetes mellitus and other illnesses and her immune status (HBV, HCV, HIV, CMV, toxoplasmosis, rubella, HSV-HZV, and syphilis). The possibility of seroconversion during pregnancy should be considered. Enquiry should be made about the course of the pregnancy. Account should be taken of the time of booking for antenatal care (late booking may be a sign of a disorganized life style and associated problems).

S. Parmigiani (✉)
Department of Pediatrics and Neonatology
Eastern Liguria Hospital, La Spezia, Italy

The results of antenatal checks should be noted: fetal growth and ultrasound results, amniotic fluid volume, maternal anemia, urine results and maternal diabetes mellitus, pregnancy-induced hypertension or pre-eclampsia. The results of vaginal or anal bacterial swabs within the month before delivery should be noted (group B streptococci or *Listeria monocytogenes*) and whether the mother was given appropriate intra-partum antibiotic prophylaxis.

A history of the pregnancy should include note of drugs taken during the pregnancy and their indications. Consider evidence of infectious illnesses or fever close to the time of delivery and take note of the timing of membrane rupturing and the quantity and color (blood or meconium staining) of the amniotic fluid.

Details of the delivery should be noted, i.e., whether vaginal, operative (forceps of vacuum extraction), cesarean section (planned or emergency, before or during the labor), and evidence of fetal distress.

The baby's presentation should be noted because abnormal limb position may be due to a breech presentation. The possibility of birth trauma (e.g., cephalhematoma, fracture of the clavicle) should be considered.

Adaptation to postnatal life should be considered, bearing in mind that during the first hours after birth the baby is in a transitional period, passing from intra- to extrauterine life.

A baby's condition during the minutes just after birth is described by the Apgar score, usually recorded at 1 and 5 minutes (see Table 3.1). Although the Apgar score may be criticized (it is subjective on the part of the observer, often recorded some time after delivery), in its favor, it is almost universally recorded. The score was described in 1953 by Dr Virginia Apgar, a North American pediatric anesthetist. She intended it to indicate whether or not resuscitation was needed. Although imperfect, there is no doubt that a low score (0 or 1, signifying an absent slowly beating heart) indicates a baby who is barely alive at the time of birth, and a score of 8 or more indicates an individual whose general condition is good. However, the Apgar score is an imperfect indicator of subsequent progress or outcome. A baby who has

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

Table 3.1 Apgar Score

Sign	0	1	2
Appearance (colour)	Blue or pale	Pink body with blue extremities	Completely pink
Pulse (heart rate)	Absent	< 100 beats/min	> 100 beats/min
Grimace (reflex irritability)	No response	Grimace	Cough or sneeze
Activity (muscle tone)	Limp	Some flexion	Active movements
Respiration	Absent	Slow, irregular	Good, crying

a high initial score may develop difficulties with gas exchange in the minutes that follow, even if these problems are transient.

Most healthy babies are inclined to breastfeed during the first hour of life, and babies recognize their mother's smell.

A baby's size is an indicator of intrauterine development and nutrition. Intrauterine growth restriction can be a consequence of poor placental function (e.g., due to diseases such as pregnancy-induced hypertension, systemic lupus erythematosus, cocaine ingestion, infection) and congenital disease, chromosomopathy, or fetal alcohol syndrome.

Observation of a baby's movements when undressed and preferably in the presence of one or both parents, allows for observation of the quality of movements (whether symmetrical, coordinate and smooth).

Eyes may be difficult to examine at birth because there is often some eyelid edema, but they must be checked later to note the presence of a red reflex. In the case of babies who are discharged early from hospital, this may need to be done at home by the family doctor or community midwifery team.

Lips, gums and palate must be examined to exclude the presence of a cleft or other malformation.

The hips should be examined to exclude congenital dislocation. During the immediate neonatal period, the ability to achieve full abduction is a useful sign. It may only be possible to elicit a positive Ortolani sign, an index of hip luxation/subluxation, later during the first week.

Arms, legs, fingers and toes should be examined to identify any abnormality (e.g., webbing, number, length). Examination of the chest should note any asymmetry during respiration, subcostal or intercostal retraction, ancillary nipples. The skin may show areas of hypo- or hyper- pigmentation, scars, blisters, pustules, petechiae, or evidence of birth trauma (cuts, bruises). The diaper area should be examined to look for anomalies of the external genitalia, an imperforate or anterior anus, and hairy tufts or dimples over the sacrum.

3.3 Clinical Aspects of CNS Development

Motor and sensory functions mature during pregnancy and are already in great part developed by the middle of the second trimester of pregnancy and the process continues after birth. Ultrasound, particularly so-called 4D ultrasound, allows for the identification and classification of fetal movements, and natural fetal behavior has been studied. Sporadic, irregular ("vermiform") movements are seen between 6 and 7 weeks' gestation, involving the whole body. Generalized, brief movements from the legs to the neck and head (such as "startle") are observed at 8 weeks' gestation. At 9 weeks, flexor movements of the cranial and caudal poles towards the centre appear, interspersed with jerks that allow small movements within the amniotic liquid and partial rotation of the head. At the tenth week, hand-to-head movements, mouth opening with tongue protrusion, swallowing, rotation along the longitudinal axis and independent movements of limb flexion and extension can be observed [1, 2].

The maturation of the central nervous system (CNS) determines an infant's response and tolerance to various sensory inputs. A premature infant may demonstrate signs of immaturity [3] such as:

- Diffuse and indeterminate sleep or waking states with frequent whimpering, facial twitches or apparent smiling
- Abrupt transitions between states
- Periods of fussiness or crying
- Low-level alertness, characterized by a dull, glassy-eyed look
- Hyper-alertness, characterized by wide-open eyes with a panicked, worried look; an appearance of extreme vigilance
- Uncoordinated eye movements: roving or floating eyes
- Immature tone, posture and general coordination.

The five senses can be altered by prematurity:

1. The earliest response to auditory stimulation has been recorded at 19 weeks' gestation, but consistent responsiveness is established by 25 weeks. Deafness is a complication of intraventricular hemorrhage or periventricular leukomalacia affecting 5–10% of preterm infants. It may also be the result of a cytomegalovirus infection, which may have caused preterm delivery. The ambient noise of a NICU is rarely less than 40 dB (as in the womb), and more often around 70–100 dB [4].
2. Functional maturation of the visual system starts at around 5 months and it is still immature at term [5]. Retinopathy of pre-maturity (ROP), formerly known as retrolental fibroplasia and affecting premature babies exposed to excessive oxygen, is nowadays largely preventable: oxygen delivery is monitored carefully and all infants below 32

weeks' gestation have regular examination of the retina following a generally accepted international protocol. Advanced stages of ROP are treated by cryo- or laser- therapy. However, decreased visual acuity or strabismus may follow. Nowadays, total blindness is infrequent.

3. Taste develops under the influence of amniotic fluid flavonoids and odorants transmitted from the maternal diet from as early as 14 weeks' gestation. Taste after birth can be disturbed by drugs, by the late introduction of oral feeding, or by the impaired development of taste centers.
4. The sensory system starts to develop at 8 weeks and is functional by 12 weeks' gestation. Being touched may be uncomfortable even for full-term infants who have not developed all the receptors and pathways, and perception may also be disturbed by drugs, e.g., maternal cocaine use. In the preterm infant, touch may be a powerful stressor. Touch should be gentle and combined with the stimulation of other senses, for example, speaking to the baby. Touching for no good reason should similarly be avoided. Parents should be taught to touch gently and about "kangaroo care".
5. The olfactory tract is part of the primitive encephalon and a baby at term is able to recognize its mother's odor. The olfactory system is fully functional by 14 weeks' gestation. Strong odors can be stressful for preterm babies who are unable to communicate this to their carer.

These signs of immaturity should be recognized and a favorable environment should be created, avoiding overstimulation. Woolf [6, 7], Brazelton [8] and Prechtl [9] described different states of behavior. The Brazelton scale assesses neonatal behavior in six states: quiet sleep, active sleep, drowsiness, alert inactivity, active awake, crying (Table 3.2). The baby should be observed in a state of quiet wakefulness.

3.4 The Preterm Infant

Maturity is determined by the length of gestation, and the severity of problems related to pre-maturity are directly related to gestation.

Weeks of gestation are generally considered as completed weeks. The World Health Organization has defined preterm infants as those with gestational age less than 37 weeks. Recently, the term "late preterm infants" (instead of "near-term") has been used for those infants that are born at a gestational age between 34 weeks, and 36 weeks and 6 days. These infants have a rather higher morbidity and mortality than term infants (gestational age ≥ 37 weeks), even though they are of similar size [6–9]. Some North American authors have also used the terms "premies" and "micropremies" to describe very immature babies.

Classification by birth weight is as follows:

- *low birth weight* (LBW), 1501–2500 g;
- *very low birth weight* (VLBW), 1001–1500 g;
- *extremely low birth weight* (ELBW), ≤ 1000 g.

Because of the survival of very light and premature babies, the term "incredibly low birth weight" has been used to refer to babies weighing less than 750 g.

A fundamental problem for all preterm infants is their poor ability to maintain body temperature, because of reduced glycogen stores (depending on gestational age) and thinner skin, with the most immature lacking the ability to shiver. Thus a primary aim is to avoid heat loss (and insensible water losses) by drying, heating, and covering the baby. This also decreases glucose consumption, reducing the risk of hypoglycemia.

The preterm baby often experiences delayed respiratory adaptation. Depending on the degree of immaturity, the lungs

Table 3.2 Neonatal states classification scale

State	Characteristics
Quiet sleep	Regular breathing, eyes closed. Spontaneous activity confined to startle and jerky movements at regular intervals. Responses to external stimuli are partially inhibited, and any response is likely to be delayed. No eye movements, and state changes are less likely after stimuli or startles than in other states.
Active sleep	Irregular breathing patterns, sucking movements, eyes closed but rapid eye movements can be detected underneath the closed lids. Infants also have some low-level and irregular motor activity. Startles occur in response to external stimuli and can produce a change in state.
Drowsiness	While the newborn is semi-dosing, eyes may be open or closed; eyelids often flutter; activity level variable and interspersed with mild startles. Drowsy newborns are responsive to sensory stimuli but with some delay, and state change frequently follows stimulation.
Alert inactivity	A bright alert look, with attention focused on sources of auditory or visual stimuli; motor activity is inhibited while attending to stimuli.
Active awake	Eyes open, considerable motor activity, thrusting movements of extremities, and occasional startles set off by activity; reactive to external stimulation with an increase in startles or motor activity. Discrete responses are difficult to distinguish due to general high activity level.
Crying	Intense irritability in the form of sustained crying, and jerky limb movement. This state is difficult to break through with stimulation.

Data from [8].

are morphologically immature and lack surfactant. Such babies may require the endotracheal administration of exogenous surfactant and mechanical ventilation. Bronchopulmonary dysplasia (chronic lung disease with O_2 dependency) is a complication of severe prematurity, which may continue to cause problems during subsequent years.

Premature infants have reduced immune defences. Furthermore, infection may be the primary cause of preterm delivery, sometimes affecting the baby before birth. Such infections, in combination with lung and brain immaturity, increase the risk of later disability (see Chapter 18).

The gastrointestinal tract is not yet adapted to enteral feeds, posing considerable challenges to those responsible for their care. Early non-nutritive feeding should be considered. Milk, preferably from the mother or a human milk bank may be started early but cautiously, particularly for the most immature infant. Careful note should be taken of early signs of gastrointestinal intolerance, e.g., increased volume or bile-staining of gastric aspirates or abdominal swelling. The most immature infants require parenteral nutrition (partial or total) to provide adequate nutrients and calories for growth, and this may need to be continued for several weeks. This practice requires a central, indwelling catheter, increasing the risk of infection.

Because of advances in the care of these very vulnerable infants, survival at the earliest gestation is improving.

Survival at early gestation and the associated risks of neurodevelopmental impairment are considered elsewhere (see Chapter 21).

Not only babies at extremely low gestation, but also those born late preterm are at risk.

Various evidence points to the environment being of major importance for appropriate development. Although neonatologists strive to recreate an extrauterine environment that is similar to that of the womb, there are many differences.

Light, painful interventions, development in air instead of surrounded by amniotic fluid, noise, stress, sleep-wake cycles interrupted by nursing procedures, continuous intravenous nutrition (without the intermittent glycemic peaks of normal feeding and maternal ingestion), fluctuations in oxygen delivery, carbon dioxide and pH levels and blood pressure may all interfere with normal brain development. A high tech/soft touch approach may be beneficial and a mother's touch and breastfeeding should be encouraged even for very tiny babies.

In some units, parents are supported by a psychologist to help with attachment. In spite of the best endeavors of staff, having a baby in a neonatal unit, often for several months, is undoubtedly stressful, giving rise to feelings of inadequacy on the part of the mother, who may feel a biological failure, and anxiety on the part of the father, who is no longer in control of the situation.

Risk Factors for Gestational Diseases

Maria De Bonis, Michela Torricelli and Felice Petraglia

4.1 Introduction

Preterm delivery (PTD) and pre-eclampsia (PE) are severe pathologies that may affect and compromise the course of pregnancy, and adverse pregnancy outcomes are important causes of perinatal morbidity and mortality [1].

Interventions to reduce the morbidity and mortality related to PTD and PE can be classified as primary (detected in all women before or during pregnancy to prevent and reduce risk); secondary (aimed at eliminating or reducing risk in women with known risk factors); or tertiary (initiated after labor has begun, with a goal of preventing delivery or improving outcomes for preterm infants).

Most obstetric interventions to reduce morbidity and mortality are classified as tertiary, but the primary prevention of prematurity-related illness is desirable.

4.2 Preterm Delivery

PTD, defined as birth before 37 weeks' gestational age, occurs with an incidence of 7–11% and represents one of the predominant causes of perinatal mortality and morbidity [2]. Very PTD is birth before 32 weeks and extremely preterm delivery before 28 weeks of gestation [3]. PTD is a syndrome initiated by various conditions, such as inflammation/infection, uteroplacental ischemia or hemorrhage, uterine overdistension, cervical disease, stress and endocrine disorders, and other immunologically mediated processes [4]. Several risk factors cause a transition from uterine quiescence to PTD, which may be associated with preterm premature rupture of membranes (PPROM). Many of the risk factors are associated with increased systemic inflammation, and this pathway might explain some of the increases in PTD associated with multiple risk factors [5].

4.2.1 Risk Factors for Preterm Delivery

Various maternal and fetal characteristics have been associated with PTD. These include maternal demography (e.g. poor socio-economic status, ethnicity, age), poor nutritional status, pregnancy history, characteristics of the present pregnancy, and associated conditions (e.g., smoking, alcohol ingestion, drugs of abuse (particularly cocaine and opiates), infection, uterine contractions and cervical length, and biological and genetic markers (Table 4.1) [6].

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

4.2.1.1 Preconceptional Factors

- *Socio-economic characteristics*: Black women are three times more likely to have a very early PTD than women from other ethnic groups [7]. Low socio-economic status, low and high maternal age, and being unmarried are also associated with PTD [8].
- *Previous PTD*: The recurrence risk in women with a previous PTD ranges from 15–50%, depending on the number and gestational age of previous deliveries. The risk of another PTD is inversely related to the gestational age of the previous PTD [9].
- *Interval between pregnancies*: An interpregnancy interval of less than 6 months confers a greater than two-fold increased risk of PTD [10].
- *Nutritional status*: A low pregnancy body-mass index (BMI) is associated with high risk of spontaneous PTD. Women with low serum concentrations of iron, folate, or zinc have more PTD than those with measurements within the normal range [11].

4.2.1.2 Maternal Disorders

- *Systemic diseases*: Thyroid diseases, asthma, diabetes and hypertension, are associated with increased rates of PTD.
- *Local or systemic infections*: Infections, such as pyelonephritis and asymptomatic bacteriuria, pneumonia and appendicitis, are associated with PTD [12]. Periodontal disease appears to have an increased risk independent of other factors [13].
- *Previous uterine surgery*: History of myomectomy, cervical cone biopsy sample or loop electrocautery excision procedures have been associated with an increase in spontaneous PTD [14].

4.2.1.3 External Factors

- *Stress*: Mothers experiencing psychological stress are at increased risk of PTD. Although the mechanism underlying the link between psychological or social stress and increased risk of PTD is unknown, a role has been proposed for corticotropin-releasing hormone [15].
- *Smoking*: Tobacco use increases the risk of PTD. Both nicotine and carbon monoxide are powerful vasoconstrictors, and are associated with placental damage and decreased uteroplacental blood flow, leading to fetal growth restriction and PTD [16].
- *Drugs of abuse*: Several maternal drugs affect the developing fetus and the baby after birth may manifest signs attributable to withdrawal. Maternal cocaine, opiate and diazepam use are particularly relevant, as is a history of excessive alcohol ingestion, especially binge drinking.

4.2.1.4 Pregnancy-Associated Risk Factors

- *Multiple pregnancy*: Multiple gestations carry a risk of PTD, and result in 15–20% of all PTD. Uterine overdistension, resulting in contractions and PPROM, is believed to be the causative mechanism for the rate of increased spontaneous PTD [16].
- *Intrauterine infection*: Intrauterine infection is an important mechanism leading to PTD. The mechanisms by which intrauterine infection lead to PTD are related to activation of the innate immune system. Microbial endotoxins and proinflammatory cytokines stimulate the production of prostaglandins and matrix-degrading enzymes. Prostaglandins stimulate uterine contractility, whereas degradation of the extracellular matrix in the fetal membranes leads to PPROM [4]. The microorganisms most commonly reported in the amniotic cavity are genital *Mycoplasma* [17].
- *Vaginal bleeding*: Vaginal bleeding caused by placental abruption or placenta praevia is associated with a very high risk of PTD, but bleeding in the first and second trimesters that is not associated with either placental abruption or placental praevia is also associated with subsequent PTD [18].
- *Bacterial vaginosis*: The mechanism by which bacterial vaginosis is associated with PTD is unknown, but microorganisms that cause the infection probably ascend into the uterus before or early during a pregnancy [19].
- *Cervical shortening and insufficiency*: During labor, the cervix shortens, softens, rotates anteriorly, and dilates. Both digital and ultrasound examinations of the cervix have shown that cervical shortening is a risk factor for PTD. The shorter the cervix, the greater the risk (<2.5 cm by vaginal ultrasound) [20].

4.2.1.5 Biochemical and Genetic Markers

Biological fluids (amniotic fluid, urine, cervical mucus, vaginal secretions, serum or plasma and saliva) have been used to assess the value of biomarkers for the prediction of PTD. Cytokines, chemokines and estriol are associated with PTD. The most useful biochemical PTD predictor is fetal fibronectin, a glycoprotein that when present in cervicovaginal fluid is a marker of choriodecidual disruption [21]. Although fetal fibronectin is normally absent from cervicovaginal secretions from 24 weeks until term, 3–4% of women undergoing routine screening at 24–26 weeks are positive, and at increased risk of PTD. A gene-environment interaction has been shown with maternal carriage of an allele of the tumor necrosis factor α (TNFα) gene and bacterial vaginosis. Genetic factors could also be involved for stress mediators of the maternal and fetal hypothalamic-pituitary axis, such as corticotropin-releasing hormone (CRH), prostaglandins and

oxytocin [22]. Several studies support the involvement of placental CRH in the mechanisms controlling the onset of labor. Maternal serum CRH concentrations are similar to the CRH curve of normal pregnancy, but with a higher level [23].

4.3 Pre-eclampsia

PE is defined as persistent blood pressure elevation, edema, and proteinuria first diagnosed after 20 weeks of gestation. The minimal criteria for the diagnosis of PE are proteinuria, defined as 300 mg or more of urinary protein excretion per 24 h, and hypertension, defined as blood pressure of 140/90 mmHg or higher [24]. PE affects 5–7% of all pregnancies and is responsible for 7–15% of maternal mortality. Severe and/or early-onset PE is an important cause of fetal and maternal morbidity and mortality. Neonatal outcomes are directly related to iatrogenic prematurity, although uteroplacental insufficiency may also be associated with the disease. The only known cure is cessation of pregnancy, although temporizing measures are often undertaken [25]. During endovascular cytotrophoblast invasion in the spiral arteries, an exaggerated inflammatory response and inappropriate endothelial cell activation are key features in the pathogenesis of PE.

4.3.1 Risk Factors for Pre-eclampsia

Several studies identified risk factors for early detection of PE (Table 4.2) [26].

Table 4.2 Risk factors for pre-eclampsia

Preconceptional
- Nulliparity
- Previous pre-eclampsia
- Family history

Maternal disorders
- Chronic hypertension and renal disease
- Obesity, insulin resistance and gestational diabetes
- Thrombophilic disorders

External factors
- Stress

Pregnancy-associated risk factors
- Multiple pregnancy
- Congenital and chromosomal anomalies

Biophysical markers
- Uterine artery Doppler sonography

Biochemical markers
- hCG, Activin A, Inhibin A, PIGF and VEGF, PAPP-A

4.3.1.1 Preconceptional Factors

- *Nulliparity*: As consequence of an abnormal response to paternal antigens in fetoplacental unit.
- *Previous pre-eclampsia*: Mothers who had PE in their first pregnancy are at higher risk for the development of PE in a subsequent pregnancy, especially when PE is severe, occurs early during the pregnancy, or is associated with a low birth weight [27].
- *A family history of pre-eclampsia*: Severe PE and eclampsia have a familial occurrence. A family history of PE is associated with a three-fold increased risk of PE and a four-fold increased risk of severe PE.

4.3.1.2 Maternal Disorders

- *Chronic hypertension and renal disease*: The risk of developing superimposed PE is particularly increased in women with severe hypertension and in those with cardiovascular or renal disease. The incidence of superimposed PE increases in patients with chronic renal disease, especially if there is coexisting hypertension.
- *Obesity, insulin resistance, and gestational diabetes*: Obesity, insulin resistance, and glucose intolerance are strongly associated with non-pregnant hypertension. Essential hypertension is an insulin-resistant state itself. Obesity is probably the most common cause of insulin resistance and represents a risk factor for developing pregnancy-induced hypertension as well as PE [28]. There is a certain degree of insulin resistance and hyperinsulinemia in pre-eclamptic women during pregnancy. The insulin resistance appears to be based on a higher mean body mass index in women with PE. Overt type 1 diabetes mellitus is associated with an increased incidence of PE [25].
- *Thrombophilic disorders*: Patients with severe early-onset PE often have hemostatic or metabolic abnormalities, which are associated with a tendency to vascular thrombosis. There is an increased incidence of activated protein C (aPC) resistance or factor V Leiden mutation in women with a history of PE and/or adverse perinatal outcome [30]. Thus women with familial thrombophilia are at increased risk not only of PE, but also of fetal loss. Protein S deficiency and aPC resistance both result in an impaired aPC patway. This impairment appears to be associated with a more aggressive course of the pathologic changes (thrombosis, acute atherosis) in the spiral arteries [31]. Classic homocystinuria is the homozygous form of the autosomal recessively inherited cystathionine-β-synthase deficiency. The incidence of hyperhomocysteinemia increases the risk for pre-eclampsia, mainly for severe early-onset PE [32].

4.3.1.3 External Factors

- *Stress*: Working women have 2.3 times the risk of developing PE compared with non-working women [33].

4.3.1.4 Pregnancy-Associated Risk Factors

- *Multiple pregnancy*: The incidence and severity of PE, the incidence of eclampsia, and the incidence of early-onset PE are significantly increased in patients with twin pregnancies, who have a four-fold increased risk of PE [34].
- *Congenital and chromosomal anomalies*: Malformations of the male genital apparatus should be considered as risk factors for PE [35]. There is also an increased incidence of pre-eclampsia in cases of hydrops fetalis. Trisomy 13 can be associated with PE, supporting the argument for a fetal factor in the pathogenesis of PE [36].

4.3.1.5 Biophysical Markers

Reduced uteroplacental blood flow and placental ischemia leads to the release of placental factors with detrimental effects on the maternal vascular endothelium, leading to a rise in blood pressure and changes in the uterine artery flow velocities. In the early days, the most important predictors of PE were those related to the early recognition of raised blood pressure in the mother; more recently, there has been detection of impaired uterine artery blood velocities and particularly their wave forms by uterine artery Doppler sonography (notch) [37]. Assessed during midtrimester, such abnormal Doppler findings indicate a substantially increased risk for the development of PE [38]. Uterine artery Doppler sonography more accurately predicted PE than intrauterine growth restriction and the most powerful Doppler index for predicting PE was an increased pulsatility with notching in the second trimester.

4.3.1.6 Biochemical Markers

Trophoblastic abnormalities play a central role in the development of PE and precede the appearance of clinical signs and symptoms; some placental hormones change in the maternal circulation, indicating altered placental function. The levels of several placental hormones are elevated in maternal serum before the diagnosis of PE, and these may be considered preclinical manifestations of the earlier stages of the disease. Such hormones have therefore been proposed as early predictive markers of PE [23]. Women with PE in the third trimester have increased maternal serum human chorionic gonadotropin (hCG) levels. Maternal hCG levels are already increased in the second trimester in pregnancies that subsequently develop PE [39].

Maternal serum activin A and inhibin A levels are increased in the presence of hypertensive disorders [40, 41]. Because activin A is involved in the control of trophoblast cell differentiation in the first trimester [42], altered expression of this protein may affect placental invasiveness, resembling the pathogenesis of PE. Inhibin A is elevated several weeks before the onset of clinical signs of PE [39, 43]. However, when both proteins are measured at 15–19 weeks', inhibin A appears to be more sensitive than activin A in predicting early-onset PE culminating with delivery before 34 weeks [43].

Phosphatidylinositol-glycan biosynthesis class F (PlGF) and vascular endothelial growth factor (VEGF) are potent angiogenic factors, inhibited by the soluble form of the vascular endothelial growth factor receptor-1 (sVEGFR-1), also known as soluble fms-like tyrosine kinase-1 (sFlt-1), which may be considered the most important candidate for preventing of PE and also targets placental growth factor. PlGF and VEGF-A are expressed by trophoblasts and show altered expression patterns in PE, and particularly lower PlGF. sFLT-1 serum concentrations are also increased in PE and correlate with the severity of the disease [44].

Pregnancy-associated plasma protein A (PAPP-A) is a large glycoprotein complex, which is predominantly produced by the placenta. PAPP-A cleaves insulin-like growth factor binding protein (IGFBP)-4 and -5 [45] and, thereby, modulates the activity of insulin-like growth factor (IGF)-1 and -2. Moreover, PAPP-A has been suggested to play a role in human implantation [46]. Its circulating levels were found to be elevated after the onset of PE and lower in women who subsequently developed PE [47].

Epigenetic Mechanisms

Felicia M. Low, Emilia Tng and Peter D. Gluckman

5.1 Introduction

While phenotypic variation such as disease vulnerability has traditionally been viewed as being determined by the interaction between genes and the environment, it is now clear that this is over-simplistic. *Developmental plasticity* describes the phenomenon whereby development of the phenotype from a given genotype is influenced by developmental experiences, and phenotypic variation in turn influences how the individual interacts with its mature environment, thus affecting disease risk. It is now recognized that developmental plasticity is underpinned by epigenetic processes, which are environmentally-induced changes in the patterns and regulation of gene expression brought about by a set of modifications in DNA and DNA-associated molecules, without changes in the base sequence. Epigenetic processes are phylogenetically old, and the mechanisms involved modulate both gene dosage and the conditions under which genes are expressed. Developmental plasticity is but one of several processes which are effectuated by epigenetic mechanisms; in mammals other processes include transposon silencing, cell differentiation, X-inactivation in females and genomic imprinting.

This chapter describes several of the most extensively studied epigenetic mechanisms to date. Their involvement in the development of metabolic and cardiovascular diseases, which stem from maladaptive fetal responses; and imprinting disorders, which result from defects in the establishment or erasure of specific epigenetic marks, is discussed.

5.2 Epigenetic Mechanisms

Epigenetics, as used in the context of this chapter, refers to the molecular mechanisms that give rise to stable, mitotically heritable changes in gene function without a corresponding change in the DNA sequence. They include chromatin remodeling through histone modifications, DNA methylation, post-transcriptional control by regulatory RNAs, and genomic imprinting.

The genome in early life appears susceptible to environmentally induced epigenetic changes that can have persistent effects on structure and function.

5.2.1 Histone Modifications

In eukaryotes, DNA is wound around an octameric complex of histone proteins – two subunits each of the histones H2A, H2B, H3 and H4, forming the nucleosome (Fig. 5.1a). Chromatin is formed when nucleosomes are packaged closely, strung together by double-stranded DNA (Fig. 5.1b). Therefore, certain covalent modifications such as acetylation, methylation, phosphorylation, sumoylation, ADP ribosylation and glycosylation to specific amino acid residues on histone proteins can cause higher order structural changes. This remodeling of chromatin can influence gene expression depending on whether the modifications result in chromatin condensation or unwinding [1].

Histone modifications often occur on lysine residues at the amino-termini of histone tails. Lysine residues are commonly changed via histone modifying enzymes such as histone acetyltransferases (HAT), histone deacetylases (HDAC), methyltransferases, kinases and ubiquitilases. The most common modifications are acetylation, which involves addition of CH_3OH in a reaction catalyzed by HAT, and methylation, which involves addition of CH_3 (Fig. 5.1c).

Generally, increased acetylation leads to an increase in transcriptional activity (so-called active chromatin; see Fig. 5.3) whereas deacetylation, catalyzed by HDAC, leads to transcriptional repression (inactive chromatin) [2]. Some histone marks may have opposing effects of gene expression depending on the residue modified; trimethylation of the ninth lysine residue on histone H3 (H3K9me3) favors gene

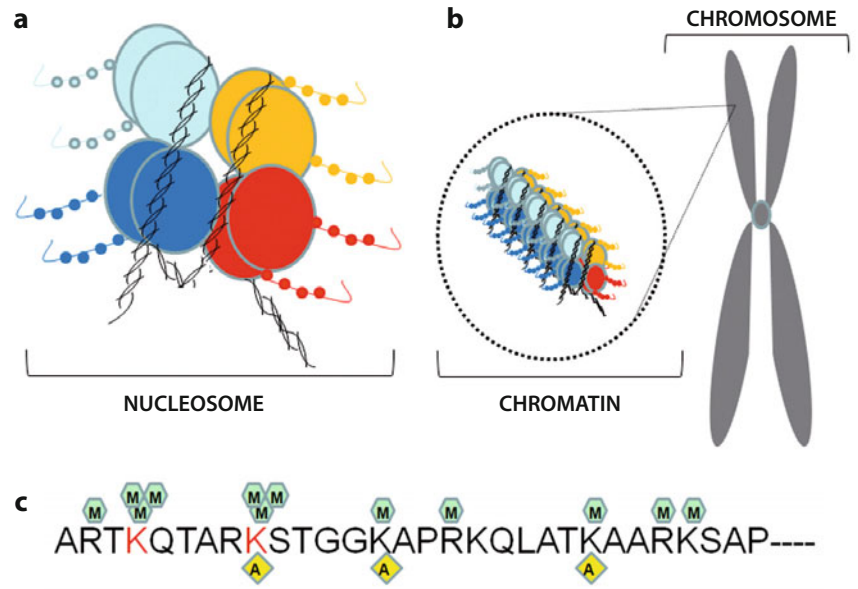

Fig. 5.1 **a** DNA is wound around an octameric complex of histones (comprising two subunits each of the four histones H2A, H2B, H3 and H4) to form the nucleosome. The amino-terminal histone tails are shown and may be epigenetically modified. **b** Chromatin consists of multiple nucleosome units strung together by double-stranded DNA. **c** Schematic representation of known modifications of the first 30 amino acids at the amino-terminal tail of H3. The lysine residues at positions 4 and 9 are indicated in red. *M* methylation; *A* acetylation

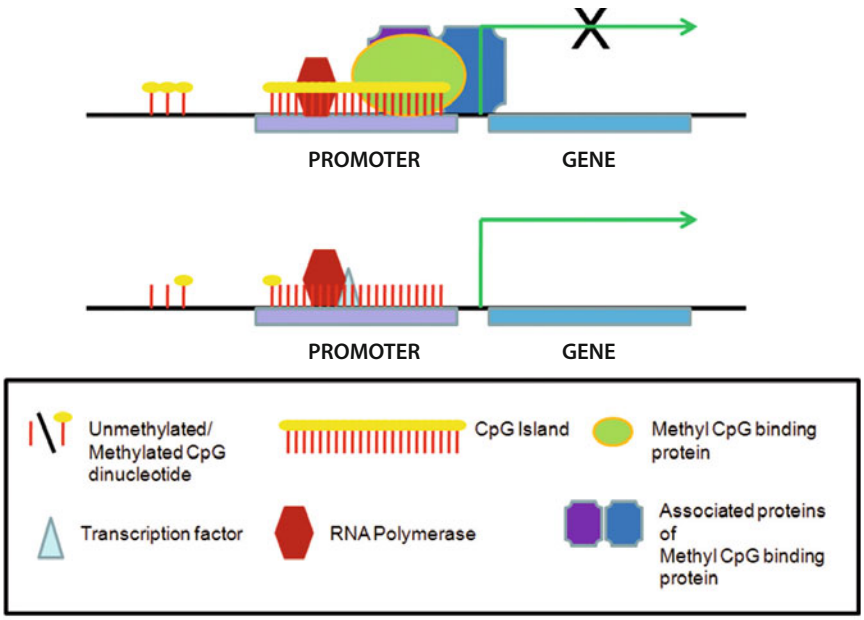

Fig. 5.2 Gene expression is modulated by nearby DNA sequences called promoters, which often include CpG islands. Methylated DNA (*top*) recruits methyl-CpG binding proteins that in turn recruit associated proteins to inhibit transcription. In contrast, unmethylated CpG islands (*bottom*) allow binding of RNA polymerase and transcription factors for initiation of transcription

silencing, while that on the fourth residue (H3K4me3) promotes gene expression.

5.2.2 DNA Methylation

DNA methylation involves the addition of a methyl group on the C5 position of cytosine residues in CpG dinucleotides (cytosine linked to guanine by a phosphate group), in a process mediated by DNA methyltransferases. A genomic region with an enrichment of CpG dinucleotides is called a CpG island. CpG islands are usually found at the promoter regions of many genes.

The methylation status of CpG islands within promoter sequences exerts a regulatory effect by modifying the binding affinity of transcription factors (specific proteins which facilitate DNA recognition by RNA polymerases) to their target sites on DNA, hence modulating transcription levels (Fig. 5.2). CpG islands are not normally methylated, thereby

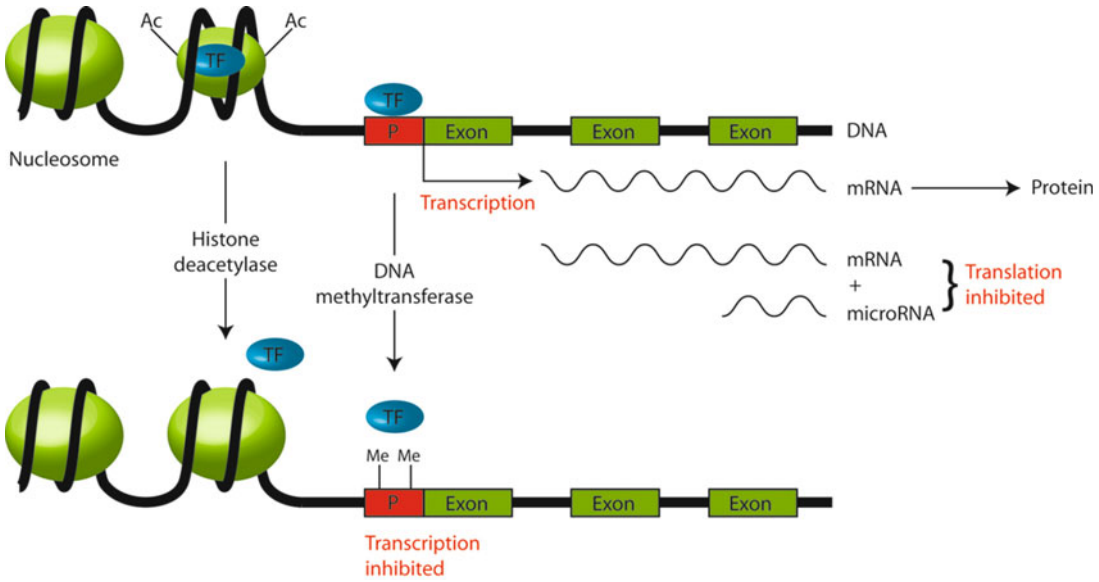

Fig. 5.3 In transcriptionally active chromatin (*top*), acetyl groups (Ac) on specific lysine residues of core histones in the nucleosome decrease their binding to DNA. The resulting "open" chromatin structure, coupled with the unmethylated state of CpG sequences in promoter regions of actively transcribed genes, facilitates access of transcription factors to DNA. Conversely transcriptionally inactive chromatin (*bottom*) is characterized by histone deacetylation and promoter CpG methylation (Me), and hence decreased binding of transcriptional factors. miRNA molecules provide post-transcriptional epigenetic control by binding to complementary sequences in the 3' end of mRNA, thus reducing the rate of protein synthesis. Modified from [7], with permission

allowing transcription to proceed. Methylated DNA however recruits methyl-CpG binding proteins such as MeCP1 and MeCP2, which in turn recruit associated proteins that cause the nucleosome to condense, thereby inhibiting transcription (Figs. 5.2 and 5.3). DNA methylation is therefore commonly associated with gene silencing, although there is increasing evidence that this may be site-dependent. It is also a key factor in other epigenetic events such as X-chromosome inactivation, tissue-specific gene expression during cell differentiation, and genomic imprinting (see later).

5.2.3 Regulatory RNAs

The regulatory role of RNA began to emerge upon the discovery of RNAs that are not translated into proteins. These so-called non-coding RNAs (ncRNAs) are processed by enzymes such as Dicer and Drosher into shorter fragments, yielding different classes such as short interfering RNA (siRNA) and micro-RNA (miRNA), which are approximately 22 nucleotides long, or small nucleolar RNAs (snoRNA) which are ~60–300 nucleotides long [3].

Mature miRNA molecules interact by base-pairing with target messenger RNA (mRNA), modulating translation or direct degradation of the double-stranded RNA molecule. Similarly, siRNAs are perfect matches for their target RNAs, which are then destined for degradation [4]. Gene expression can therefore be regulated at the post-transcriptional level (Fig. 5.3).

SnoRNAs act as guides of specific protein complexes that perform specific nucleotide modifications by base-pairing with their targets near modification sites. SnoRNAs have been implicated in physiological functions that regulate feeding and growth, and in pathological conditions such as the Prader-Willi and Angelman syndromes (see later) and cancer [3].

5.2.4 Genomic Imprinting

Some mammalian genes are expressed from only the maternal or paternal allele – a phenomenon known as genomic imprinting. Many imprinted genes play major roles in fetal growth and nutrition as they are required for the formation of a functional placenta. The first genes shown to be imprinted were the fetal growth factor *IGF2* and its receptor *IGF2R*. More than 100 imprinted genes have been identified to date in mice and humans, with a majority of them located in clusters throughout the genome. These clustered genes usually contain a few protein coding genes and at least one ncRNA gene. Each gene cluster is regulated by a cis-acting element called the Imprinting Control Region (ICR). Between them, the ICRs of the chromosome pair acquire different levels of

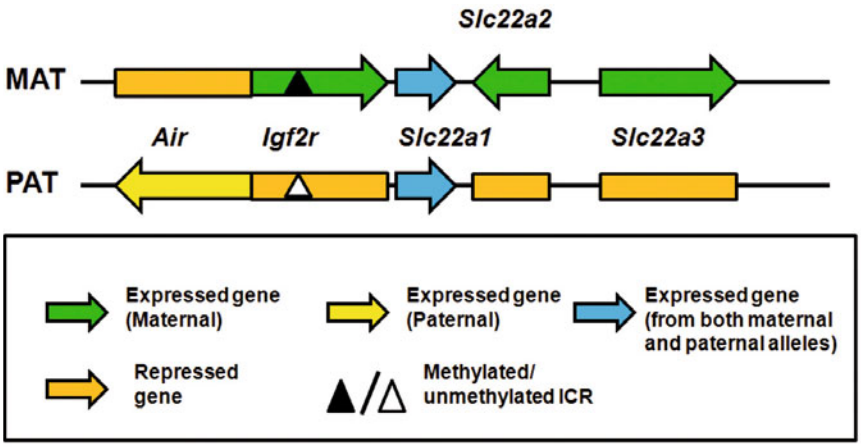

Fig. 5.4 The *Igf2r/Air* imprinted region. *Igf2r*, *Slc22a2* and *Slc22a3* are maternally expressed protein coding genes. *Slc22a1* is a biallelically expressed gene (expressed from both maternal and paternal alleles). *Air* is paternally expressed and produces an ncRNA. The ICR contains the *Air* promoter and is methylated on the maternal allele. When the *Air* transcript is truncated, biallelic expression of *Igf2r*, *Slc22a2* and *Slc22a3* is acquired, indicating a role for the *Air* ncRNA in the repression of the paternal alleles

methylation; this determines which allele is silent or active, thereby enabling imprinting control of all the genes within the cluster [5]. An example of the imprinted mouse gene *Igf2r* and how it is regulated is shown in Fig. 5.4.

A consequence of genomic imprinting is that viable embryos must receive two haploid genome complements from each parent. Parent-specific imprinting marks are established during gametogenesis. Deletions, duplication, mutations or alterations of imprinting of the only active allele, or loss of imprinting of the inactive allele, leads to an imbalance in the dosage of the gene product. The loss or gain of function of imprinted genes may have phenotypic consequences.

5.3 Developmental Plasticity, Epigenetics and Disease Risk

The influence of fetal environment on later-life susceptibility to chronic, non-communicable disease has been demonstrated by a multitude of epidemiological and experimental studies. In humans, in utero exposure to adverse conditions such as maternal under-nutrition has been associated with hypertension, ischemic heart disease, glucose intolerance, insulin resistance, type 2 diabetes mellitus, obesity and reproductive disorders in adulthood [6]. In rodent models used to simulate human pathology, manipulation of maternal nutrition (e.g., food intake or protein restriction), stress (e.g., via glucocorticoid administration) or physical condition (e.g., ligation of uterine arteries to reduce uteroplacental blood flow, thus inducing intrauterine growth restriction) can induce slowed fetal growth and permanent changes in cardiovascular and metabolic function in the offspring [7]. The fetus' ability to respond to challenging environmental cues and adjust its developmental trajectory to match its environment reflects the processes of developmental plasticity. Although these responses are adaptive and aimed at promoting fitness later in life, a mismatch between the eventual phenotypic outcome and the later environment may manifest as chronic non-communicable disease, and this is the basis for the "developmental origins of health and disease" paradigm [6]. Indeed, there is growing evidence that developmental plasticity can account, at least in part, for a broad array of diseases.

The mechanistic basis of the effect of early environmental cues on subsequent susceptibility to metabolic disease has been investigated with animal studies. For example, macaque fetuses whose mothers received a high-fat diet demonstrated impaired lipid metabolism in association with a raft of epigenetic changes such as increased histone acetylation. In rats, a low-protein maternal diet resulted in hypertension and endothelial dysfunction in offspring, with concomitant changes detected at the epigenetic and gene expression levels; these included gene promoter hypomethylation, and accordingly protein overexpression, of hepatic glucocorticoid receptor (GR) and peroxisome proliferator-activated receptor-α (PPAR-α). A recent study in children found that a mother's carbohydrate intake during early pregnancy was associated with methylation of the *RXRA* gene promoter, which in turn could account for more than 20% of variance in adiposity at age 6 or 9 years [8].

The epigenetic mechanisms underlying several imprinting disorders are well established. Human chromosome 15q11-13 contains an imprinted cluster called the Prader-Willi/Angelman syndrome (PWS/AS) region. Incorrect establishment of imprinting in this region results in two distinct neurological disorders, Prader-Willi syndrome (PWS) and Angelman syndrome (AS). PWS is characterized by multiple symptoms including hypotonia, hyperphagia, obesity and short stature. Psychomotor development is mildly affected and behavioral problems are evident. Patients with AS show a completely different phenotype characterized by severe mental retardation, absent speech, autistic-like behavior, severe epilepsy and postnatal microcephaly [8]. PWS is caused by the loss of the normal paternal contribution of gene expression, whereas AS is caused by the loss of the normal maternal contribution.

Other imprinting disorders include Silver-Russell syndrome and Beckwith-Wiedemann syndrome, which arise

from imprinting defects in human chromosome imprinted region 11p15.

Rett syndrome is a devastating X-linked neurological disease that affects females. Girls with this condition appear to develop normally, but show signs of deteriorating motor and cognitive function such as repetitive teeth-grinding, hand-wringing and autistic-like behaviors sometime between the age of 6 and 18 months. This eventually culminates in severe intellectual disability. Rett syndrome is associated with the failure of mutated *MeCP2* to regulate transcription of a specific gene, *DLX5*, one allele of which is normally imprinted. Absence of *MeCP2* leads to increased production of DLX5 protein through the loss of silent chromatin and the activation of additional neighboring chromatin [10], ultimately affecting brain development. Rett syndrome is illustrative of how different epigenetic mechanisms – in this case loss of imprinting and chromatin remodeling – can act in concert to cause various perturbations in gene expression.

5.4 Reversibility of Developmentally-Induced Epigenetic Changes

The "plastic" responses demonstrated by the developing fetus to cope with an adverse prenatal environment have generally been considered to be irreversible. However, our work with animal models has demonstrated the possibility of reversing phenotypic fates induced in utero or in early development. For example, offspring of undernourished rats develop obesity, hyperinsulinemia and hyperleptinemia in adulthood, especially in the presence of a high-fat diet. Intervention by way of neonatal leptin administration to primed rat pups normalized weight gain, insulin levels and leptin concentrations. The corrective effects on phenotype were accompanied by normalized promoter methylation and expression of *Ppar-alpha* [7, 11], reflecting an epigenetic basis for the physiological mechanisms that lead to either phenotype. Other studies have suggested that dietary intervention using n-3 fatty acids may reverse hyperleptinemia and hypertension.

In the rat, variations in postnatal maternal care stably alter the development of behavioral and endocrine responses to stress in the offspring. High levels of maternal care over the first week of postnatal life are associated with reduced fearfulness and a dampened hypothalamic-pituitary-adrenal axis response when exposed to stress. Interestingly, pharmacologic administration in adulthood may alter these behavioral responses by changing the epigenetic status of relevant genes, in particular the hippocampal *GR*. The administration of the HDAC inhibitor trichostatin A in stress-challenged offspring that had received lower maternal care induces behavior more similar to that of offspring exposed to high levels of maternal care. The methyl donor L-methionine induces the opposite effect, with adult offspring exposed to high maternal care exhibiting a potentiated behavioral response to stress. The effects of these interventions have been linked to methylation and expression levels of hippocampal GR [12].

At present, the prevention or reversibility of developmentally induced epigenetic changes has only been investigated with animal models. Nevertheless, the contribution of epigenetic mechanisms to the elucidation of developmental pathways to human disease is now well recognized. It appears increasingly likely that specific epigenetic marks can serve as biomarkers of later life disease risk. The clinical implications of such prognostics are clear – by identifying individuals with increased susceptibility to chronic disease in later life, appropriate nutritional, pharmacological or educational interventions could be then employed as preventative measures. A particular focus on the prenatal and early postnatal periods appears to be prudent.

Congenital Malformations and Syndromes: Early Diagnosis and Prognosis

Giovanni Corsello and Mario Giuffrè

6.1 Introduction

Congenital malformations are defects of the morphogenesis of organs or body regions identified during intrauterine development or at birth. They may be isolated and single, or multiple. Their global birth prevalence is about 2–3%. Congenital defects may be caused by genetic and/or environmental factors, acting singly or in combination. Diagnostic and therapeutic tools have allowed better identification of congenital malformations and have reduced long-term morbidity and mortality in affected patients. Because of increased life expectancy, congenital malformations today represent a major issue in health care because of the resources needed for multidisciplinary care.

6.2 Classifications

Based on clinical criteria, *major malformations* are defined as defects causing functional impairment and therefore needing medical or surgical treatment. Defects that do not produce functional impairment and do not require medical intervention are termed *minor malformations* if their prevalence at birth is less than 4% and *phenotypic variants* when the birth prevalence is higher. Major and/or minor congenital malformations are frequently associated; apparently isolated defects may be associated with malformations that are not clinically evident at birth.

On the basis of etiological criteria, it is possible to distinguish primary malformations, secondary malformations (disruptions) and deformations (Table 6.1). *Primary malformations* are morphogenic defects arising from an intrinsic error of development with a genetic origin. *Disruptions* occur when an environmental factor interferes with an otherwise normal developmental process, causing global impairment or specific damage affecting a single developmental region. The causes of secondary malformations may be biological,

Table 6.1 Etiologic classification of congenital malformations

Primary (genetic)	Secondary (environmental)
Chromosomal abnormalities • Numeric – polyploidy – polysomy – monosomy • Structural – deletions – duplications – insertions – translocations Monogenic • Point mutations – nonsense – mis-sense – frameshift • Dynamic mutations – triplet amplification • Epigenetic regulation – imprinting defects – uniparental disomy Polygenic – oligohydramnios – uterine malformations	Biologic agents • Viruses – cytomegalovirus – rubella – herpes viruses • Bacteria – *Treponema pallidum* • Parasites – *Toxoplasma gondii* Chemical agents • Drugs – antiblastics – anticonvulsants – antibiotics • Abuse substances – alcohol – smoke – cocaine – opiates • Metabolic conditions – hyperglycemia, hyperinsulinemia – hyperphenylalaninemia – hyperandrogenism • Physical agents – ionizing radiation – electromagnetic radiation • Vascular disruptions – subclavian artery vascular disruption – twin-twin disruption sequence • Mechanical causes (deformations) – amniotic bands – twinning – uterine tumors

chemical, metabolic, or physical. *Deformations* arise from extrinsic mechanical compression of one or more regions of the body during fetal development. The most common causes of deformations are amniotic bands, twinning, uterine malformations and masses.

Patients with multiple malformations can be classified as having syndromes, sequences, associations, or dysplasias. *Syndromes* are conditions where all the structural defects arise from a single etiological factor, which may be genetic or environmental. *Sequences* are characterized by a cascade of dysmorphic processes, linked by a cause/effect relationship with a single initiating event. Thus, a primary defect may induce several secondary defects, which are chronologically and pathogenetically related. *Associations* are sporadic events with different defects being present more frequently than would be expected if they were random events, without evidence of any etiological or pathogenetic relationship. In recent years, some associations have been recognized as disorders of blastogenesis, which are caused by genetic or environmental factors that interfere with early development when the embryo is a single developmental field, and producing defects in apparently unrelated organs and body regions. Blastogenesis is the first 4 weeks after conception and is characterized by processes that determine the midline and body axes, symmetry and lateralization, neurulation and somite formation. Some associations are identified by an acronym of the defects, such as VACTERLS (Vertebral defects, Anorectal atresia, Cardiac anomalies, Tracheoesophageal fistula, Esophageal atresia, Renal anomalies, Limb defects, Single umbilical artery) and CHARGE (Coloboma, Heart disease, Atresia of choanae, Retarded mental development, Genital hypoplasia, Ear anomalies). *Dysplasias* are structural defects involving specific tissues where a single gene mutation may determine the abolition or reduction of protein synthesis as well as the production of defective proteins.

6.3 Clinical Considerations

The birth of a baby with congenital malformations is the starting point of a clinical process that is aimed at making a precise diagnosis [1, 2]. This leads to appropriate clinical planning and definition of prognosis and counselling of the parents. Different causal pathways may lead to a similar phenotype [3, 4] and the diagnostic process may be long and difficult, requiring follow-up to establish the natural history of the disorder. The diagnostic process includes an accurate history, description of the phenotype, with appropriate imaging and laboratory tests. Improvements in informatics have led to the development of computerized systems to improve diagnostic accuracy. The history should include consideration of the whole family (with the definition of a genealogical tree and the identification of risk factors (consanguinity, multiple abortions, stillbirths, advanced maternal and/or paternal age), the preconceptional period and environmental factors (infections, maternal metabolic diseases, diabetes mellitus, drugs, alcohol) and the pregnancy. Analysis of the phenotype is aimed at the identification and description (with photographic documentation) of structural defects (isolated and multiple, major and minor) and should include a description of clinical associations with genetic syndromes, such as neuropsychomotor retardation, growth restriction, disorders of sexual differentiation or pubertal development.

6.4 Genetic Counselling and Prenatal Diagnosis

Genetic counselling is defined as the non-directive process of communicating with and giving information to a family (usually the parents) to enable the making of decisions relating to patients with genetic diseases that are considered, responsible and rational. It is important that genetic counsellors have: (a) a confirmed diagnosis for the index patient, (b) an up-to-date knowledge of the natural history of the disease, (c) an understanding of its prognostic and therapeutic implications, (d) knowledge of its pattern of inheritance, and (e) an awareness of the possibilities for early (prenatal) diagnosis. The main factors that determine a need for genetic counselling are the presence of an index case with a congenital malformation or of genetic disease in the family as well as the presence of parental risk factors (consanguinity, advanced maternal age, recurrent abortions, mutation carrier). If the disease is multifactorial (due to a combination of genetic and environmental factors), a recurrence risk may be given only on the basis of an empirical approach that takes account of the prevalence in a certain population or at a certain maternal age, number of affected subjects and consanguinity within the family. In the case of monogenic diseases with Mendelian inheritance (autosomal dominant, autosomal recessive, X-linked), the relative recurrence risk must be explained to the family, who must also be informed about available opportunities for early diagnosis (preconceptional, prenatal, neonatal).

The recent identification of complex genetic mechanisms (genomic imprinting, uniparental disomy, triplet amplification) has increased the number of diseases in which is possible to give helpful genetic counseling.

6.5 Associations

Associations are usually sporadic conditions with a low recurrence risk. Environmental factors (alcohol, drugs, maternal diabetes) as well as chromosomal and single gene disorders may interfere with the blastogenic processes. A genetic background may also increase an individual's susceptibility to environmental factors

6.5.1 VACTERLS Association

Characterised by the manifestation of some or all of the defects summarized by the acronym: Vertebral defects, Anorectal atresia, Cardiac anomalies, Tracheoesophageal fistula, Esophageal atresia, Renal anomalies, Limb defects, Single umbilical artery. Tracheoesophageal and anorectal defects require early surgery during the neonatal period. The most frequent heart defects affect the ventricular septum. Limb defects include radial ray abnormalities (radial hypoplasia, thumb aplasia or hypoplasia as well as its duplication), polydactyly and syndactyly. Other features may be prenatal and postnatal growth restriction, ear and external genitalia abnormalities. VACTERLS association is often sporadic with a low recurrence risk. It is more frequent in the offspring of diabetic mothers. In some patients with associated obstructive hydrocephalus, gene mutations with Mendelian inheritance have been documented. Most patients have normal cognition, although they may present as failure to thrive and with neuromotor disabilities.

6.5.2 Infants of Diabetic Mothers

Congenital malformations in the offspring of diabetic mothers are clinically heterogeneous. Their frequency is 2–4 fold higher than in the general population. The relative risk for malformations is much higher in newborns of women with type I insulin-dependent diabetes mellitus and is inversely correlated with the effectiveness of maternal glycemic control, particularly during the periconceptional period. Several factors are involved in the pathogenesis of such defects: hyperglycemia, hyperglycosylation of proteins involved in differentiation, chronic hypoxia, polycythemia/hyperviscosity, and lactic acidosis. All these factors may interact and interfere with blastogenesis, inducing abnormalities of the midline structures and symmetric organs. All types of malformations (skeletal, cardiac, renal, gastrointestinal, CNS) are more common in the infants of diabetic mothers. Some are specific, such as caudal dysgenesis, characterized by defects of vertebral, urogenital and intestinal structures arising from the caudal mesoderm, with a wide spectrum of expression including sirenomelia, in which there is also a complex vascular defect. The fetus may be macrosomic because of fetal hyperinsulinemia, although a placental microangiopathy may also cause intrauterine growth restriction.

6.6 Sequences

Malformation sequences may be caused by genetic as well as environmental factors. Several organs and systems may be involved in malformation sequences (Table 6.2).

6.6.1 Holoprosencephalic Sequence

Holoprosencephalic sequence presents at birth with a wide spectrum of defects of the encephalon and the median craniofacial areas due to a developmental defect of the median subdivision of the prosencephalic vesicle and surrounding mesoderm. It is characterized by a wide range of etiological factors, being found in patients with chromosomal aberrations, monogenic mutations and environmental disruptions (gestational diabetes, cytomegalovirus).

Three anatomical variants (alobar, semilobar and lobar) and four clinical variants (cyclopia, ethmocephaly, cebocephaly and premaxillar agenesis) have been described. Clinical evaluation must include CNS imaging to define the full phenotype. The severity of CNS defects is the main reason for the high and early lethality of the condition. If the phenotype is only partially expressed, longer survival is possible,

Table 6.2 Main malformation sequences

Name	Developmental field and organs involved
Holoprosencephaly	Precordial mesoderm, prosencephalic vesicle, rinencephalon, orbits, nose, premaxilla
Septo-optic dysplasia	Optic chiasm, hypophysis
Pierre Robin	Jaw bone, oro-pharyngeal region
DiGeorge	4th brachial arch, 2nd and 3rd brachial pouches
Poland	Pectoral muscle, superior limb
Klippel-Feil	Spine
Potter	Kidneys, urinary tract, lungs, limbs, facies
Prune belly	Urinary tract, abdominal wall
Bladder-cloacal extrophy	Peri-umbilical mesoderm
Rokitanski	Muller ducts
Sirenomelia	Caudal mesoderm
Caudal regression	Caudal mesoderm
Premature rupture of amnion	Median axis, limb deformations, facial clefts
Fetal akinesia	Multiple body regions
Twin-twin disruption sequence	Multiple body regions

frequently associated with relevant neurologic problems. The parents and relatives of patients must be investigated for minor signs of the sequence (hypotelorism, single median incisor) in order to recognize a possible autosomal dominant inheritance. Most cases are multifactorial and the recurrence risk for families with a sporadic case is estimated at around 6%.

6.6.2 Pierre Robin Sequence

Pierre Robin sequence is a developmental defect of the mandible and surrounding oro-pharyngeal region. It is characterized by microretrognathia, cleft palate and functional disturbances (swallowing deficit, respiratory distress). A deficiency of mesoderm induction may cause a primary cleft palate (V-shape). Alternatively, the cleft palate may be secondary to jaw arch hypoplasia, which leads to the position of the tongue being fixed between the palatine processes, causing a defect of fusion of the secondary palate in the midline (U-shape). Respiratory obstruction is caused by the tongue falling backwards and by a primitive pharyngeal stenosis (secondary to a migration deficit of neural crest cells). The sequence may present with a wide phenotypical spectrum, either in isolation or as part of a more complex syndrome (del 18q, Stickler syndrome). All these variables influence the prognosis. Newborns may require prolonged respiratory and/or nutritional support, long-term hospitalization and follow-up. In the most severely affected cases, surgery to the jaw distraction may improve the outcome.

6.6.3 Potter Sequence

The Potter sequence is caused by absent or severely reduced fetal urine output from the first trimester. It may be secondary to bilateral renal agenesis (a differentiation defect of the metanephric blastema) or to other renal and urinary tract malformations. The cascade mechanism starts with diminished urine production by the fetus; this leads to a reduced volume of amniotic fluid (anhydramnios or oligohydramnios), which give rise to pulmonary hypoplasia, leading to respiratory distress at birth, facial dysmorphism (prominent nose and flat profile), diminished fetal movements with multiple postural deformations particularly of the lower limbs. When the phenotype is fully expressed, the severe renal and pulmonary damage is responsible for the high perinatal mortality. Prenatal diagnosis by ultrasound reveals the kidney defect, oligohydramnios and other associated malformations. The sequence is often sporadic, with etiological heterogeneity and a recurrence risk of about 3%. It may occasionally be associated with other defects in a more complex syndrome (Meckel-Gruber syndrome: occipital encephalocele, renal cystic disease, polydactyly and an autosomal recessive inheritance).

6.6.4 Prune Belly Sequence

This sequence was named because of the characteristic appearance of the abdomen (wrinkled skin, also referred to as "flabby abdomen") in the affected newborns. The sequence may be related to various defects of the genitourinary tract, involving the proximal urethra (urethral agenesis, cloacal persistence, urethral stenosis, posterior urethral valves in males) [5]. Urethral obstruction is responsible for oligohydramnios (and possible secondary Potter sequence) and accumulation of urine in the proximal renal tract, leading to parenchymal damage (bladder dilatation, bilateral ureteric dilatation and hydronephrosis). Bladder hypertrophy and dilatation may interfere with development of the abdominal wall muscles, diaphragm and testicular migration in the scrotum in males (cryptorchidism). Abdominal wall muscle hypoplasia is responsible for the prune belly appearance because of visible intestinal loops through the thin abdominal wall. Diaphragmatic defects and oligohydramnios cause lung hypoplasia and severe respiratory distress at birth. Although early prenatal diagnosis by ultrasonography is possible, the differential diagnosis between isolated renal cystic conditions and obstructive uropathies may be difficult. Prenatal bladder catheterisation allows urine to flow into the amniotic cavity and must be followed by surgical correction after birth.

6.7 Syndromes

6.7.1 Chromosomal Abnormalities

The overall incidence of chromosomal anomalies is estimated at about 1:170 live births. Their prevalence at conception is much higher, giving rise to a spontaneous abortion or fetal death because of developmental impairment. About 50% of spontaneous abortions have an abnormal chromosomal structure. Chromosomal aberrations may affect *autosomes* and/or *sex chromosomes* and may involve their number or structure. *Numeric aberrations* have a prezygotic origin (meiotic non-disjunction, frequently related to advanced maternal age). They may also arise from a postzygotic error when they are present only in a variable proportion of cells (mosaics). *Structural aberrations* may occur de novo from a meiotic rearrangement or may be inherited from one parent, who carries a balanced non-symptomatic chromosomal translocation.

6.7.1.1 Down Syndrome (Trisomy 21)

Down syndrome is the most frequent chromosomal aberration at birth (about 1:700). It is determined by a trisomy of chromosome 21. In most (95%) cases, trisomy 21 is secondary to a maternal meiotic non-disjunction of homologous chromosomes

21, more rarely there may be a Robertsonian translocation or a post-zygotic mitotic non-disjunction (mosaic with milder phenotype). The incidence is related to maternal age at conception (1/1500 at 20 years and 1/28 at 45 years). Overall recurrence risk is low (about 1%), although it significantly increases when one of the parents carries a balanced translocation. The phenotype at birth is characteristic: main facial features are Brushfield spots (grey spots in the median zone of the iris), upslanting palpebral fissures, epicanthal folds, small nose, small mouth with prominent tongue, flat facial profile, brachycephaly with a flat occipital bone, small low-set ears, short neck with redundant skin folds. Newborn babies are hypotonic with lax joints. A single palmar crease and clinodactyly of the little finger are frequent. Organ involvement includes congenital heart defects (atrioventricular canal, ventricular septal defects, tetralogy of Fallot), duodenal atresia or stenosis, Hirschsprung's disease, hypothyroidism and urinary tract malformations. Long-term follow-up is required because of psychomotor and mental retardation, growth retardation, occurrence of autoimmune diseases, immunodeficiencies and leukemia. Survival rates and the quality of life have improved significantly with educational and screening programs and the development of multidisciplinary follow-up.

6.7.1.2 Edwards Syndrome (Trisomy 18)

Edwards syndrome is determined by trisomy of chromosome 18, sometimes as a mosaic or in association with other chromosomal abnormalities. Its birth prevalence is about 1:8000 because most affected fetuses abort spontaneously. Newborns show severe prenatal growth restriction, dolicocephaly with prominent occiput and low-set dysplastic external ears, jaw hypoplasia, flexed hands with the index finger overlapping the middle finger, single palmar crease, and talipes with rocker-bottom feet. There are frequently associated malformations (heart, renal, intestinal, CNS), which are responsible for the very grave prognosis and high neonatal mortality.

6.7.1.3 Patau Syndrome (Trisomy 13)

Determined by trisomy of chromosome 13, sometimes with chromosomal translocation, or rarely as mosaic. Its birth prevalence is about 1/10,000. Newborns show prenatal growth restriction, a small trigonocephalic skull, areas of aplasia cutis on the scalp, cleft lip and palate, microphthalmia, variable hypotelorism up to cyclopia (i.e., expression of an associated holoprosencephalic sequence), postaxial polydactyly and/or syndactyly, forced flexion of the fingers, single palmar crease, plantar convexity, and cryptorchidism. Other organs are frequently involved (heart, kidneys). Patients with fully expressed phenotype usually die during the first month of life, those with milder signs (mosaics) may survive with severe developmental deficits.

6.7.1.4 Wolf-Hirschhorn Syndrome (4p-)

This is a rare condition determined by deletion of the distal part of the short arm of chromosome 4. Newborns present with prenatal growth restriction, hypotonia, severe microcephaly with brachycephaly, prominent nose, downturned corners of the mouth, arched palate, jaw hypoplasia, hypertelorism, downslanting palpebral fissures, iris coloboma, large low-set external ears. Heart, renal and skeletal defects are frequent. The degree of extension of the chromosomal deletion influences the severity of phenotype and neonatal mortality rate. Surviving patients show severe postnatal growth retardation and psychomotor developmental delay.

6.7.1.5 Cri-du-chat Syndrome (5p-)

Cri-du-chat syndrome is due to a variable deletion of the short arm of chromosome 5. Named because of the characteristic high-pitched cat-like cry of affected newborns caused by hypoplasia of laryngeal cartilages, which disappears after the first months of life. Other phenotypical features are microcephaly, round face, hypertelorism, micrognathia, epicanthal folds, low-set ears. At birth there is generalized hypotonia. Later there is limb hypertonia and severe psychomotor and mental retardation.

6.7.1.6 Mosaic 8 Chromosome Trisomy

The full trisomy of chromosome 8 is extremely rare in humans. It is more common as a mosaic. The phenotype of mosaic trisomy 8 includes scaphocephaly, ankylosed large joints, clubfoot, absent or hypoplastic patellae, arachnodactyly and brachydactyly. Deep grooves in the palms and soles (Fig. 6.1)

Fig. 6.1 Deep plantar grooves in a newborn with mosaic 8 chromosome trisomy

Fig. 6.2 Foot lymphedema in a baby with Turner syndrome

are virtually diagnostic in infancy but become less prominent with age. The face is characterized by a prominent pouting lower lip and small jaw. Mental retardation may be present but is often mild and may remain undetected.

6.7.1.7 Turner Syndrome

Turner syndrome is the most frequent aneuploidy of sex chromosomes with a birth prevalence of 1/2500. It is determined by a monosomy of chromosome X, which may be complete (50%) or partial (20%); it frequently presents as a mosaic with a milder phenotype (30%). During the neonatal period, the diagnosis is suspected because of lymphedema of the hands and feet (Fig. 6.2), nail dysplasia, neck pterygium, a large mouth with downturned corners, dysplastic external ears and left heart output defects (aortic coarctation, left heart hypoplasia). In addition, there may be a prenatal history of cystic hygroma. The clinical phenotype changes with age when other features become evident: short stature, short neck, low posterior hairline, restricted thorax, cubitus valgus, shortness of the fourth metacarpal bone, primary amenorrhea, absence of secondary sexual signs, an endocrine profile of gonadal dysgenesis. Life expectancy is not reduced, but long-term follow-up is required and appropriate hormonal therapy (growth hormone in the first decade and oestrogen-pregesterone after puberty must be given in order to improve height and induce the menstrual cycle.

6.7.1.8 CATCH 22 Syndrome

CATCH 22 is an acronym of the main clinical features (Cardiac abnormality, Abnormal face, Thymic hypoplasia, Cleft palate, Hypoparathyroidism, chromosome 22 microdeletion). This syndrome combines some clinical conditions which were previously described separately (Velo-Cardio-Facial syndrome, Di George sequence). It is due to a deletion of the chromosomal region 22q11.2. Clinical expression is variable and FISH analysis is required to confirm the diagnosis and to define the extent of deletion and the genes involved (contiguous gene syndrome) [6]. Heart defects are conotruncal (aortic arch interruption, common arterial trunk, tetralogy of Fallot). When the brachial structures are involved, there is dysfunction of the immune system (T-cell deficiency) and parathyroidal abnormalities with low serum calcium levels. During the neonatal period, the full expression of the phenotype results in hypocalcemia and craniofacial dysmorphism (micrognathia, cleft palate, anteverted nares, low-set external ears) with a conotruncal heart defect and absent thymic shadow at chest X-ray delineating the phenotype with full expressivity.

6.7.2 Monogenic Disorders

Monogenic disorders are single gene mutations with a Mendelian mode of inheritance. The genotype-phenotype correlation remains undefined for many conditions. Each syndrome may be due to different mutations in the same gene or in different genes (genetic heterogeneity). The same mutation may determine different phenotypes (phenotypical variability) in the same family and appears to depend on interference by other genetic and/or environmental factors. In addition, epigenetic factors (e.g., DNA methylation) may act during the differentiation processes to modify gene expression and may depend on the parental origin of the gene (genomic imprinting).

6.7.2.1 Cornelia de Lange Syndrome

Affects 1/10,000 newborns and is usually sporadic due to de novo mutations (gene locus at 5p13.1 encoding for the NIPBL protein) [7]. Newborns show a typical facial appearance (microbrachycephaly, low anterior and posterior hairline, synophrys, small nose with a depressed nasal bridge, anteverted nares, long philtrum, "carp" mouth, maxillary prognathism, low-set ears) (Fig. 6.3), with intrauterine and postnatal growth retardation, hypertrichosis and upper limb anomalies (small limbs, reduction defects including phocomelia, limited elbow extension, single palmar crease, oligosyndactyly).

Urogenital, heart and intestinal malformations may also be present. All patients have psychomotor and growth retardation. Infections, feeding difficulties and neurologic disturbances (seizures, motor and speech retardation) require long-term multidisciplinary follow-up and family support.

Fig. 6.3 Typical facial appearance of a newborn baby with Cornelia de Lange syndrome, showing synophrys, a depressed nasal bridge, anteverted nares, long philtrum, carp mouth

6.7.2.2 Rubinstein-Taybi Syndrome

A rare sporadic syndrome characterized by mental retardation, facial abnormalities, broad thumbs and toes. There is genetic heterogeneity and about 25% of patients present with mutations or microdeletions in the gene encoding the transcriptional coactivator CREB-binding protein (16p13.3) [8]. Familial cases with autosomal dominant inheritance have been described. The main craniofacial features (Fig. 6.4) are microcephaly, frontal bossing, large anterior fontanelle, downslanting palpebral fissures, broad nasal bridge, beaked nose, epicanthal folds, strabismus, maxillary hypoplasia, high arched palate, external ear abnormalities. There is hand and foot involvement (broad distal phalanges of thumbs and halluces with medial deviation, clinodactyly or duplication). There may also be hirsutism and abnormalities of the skeleton (spinal, pelvic), heart (septal defects, patent ductus arteriosus) and urogenital tract (hypospadias, cryptorchidism). Growth retardation, skeletal maturation delay and severe mental retardation are more common with increasing age.

Fig. 6.4 Newborn with Rubinstein-Taybi syndrome showing microcephaly, frontal bossing, downslanting palpebral fissures, broad nasal bridge, beaked nose, epicanthus, maxillary hypoplasia

6.7.2.3 Marfan Syndrome

A congenital defect of connective tissue involving the skeleton, eye and cardiovascular system. It is determined by heterozygous mutations in the *FBN1* gene (15q21.1) encoding for fibrillin 1 protein, which is a component of collagen [9]. It is inherited as an autosomal dominant with variable clinical expression; about 25% of cases are sporadic, due to de novo mutations correlated with advanced paternal age. Newborns show arachnodactyly, long and thin limbs, increased length joint laxity and hypermobility, muscular hypotonia, hernias, pectus carinatum or excavatum. Cardiac abnormalities comprise mitral valve prolapse and aortic defects (aortic root dilatation and aortic aneurysm). Patients with most severe neonatal phenotype (neonatal Marfan syndrome) have high early mortality rates. Skeletal and cardiac problems usually evolve with growth (kyphoscoliosis, progressive aortic dilatation, aortic dissection) and ocular signs develop (ectopia lentis, early glaucoma).

6.7.2.4 Noonan Syndrome

Noonan syndrome is a relatively frequent (1/2000) condition with some phenotypic features similar to those of Turner syndrome (male Turner, pseudo-Turner). It is due to mutations in the *PTPN11* gene (12q24.1), with sporadic as well as familial cases [10]. The inheritance is autosomal dominant and parents must be always investigated for mild clinical signs. Newborns show hypertelorism, upslanting palpebral fissures, low-set posteriorly rotated ears, neck pterygium, a shield chest with deformation of the sternum, and lymphedema (Fig. 6.5). Cardiac involvement is mainly of the pulmonary outflow tract (pulmonary valve dysplasia and stenosis, cuspid thickening and hypomobility). Other possible features are cryptorchidism in males and a bleeding tendency, due to thrombocytopenia and partial deficiency of coagulation factors. Later in infancy, other signs become evident: postnatal growth retardation (with short stature and retarded bone age), triangular face, mild psychomotor and intellectual retardation. Life expectancy depends exclusively on the severity of heart manifestations.

Fig. 6.5 A patient with Noonan syndrome with hypertelorism, upslanting palpebral fissures and shield chest

6.7.2.5 Prader-Willi Syndrome (PWS)

Determined by the failure of expression of genes of paternal origin in the 15q11-q13 region. These genes are normally subjected to maternal imprinting (DNA methylation) which avoids maternal copy transcription and determines a functional gene monosomy (only the paternal copy is expressed). This condition may arise from microdeletions of paternal chromosome 15 (70%), maternal uniparental disomy (25–30%) or imprinting center defects. Methylation testing identifies almost all patients; FISH and microsatellite DNA analysis may reveal microdeletions and maternal UPD. PWS newborns (Fig. 6.6) present with congenital hypotonia, a prenatal history of reduced fetal movements, poverty of facial expression, dolicocephaly with reduced bitemporal diameter, almond-shaped eyes with upslanting palpebral fissures, a small mouth with downturned corners and thin upper lip, small hands and feet and genital hypoplasia with cryptorchidism in males [11]. Hypotonia of the respiratory, orofacial and pharyngoesophageal muscles cause variable degrees of respiratory and feeding difficulties (poor suction and swallowing), which are present from birth and tend to improve after the neonatal period. After the first year of life, the phenotype modifies and is characterized by hyperphagia, obesity, sleep disturbances, short stature, hypogonadotropic hypogonadism, mild to moderate mental retardation, speech delay. Treatment with growth hormone (GH) is possible and good clinical results have been reported.

Fig. 6.6 The neonatal phenotype of Prader-Willi syndrome: hypomimic face, reduced bitemporal diameter, almond-shaped eyes, small mouth with downturned corners and thin upper lip

6.7.2.6 Beckwith-Wiedemann Syndrome (BWS)

A sporadic condition determined by an altered balance between cooperating genes in the region 11p15. The genetic mechanism is complex and involves imprinted genes encoding for several important growth factors and receptors. Various genotypic abnormalities have been described in BWS patients, e.g., microduplication of paternal region 11p15, microdeletion of the maternal region, and mutations and paternal uniparental disomy of chromosome 11. The main neonatal clinical features (Fig. 6.7) are exomphalos, macroglossia and gigantism (EMG syndrome). Other features are visceromegaly, adrenocortical cytomegaly, dysplasia of the renal medulla, typical linear indentations of the helix and the auricular lobe of the ear, hypoglycemia during the first days of life, limb hemihypertrophy. Prenatal diagnosis may be because of exomphalos and generalized overgrowth seen on ultrasound scanning. The neonatal diagnosis is based on clinical findings, although careful molecular cytogenetic analysis of the 11p15 region is recommended. Overgrowth and macroglossia tend to become less evident with age, but there is an increased risk of malignant tumors (Wilms' tumor, adrenal carcinoma, hepatoblastoma).

6.7.2.7 Silver-Russell Syndrome

Silver-Russell syndrome is a sporadic condition with genetic heterogeneity. Various genetic loci have been involved [12]. In some patients it is caused by hypomethylation at distal chromosome 11p15 (the opposite of patients with Beckwith-Wiedemann syndrome). In others, it is related to a maternal uniparental disomy of chromosome 7. The neonatal phenotype is characterized by severe intrauterine growth restriction with normal development of the skull (pseudohydrocephalic appearance), poor postnatal growth, craniofacial features (triangular shaped face and broad forehead), body asymmetry and

Fig. 6.7 Exomphalos, macroglossia and gigantism

a variety of minor malformations (clinodactyly and syndactyly of the little finger). The phenotypic expression changes during childhood and adolescence, with the facial features and asymmetry usually becoming more subtle with age. GH therapy should be considered to improve final height.

6.7.2.8 Goldenhar Syndrome (GS)

Goldenhar syndrome is a spectrum of malformations involving the eye, ear and vertebrae with heterogeneous etiology and a highly variable phenotype [13]. Its prevalence at birth is about 1/5000. Most cases are sporadic, although some families with autosomal dominant inheritance have been described. GS originates from a vascular disruption of the first and second branchial arches, with consequent malformations of related organs and tissues. Defects are more often unilateral and an increased incidence has been reported in the offspring of diabetic mothers, as have other disorders of blastogenesis. GS newborns show multiple craniofacial anomalies (Fig. 6.8): hemifacial microsomia, ipsilateral deformity of the external ear (preauricular tags, atresia of the external auditory canal, anomalies in size and shape of the external auricle), epibulbar dermoid, coloboma of the upper eyelid. In addition, defects of the cervical vertebrae (hemivertebrae, fusions, segmental agenesis), cleft palate, choanal athresia, heart, kidney and CNS defects may be found. Auditory function must be assessed early to preserve speech and cognitive development.

6.7.2.9 Smith-Lemli-Opitz Syndrome (SLOS)

A rare (1/30,000) autosomal recessive condition, caused by mutations in the gene encoding steroid delta-7-reductase, which maps to the region 11q12-q13 [14]. The enzyme deficiency causes a severe deficit of endogenous cholesterol production and its derivative compounds (sexual steroids, components of the myelin and cellular membranes), starting from intrauterine life. SLOS newborns show intrauterine growth restriction, severe hypotonia, microdolicocephaly, high forehead, palpebral ptosis, anteverted nares and micrognathia. There may be other features, such as agenesis of the corpus callosum, cleft palate, syndactyly of second and third toes, congenital heart defects, liver dysfunction. Male patients usually have hypospadias, micropenis, cryptorchidism and sometimes various degrees of ambiguous genitalia, because of the prenatal androgen deficiency. There are low cholesterol and elevated 7-dehydrocholesterol levels in the blood. The underlying mutation is identified by gene sequence analysis, which allows confirmation of the prenatal diagnosis for at-risk couples. Failure to thrive worsens with age and there is always severe psychomotor delay. Patients may be helped by exogenous cholesterol supplementation, particularly for the biliary acid profile.

Fig. 6.8 Hemifacial microsomia and atresia of external auricle in a baby with Goldenhar syndrome

6.8 Disruptions

Some congenital malformations can be related to exogenous factors, which act during intrauterine life, inducing abnormalities of developmental and differentiation processes. The most susceptible period is the first trimester of pregnancy in which the identification of developmental fields, organogenesis and differentiation take place. Biological, chemical, metabolic, physical and mechanical agents (Table 6.1) may cause defects of morphogenesis. The etiologic identification is important for effective genetic counselling and reducing the risk of recurrence in an affected family.

6.8.1 Biologic Agents

Most morphogenetic defects determined by biological agents are pathogenetically and clinically characterized. A high IgM level soon after birth is strongly suggestive of a prenatal infection of the fetus, although only 30% of these newborns show clinical consequences. The earlier the timing of intrauterine infection (particularly during the first trimester of gestation), the more severe is the effect of morphogenetic defects due to viral and bacterial agents and there is usually associated intrauterine growth restriction. The most common embryofetopathies due to biologic agents are described in Table 6.3.

6.8.2 Chemical Agents

Any substance introduced to the human organism can be considered as a chemical agent. They may be drugs or foods associated with flawed lifestyle choices (alcohol consumption, cigarette smoking, ingestion of substances of abuse) or produced by maternal metabolism in specific situations. Some drugs and single molecules, which are well tolerated by an adult, may be seriously dangerous for the development of the embryo and fetus. Drug testing in human pregnancy is difficult and all drugs have therefore to be considered potentially harmful, requiring careful risk/benefit evaluation. Substances may cross the placenta and reach the fetus and placental function may reduce or increase their effects. Individual metabolism may influence the clinical effects, dosage and timing of administration. The most frequent disruptions by chemical agents are reported in Table 6.4.

Table 6.3 Main disruptions determined by biologic agents

Biologic agent	Phenotype
Cytomegalovirus	Microcephaly, intracranial calcifications, psychomotor delay, sensorineural hearing loss, chorioretinitis, hepatosplenomegaly, thrombocytopenia, virus presence in secretions and biologic fluids (urine)
Rubella virus	Microcephaly, psychomotor delay, congenital cataract, sensorineural hearing loss, heart defects, hematologic alterations (anemia, thrombocytopenia)
Varicella-zoster virus	Mental retardation, cortical atrophy, seizures, chorioretinitis, skin scars
Treponema pallidum	Palmoplantar pemphigus, exanthema with skin scars, anemia, thrombocytopenia, hepatosplenomegaly, myocarditis, chorioretinitis, muco-hematic rhinitis, skeletal alterations (lacunae, caput quadratum, metaphyseal ossification defects, osteochondrites and secondary pseudoparalysis)
Toxoplasma gondii	Hydrops, hydrocephalus, intracranial calcifications, chorioretinitis, cataract, seizures, hepatosplenomegaly, skin rush

Table 6.4 Main disruptions determined by chemical agents

Chemical agent	Phenotype
Anticonvulsant drugs	Cleft lip and palate, neural tube defects, congenital heart defects – hydantoin (microcephaly, mental retardation, CNS abnormalities, small nose, facial bone hypoplasia, epichantus, hypertelorism, strabismus, cleft lip and palate, micrognathia, short neck, heart defects) – trimethadione (microcephaly, facial bone hypoplasia, palpebral synophrys, epicanthus, external ear dysplasia, urogenital defects, heart defects) – valproic acid (trigonocephaly, reduced bitemporal diameter, facial bone hypoplasia, small nose, cleft lip and palate, urogenital and limb defects)
Alcohol	IUGR, peculiar face (microcephaly, short palpebral fissures, small nose with anteverted nares, hypoplastic nasal philtrum, microretrognathia), neurologic abnormalities (hypotonia, seizures, poor motor coordination, mental retardation)
Cocaine	Prematurity, IUGR, microcephaly, urogenital and skeletal malformations
Heroin	IUGR, low birth weight, congenital malformations
Maternal diabetes	Macrosomia, hypoglycemia, hypocalcemia, ventricular septal hypertrophy, caudal dysgenesis, any kind of congenital malformations (skeletal, cardiac, renal, intestinal, CNS, etc.)
Maternal hyperphenylalaninemia	Defects of cellular proliferation and migration with myelinization delay (IUGR, severe microcephaly, hypotelorism, prominent nose, low-set dysplastic external ears, mental retardation, cleft lip and palate, conotruncal heart defects)

6.8.3 Vascular Disruptions

Any vascular accident during early embryonic and fetal development may determine subsequent morphogenetic defects in the relevant body region.

Disruption of the subclavian artery includes a heterogeneous group of clinically and etiologically different conditions, characterized by alteration of different mesodermal structures supplied by the subclavian artery. Thus, the Poland sequence includes pectoral muscle agenesis and ipsilateral superior limb reduction defects. Kidney and urinary tract defects are frequently associated, expanding the phenotype towards an acro-pectoral-renal developmental field.

Twin-twin disruption sequence (TTDS) may involve various structures such as the brain, brachial arches, limbs, gut, and kidneys. It is caused by the intrauterine developmental impairment and subsequent death of a monozygotic twin. The presence of vascular placental anastomoses between the arterial supplies of twins and abnormal communicating flow allows the passage of thromboemboli to the surviving twin, with reduced or interrupted blood flow causing structural damage. The complex vascular interactions between monozygotic twins may result in other vascular disruptions (e.g., because of an acardic twin) or a twin-twin transfusion sequence, which are particular features of monozygotic twins.

6.9 Dysostoses

A heterogeneous group of birth defects with single or multiple involvement of skeletal segments (with no systemic cartilaginous tissue involvement), due to mutations of the genes involved in bone development. Dysostoses classification is based on phenotypic criteria and the body region most involved. In some instances a genetic classification is now possible. Most syndromal craniosynostoses are determined by mutations in fibroblast growth factor receptor (*FGFR*) genes, with string evidence of genetic heterogeneity (the same condition being determined by different mutations in the same gene or in different *FGFR* genes) and genetic pleiotropism (the same mutation being responsible for different phenotypes). Genotype/phenotype correlation is not possible for all cases and it can be influenced by other genes (epistatic) as well as other interactive cytoplasmic and environmental factors.

6.9.1 Craniofacial Dysostoses

Full fusion of all cranial sutures is normally achieved at about 25 years of age. Craniosynostoses depend on a precocious closure of one or more cranial sutures and may cause a restriction in the size of the cranium. The closure of a suture limits cranial growth at that site and there is increased cranial growth at the other sutures, producing deformation of the skull (sometimes with brain growth restriction, hydrocephalus, and intracranial hypertension). Skull morphology depends on suture involvement (nature, timing, extension and symmetry). The overall incidence of craniosynostoses is estimated to affect about 1/3000 newborns. It may present in isolation or as part of a more complex syndrome.

6.9.1.1 Non-Syndromal Craniosynostoses

Scaphocephaly depends on the premature fusion of the sagittal suture with consequent restriction of growth along the transverse axis and compensatory increased growth along the antero-posterior axis. *Plagiocephaly* depends on the premature fusion of a single coronal suture with consequent ipsilateral growth restriction and flattening of the frontal bone; the involvement of facial structures varies from simple deviation of nasal septum to severe asymmetry of the sphenoid and maxillary bones. *Brachycephaly* is due to premature fusion of both coronal sutures with consequent growth restriction along the antero-posterior axis and compensatory increase in skull height; hypoplasia of the frontal region is often present. *Acrocephaly* depends on the premature fusion of the coronal and sagittal sutures with consequent severe growth restriction along both antero-posterior and transverse axes and compensatory increased development of the frontal region. Intracranial hypertension is frequently present and requires early surgical correction to avoid severe CNS complications. *Trigonocephaly* is due to the premature fusion of the metopic suture, often evident because of a longitudinal bone crest in the median frontal region, giving the skull a triangular appearance with hypotelorism and flattening of the lateral frontal regions. *Cloverleaf skull* is due to the premature fusion of the coronal, sagittal and lambdoideal sutures with excessive skull growth in height and to both sides, giving a trilobar appearance. Intracranial hypertension is consistently severe and gives rise to CNS complications.

6.9.1.2 Syndromal Craniosynostoses

Apert syndrome is a rare and serious phenotype described in newborns with acrocephaly and syndactyly of the hands and feet (Fig. 6.9). The premature fusion of both coronal sutures is responsible for acrocephaly, frontal bossing, flat occipital bone, facial dismorphic features (downslanting palpebral fissures, exophthalmus, hypertelorism, small upturned nose, maxillary hypoplasia, low-set ears). Hands and feet present a complete syndactyly (spoon shaped hand) with bone and nail fusion. Synostosis may also found in the carpal and tarsal bones and cervical vertebrae. Mental retardation may be present, as well as intracranial hypertension, particularly in absence of early neurosurgical correction. A complex surgical program must be planned for the correction of multiple

Fig. 6.9 Baby with Apert syndrome showing acrocephaly, frontal bossing, exophthalmus, small upturned nose, maxillary hypoplasia, spoon shaped hands

synostosis (skull remodelling, hand surgery). Apert syndrome is due to mutations in the exon 7 of the *FGFR2* gene (different mutations have been identified), with autosomal dominant inheritance and a high rate of de novo mutations correlated with advanced paternal age [15].

Crouzon syndrome is the most frequently reported syndromal craniosynostosis, characterized by acrocephaly with no hand and foot involvement. Premature fusion of the coronal sutures causes the acrocephaly, frontal bossing and flat occipital bone. Looking at the face, there is hypoplasia of the midline structures, reduced orbital volume and ocular proptosis, strabismus, a small upturned nose, and maxillary hypoplasia. Fusions of cervical vertebrae and mild mental retardation may occur. Crouzon syndrome may be due to different mutations of the *FGFR2* gene with a wide range of phenotypical expression. It may be sporadic, due to a de novo mutation often related to advanced paternal age, or familiar with autosomal dominant inheritance.

Muenke syndrome is a relatively frequent unilateral coronal craniosynostosis with brachydactyly. It is caused by a mutation (Pro250Arg) of the *FGFR3* gene, with autosomal dominant inheritance and variable clinical expression [16]. Most cases are familial, but unless there is an index case in the family, the diagnosis may be missed in newborns with a mild phenotype.

Pfeiffer syndrome is a rare acrocephalosyndactyly caused by several mutations in *FGFR1* and *FGFR2* genes, with autosomal dominant inheritance and variable clinical expressivity. Premature fusion of the coronal sutures causes acrocephaly, frontal bossing and flat occipital bone. Concomitant synostosis of sagittal and lambdoideal sutures may cause a cloverleaf appearance of the skull. The face is characterized by downslanting palpebral fissures, ocular proptosis, strabismus, hypertelorism, maxillary hypoplasia, and low-set ears. Hands and feet usually show hypoplasia of the first ray (large first finger and toe, trapezoidal toe) and various degree of postaxial syndactyly. There may be associated elbow ankylosis or synostosis and vertebral fusions. Most severely affected patients require early surgical correction to prevent CNS complications. The prognosis is related to the degree of phenotypical expression.

6.9.1.3 Treacher-Collins Syndrome (Franceschetti Syndrome)

This syndrome is characterized by a developmental defect of jaw and facial bones. There is wide variability. It is determined by several different mutations in the gene encoding the treacle protein, which has a key role in early craniofacial development [17].

Neonatal features are downslanting palpebral fissures, palpebral coloboma, malar hypoplasia, macrostomia, micrognathia, external ear hypoplasia with atresia of the middle ear and hearing loss. Cleft palate and choanal atresia may also be present. In the most severely affected patients, there may be impaired nutrition and respiratory function. Growth and psychomotor development are usually normal, but affected children need long-term multidisciplinary follow-up. Hearing loss requires early treatment to preserve speech development. Surgical treatment may correct bony defects and achieve useful functional and aesthetic advantages.

6.9.1.4 Nager Syndrome (Acrofacial Dysostosis Nager Type)

A sporadic condition with genetic heterogeneity (both autosomal dominant and autosomal recessive inheritance have been described). Patients have a mandibulofacial dysostosis with associated preaxial limb abnormalities (Fig. 6.10). The mandibulofacial dysostosis is mainly characterized by microcephaly, severe micrognathia and malar hypoplasia, low-set posteriorly rotated ears and external auditory canal atresia. The limb deformities consist of radial aplasia or hypoplasia, radioulnar synostosis with limitation of elbow extension and hypoplasia or absence of the thumbs.

Fig. 6.10 Baby with Nager syndrome showing microcephaly, micrognathia, malar hypoplasia and preaxial limb reduction defects

6.9.2 Thoraco-vertebral Dysostoses

Klippel-Feil anomaly is a developmental defect of the spine, with possible changes at cervical, thoracic and/or lumbar level (short neck, pterygium, kyphosis, scoliosis). X-ray investigation of the spine is required to show vertebral changes (fusions, hemivertebrae, hemispondyls) and complete the diagnostic work-up – there are three clinical variants. It is more frequent in females. Its etiology is heterogeneous, with genetic and environmental (vascular disruptions) causes. It may also be part of a more complex phenotype (cervico-oculo-acoustic syndrome, MURCS association).

6.9.3 Limb Dysostoses

Digital defects are caused by a differentiation defect of one or more contiguous bones. Digital development is determined by a complex genetic system, which is phylogenetically common to most vertebrates. Digital anomalies may be sporadic or familial with Mendelian inheritance, and may be associated with other digital defects (polysyndactyly) and other syndromic defects.

Polydactyly may be defined as the presence of one or more supernumerary fingers or toes. It is termed as complete if it involves all phalanges, partial if it involves only distal phalanges (duplication). In the preaxial forms, the extra digit is related to the thumb; in the postaxial forms it is related to the little finger.

Syndactyly is the fusion of two or more digits: it may involve only skin and muscle or include the bones. In the most severe cases, it may affect all the fingers of the limb causing a "spoon" appearance. *Symphalangism* is the fusion of one or more phalanges in the same digit, with severe ankylosis of the interphalangeal joint.

Brachydactyly is the shortening of a digit due to developmental defect of one or more phalanges. It is often associated with metacarpal or metatarsal hypoplasia.

Ectrodactyly is a severe developmental anomaly of the median axis of the hand or foot causing a "lobster claw" appearance. It is usually caused by a genetic etiology and may be associated with other malformations (e.g., ectodermal defects and cleft palate in the ectrodactyly-ectodermal dysplasia-cleft syndrome [EEC syndrome]).

Oligodactyly is the absence or severe hypoplasia of one or more digital axes. It may be preaxial or postaxial and is frequently associated with other defects.

6.10 Osteochondrodysplasias

A wide and heterogeneous group of genetically determined conditions, involving the development and growth of bony and cartilaginous tissues. The bone involvement is often prenatally diagnosed, although some cases become evident after birth. The overall prevalence at birth is about 1/5000. There has been a significant reduction in recent years because of ultrasonographic prenatal diagnosis of the most severe conditions. The classification of osteochondrodysplasias, based on phenotype, has recently been modified by advances in molecular genetics applied to genes involved the the synthesis of collagen and elastin, fibroblast growth factor receptors, cartilaginous proteins, vitamin D – receptor complex, lysosomal and peroxisomal enzymes.

Lethal osteochondrodysplasias are characterized by death during the perinatal period because of generalized involvement including long bones, spine and cranial bones. Mortality is mainly related to respiratory failure (due to skeletal abnormalities and lung hypoplasia) and associated visceral and CNS malformations. Milder osteochondrodysplasias (with normal life expectancy, short stature and abnormal bone development) may benefit from surgical bone elongation and other corrective surgery and rehabilitation programs.

Fig. 6.11 Neonatal achondroplasia with rhizomelic short limb dwarfism, megalencephaly, frontal bossing, facial bone hypoplasia, narrow thorax

6.10.1 Achondroplasia

This is the most common cause of disproportionate short stature with short limbs, determined by a heterozygous mutation (Gly380Arg) of the *FGFR3* gene at 4p16.3. It is inherited as an autosomal dominant trait with a high rate of de novo mutations (80–90% of patients), and is related to advanced paternal age. The recurrence risk is low if parents are not affected. The phenotype at birth (Fig. 6.11) is characteristic: megalencephaly, frontal bossing, depressed nasal bridge, facial bone hypoplasia, prognatism, narrow thorax, rhizomelic short limb dwarfism, brachydactyly, trident hands, hypotonia. Psychomotor development is normal. Patients frequently develop severe orthopaedic complications (lumbar hyperlordosis). In some cases CNS complications, such as the cord compressions and hydrocephalus, may occur during childhood.

6.10.2 Thanatophoric Dwarfism

A severe bone dysplasia with high perinatal lethality, due to a heterozygous mutation of the *FGFR3* gene at 4p16.3. All patients are sporadic and due to de novo autosomal dominant mutations. The phenotype is characterized by severe micromelic dwarfism with bowing and deformations of long bones, "telephone receiver" femurs, narrow thorax, severe platyspondyly (flattening of the vertebral bodies), facial bone hypoplasia, craniosynostosis.

6.10.3 Camptomelic Dwarfism

A severe autosomal recessive bone dysplasia with high perinatal lethality and female prevalence. Due to mutations in the *SOX9* gene at 17q24-25. The phenotype includes sex reversal (female external genitalia with male chromosomes), macrocephaly, large fontanelles, broad depressed nasal root, micrognathia, short neck, pectus carinatum, short limb dwarfism, talipes, anterior bowing of tibiae, poor ossification signs [18].

6.10.4 Diastrophic Dysplasia

A rare autosomal recessive condition due to mutations of the *SLC26A2* gene at 5q32-q33.1. The distinct morphologic abnormality of the growth plate consists of an irregular distribution of degenerating chondrocytes in the resting cartilage with areas of intracartilagenous ossification. Patients have rhizomelic short limb dwarfism, bilateral clubbed foot, cystic lesions of the pinnae with calcification of the cartilage, premature calcification of the costal cartilages, kyphoscoliosis, hip contractures, cleft palate. The "hitchhiker" thumb is particularly characteristic and is due to a deformity of the first metacarpal. Intelligence is normal. Short stature with skeletal abnormalities becomes more marked with advancing age.

6.10.5 Pseudodiastrophic Dysplasia

An autosomal recessive condition described by Burgio in patients with a phenotype similar to diastrophic dysplasia but with proximal phalangeal joint dislocation, normal first metacarpal, platyspondyly, tongue-like lumbar vertebral deformities, marked lumbar lordosis without cystic deformity of the helix. The histologic appearance is different from diastrophic dysplasia and no *SLC26A2* mutations have been demonstrated. Most patients die during the first months of life.

6.10.6 Osteogenesis Imperfecta

A genetically and phenotypically heterogeneous group of conditions characterized by frequent bone fractures [19]. Most frequently affected genes are those encoding for type 1 collagen (*COL1A1* on 17q21-q22 and *COL1A2* on 7q22) with autosomal dominant (AD) and autosomal recessive

(AR) inheritance. Four different clinical variants have been differentiated, but only type II and type III present at birth with a severe phenotype and high perinatal lethality:

- type I (AD, triangular face, blue sclerae, otosclerosis with secondary hearing loss, mitral valve prolapse, macrocephaly, joint hyperlaxity, possible dental abnormalities);
- type II (AD/AR, ossification deficiency, craniotabes, pseudohydrocephalic skull, micrognathia, small nose, blue sclerae, cardiac valve degeneration, endocardic and aortic microcalcifications, multiple dental abnormalities);
- type III (AD/AR, blue sclerae, hydrocephalus, cortical atrophy, joint hyperlaxity, shortness and bowing of limbs, possible dental abnormalities);
- type IV (AD, macrocephaly, frontal bossing, hearing loss, joint hyperlaxity, osteoporosis, mild long bone deformations, possible dental abnormalities).

6.10.7 Osteodysplastic Primordial Dwarfism

A group of brachymelic microcephalic dwarfisms with likely genetic heterogeneity and autosomal recessive inheritance. Different clinical variants have been described in patients with a prenatal onset of severe dwarfism (Fig. 6.12), microcephaly, delayed closure of fontanelles, prominent eyes and strabismus, microretrognathia, pointed nose, high arched palate, oligodontia, small low-set dysplastic ears, sparse scalp hair, pectus carinatum, delayed bone age, severe osteoporosis, multiple skeletal abnormalities (hip dislocation, coxa vara, joint contractures, short bowed long bones, small proximal femoral epiphyses, thin diaphyses of long bones, brachydactyly, talipes). Postnatal failure to thrive, mental retardation, sensory defects are consistently present during growth. Life expectancy is reduced.

Fig. 6.12 Patient with osteodysplastic primordial dwarfism with microcephaly, severe shortness and deformations of long bones, redundant skin folds at limbs

Prenatal and Postnatal Inflammatory Mechanisms

Christian P. Speer

7.1 Introduction

During the past 15 years, intrauterine inflammation has been identified as an etiologic key factor of fetal and neonatal morbidity and mortality, as well as an adverse long-term outcome of very immature preterm infants. Various microorganisms residing in the maternal recto-vaginal tract may invade the chorioamniotic membranes and eventually induce an inflammatory response in the amniotic cavity, the fetus and the mother [1].

As a consequence of these ascending infections, preterm premature rupture of membranes, maternal amnionitis and preterm birth may ensue. Recent epidemiological data indicate that histologic chorioamnionitis might be much more prevalent in early gestational ages: in approximately 60% of very immature preterm infants of 25–26 weeks' of gestational age histologic chorioamnionitis was present [2], and in nearly half of second-trimester placentas microorganisms were detected within the chorionic plate [3]. In addition, high concentrations of various pro-inflammatory mediators have been identified in amniotic fluid of high risk pregnancies. Besides ascending microbial infections, maternal bacteremia has been shown to initiate a similar sequence of inflammation in the placenta and the amniotic cavity. This intrauterine inflammation may eventually induce a fetal inflammatory response with devastating consequences for the affected preterm infant (Fig. 7.1).

In a number of studies, a strong association between a fetal inflammatory response syndrome and adverse neonatal outcome has been reported. Besides an increased incidence of neonatal early-onset sepsis, more preterm infants developed bronchopulmonary dysplasia (BPD) and brain injury following intrauterine exposure to infection and inflammation. Since the pathogenesis of this intrauterine maternal and fetal disease is only poorly understood, we are currently unable to identify a fetus at risk who might subsequently develop serious sequelae following exposure to prenatal inflammation. Clinical observations indicate that fetal exposure to severe maternal

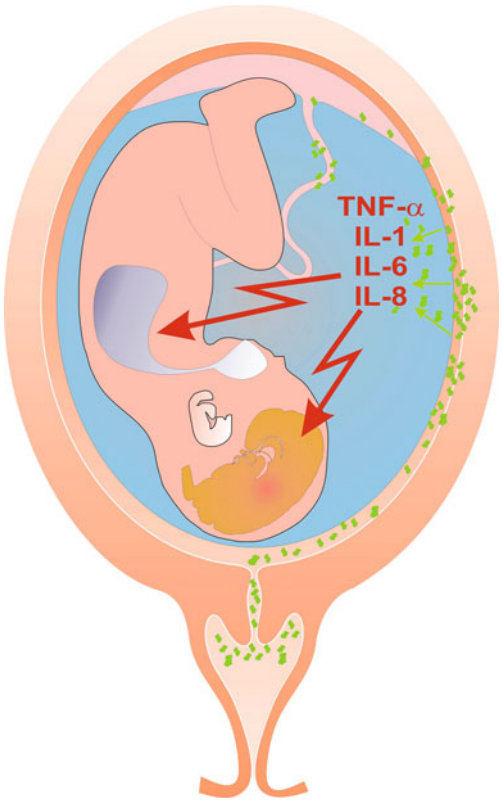

Fig. 7.1 Ascending infection, preterm premature rupture of membranes and maternal amnionitis may result in an intrauterine inflammation reflected by increased intramniotic concentrations of proinflammatory cytokines (TNF-α, IL-1, IL-6, IL-8), which can induce a systemic fetal inflammatory response. There is a clear association between fetal systemic inflammation and adverse neonatal outcome, especially an increased risk of BPD and cerebral injury

chorioamnionitis might not necessarily result in an inflammatory response of an individual fetus. In contrast, a rather smouldering or almost unapparent amniotic infection/inflammation might induce a severe fetal reaction.

This article will summarize our current knowledge of pre- and postnatal inflammatory mechanisms in the human fetus and preterm infants in a condensed form, with the main emphasis on acute and chronic inflammatory events in the preterm infant's lung. This aspect has been reasonably well studied, and has been continuously discussed and updated [4–7]. BPD is an evolving process of lung injury, which may affect normal alveolarization and pulmonary vascular development in preterm infants with a possible lifelong impairment of lung function and other developmental consequences.

7.2 Intrauterine Infections/Inflammation and Fetal Involvement

Animal experiments indicate that intraamniotic endotoxin (lipopolysaccharide [LPS]) initiates inflammation in various placental cell types by signaling via Toll-like receptor 4 (TLR4), which subsequently activates nuclear factor κB and a cascade of inflammatory mediators [8, 9]. In fact, various pro-inflammatory cytokines, inflammatory cells and other inflammatory factors have been detected in amniotic fluid and placental tissue of pregnant women at risk. In addition, the presence of proteomic biomarkers characteristic of inflammation in the amniotic fluid was associated with an increased fetal inflammatory response at birth [10]. Moreover, endothelial cell activation with up-regulation and shedding of cell adhesion molecules was present in histologic chorioamnionitis and fetal funisitis [7].

Increased concentrations of pro-inflammatory cytokines in fetal cord blood indicating a systemic inflammatory response during chorioamnionitis were identified as independent risk factors for BPD and brain injury [4–7, 11, 12]. A pronounced infiltration of inflammatory cells, an increased expression of cytokines and large number of apoptotic airway cells have been observed in lung tissues of stillborn human fetuses with funisitis that have been exposed to chorioamnionitis [4].

The potential role of *Ureaplasma urealyticum* (Uu) in fetal disease is currently unclear. Uu is the microorganism most frequently isolated from the amniotic fluid in preterm births and a predominant pathogen detected in the airway secretions immediately after birth [13]. In the Alabama preterm birth study, Uu and *Mycoplasma hominis* were detected in the cord blood of 23% of very immature preterm infants which were more likely to have a fetal systemic inflammatory response syndrome and probably BPD [13].

In animal experiments, antenatal Uu infection contributed to a prolonged pro-inflammatory response, early fibrosis, and changes in morphology and lung function in the immature lung [14].

The fetal inflammatory response to intrauterine infection may also play a crucial role in the pathogenesis of preterm infants' brain injury. The inflammation signal is likely transmitted across the blood-brain barrier and initiates a neuroinflammatory response which can persist over a period of time and sensitize the brain to subinjurious insults in the postnatal period [11, 12].

7.3 Postnatal Factors Inducing Pulmonary Inflammation

7.3.1 Infection

Early-onset sepsis and systemic nosocomial infections have clearly been identified as individual risk factors for BPD. Besides direct adverse effects of microbial pathogens on pulmonary tissues, activated inflammatory cells and mediators may affect the integrity of endothelial and bronchoalveolar cells and may induce an inflammatory sequence which will be described in more detail below. In addition, vasoactive prostaglandin mediators released during septicemia have been shown to prevent ductal closure or to induce reopening. Interestingly, the presence of Uu in the respiratory tract of preterm infants, even without clinical or laboratory signs of infection, was correlated with elevated cellular and molecular markers of inflammation and has been associated with an increased risk of BPD [4].

7.3.2 Mechanical Ventilation

Many *in vitro* studies and animal experiments clearly confirm that any ventilatory trauma of the immature lung may be injurious to airways and lung tissue.

Over-distension of the lungs or cyclic opening and closing of lung units causes disruption of structural elements and release of pro-inflammatory mediators with a subsequent neutrophil influx [4–7]. However, certain ventilatory strategies may cause more damage than others. The strongest inflammatory reaction was observed in those ventilatory strategies with high peak pressure and no positive end-expiratory pressure. "Priming" of the fetal lung by intrauterine endotoxin or exposure to pro-inflammatory cytokines generated during chorioamnionitis is most likely a considerable pathogenetic factor in the initiation of the pulmonary inflammatory sequence. As a consequence, basically each form of mechanical ventilation may act as a "second strike" and may amplify or aggravate the inflammatory reaction in the immature lung [4–7]. Moreover, it has been convincingly demonstrated that even a relatively "traumatic" bag and mask resuscitation immediately after birth causes disruption of structural elements with release of pro-inflammatory mediators.

7.3.3 Hyperoxia

Very immature preterm infants are particularly susceptible to hyperoxia since the activity of antioxidant system is much lower compared to term newborns. These babies have profound deficiency in antioxidant enzyme activity and a very high risk of suffering from potential detrimental effects of hyperoxia and hyperoxemia during the first weeks of life. In various experimental settings, hyperoxia has been shown to be a strong and independent inducer of various inflammatory cells and mediators. Oxidative stress affected a complex orchestra of genes involved in inflammation or extracellular matrix turnover, and the majority of pro-inflammatory genes were up-regulated [4–7].

7.4 Cellular and Humoral Mediators of Inflammation

7.4.1 Neutrophils and Macrophages

Neutrophils, monocytes and macrophages play a central and crucial role in pre- and postnatal inflammatory events. Immediately after initiation of mechanical ventilation, a neutrophil influx into the airways was observed in animals as well as preterm infants, and this reaction was associated with a decrease in the number of circulating neutrophils. This phenomenon was shown to correlate with the extent of pulmonary edema formation which reflects an injury of the alveolar-capillary unit. Circulating neutrophils and monocytes become rapidly activated within 1–3 hours following the initiation of mechanical ventilation as reflected by CD 11b expression. Most likely, activated neutrophils adhere to the endothelium of the pulmonary vascular system and thus initiate a sequence of pathogenetic events. Activated macrophages secrete numerous cytokines and pro-inflammatory mediators which orchestrate the inflammatory response, particularly neutrophil recruitment. Several investigators have convincingly demonstrated that preterm infants with BPD had much higher and persisting numbers of neutrophils and macrophages in their bronchoalveolar lavage fluid than did infants who recovered from respiratory distress syndrome (RDS) [4–7].

Since apoptosis of inflammatory neutrophils and their timely removal by resident macrophages are critical to the resolution of inflammation, neonatal neutrophils which seem to have a prolonged survival may perpetuate inflammatory processes [4–7].

7.4.2 Pro- and Anti-inflammatory Cytokines

Pro-inflammatory cytokines are the most important mediators in the initiation of pre- and postnatal inflammatory response and in the evolution of inflammation. Tumor necrosis factor-α (TNF-α), interleukin-1 (IL-1), IL-6 and IL-8 are synthesized by various chorioamniotic and inflammatory cells upon stimulation by microorganisms, LPS, and other bacterial cell wall products already in utero or following postnatal infections or biophysical factors. Pro-inflammatory cytokines do not cross the placenta. Increased protein levels and high mRNA expression of pro-inflammatory cytokines have been demonstrated in airway secretions, bronchoalveolar and pulmonary cells, and in the systemic circulation of infants with evolving BPD. For example IL-1 induces IL-8 expression of epithelial cells via a nuclear transcription factor (NFκB)-dependent pathway. IL-8 is involved in the initiation of cellular-endothelial interactions and is probably the most important chemotactic factor in the lung. Recently, a transient over-expression of IL-1 in rat lung by adenoviral gene transfer was accompanied by a local increase in TNF-α expression and a vigorous inflammatory reaction with profound tissue injury and fibrotic changes. Moreover, perinatal expression of IL-1β in pulmonary epithelial cells of a bi-transgenic mouse model induced a lung disease which was clinically and histologically similar to BPD in very immature preterm infants. The presence of TNF-α positive macrophages in lung tissue of preterm infants who had died of severe RDS was strongly associated with a loss of endothelial basement membrane and a destruction of interstitial tissue [4–7]. Experimental and clinical data convincingly indicate that the profound pro-inflammatory cytokine response present in the airways and pulmonary tissue of preterm infants may reflect an inability to regulate inflammation through an adequate expression of anti-inflammatory cytokines such as IL-10 and others. Especially in preterm infants exposed to chorioamnionitis or affected by fetal inflammatory response syndrome, an insufficient inhibition of a high fetal pro-inflammatory cytokine response shortly after birth may increase the risk of BPD [15].

7.4.3 Oxygen Radicals and Proteolytic Mediators

Exposure of preterm infants to high oxygen concentrations can induce direct oxidative cell damage through increased production of reactive oxygen species [16]. Oxygen radicals are not only released by neutrophils and macrophages at sites of inflammation, but are also generated under hyperoxic conditions by free iron or by the cell-bound xanthine oxidase system. Reactive oxygen species exert direct toxic effects on bronchoalveolar structures by induction of inflammation, lipid peroxidation, oxidative inactivation of protective antiproteases and up-regulation of metalloproteinases [4–7]. Animal experiments indicate that oxidative stress is a very early and potent factor in the initiation of pulmonary inflammation [9]. Most importantly, the activity of antioxidant enzymes in

preterm infants is much too low to sufficiently combat oxidative injury. Preterm infants have a profound deficiency of antioxidant activity prior to delivery, immediately after birth and during the first weeks of life, which is the most vulnerable period for an oxidative injury since many babies at risk are receiving high inspiratory oxygen concentrations and are most likely to be exposed to hyperoxia.

At sites of inflammation neutrophils and macrophages release various potent proteases such as elastase, metalloproteinases and others, which play a predominant role in the destruction of the alveolar-capillary unit and the extracellular matrix as well as in remodelling throughout all stages of lung development. In general, data from *in vitro* studies, animal experiments and clinical observation in preterm infants indicate that an imbalance between proteases and protease inhibitors may essentially contribute to lung injury and the pathogenesis of BPD. For example, an imbalance between elastase, a powerful neutral protease, and α_1-proteinase inhibitor has been demonstrated within the airways of preterm infants. α_1-proteinase inhibitor was shown to be functionally inactivated by reactive oxygen species. As a result of elastolytic damage, increased concentrations of various markers of tissue destruction have been identified in airway secretions and urine of preterm infants. This is of particular concern in light of studies showing a markedly reduced alveolar septation in the lungs of infants with BPD [4–7].

Numerous inflammatory mediators and cells have detrimental effects on microvascular integrity. Increased alveolar-capillary permeability is pathognomonic for the early and later stages of inflammation and is clearly associated with a deterioration of lung function. Protein leakage into the alveoli and airways of preterm infants takes place within one hour after initiation of mechanical ventilation. At a postnatal age of 10–14 days, preterm infants who later developed BPD had high concentrations of albumin and other serum proteins in their airway secretion, a phenomenon that contributes to edema formation, to inactivation of the surfactant system and worsening the lung function. Magnetic resonance imaging in infants with BPD confirmed an increased water content and a gravity-induced collapse of the lung [4–7].

7.5 Conclusions

Intrauterine infection and inflammation characterized by chorioamnionitis and a fetal inflammatory response syndrome play a crucial role in the pathogenesis of fetal organ injury. Fetal exposure to inflammatory cells, cytokines and other pro-inflammatory mediators can initiate and induce a pulmonary inflammatory response which might directly affect the alveolar-capillary unit and tissue integrity. It may also be associated with various postnatal factors such as infection, oxygen toxicity and mechanical ventilation and may contribute – at least in part – as a multiple-hit scenario to the development of BPD. As a devastating consequence of the continuous inflammatory process, normal alveolarization as well as vascular development can be compromised with lifelong consequences for the preterm infant. Similarly, a neuroinflammatory response in the fetal central nervous system secondary to fetal infection and/or systemic inflammation is a likely injurious pathomechanism for the developing brain.

The Fetus at Risk: Chorioamnionitis

Mikko Hallman and Tuula Kaukola

8.1 Introduction

Infection and inflammatory injury are the major threats during pregnancy. The extraembryonic tissues play important roles in protecting the fetus. From 10–12 days post conception (p.c.), yolk sack and allantoic vessels provide nutrition to the embryo. By 20 days conception p.c. fetal vessels are discernible in developing villi. They communicate with the embryo via a connecting stalk that later develops into the umbilical cord. By 40 days p.c. the embryo is completely surrounded by the amniotic cavity and attached via the umbilical cord to the hemo-monochorial placenta [1]. Upon complete adherence of the fetal membranes to the decidua at about 20 weeks of gestation, bacterial inflammation may directly penetrate the chorioamnion from any direction and contaminate the amniotic fluid [2, 3]. In high risk pregnancies the protective fetal chorioamnion and placental villi are challenged in multiple ways. These tissues respond by inflammation, producing mediators that may promote labor or affect the fetus in multiple ways. This chapter focuses only on the consequences of chorioamnionitis in the fetus comparing the affected fetuses to the gestation controls.

8.2 Diagnosis and Incidence of Chorioamnionitis

Histologic chorioamnionitis (HCA) is characterized by mostly polymorphonuclear neutrophil (PMN) infiltration of the placenta, fetal membranes and/or umbilical cord. Pathological exam of the placenta, fetal membranes and umbilical cord defines chorioamnionitis (CA) [1, 4]. In most cases HCA is a silent condition, not presenting any detectable symptoms in the mother. However, it is a sign of activation of the immune defense associating with inflammatory activation of preterm labor. Chorioamnionitis is a well accepted risk factor of spontaneous premature birth.

Analysis of a marker of PMNs in amniotic fluid provides accurate diagnosis of CA [5]. The levels of interleukin-6 (IL-6), IL-8 and tumor necrosis factor-α (TNF-α) have been found to be high in the amniotic fluid [6]. However, amniocentesis is not indicated for diagnosis of CA. After birth, the inspection of the placenta, its vessels and the fetal membranes helps to understand the pregnancy outcome. Placentas with severe chorioamnionitis reveal marginal hemorrhages and the amniotic surfaces are covered with invisible white leukocyte-enriched film. Histological specimens are recovered from three sites: chorionic plate, fetal membranes as a roll from the site of spontaneous membrane rupture and segments of umbilical cord [1, 4]. Histological chorioamnionitis is often classified into three grades: (1) mild (5–10 neutrophils per high power field [HPF]); (2) moderate (11–30 neutrophils/HPF); (3) severe (>30 neutrophils/HPF). Involvement of all compartments is studied separately. Chorioamnionitis is additionally defined on the basis of the distribution of inflammation.

Clinical chorioamnionitis presents as maternal fever, foul-smelling vaginal discharge, uterine tenderness and laboratory findings, e.g., leukocytosis or elevated C-reactive protein. In the era of early treatment of infections, two positive criteria (one clinical, one chemical/ laboratory) establish diagnosis. In severe clinical CA, elective delivery is considered for fetal indication.

Prelabor rupture of fetal membranes (PROM) exposes the intra-amniotic space to ascending infection and is mostly associated with CA. In several reports, the cases of preterm PROM are considered under CA or clinical CA, although the diagnosis of HCA is not confirmed. This complicates the comparison of the outcomes between different studies.

Histologic CA is evident in many preterm births (PTB) after spontaneous onset of labor and only in 2–10% of term births (Table 8.1). Although the association between HCA and

Table 8.1 Prevalence of pregnancy conditions and incidence of chorioamnionitis (HCA) in pregnancy conditions

Pregnancy condition	Prevalence % of all births	HCA % in given pregnancy condition
Term	85–92	2–10
Post-term	1–5	5–15*
Preterm	5–13	15–25
– Spontaneous onset	3–9	25–35
PROM	1.5–4	50–80
32–36 weeks	2–7	20–30
28–32 weeks	0.6–1.2	30–50
<28 weeks	0.3–0.6	40–70
– No spontaneous onset	2–4	5–15

* Meconium in amniotic fluid (50%) associates with green staining of chorioamnion that contains meconium-laden macrophages; associated chorioamnionitis suggests infection.
The ranges of the incidence figures are based on population studies that, however, may not be representative [25, 38, 42]. The reported incidence figures are likely understated, since more extensive examination of fetal membranes reveals a higher incidence of inflammatory cells [43].
In preterm PROM, labor nearly always starts spontaneously.

spontaneous PTB is strong, neither the specificity nor the sensitivity is very high. In near-term births due to spontaneous onset of labor, HCA is less frequent (10–25%) than in extremely preterm spontaneous births (50–80%). Yet, even in elective term births without labor, bacterial organisms may be present [7].

Fetal inflammatory response syndrome (FIRS) is defined as an increase in IL-6 in cord blood in CA [8]. Funisitis is another diagnostic criterion of FIRS. Although FIRS is associated with an increased risk of early postnatal infection, most of the premature newborn affected by FIRS (> 90%) have negative blood cultures. According to a regional cohort of 163 preterm Finnish infants, born before 32 weeks of pregnancy, 50% of HCA cases had FIRS on the basis of funisitis, elevated cord IL-6, or both.

8.3 Antenatal Findings in Chorioamnionitis

In term pregnancies, maturation and shortening of the cervix and rupture of fetal membranes expose the amniotic space to microbes. In the setting of spontaneous preterm labor, the inflammatory mediators in general play a much more prominent role in the activation of the labor process than in term labor. Histological inflammation may persist for a long period during pregnancy as a condition with apparently little consequence. It has been postulated that after mid-pregnancy when the expanding fetal membranes seal the endometrial cavity, the incidence of ascending inflammation becomes rare [9].

Besides microbes and endotoxins, other triggering agents (host *vs* graft reaction, meconium) may play a role in the etiology. In HCA, the amniotic fluid or fetal membranes reveal microbes that, however, may also be detected in elective births without labor using molecular probes specific for bacteria [6, 7, 9]. The most common microbe is *Ureaplasma urealyticum* (20–40%) (Table 8.2). The traditional pathogens (Group B Streptococci, *E. coli*, Enterococci, *Listeria monocytogenes*) are not very common (2–10%).

The ascending route is the most common in HCA and bacterial vaginosis (BV) is a risk factor. In BV, the incidence of lactobacilli as a normal vaginal inhabitant has decreased at the expense of other microbes, including *Gardnerella vaginalis*, *Mobiluncus* spp., anaerobic gram-negative rods, *M. hominis* and *Ureaplasma urealyticum*. Most of microbes in BV are frequently detected in HCA. However, BV predicts the risk of preterm birth with a low specificity [10]. Periodontitis is another proposed risk factor of spontaneous PTB [11]. Antibiotics

Table 8.2 Fetal consequences of chorioamnionitis or chorioamnionitis with complicating event. Comparison to infants born preterm with similar gestation and without evidence of chorioamnionitis

Postnatal morbidity	Histologic chorioamnionitis	+Fetal inflammation	+Clinical chorioamniontis	+PROM
Infection	↑	↑↑	↑↑	↑↑
RDS	↓	~* or ↓	~* or ↓	~* or ↓
BPD	~ *	–	–	~ or ↑*
Severe RDS	~* or ↓	–	–	↑
IVH	~ or ↑*	~ or ↑	↑	↑
CP	~or ↑*	–	↑	↑

* Progress in antenatal and neonatal treatment practices (antenatal glucocorticoid and gentle neonatal cardiopulmonary treatment practices) have decreased the serious morbidity. Explanations: (~) both lower and higher incidences reported; (–) reports nonexistent or scanty.

have not been beneficial in prolonging the overall duration of high-risk pregnancy without PROM according to available meta-analyses. After preterm PROM, antibiotic prophylaxis (macrolide ± additional antibiotics *vs* expectant management) increases the duration between PROM and birth [12].

8.3.1 Specific Infections Associated with Chorioamnionitis

Placental villi are affected in infections causing intrauterine growth restriction [13]. *Treponema pallidum* causes hypercellular villitis with mononuclear infiltration, sometimes necrotizing funicitis or plasma cell rich CA. Intrauterine candidiasis is associated with clusters of characteristic structures, surrounded by inflammatory cells in umbilical cord, placenta and fetal membranes. Typical placental findings of severe *Cytomegalovirus* infection include plasmacytic villitis, thrombosis of villous capillaries, necrosis of villous tissues, and inclusion-bearing cytomegalic cells. *Toxoplasma gondii* is associated with lymphoplasmacytic villitis and sclerosis, along with toxoplasma cysts in amnion/chorion. Enteroviruses, mumps, and rubella cause distinct placental inflammatory lesions. *Listeria* infection causes acute necrotizing villitis and CA. Early-onset Group B Streptococci (GBS) causes CA and amniotic fluid is a growth media of GBS. The high risk mothers are frequently heavily colonized with GBS (vaginal flora, urinary tract, breast milk). In these cases early neonatal GBS is effectively prevented by intrapartum administration of antibiotics. The recurrence rate of the carrier status is high (see Section X: Fetal and Neonatal Infections).

Ureaplasma urealyticum is the most frequently isolated microbe in CA. *Ureaplasma* spp. may cause pneumonia and occasionally bacteremia and meningitis in susceptible newborn infants. According to randomized trials, erythromycin treatment against *Ureaplasma* species prolonged the duration of pregnancies after preterm PROM. Further randomized trials are required to demonstrate that appropriate antimicrobial treatment of the high-risk infants eradicates *Ureaplasma* spp. and decreases the risk of BPD [14].

The causes of increased susceptibility in some pregnancies to CA remain to be studied. Genetic factors may influence the individual susceptibility, as some mutations or alleles cause defects in innate immunity or failures of appropriate antibody formation. Environmental risk factors warrant further investigation and development of vaccines against specific pathogens would offer a tool for prevention.

8.3.2 Inflammation without Microbes

Villitis of unknown etiology (VUE) is found in 5–15% of predominantly term placentas. It is associated with intrauterine growth restriction, fetal death and perinatal asphyxia. In VUE, CD3-positive maternal T lymphocytes gain access to the villous stroma. Fetal antigen-presenting cells (Hofbauer cells) expand and express class II major histocompatibility complex molecules. Maternal monocyte-macrophages in the perivillous space likely amplify the immune response. VUE may represent a state combining maternal allograft rejection and graft *vs* host disease mechanisms [15, 16].

Meconium that is prevalent in post-term (20–70%) and term (5–15%) pregnancies, associates with green staining of chorioamnion containing meconium laden macrophages and occasionally chorioamnionitis.

8.4 Chorioamnionitis as a Risk Factor for Acute and Chronic Diseases

It has been proposed that the ascending inflammation is mainly distributed transcellularly via amniotic fluid. On the other hand, in clinical chorioamnionitis transplacental spreading prevails. According to experimental studies and clinical observations, placental circulation is adversely affected as a result of transplacental inflammatory insult [17], whereas the transcellular spreading of inflammation acutely boosts the host defense [18, 19]. The fetal consequences of CA are additionally dependent on severity and etiology of the inflammation, as well as multiple, poorly understood genetic and environmental risk factors. Amniotic fluid, contaminated with inflammatory cells, cytokines and/or microbes, is swallowed as well as exposed to developing airways during fetal breathing movements. Hematogenous spreading by direct invasion via placental villi or umbilicus to the fetal compartment is another route. CA is not always diagnosed by histology. Defining CA biochemically (inflammatory cytokines), microbiologically or clinically will alter the target population and hence the associated risk [20].

8.4.1 Experimental Data

Introduction of bacterial endotoxin (LPS) or proinflammatory cytokine (IL-1) to amniotic fluid evokes an acute maturation of the surfactant system [18, 19]. This cytokine-induced pulmonary epithelial differentiation enhances the capacity of premature neonatal respiratory adaptation. Its effect is additive with that of glucocorticoid [19]. LPS or cytokine (e.g., IL-8) induces acute airway inflammation that may spread systemically [21]. Antenatal glucocorticoid protects the preterm fetus affected by FIRS against vascular insults, stabilizing the blood pressure and strengthening endothelial and epithelial barriers in blood vessels after premature birth. In pregnant rodents, a high dose of LPS to the maternal compartment induces an acute fetal perfusion defect, illustrated by increased

resistance in placental villous perfusion and resulting in low-output fetal cardiac failure. According to animal model data, acute transplacental inflammatory insult may result in brain injury [22]. Inflammation may gain access into the immature brain as specific chemokines serving as ligands for their receptors in the target tissue or promoting neutrophil-mediated breakdown of blood-brain-brain barrier [23]. Intracerebral cytokine storm promotes free radical attack, necrosis, apoptosis and brain injury. Immature oligodendrocytes are especially vulnerable (see Chapter 128).

8.4.2 Pulmonary Consequences of CA

The reports of premature patients from the early 90s associate CA mostly with adverse outcomes. In these studies, clinical CA was overrepresented, antenatal glucocorticoid was rarely given, and advanced neonatal respiratory care were not available. The early study of Watterberg revealed an association between CA and a low risk of RDS and a high risk of BPD as studied in 53 preterm infants [24]. The risk of BPD associated with increased tracheal IL-1β levels [24]. Later reports representing the era of antenatal glucocorticoid and surfactant therapy confirm a HCA-associated substantial decrease in the risk of RDS, and no increase in the risk of BPD [25–27].

Recent cohort studies with larger populations have additionally found that in very preterm infants the high proinflammatory cytokines detected in cord blood in HCA often *decrease* shortly after birth and do not associate with adverse pulmonary consequences [26, 27]. However, within 24 hours after a very preterm birth, very high levels of specific cytokines, many from non-CA pregnancies, associate with both RDS and BPD [26]. Modest inflammatory response in CA may additionally be due to immune paralysis that associates with antenatal glucocorticoid treatment [28] or complicates prolonged PROM [29]. Structural immaturity of the lung after extremely preterm birth predisposes to "new" BPD, suggesting that inhibition of angiogenesis and of formation of true alveoli play important roles in the pathogenesis BPD [30]. Fetal inflammation exposes the lungs to a lower risk of growth failure and lack of alveolarization than inflammation or recurrent infections after extremely preterm birth. It is possible that environmental factors, such as high oxygen tension after birth, plays an important interactive roles in pathogenesis. In infants born after 32 weeks of pregnancy, the development of lung structure is more advanced and the risk of BPD is very low, despite serious acute neonatal lung disease.

8.4.3 Neurological Consequences

Half of all children with CP are born at term (CP prevalence 1–1.5 per 1000 term born) including mostly cases of hemiplegia and quadriplegia, whereas in very preterm infants diplegia predominates and CP cases are fairly common in this population (4–8 per 100 preterm) [31]. The pattern of cord blood immunoproteins predicting CP is different in very preterm and term infants [32].

According to a large population based cohort, the incidence of CP among term and preterm infants has remained stable, or even declined, since the 70s, suggesting that advances in treatment practices influence the long-term outcomes [31].

8.4.4 Infants Born Very Preterm

In many but not all studies, CA is a risk factor of IVH among infants born very preterm [33–35]. Despite common use of antenatal glucocorticoid and more gentle neonatal treatment practices, decreasing the risk of IVH, CA has been linked to IVH, emphasizing the role of immunological activation in fetus as a pathway to cerebral injury before birth. In populations mostly representing *clinical* CA, the risk of revere IVH is increased in preterm infants [36]. There is also evidence of increased risk of CP and cognitive problems in preterm infants born in clinical CA [37]. Besides clinical CA, cases of "silent" CA with an additional defect in placental perfusion are associated with abnormal neurological outcome [33]. However, infants born with HCA as a whole do not have a higher frequency of neurodevelopmental problems than the gestation controls [38]. More prospective cohort studies are underway.

8.4.5 Infants Born Near-Term to Term

A case-control study of a cohort of ~200,000 infants born at 36 weeks or later in gestation during the years 1991 and 1998 revealed CA or endometritis in 14% of CA cases and 4% of random controls, translating CA as an independent risk factor (OR 3.8, CI 1.4–9.3) of CP [39], consistent with other studies. Clinical CA and maternal fewer were associated with increased risk.

The diagnosis of silent HCA covered only less than 25% of the CA population and there was no detectable association between silent HCA and CP. In a meta-analysis a significant association was found both between clinical CA and CP (RR 1.9, 95% CI 1.5–2.5) and between clinical CA and cystic periventricular leukomalacia (RR 2.6, 95% CI 1.7–3.9) [40].

Quadriplegia as a separate trait in term and near-term neonates was associated with severe hypoxic-ischemic insult. In contrast, hemiplegia is associated with brain infarction, and one risk factor of brain infarction was preterm PROM [41].

Diagnosis of Fetal Distress

Felice Petraglia, Carlotta Boni, Filiberto M. Severi and Jane Norman

9.1 Fetal Distress

Fetal distress is a very broad term, which can be used in many clinical situations. Although it is difficult to give a precise clinical definition, obstetricians usually use this term to indicate that the fetus is becoming hypoxic. Immediate delivery has to be considered, because neurological damage may occur when the fetal brain is deprived of oxygen.

The diagnosis of fetal distress based upon heart rate is imprecise because heart rate patterns are only a reflection of the efficiency of physiological mechanisms which depend on blood flow and oxygenation. Furthermore, activity of this control mechanism is influenced by the pre-existing state of fetal oxygenation as with chronic placental insufficiency. Therefore, heart rate patterns are now described as "reassuring" or "non reassuring": in the case of a "non reassuring" heart rate pattern, there is a risk of fetal distress.

The recognition of risk and the knowledge of appropriate measures to treat fetal distress are of the utmost importance. Antepartum fetal testing is used to assess hypoxia in high-risk pregnancies, and monitoring during labor supplies information on the status of the fetus prior to birth.

9.1.1 Fetal Oxygenation

9.1.1.1 Physiology

Oxygenation may be defined as the process of transporting molecular oxygen from air to the tissues of the body. In the fetus this first involves oxygen transfer across the placenta; then there is reversible binding of oxygen to fetal hemoglobin and transport in the fetal blood stream; and, finally, oxygen consumption for growth and metabolism. Energy is derived from the combination of oxygen and glucose to form carbon dioxide and water [1]. Removal of carbon dioxide and protection against acidosis is the reverse mechanism of oxygen delivery and is helped by the rapid diffusion, high solubility and volatility of carbon dioxide. In the adult, carbon dioxide is excreted in the lungs while bicarbonate and hydrogen ions are removed by the kidney. In the fetus, both these functions are carried out by the placenta. When there is inadequate oxygen supply, the Krebs cycle cannot operate and pyruvate is converted to lactic acid. This enters the blood and there is a systemic acidosis, unless it is either metabolized or excreted. The amount of oxygen bound to hemoglobin is not linearly related to oxygen tension (pO_2). Each type of hemoglobin has a characteristic oxygen dissociation curve which can be modified by various factors, such as pH and the concentration of 2,3-diphosphoglycerate (2,3-DPG). For example, when 2,3-DPG rises in response to anemia or hypoxia, it binds to and stabilizes the deoxygenated form of hemoglobin, resulting in a shift of the oxygen dissociation curve to the right and therefore release of oxygen to the tissues. Although *in vitro*, both adult (HbA) and fetal (HbF) hemoglobins have the same oxygen dissociation curves, adult human blood has a lower affinity for oxygen than fetal blood because of its greater binding to 2,3-DPG. The higher affinity of fetal blood for oxygen helps the transplacental transfer of oxygen. Furthermore, since the P50 of fetal blood is similar to the umbilical arterial pO_2, the fetus operates over the steepest part of the hemoglobin oxygen dissociation curve and, therefore, a relatively large amount of oxygen is released from the hemoglobin for any given drop in pO_2 [1].

9.1.1.2 Hypoxia

Fetal hypoxia is a condition characterized by oxygen deficiency in the tissues: any cause that leads to a conversion from an aerobic to an anaerobic metabolism produces less energy and more acid. If the oxygen supply is not restored, the fetus dies.

Department of Pediatrics, Obstetrics and Reproductive Medicine
Section of Obstetrics and Gynecology, University of Siena, Siena, Italy

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

Table 9.1 Causes of reduced fetal oxygenation

Maternal	– Respiratory insufficiency – Hypotension – Hypertension – Collagen/vascular disease – Diabetes – Shock – Hemolytic crisis – Asthma/bronchospasm
Placental	– Abruptio placentae – Infarction – Confined mosaicism – Placenta previa
Uterine	– Rupture – Hyperstimulation – Prolonged labor
Fetal	– Arrhythmia – Hydrops – Myocarditis – Congenital abnormality
Umbilical cord	– Funicular loop – Compression – Prolapse – Vasa previa bleeding

Hypoxia may result from:

1. reduced placental perfusion with maternal blood and a consequent decrease in fetal arterial blood oxygen content due to low pO_2 (hypoxemic hypoxia);
2. reduced arterial blood oxygen content due to low fetal hemoglobin concentration (anemic hypoxia);
3. reduced blood flow to the fetal tissues (ischemic hypoxia) [1].

Reduced fetal oxygenation may result from a variety of sources (Table 9.1) [2].

9.2 Clinical Diagnosis (of Fetal Distress)

9.2.1 Antenatal Surveillance

9.2.1.1 Identification of a Fetus at High Risk of Distress

The identification of at-risk pregnancies and their surveillance are currently of high priority in obstetric practice. Fetal distress and antepartum death can be substantially reduced if fetal surveillance is aimed at the early detection of signs of fetal oxygen deprivation. Ultrasound imaging has helped with detection of the vulnerable fetus.

The purposes of ultrasonography studies are: (i) to have accurate pregnancy dating, to diagnose multiple pregnancies and to detect fetal anomalies; and (ii) to monitor fetal growth and to recognize small for gestational age (SGA) and growth restricted (FGR) fetuses who may be more susceptible to the damaging effects of fetal hypoxia.

It is not always easy to decide whether a fetus is SGA as a result of genetic causes or if it suffers from placental insufficiency and malnutrition (intrauterine growth restriction [IUGR]) (Fig. 9.1), but it is important to detect fetuses with an asymmetric profile of growth because these fetuses are at significant risk of hypoxia, acidosis and death. This condition is also a common cause of premature delivery, is associated with increased perinatal mortality and morbidity and is considered synonymous of "chronic fetal distress". The identification of SGA pregnancies allows for monitoring and optimizing the mode and time of delivery.

If IUGR is suspected, it is important to perform an ultrasound biometric evaluation of the fetus as early as possible and then to follow fetal growth with serial and repeated (every 2 weeks) ultrasound investigations.

Before assessing fetal size, it is necessary to make an accurate assessment of gestational age.

Determination of Gestational Age and Assessment of Fetal Size

The accurate assessment of gestational age is very important in everyday clinical practice.

Fetal body measurements reflect the gestational age of the fetus. This is particularly true in early gestation (first and early second trimester). In patients with an uncertain last menstrual period, biometric measurements must be made as early as possible to date the pregnancy accurately. The embryo crown-rump length (CRL) measured obtained by ultrasound, has been shown as the best parameter during the first trimester (accuracy: ± 5–7 days). This measurement can be made between 6 and 13 weeks and gives a very accurate estimation of the gestational age.

The use of multiple parameters (biparietal diameter [BPD]; head circumference [HC]; transverse cerebellum

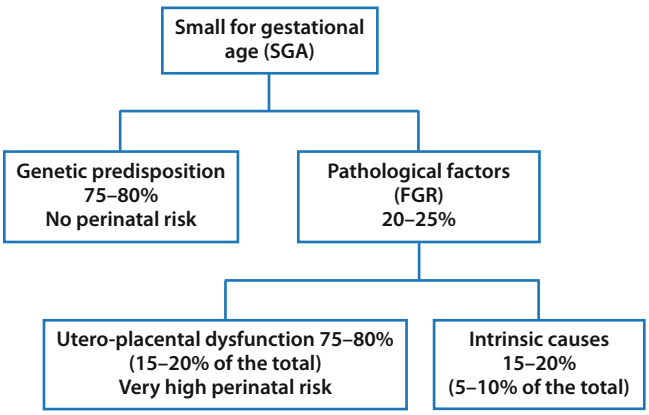

Fig. 9.1 Reduced fetal growth: etiopathogenesis

Table 9.2 Second trimester: accuracy of multiple parameters in the determination of gestational age

Weeks	BPD	HC	FL
12-18	± 1.19	± 1.19	± 1.38
19-24	± 1.73	± 1.48	± 1.80
25-30	± 2.18	± 2.06	± 2.08

Table 9.3 SGA: US diagnostic accuracy

Ultrasound parameters	Sensitivity (range)	Specificity (range)
Abdominal circumference	67–86%	80–92%
Ratio among biometrical parameters	62–82%	80–93%
Fetal weight estimation (FWE)	64–83%	79–96%

diameter [TCD]) is generally recommended for the determination of gestational age in the second trimester (Table 9.2).

To assess if a fetus has normal growth, the following fetal biometry is used:

1. BPD and HC;
2. abdominal circumference (AC), which is the most important measurement in the second half of pregnancy; it reflects fetal size and weight rather than age [3];
3. femur length (FL), which reflects longitudinal growth of the fetus.

Repeated measurement of AC is considered the most sensitive parameter for following fetal growth (Table 9.3). In recent years, three dimensional ultrasound and measurements of fetal subcutaneous tissue have been porposed as methods that may improve the accuracy of fetal size calculations [4, 5].

When the suspicion of IUGR is confirmed, fetal surveillance, placental function and fetal behavior measurements should be initiated and fetal growth should be followed longitudinally with other diagnostic methods (see § 9.3).

9.2.1.2 Identification of Fetal Distress

Fetal distress may be discovered in pregnancy ("antepartum testing") or during labor and delivery ("intrapartum testing") using different approaches.

9.3 Antepartum Testing

There are various tests that allow clinicians to evaluate fetal oxygenation and fetal well-being. These are described below.

9.3.1 Biophysical Profile (BPP)

The integration of aspects of fetal behavior, such as gross body movements, breathing movements and fetal tone, together with cardiotocography (see below) and the amount of amniotic fluid constitute the fetal BPP. Described by Manning, the BPP is based on ultrasound and is widely used for antepartum fetal surveillance [6]. It can be done in the later stages of pregnancy from the beginning of the third trimester. The test is more frequently used in cases where the pregnancy is over 40 weeks to ensure fetal well-being; in some cases it is performed because of the presence of high-risk factors (previous pregnancy loss in the second half of pregnancy, maternal hypertension, diabetes mellitus, IUGR, etc).

BPP has been tested only in high-risk pregnancies, and there is evidence from uncontrolled observational studies that it has a good negative predictive value for fetal death. It is not suitable for fetal surveillance in unselected populations.

BPP is a score based on five parameters: a score of 0 (abnormal) or 2 (normal) is given for each of five categories (Table 9.4).

The second part of the test consists of a CTG evaluation (see § 9.3.2.1).

Table 9.4 Fetal biophysical profile

Biophysical variable	Normal (score = 2)	Abnormal (score = 0)
Fetal tone	1 or more episodes of active extension with return to flexion of fetal limb(s) or trunk (opening and closing of hand considered normal tone)	Slow extension with return to partial flexion, movement of limb in full extension, absent fetal movement, or partially open fetal hand
Gross body movements	2 or more discrete body/limb movements within 30 min (episodes of active continuous movement considered as a single movement)	<2 episodes of body/limb movements within 30 min
Fetal breathing movements	1 or more episodes of ≥20 s within 30 min	Absent or no episode of ≥20 s within 30 min
Qualitative amniotic fluid volume	1 or more pockets of fluid measuring ≥2 cm in vertical axis	Either no pockets or largest pocket <2 cm in vertical axis
Fetal heart rate (FHR)	2 or more episodes of acceleration of ≥15 bpm and of >15 s associated with fetal movement within 20 min	1 or more episodes of acceleration of fetal heart rate or acceleration of <15 bpm within 20 min

Modified from [6].

A score below 6 is not reassuring and is considered borderline. The test may be repeated as often as daily until delivery, although most often it is a one time event, or a weekly event depending on the reason for the biophysical profile.

9.3.1.1 Amniotic Fluid Evaluation

This is an important parameter for the assessment of fetal well-being. Amniotic fluid volume is a reflection of placental perfusion and normal fetal blood flow from the placenta and may be decreased when there are factors causing growth restriction [7].

Although an experienced examiner can assess the adequacy of the amniotic fluid volume, an amniotic fluid index (AFI) has been developed to standardize this assessment. This index is obtained by calculating the sum of deepest pocket of amniotic fluid in each of the four quadrants of the uterus. Another technique is the vertical measurement of the major pocket (Manning technique: cut-off 10 mm).

During the third trimester, normal amniotic fluid correlates with an AFI of 10–20 cm. Borderline values are 5–10 cm for decreased fluid and 20–24 cm for increased fluid depths. Pregnancies with decreased amniotic fluid volume are an indication for additional surveillance and assessment. For some authors, prospective evaluation of amniotic fluid index alone in low-risk pregnancies does not seem to be a good predictor of complications during a pregnancy or the perinatal period [7, 8], but others consider that reduced amniotic fluid volume indicates chronic oxygen deficiency: perinatal mortality in pregnancies with oligohidramnios is 50 times higher than in pregnancies with normal AFI.

9.3.1.2 Amnioscopy

At term, it is possible to visualize the amniotic fluid colour using amnioscopy. If it is clear, the liquor is considered normal; if it is colored, there is a possibility of fetal distress because during fetal hypoxia there is an increase in fetal intestinal peristalsis with the release of meconium from the fetal rectum. This investigation is no longer used as often as it was in the past.

9.3.2 Cardiotocography

Cardiotocography (CTG) is the recording (-graphy) of the fetal heartbeat (cardio-) and the uterine contractions (-toco-). Recordings are done using two separate transducers, one for the measurement of the fetal heart rate and the other for measuring uterine contractions.

The CTG trace shows two lines: the upper shows the fetal heart rate in beats per minute; the lower is a recording of uterine contractions. Interpretation of the results of the monitoring is complex and different patterns can be seen on a CTG.

1. *Baseline rate*. The baseline rate should be between 110 and 150 beats per minute (bpm) and is measured when the fetal heart rate is stable (i.e., without accelerations and decelerations). It should be taken over a period of 5–10 minutes. The rate may change over a period of time but normally remains fairly constant.
2. *Bradycardia*. This is defined as a baseline heart rate of less than 110 bpm. A suspicious bradycardia is defined as being between 110 and 100, whereas a pathological pattern is below 100. A steep sustained decrease in fetal heart rate is indicative of fetal distress.
3. *Tachycardia*. A suspicious tachycardia is defined when the FHR is between 150 and 170 bpm, whereas a pathological pattern is above 170 bpm. Tachycardias can be a response to fever, fetal infection, fetal movements, tocolytic drugs, use of tea or coffee and occasionally a sign of fetal distress (in conjunction with other abnormalities). An epidural may also induce a tachycardia in the fetus.
4. *Baseline variations*. The short-term variations in the baseline should be between 10 and 15 bpm (except during fetal sleep, which should be no longer than 60 minutes). Prolonged reduced variability along with other abnormalities may indicate of fetal distress.
5. *Accelerations*. This is a transient increase in the fetal heart rate of greater than 15 bpm for at least 15 seconds. Two accelerations in 20 minutes are required for the trace to be considered "reactive" i.e., normal. Accelerations are a good sign as they show fetal responsiveness and the integrity of mechanisms controlling the heart rate.
6. *Decelerations*. These may either be normal or pathological. Early decelerations occur at the same time as uterine contractions and are usually due to fetal head compression and therefore occur during the first and second stages of labor with descent of the head. They are normally benign. Late decelerations begin after the start of a contraction and persist after the end of a contraction and suggest fetal distress. Variable decelerations vary in timing and shape with respect to each other and may indicate hypoxia or cord compression.

9.3.2.1 Non Stress Test (NST)

Since its introduction during the 1970s, the non stress test (NST) has remained one of the cornerstones of fetal surveillance. It is based on CTG and it reflects cardio-respiratory regulation of fetal heart: the monitor records fetal heart rate in conjunction with uterine activity.

The purpose of NTS is to try to identify potential fetal compromise as a result of placental insufficiency and hypoxia and to take corrective action [9]. It is used to identify signs of fetal distress in all situations in which pregnancy complications may cause harm to the fetus. It can also be performed as a precaution when there have been problems complicating

a previous pregnancy or in the presence of risk factors (e.g., diabetes, intrauterine growth restriction).

The test is more frequently done between 38 and 42 weeks' gestation; however, it can be used as early as the beginning of the third trimester.

A normal test is defined as a "reactive" pattern that requires a minimum of two accelerations (15 bpm increase from the baseline during 15 s) during a 20 minute test. A reactive trace after 10–20 minutes is generally regarded as sufficient for normality. A "non-reactive" result suggests the possibility of fetal distress, requiring further assessment (biophysical profile, a stress test).

The predictive value of a non-reactive NST is poor when outcome parameters such as fetal death and fetal distress during labor are used [10]. A reactive test can be expected to impose a 10 fold lower risk of intervention for fetal distress during labor than a pregnancy with a non reactive test. However, there are wide observer differences in the qualitative interpretation of the FHR trace and agreement between observers is low, especially for decelerations, which are the most difficult pattern to interpret. For this reason, to eliminate observer variability and to increase the accuracy of CTG, a computerized analysis, was developed by Dawes and coworkers [11, 12]. Nowadays use of the computerized CTG has increased the predictive ability of NST for the diagnosis of fetal hypoxia during the antepartum period compared with the traditional CTG – compared to computer analysis, observers fail to identify 36% of FHR traces with at least one deceleration.

9.3.2.2 Contraction Stress Test (CST)

The contraction stress test may be used after a non reactive NST. This test monitors the response of fetal heart rate to uterine contractions. These contractions may occur on their own or following the administration of oxytocin.

A normal placenta has extra capacity for transporting oxygen, allowing large amounts of oxygen to pass easily from the maternal to the fetal circulation. If the placenta is damaged, less oxygen may cross. When there are contractions, the vessels feeding the placenta are squeezed, limiting the blood flow and oxygen delivery. If the oxygen passage across the placenta drops below a certain point, the fetus responds with a specific type of heart rate deceleration, which occurs after the peak of a contraction and which is known as a "late deceleration" [10].

The contraction stress test is considered "positive" if there are regular late decelerations. When no late decelerations occur, the CST is negative, and this is considered reassuring. A positive CST is a sign that the placenta may not be delivering adequate amounts of oxygen to the fetus. Given a positive CST, a pregnancy at term should be delivered, although this is not necessarily apporpraite for very premature pregnancies.

Because a contraction stress test takes more time to perform than a biophysical profile, it is seldom done these days.

9.3.3 Doppler Examination of Fetal and Placental Circulation

Doppler ultrasound provides a non-invasive method for the study of the fetus's hemodynamic status.

The application of Doppler to obstetrical ultrasound provides new knowledge about fetal circulatory physiology in health as well as in those compromised by chronic hypoxia because of placental insufficiency. This functional assessment of fetal well-being is done by observing fetal movements, breathing, muscle tone and heart rate. Additionally, the volume of amniotic fluid gives an indirect assessment of the pregnancy.

Investigation of the flow patterns of the uterine and umbilical arteries gives information on flow through the uteroplacental and feto-placental circulations respectively. Doppler studies of fetal organs are used to detect the hemodynamic rearrangements that occur in response to fetal hypoxemia, in particular by insonnation of the middle cerebral arteries (MCA) and ductus venosus (D).

The Doppler indices (Table 9.5) indirectly reflect the impedance of the circulation downstream to the point of insonnation, and there is a significant association between abnormal Doppler indices and fetal hypoxia, fetal acidosis, and adverse perinatal outcome.

Doppler ultrasonography is not routinely employed in low-risk pregnancies, but has been extensively used for maternal-fetal evaluation in high-risk pregnancies, contributing to a reduction in perinatal mortality, especially in the management of IUGR. The jeopardized fetus seems to be at the highest risk of imminent demise when Doppler abnormalities are observed in the arterial and especially venous circulation (ductus venosus and umbilical vein). The temporal sequence of abnormal Doppler changes in the peripheral and central circulatory systems of the growth restricted fetus have been described: early abnormal Doppler findings in the umbilical and middle cerebral arteries are followed by reversal of flow in the ductus venosus or pulsatile umbilical venous flow.

For this reason the use of Doppler velocimetry is of great importance in high-risk pregnancies and in cases of non-reassuring tests results.

9.3.3.1 Utero-Placental Vessels

Both the uterine and other utero-placental vessels have been studied with Doppler sonography.

Table 9.5 The most widely used indices used for studying utero-placental, placental and fetal arteries

Doppler indices	
Systolic/Diastolic ratio (S/D)	Systolic peak/end-diastolic velocity
Resistance Index (RI)	S-D/S
Pulsatility Index (PI)	S-D/mean velocity

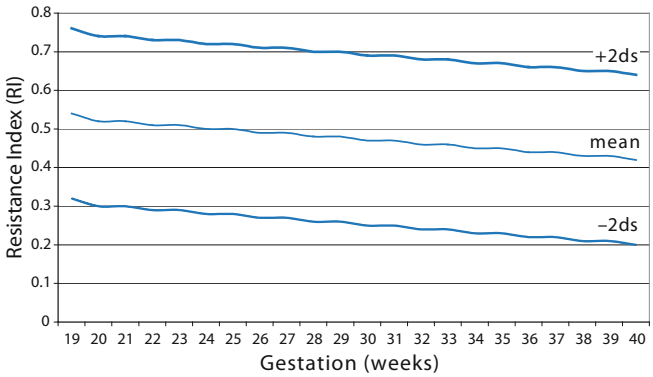

Fig. 9.2 Uterine artery resistance index

Uterine arteries are two symmetrical vessels that bring the oxygenated blood of the mother to the placenta.

There are numerous Doppler studies on uterine and spiral arterial flow during normal first trimester pregnancies which demonstrate a high vascular resistance that progressively disappears during the second trimester as a consequence of decreased resistance downstream. Decreasing vascular impedance with gestation (Fig. 9.2) is probably a consequence of dilatation of spiral arteries induced by trophoblast infiltration, hormonally mediated vasodilatation and a decrease in maternal blood flow viscosity. Thus, changes in uterine blood flow are correlated with the development of complications in later pregnancy: if the process of trophoblastic invasion of the spiral arteries' muscular walls is incomplete, the arteries are still able to respond to vasoactive stimuli, which results in vasoconstriction. In these pregnancies the uteroplacental circulation remains in a state of high resistance, which causes generalized endothelial cell injury, compromising vascular integrity and an atherosis-like process in the small arteries resulting in vessel occlusion, local ischemia and necrosis. As a consequence of vasoconstriction, a chronic inadequate blood supply to the growing placenta leads to a poor outcome (spontaneous abortion, IUGR, stillbirth, or preeclampsia).

When an abnormal adaptation of pregnancy occurs, impedance to flow increases and Doppler examination often demonstrates the presence of an high resistance index (RI) (the most significant quantitative parameter) and/or the presence of an early mono- or bi- lateral diastolic notch (qualitative parameter). The latter parameter is the abnormality correlated most closely with a poor pregnancy outcome.

Adverse outcomes associated with abnormal uterine artery flow velocity include: pre-eclampsia and fetal growth restriction and its sequelae, mainly fetal distress.

For this reason, in high-risk women, accurate utero-placental investigation during the first and second trimester of pregnancy allows the clinician to identify, and therefore to monitor, fetuses at high-risk of distress. Through the investigation of uterine artery flow in high-risk pregnancies, it has been shown that if the fetus has a normal umbilical flow, the compromise in growth will be mild, the risk of fetal distress slightly above normal, and the most common indication for intervention is maternal, not fetal. Present evidence does not support routine Doppler ultrasound for low-risk or unselected populations, which does not appear to benefit mother or baby [13].

Recent studies have shown that Doppler studies of the uterine arteries can be useful also during the third trimester of pregnancy: when both middle cerebral artery and uterine arteries show abnormal Doppler indices, the fetus has a significantly higher rate of poor outcome even in the presence of normal umbilical indices [14].

9.3.3.2 Feto-Placental Vessels

The umbilical artery was the first fetal vessel to be evaluated by Doppler velocimetry and Doppler velocimetry of the umbilical artery (UA) provides a non-invasive measure of the feto-placental hemodynamic state.

Umbilical arteries can be identified by Doppler ultrasound as early as 6–8 weeks, when the Doppler flow velocity profile shows only a systolic component. By 20 weeks, all fetuses should have end-diastolic flow in the umbilical vessels. As the pregnancy progresses, placental resistance shows a progressive decrease during gestation (Fig. 9.3) and there is an increasing diastolic flow velocity. A mature umbilical artery flow velocity waveform is usually achieved by 28–30 weeks, but some fetuses,, e.g. twins, may show delayed maturation. Several studies have revealed a large standard deviation up to 26–28 weeks in the umbilical S/D ratio that reflects variations in placental development. Eighty percent of the flow velocity waveform is a reflection of the resistance beyond the point of measurement, but 20% can be a forward flow effect that is reduced in cardiac output changes, arrhythmias, and bradycardia.

Abnormality of the pulsatility index (PI) (the most significant quantitative parameter) has been correlated with feto-placental vascular maldevelopment. Changes in umbilical artery velocity waveforms reflect changes in the placental bed vascular resistance. The primary and secondary branches of the umbilical circulation are in place after the first trimester.

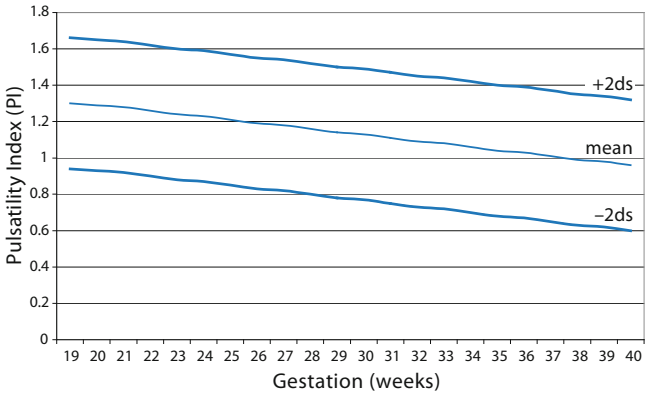

Fig. 9.3 Umbilical artery pulsatility index

For the next 3 months there is active proliferation of tertiary branches. Placental histology showed that growth-restricted fetuses with abnormal flow velocity have half as many tertiary arterioles as normal fetuses [15]. Pathological studies have demonstrated that increased impedance in the umbilical arteries becomes evident only when at least 60% of the placental vascular bed is obliterated.

Although it may not be a separated entity, absent or reversed diastolic (ARED) flow in the umbilical artery has been the subject of a considerable body of literature. Clinical studies of umbilical arterial flow velocity waveforms in IUGR have reported a progressive increase in impedance to flow until end-diastolic flow becomes absent and, in extreme cases, reversed. This is associated with a high perinatal morbidity and mortality. In pregnancies with ARED flow, the capillary loops in terminal villi are decreased in number, longer and with fewer branches than in normal pregnancies. For this reason, there is a strong association between the ARED velocity and hypoxia/acidosis [16].

When there is reversed flow, it may be a clinical emergency because most of these fetuses will die within 2 weeks. The ARED flow, as a test for hypoxia, shows a high sensitivity, specificity, positive predictive value and negative predictive value [17]. However, where flow is continuous throughout diastole, only a very high S/D ratio (greater than 4.5) is associated with hypoxia. Furthermore, the observation of ARED flow in the umbilical artery Doppler surveillance of pregnancies at risk for fetal distress has great clinical importance, especially in pregnancies associated with fetal growth restriction [18]. Umbilical artery Doppler applied to high-risk pregnancies significantly lowers perinatal mortality, the need for induction of delivery and the emergency cesarean section rate.

9.3.3.3 Fetal Vessels

Alteration in fetal vessel blood flow reflects an important hemodynamic modification that occurs in association with IUGR and fetal hypoxemia. The Doppler-detectable modifications in the fetal circulation associated with these conditions include increased resistance in both the umbilical artery (as described before) and fetal peripheral vessels, in association with decreased resistance in the fetal cerebral vessels.

Studies of other vascular beds in the fetus, including the cerebral circulation and the central arterial and venous systems, have increased the knowledge of compensatory and adaptive mechanisms and the time sequence of circulatory changes in the fetus subjected to hypoxia and severe growth restriction.

Arterial Compartment

The circle of Willis is an easy landmark to identify using ultrasound. Color flow makes it easy to see the common carotid and the anterior, middle and posterior cerebral arteries.

Measurement by Doppler of the peak systolic flow velocity (PSV) of the fetal middle cerebral artery (MCA) is a predictor of moderate or severe fetal anemia [19] and can be used to avoid unnecessary invasive procedures in pregnancies complicated by red blood cell isoimmunization.

Study of this vessel also yields important information for the detection of fetal distress. In some growth restricted fetuses, the cerebral vessels are dilated. Usually these are fetuses with reduced umbilical artery flow velocity. This implies that fetuses with mild hypoxia will have dilated cerebral vessels as a compensatory response: this explains the so-called "brain sparing" effect seen in asymmetrical growth restriction. These changes occur early and may be present for weeks or even months before birth. Some data suggest that they may persist into the early neonatal period. Study of the MCA is becoming essential for the understanding of fetal hypoxia, particularly in the early third trimester, when a surveillance program can be introduced (Fig. 9.4).

Fetal arterial Doppler studies are useful in the differential diagnosis of small for gestational age fetuses. In the hypoxemic group, due to impaired placental perfusion, the PI in the umbilical artery is increased and, in the fetal MCA the PI is decreased. Consequently, the ratio between the umbilical artery and middle cerebral artery PI (UA/MCA) is increased. An abnormally low UA/MCA ratio is associated with increased perinatal morbidity and mortality: when performed before 34 weeks of gestation. Use of the UA/MCA ratio seems to improve the prediction of perinatal outcome compared to the umbilical artery PI alone. However, the UA/MCA ratio does not appear to correlate significantly with fetal outcome when performed after 34 weeks' gestation. In third trimester fetuses, the ratio between PI in the fetal descending thoracic aorta and the MCA may be more useful.

In IUGR fetuses the trend changes of the MCA-PI and MCA-PSV provide more clinical information than one single measurement. A high MCA-PSV predicts fetal distress and perinatal mortality better than a low MCA-PI. For this reason MCA-PSV might be valuable in the clinical assessment of IUGR fetuses that have abnormal UA Doppler [20].

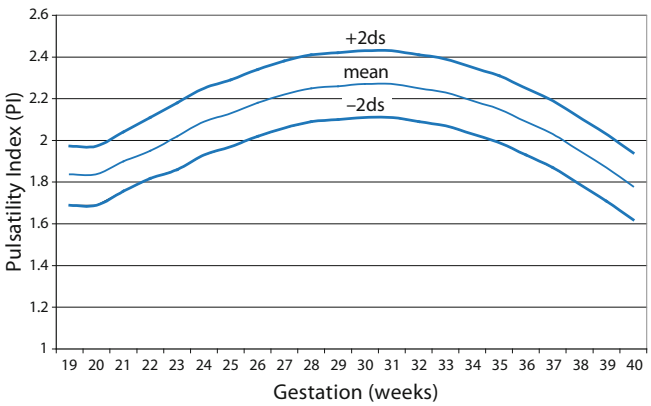

Fig. 9.4 Middle cerebral artery pulsatility index

Fetal Arterial Blood Flow Redistribution

The "brain-sparing" effect is a phenomenon where fetuses that are hypoxic preferentially perfuse the brain, heart, and adrenals at the expense of the integument, viscera, gut, and kidneys.

Although knowledge of the factors governing circulatory rearrangements and their mechanism of action is incomplete, it appears that partial pressures of oxygen and carbon dioxide play a role, presumably through their action on chemoreceptors. This mechanism allows preferential delivery of nutrients and oxygen to vital organs, thereby compensating for diminished placental resources. However, compensation through cerebral vasodilatation is limited and a plateau corresponding to a nadir of PI in cerebral vessels is reached at least 2 weeks before the onset of late fetal heart rate decelerations [21] and the development of the fetus is jeopardized. This suggests that maximal vascular adaptation to hypoxemia precedes the critical degree of impairment of fetal oxygenation, after which vascular dilatation may be suppressed by the development of cerebral edema. An alternative explanation may be that in severe hypoxemia, an increase in PI is the consequence of alterations in flow due to reduced cardiac contractility and to a fall in absolute cardiac output. Consequently, arterial vessels are not suitable for the longitudinal monitoring of growth-restricted fetuses and cardiac and venous velocity waveforms give more information about fetal well-being or compromise.

Cardiac and Venous Compartment

Cardiac flow is influenced by the modifications of arterial impedance to flow. As long as the fetus is able to compensate for a reduced placental supply by arterial redistribution (a brain sparing effect), there is preferential myocardial oxygenation, which delays the development of right heart failure despite an increasing afterload. Cerebral vasodilatation produces a decrease in left ventricular afterload, whereas increased placental and systemic resistance produce increased right ventricular afterload. At this stage, fetal Doppler measurements show high placental resistance and arterial redistribution in the presence of normal venous waveforms and the majority of fetuses have normal, reactive heart rate traces and biophysical profiles. Progressive changes in the venous circulation may indicate failure of the compensatory mechanism and herald the development of right heart failure due to myocardial hypoxia [22].

Longitudinal studies of deteriorating growth-restricted fetuses have shown that PSV and cardiac output gradually decline, suggesting a progressive worsening in cardiac function. Similarly, there is a symmetrical decrease in ventricular ejection force at the level of both ventricles, despite the dramatically different hemodynamic conditions present downstream of the two ventricles (i.e., reduced cerebral resistances for the left ventricle and increased splachnic and placental resistance for the right ventricle). This supports a pivotal role of the intrinsic myocardial function in the compensatory mechanism of the growth-restricted fetus following the establishment of the brain-sparing effect. Ventricular ejection force dramatically decreases in a short time interval (about 1 week), showing an impairment of ventricular force close to fetal distress. As a consequence, cardiac filling is also impaired [23].

Late Doppler changes generally accompany metabolic deterioration and are a result of declining cardiac function and abnormal organ autoregulation.

Increasing venous Doppler indices are the hallmark of advancing circulatory deterioration since they indicate a decreasing ability of the heart to accommodate venous return.

Fetal hypoxemia is associated with reduced umbilical venous blood flow, but, despite this decrease, a normal PSV in the ductus venosus is maintained. In the growth-restricted fetus, the percentage of umbilical venous blood passing through the ductus venosus is increased from about 40% (in normal fetuses) to about 60%. Thus there is a redistribution of venous blood flow in favor of the ductus venosus at the expense of hepatic blood flow in growth restricted fetuses. Unlike peak velocity during ventricular systole, flow velocities during atrial contraction are reduced or even reversed. One may speculate that increased end-diastolic right ventricular pressure would not influence ductus venosus blood flow velocities during atrial contraction, as flow is preferentially directed through the foramen ovale to the left atrium. However, the foramen ovale is closed during atrial contraction and blood flow velocity through the foramen ovale decreases to zero.

Altered venous flow velocity waveforms are more closely related to intrauterine fetal jeopardy than changes in arterial flow, which may occur quite early during the course of impaired placental function.

The degree of fetal acidemia can be estimated from Doppler measurements of pulsatility in both the arterial system and the ductus venosus. With moderate acidemia (pH between –2 and –4 standard deviations from the normal mean for gestational age), almost all fetuses have a MCA PI below 2 standard deviations, whereas there is a wide scatter of individual results for the ductus venosus, with the majority of measurements being still within the reference ranges. With increasing severity of hypoxemia and acidemia, ductus venosus PI increases [24] and, in the most severe cases, velocities with atrial contraction were reduced to zero or even become negative.

However in severe fetal growth restriction, abnormal Doppler velocimetry of the ductus venosus is the only significant parameter associated with perinatal death and low 5 minutes Apgar scores [25].

Doppler Findings and the Prediction of Perinatal Risks

Elevations of placental blood flow resistance and venous Doppler indices frequently progress in parallel. The recognition

of venous Doppler changes has led to re-examination of the relationship between prenatal Doppler findings in growth restricted fetuses and perinatal outcome.

Previously, delivery was recommended when umbilical artery Doppler end-diastolic velocities were absent or reversed. However, the Growth Restriction Intervention Trial (GRIT) [26] showed that if there was early onset IUGR, early and preterm delivery were independent risk factors for adverse neurodevelopment at 2 years of age. Safe prolongation of pregnancy in these fetuses is therefore critical. Daily biophysical profile scoring in fetuses with absent or reversed umbilical artery end-diastolic velocity with strict delivery criteria has been associated with good outcomes, suggesting that safe prolongation of these pregnancies is indeed possible. It is now apparent that prediction of perinatal risk based on umbilical artery alone, without accounting for venous circulatory changes, is inadequate. Prediction of stillbirth and acidemia are significantly enhanced by the addition of venous Doppler findings, irrespective of the umbilical arterial end-diastolic velocity. This rate increases when the arterial end-diastolic velocity is absent or reversed but venous Doppler indices are still normal, and increases further when venous Doppler indices become abnormal (predominantly due to an increase in the rate of stillbirth). If the prevalence of stillbirth is 25%, abnormal venous Doppler findings have 65% sensitivity and 95% specificity for the prediction of stillbirth. Depending on the cutoff (2 *vs* 3 SD) and the combination of veins examined, the sensitivity for acidemia ranges from 70% to 90% and specificity from 70% to 80%. Randomized trials investigating the utility of venous Doppler in the management of preterm growth restricted fetuses are underway.

9.4 During Labor Surveillance

9.4.1 Identification of Fetal Distress

Maternal blood flow to the placenta may be severely diminished by uterine contractions, so the potential for fetal hypoxia increases during labor. In the last century some asphyxiated fetuses were noted to have abnormally fast or slow heart rates, so heart auscultation evolved as a component of intrapartum care. However, the human ear is insensitive to subtle changes in rate, so electronic methods of recording have been developed. These methods generate paper traces that show features not obvious on auscultation, including the degree of variation of the heart rate and the shape of accelerations and decelerations in rate (the CTG).

Identification of fetal distress based on fetal heart rate patterns is imprecise and intrapartum Doppler velocimetry was studied as a potential adjunct to conventional intrapartum fetal monitoring but it was concluded that this technique was a poor predictor of adverse perinatal outcomes [1].

9.4.2 Monitoring of Fetal Heart Rate

The pattern of the fetal heartbeat during labor is often a good indicator of fetal well-being. The normal fetal heart rate (FHR) is 120–160 bpm. A normal heart rate suggests that the fetus is receiving enough oxygen from the mother's bloodstream. The typical fetal heart rate pattern is to slow somewhat during a contraction and increase again at the end of a contraction. Abnormal variations in heart rate can indicate decreased oxygen in the blood and tissues of the fetus that can potentially damage the fetus. The fetal heart can be monitored either intermittently by auscultation or continuously by CTG.

9.4.2.1 Auscultation with Fetal Stethoscope or Doppler Ultrasound Stethoscope

The fetal heartbeat and variability can be checked before, during, and after contractions, either using a Pinard fetal stethoscope or a Doppler ultrasound stethoscope, a small hand-held device which uses sound waves to monitor the heart beat. In low risk births, the American College of Obstetricians and Gynecologists [27] suggests monitoring at least every 30 minutes during active labor, and at least every 15 minutes during the second stage of labor. When risk factors are present, the fetal heart should be evaluated every 15 minutes, and every 5 minutes in the second stage. The mother's abdomen may be also palpated to check for the strength of contractions.

9.4.2.2 Electronic External or Internal Monitoring

In 2002, approximately 3.4 million fetuses (85% of approximately 4 million live births) in the United States were assessed by continuous cardiotocography, also known as electronic fetal monitoring (EFM), making it the most commonly performed obstetric procedure.

A hand-held Doppler ultrasound probe can be used to calculate and display, but not permanently record, the FHR. Electronic fetal monitors are used to both determine the FHR and continuously record it in graphical form. External measurement means taping or strapping the electrodes to the maternal abdominal wall, with a small Doppler ultrasound heart electrode overlying the fetal heart, and the contraction electrode measuring the tension of the abdominal wall, an indirect measure of the intrauterine pressure. Both electrodes are connected to video screens and a printer which produces graphs of the fetal heart rate and "intensity" of the contractions.

Internal measurement requires the cervix to be at least 2 cm dilated as it involves inserting a pressure catheter into the uterine cavity, as well as attaching a scalp electrode to the fetal head to adequately measure the heart rate. Membranes must be ruptured to place the electrodes. The electrode measures the fetal heart rate. It is used in some high-risk births if

the external monitor shows suspicious results or if external monitoring is not generating an adequate trace. Internal monitoring offers better accuracy of readings than external monitoring, but there is an increased risk of infection after application of the electrode. The advantage of internal monitoring is that it is immediately apparent if the fetal heart rate slows down, stops, or is slow to recover from contractions. It can detect reduced oxygen flow due to cord compression (more common after rupture of the membranes), oxytocin augmented contractions, or narcotic and epidural related changes in maternal blood pressure.

During the *first stage* of labor, a moderate fetal tachycardia may be considered a circulatory mechanism of adaptation against moderate fetal hypoxia. By contrast, a severe tachycardia is a clear sign of fetal hypoxia: it can be associated with high maternal temperature, or fetal cardiac malformations or medications administered to the mother. The same is true for a bradycardia: a moderate bradycardia is considered without clinical significance, but a marked bradycardia is a sign of severe fetal hypoxia.

Similar considerations relating to the use of CTG apply as during the antepartum period for what concerns *baseline variability*. Accelerations are, as before labor, an expression of normality. Early decelerations are not usually a sign of fetal distress. They are likely generated by vagal stimulation due to cephalic compression and are more frequent after rupture of the membranes.

Variable decelerations are usually due to umbilical cord compression. They may occur in association with fetal distress due to hemodynamic changes. However, late decelerations are a typical expression of fetal hypoxia. Their timing and shape are directly correlated with the severity of fetal hypoxia: the time elapsing between the contraction and the deceleration is directly proportional to the fetal partial oxygen pressure.

Obviously, in the presence of both late decelerations and baseline abnormalities the prognosis is more serious.

Interpretation of the cardiotocogram is more difficult during the *second stage* of labor. In this period only a severe and persistent bradycardia is considered of serious prognotic significance, especially when associated with abnormalities in variability.

If the CTG is normal during labour, intermittent auscultation may be appropriate. It is considered normal if the FHR is between 120 and 160 bpm. It is also suggested that monitoring should be undertaken for 20–30 minutes every 2 hours during labor.

The ability of the EFM to identify the fetus that may be becoming asphyxiated and may therefore benefit from intervention is limited, and its use has failed to lead to reduced rates of cerebral palsy and neurologic injury [28]. There are no studies comparing CTG with an absence of intrapartum monitoring, but trials comparing CTG with an intermittent auscultation showed no reduction in the overall risk of perinatal death (relative risk [RR] 0.85; 95% confidence interval [95% CI] 0.59–1.23) or cerebral palsy (RR 1.74; 95% CI, 0.97–3.11) [29]. What studies have demonstrated is that CTG compared with intermittent auscultation leads to the over-diagnosis of fetal distress: the "false positive" rate for fetal distress diagnosis is estimated at between 40% and 71% [30] and also leads to higher operative delivery rates by cesarean section or assisted vaginal delivery (RR 1.66; 95% CI; 1.30–2.13 and RR 1.16; 95% CI, 1.01–1.32, respectively). For this reason, Continuous Electronic Fetal Monitoring should be reserved for high-risk pregnancies (Table 9.6).

Table 9.6 High-risk pregnancies

- Abnormalities on intermittent auscultation or at CTG monitoring at the beginning of the labor
- Discolored amniotic fluid
- Oxytocin infusion
- Fever during labor
- Other conditions of pathological labor

If CTG monitoring shows a non-reassuring FHR many sources recommend fetal scalp sampling to determine whether there is fetal distress and whether interventions are necessary (see below).

There is controversy regarding electronic monitoring in high-risk situations, such as premature labor, placenta or cord problems, or when there is a complicating disease like diabetes, hypertension, or sickle cell anemia. There is little evidence that EFM is beneficial compared to frequent auscultation.

However, as the Cochrane review [29] concluded with some dejection, there is little evidence that the use of EFM will diminish in the near future. It seems that we will have to wait for the advent of new technologies, which will be more effective in monitoring fetal well-being during labor.

9.4.3 Monitoring of Fetal Oxygenation

9.4.3.1 Pulse Oximetry

Fetal pulse oximetry has been advocated as a means of improving the specificity of CTG in intrapartum fetal surveillance.

The first-line method for evaluating fetal oxygenation during labor is electronic fetal heart rate monitoring. Despite the extensive use of FHR monitoring during labor, it has a poor specificity of 38%, and its sensitivity is 94% for detecting fetal death and hypoxia [31]. As explained before, a high proportion of FHR tracings are not reassuring, even when the fetus is in good condition. Until recently, the only adjuvant for the assessment of fetal hypoxia and acidosis was fetal scalp blood sampling, which is invasive and traumatic to the fetus and can only assess the fetus on an intermittent basis and can be inaccurate if contaminated with amniotic fluid. Fetal pulse oximetry was introduced into clinical practice

about 30 years ago, but it has only recently been possible to use it for the management of fetal well-being. It was developed as a less traumatic and invasive method of assessing fetal oxygenation than fetal scalp sampling. It allows for the real-time and continuous assessment of the fetus [32, 33]. It uses a probe that sits inside the vagina during labor. It is possible only if the membranes are ruptured because the probe has to be placed on fetal skin.

Fetal oxygen saturation decreases between the first and the second stages of labor (from 60% to 53%): a value of 30% is considered pathological. A fetal oxygen saturation of 30% for 10 minutes is associated with acidosis and a poor fetal outcome. Low values of fetal oxygen saturation are associated with an abnormal CTG trace (low variability) [34].

There are still controversies about the benefits of fetal pulse oximetry. Some authors have concluded that fetal pulse oximetry during active labor provides a more accurate assessment of fetal well-being and may reduce the need for interventions. In the view of others, the addition of fetal pulse oximetry does not reduce overall cesarean section rates. A Cochrane review comparing EFM alone with EFM plus fetal pulse oximetry included one randomized control study (RCT) involving 1,010 participants. There was a reduction in the rate of cesarean deliveries performed for non-reassuring tracings, but no difference in overall cesarean section (CS) rates [35]. Since then, three additional RCTs have similarly failed to show benefit [36–38]. A better method for the evaluation of fetal well-being in labour is required [39]. For this reason, the use of this device is not recommended because there is insufficient evidence of any benefit. Its use is not endorsed by the American College of Obstetricians and Gynecologists.

9.4.3.2 Fetal Scalp Blood Sampling

A sample of blood from the fetal scalp may be tested during labor to determine the acidity of the blood. This test is called fetal blood sampling. If the fetus is not getting enough oxygen, the blood becomes highly acidic.

Fetal blood sampling is typically performed using a kit. An amnioscope with a light source is used to expose the fetal scalp. The blood is collected in long, heparinized capillary tubes. The test requires that the cervix be dilated at least 2–3 cm, and can be difficult to perform.

Capillary blood collected from the fetal scalp usually has a pH lower than umbilical venous blood, and correlates well with fetal arterial values. However, scalp edema can result in erroneous results. A scalp pH value of less than 7.20 has traditionally been used to represent the critical value for identifying fetal acidosis (Table 9.7). However, a scalp pH below 7.15 is more representative of the tenth percentile and is closer to the threshold currently used in umbilical cord blood analysis to define fetal acidemia associated with neurological deficits.

Table 9.7 Recommended fetal management according to the pH value obtained by fetal scalp blood sampling

pH value	Management
pH >7.25	Repeat test if CTG continues to deteriorate
pH 7.21–7.24	Repeat test in 30 minutes
pH <7.20	Aim for delivery within 30 minutes

The accuracy of intermittent fetal scalp pH assessment for predicting neonatal acidosis with subsequent neurologic sequelae has been questioned. It is no longer used in many institutions, although its use can result in fewer cesarean deliveries performed for the indication of non-reassuring fetal status.

The degree of technical skill required, cost, need for continuous availability of standardized equipment and trained personnel and maternal discomfort have precluded use of this modality in many labor and delivery units.

The test has poor sensitivity and positive predictive value (PPV) for predicting umbilical arterial pH <7.0 (sensitivity 35%, PPV 9%). The test also has poor sensitivity and PPV for identifying newborns with hypoxic-ischemic encephalopathy (sensitivity 50%, PPV 3%) [40].

9.4.3.3 Fetal Electrocardiography

A technical system, the fetal heart monitor, monitors the fetal electrocardiogram (ECG) during labor. It can be used as an adjunct to continuous electronic FHR monitoring during labor. Use of this device is based on the principle that fetal hypoxemia can result in elevation or depression of the ST segment. The monitor's software automatically identifies and analyzes changes in the T wave and the ST segment of the fetal ECG, which is obtained via a spiral electrode attached to the fetal scalp. The use of ST waveform analysis has been associated with statistically significant reductions in the number of scalp sampling procedures. A Cochrane review showed no difference in perinatal death, neonatal encephalopathy, cerebral palsy, low Apgar scores, neonates with severe metabolic acidosis at birth, neonatal intensive care unit admission or cesarean delivery rate between controls (EFM alone) and study subjects (EFM plus STAN) [41, 42]. Thus, this technique appears to improve the clinician's ability to discriminate between fetuses in need of intervention and those who can be managed expectantly.

The fetal heart monitor has been approved by the United States Food and Drug Administration as an adjunct to the assessment of non-reassuring FHR tracings in pregnancies over 36 weeks of gestation, in labor, with vertex presentation and ruptured fetal membranes.

The device should not be used if there is a contraindication to placement of a fetal scalp electrode. This technique is promising, but at this time there are inadequate clinical and cost data from a variety of hospital settings to allow a recommendation for routine use.

Multiple Pregnancies

Maria Angela Rustico, Mariano Lanna and Enrico Ferrazzi

10.1 Epidemiology of Natural Twinning

10.1.1 Actual Trend

The cultural modifications in women's reproductive strategies over the past 50 years have drastically influenced the demographic scenario. Higher levels of education and a desire for economic and social success, as well as difficulties in finding a permanent job, have played a major role in modifying the reproductive strategies, as evidenced by delayed parenthood and the reduction in family size [1]. In addition to this expected twinning rate due to advancing maternal age, there is also evidence that natural twinning has increased in women who have been exposed to assisted reproduction technologies [2].

10.1.2 Dizygotic Twinning

In humans, multiple pregnancies arise more frequently from fertilization of two separate oocytes (1.2% of pregnancies). The incidence of excessive follicular recruitment is more or less 31% in mothers of dizygotic (DZ) twins. The DZ twinning rate is affected by race, genetic factors, seasonality, maternal age and parity, endogenous gonadotropins, fertility drugs and sex of the embryo [3]. The incidence of twin pregnancy also varies from country to country, the highest rates being reported in Nigeria (5%), and the lowest in Japan. In Italy the best estimate of DZ twinning is 1%. It has been suggested that genetic predisposition and malnutrition may play a role in this different frequency. Maternal age up to 35–39 years is linked with increasing twinning rates and this pattern has been attributed to the rise in the level of gonadotropins with age [2]. There is a slight tendency for twins to have been conceived during summer as compared with singletons; and this may reflect the effect of increased light during summer on the pineal gland, resulting in melatonin production, and consequent decreased inhibition of pituitary follicle-stimulating hormone (FSH) release [3].

10.1.3 Monozygotic Twinning

The constant frequency of monozygotic (MZ) pregnancies over time and in different areas, and the lack of association between maternal age and frequency of MZ twinning, suggests that MZ twins are largely determined by genetic mechanisms. In fact an excess of monozygotic twins occurs in mothers who are themselves one of monozygotic twins, whereas there is no evidence for a paternal effect on MZ twinning [2].

10.2 Epidemiology of Iatrogenic Twinning

There have always been some naturally, or spontaneously, occurring multiple pregnancies (with twins being more frequent than triplets, and quadruplets or even higher multiples being much rarer). However, the frequency has increased enormously since assisted reproductive technologies (ART) have become available. Because of the higher morbidity and mortality associated with twins and particularly triplets, every effort should be made to reduce incidence [3]. In Europe, the overall rate of multiple pregnancy in 2002 was 23% compared to 26% in 2000. This reduction has been determined by the transfer of fewer embryos, except in Italy where a controversial law obliged the transfer of three embryos until it was recently modified. A similar high prevalence of twinning in ART pregnancies was reported in 2006 in the USA (26%), where such a policy had not been universally adopted. In the

USA the proportion of multiple births attributable to ovulation induction or ART is 33%. In triplets and higher-order multiple pregnancies this rate must be even higher.

10.3 Placentation

10.3.1 Chorionicity and Zygosity

Two thirds of spontaneous twin pregnancies are dyzygotic (DZ), resulting from the fertilization of two eggs by different spermatozoa, and are therefore dichorionic (DC). The DC twin placenta of DZ twins may be composed of separate disks, or alternatively, the two placental portions may be fused. Vascular communications are almost totally absent. The other third of spontaneous twin pregnancies are monozygotic (MZ), occurring when one single fertilized egg gives rise to two separate embryos. Of these MZ pregnancies, a third are DC. The other two thirds are monochorionic diamniotic (MCDA), meaning that a single placenta serves both embryos, and that vascular communications connecting the twins are always present. Between 2 and 5% of monochorionic (MC) twins are monoamniotic (MCMA). When twinning occurs after approximately 12 days from conception Siamese twins are generated (Fig. 10.1).

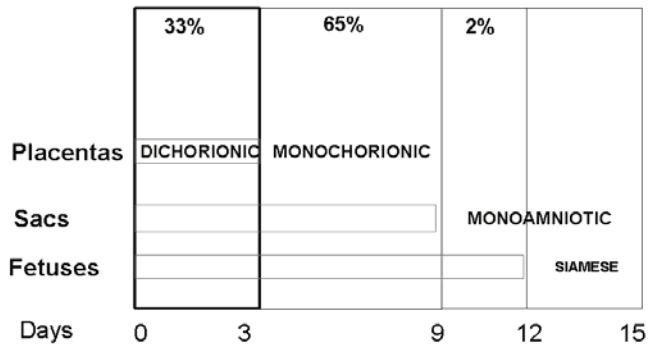

Fig. 10.1 Partition of placentas and chorion, amniotic sac and fetuses as a function from days of conception in monozygotic twinning

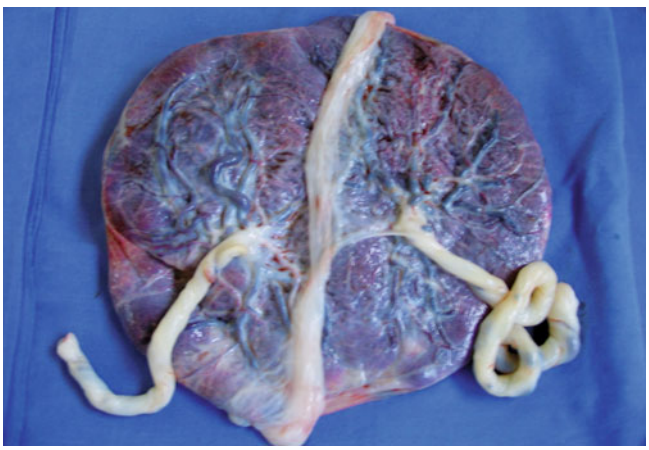

Fig. 10.2 Monochorionic placenta

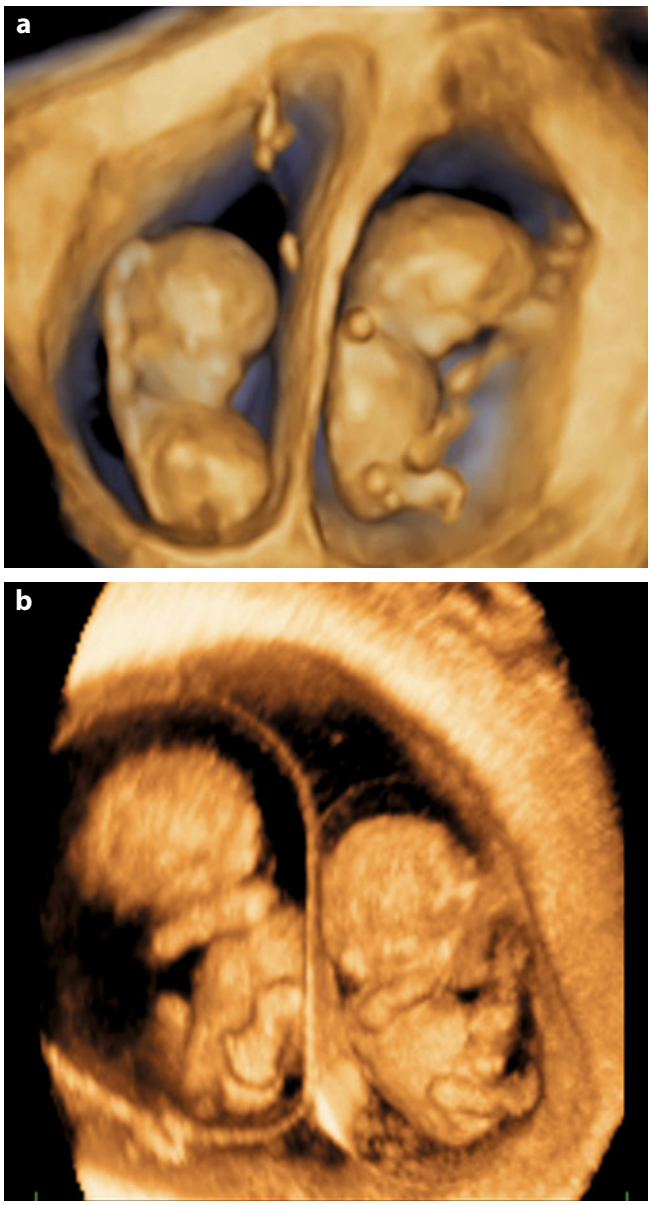

Fig. 10.3 **a** Dichorionic twins (lambda sign): chorion and decidua between the two sacs. **b** Monochorionic twins (T sign), only extraembryonic coelom between the two amniotic membranes

Because of their placental angioarchitecture (Fig. 10.2), MC twins are more susceptible to additional complications than DC twins. In fact, the presence of vascular anastomosis, which mediates unidirectional or bidirectional flow between the two circulations, greatly influences intrauterine development and plays a crucial role in causing those complications specific to MC twins, leading to a higher morbidity and mortality than in DC twins [4].

In multiple pregnancies, ultrasound is a very accurate technique (100% sensitivity and 99% specificity) for determining chorionicity (Fig. 10.3). In twin pregnancies, in the first or early second trimester, ultrasound examination is mandatory to determine chorionicity in order to assess the obstetric risk which is significantly different in DC and MC twins.

10.4 Fetal Complications of Twin Pregnancy

10.4.1 Miscarriage and Fetal Loss

10.4.1.1 Definitions

The World Health Organization in 2008 reported a consensus on definitions concerning miscarriage and fetal loss. Preclinical spontaneous miscarriage: a pregnancy diagnosed only by the detection of HCG in serum or urine, which does not develop into a clinical pregnancy. Spontaneous abortion/miscarriage: the spontaneous loss of a clinical pregnancy as diagnosed by ultrasound that occurs before 20 completed weeks of gestational age (18 weeks post fertilization) or, if gestational age is unknown, the loss of an embryo/fetus of less than 400 grams. Vanishing sac(s) or embryo(s): spontaneous disappearance of one or more gestational sacs or embryos in an ongoing pregnancy, documented by ultrasound.

10.4.1.2 Epidemiology

The "vanishing twin" phenomenon, which has been viewed as part of the general fetal wastage in human reproduction, suggests that while multiple conceptions are not rare events, multiple pregnancies are strongly selected against, especially during the early stages of embryonic development. The incidence of miscarriage during the first trimester is estimated to be between 10 and 20%. The true incidence of vanishing twins is difficult to assess. Landy and Keith [5] reviewed the majority of pertinent studies, most of which described pregnancies conceived as a result of ART. Using these data it was estimated that ~30% of these twins will ultimately result in singletons and <10% will end in a complete abortion.

10.4.1.3 Etiology

It is thought that intrinsic abnormalities within the embryo are the major reasons for failed conceptions or early fetal death. The most significant intrinsic factor contributing to embryonic loss is aberrations in the first meiotic division resulting in non-dysjunction and aneuploidy. Trisomies 13, 15, 16, 18 and 21 account for the most common autosomal trisomies in spontaneous pregnancy losses. Some authors have observed an increased risk of fetal death, and in particular spontaneous abortion with increasing maternal age, and there is clear evidence from oocyte donation programmes that this risk is associated with the ageing of the oocytes [6].

10.4.1.4 Diagnosis

The diagnosis of miscarriage is made by ultrasound (US) examination. A biochemical pregnancy is considered when implantation is revealed on day 16 by blood test, but there is a negative US scan result on day 23 [7].

10.4.2 Fetal Growth Restriction

10.4.2.1 Definition

Intrauterine growth restriction (IUGR) is a sonographic diagnosis consisting of either an estimated fetal weight below the 5th percentile of the intrauterine growth chart for gestational age, or declining abdominal fetal growth below the 5th percentile, or declining more than 40 centiles from mid-pregnancy to third trimester. Abnormal uterine Doppler velocimetry and/or an abnormal umbilical Doppler velocimetry are considered additional criteria of severity (Italian Society of Ultrasound in Obstetrics and Gynecology). In a twin pregnancy, a growth discordance of more than 20% in estimate fetal weight is an index of selective growth restriction.

10.4.2.2 Epidemiology

Neonates from multiple gestations are over-represented among preterm and low birth weight infants. Multiple pregnancies weigh less than their singleton counterparts. The prevalence of small for gestational age newborns in multiple pregnancy is higher than expected in singletons. Although many variables may influence the reference standard, the prevalence of small for gestational fetuses varies between 12 and 47%.

10.4.2.3 Etiology

For most of a pregnancy, twins grow at the same rate as singletons, regardless of chorionicity, up to at least 32 weeks' gestation. Thereafter, twins show a slower rate of growth [8]. The decreased rate may be related to uteroplacental insufficiency. It is thought that, at some point in the third trimester, the placenta can no longer maintain the nutrient requirement of both fetuses. In patients with triplets or high-order multiples, this process occurs earlier.

When growth restricted fetuses are diagnosed in a twin pregnancy, one should keep in mind the diverse etiologies of IUGR (such as genetic/chromosomal problems, fetal anatomical anomalies, placental and cord abnormalities, maternal

complications) rather than assuming that the cause is uteroplacental insufficiency, which is more frequent in twins than singletons. Although IUGR can complicate a pregnancy with growth discordance, the latter does not necessarily imply the former unless growth discordance is less than 20%. It is important to note that IUGR can affect both twins, leading to both twins being small but not discordant

10.4.2.4 Diagnosis

Knowledge of chorionicity assessed during the first trimester or by gender discordance is paramount for managing patients with growth abnormalities. Since fetal growth is a dynamic process, serial ultrasound is helpful in the assessment of fetal growth in patients with multiple fetuses. In utero growth discordance is most often defined as the difference in sonographic estimated fetal weights expressed as a percentage of the larger twin's estimated fetal weight. Growth discrepancy may be mild (<15%), moderate (15–30%), or severe (>30%). This wide range (from 15 to 30%) is the consequence of clinical neonatal examination. It might help to note that a study by Naeye [9] in 1964 showed that the total number of organs and cells is not reduced until growth discrepancy is more than 25%. However, in less severe cases, weight discrepancy is determined by a smaller volume of cell cytoplasm. A clinical diagnosis of growth discordance is better achieved by adding information about feto-placental conditions to biometric growth curves: for example, amniotic fluid index, Doppler examination of the umbilical artery and fetal vessels, computerized analysis of fetal heart rate, maternal complications that frequently cause placental insufficiency such as gestational hypertension and preeclampsia.

10.4.2.5 Consequences

IUGR has long been known to be associated with perinatal morbidity and mortality. Neonatal morbidity such as meconium aspiration syndrome, hypoglycemia, polycythemia and pulmonary hemorrhage may affect up to 50% of IUGR neonates. The high prevalence of IUGR in twin pregnancies suggests that such patients should be included in protocols relating to the management of high risk pregnancies.

10.5 Preterm Delivery

10.5.1 Definition

Preterm birth (PTB) is defined as a delivery at less than 37 completed weeks' gestation. This condition can be further divided into late preterm (33–37 weeks), moderate preterm (28–32 weeks), and severe preterm (20–27 weeks).

10.5.2 Epidemiology

There is a wide variation in preterm birth rates between countries, mostly because of different iatrogenic practices. In many states of the European Union, about half the children born following multiple births were preterm, accounting for between 18 and 25% of preterm birth in each country. The proportion of births before 37 weeks in twins ranges from 68.4% in Austria to 42.2% in the Republic of Ireland. This reflects different clinical protocols and the consideration of twin pregnancies being at high risk and providing parents with leave from work and other social maternal benefits.

10.5.3 Etiology

The etiology of preterm birth depends on multiple factors. The most investigated etiologies both in singletons and twins are infection and maternal stress. Twin pregnancy with its impact on cervical integrity is per se a risk factor for ascending infections. Twin pregnancy is also a risk factor for psychological and physical maternal stress. Other minor risk factors for preterm birth are: cervical incontinence, uterine malformations, infertility, previous preterm birth or intrauterine fetal death, low social status, male fetal sex.

10.5.4 Diagnosis

High risk for PTB should induce clinicians to make a careful assessment of risk factors and to use appropriate diagnostic tests. Among these the evaluation of short cervical length by transvaginal sonography seems to be the best predictor of PTB. Infection and other possible direct causes of PTB should be excluded. Fetal fibronectin in vaginal secretions may add to the usefulness of cervical length measurements. A cervical length ≤25 mm at 18 weeks and ≤22 mm at 24 weeks seems the best predictors of preterm delivery.

10.5.5 Prevention

Cervical length measurement, the fibronectin test and the assessment of uterine contractions might diagnose impending PTB, but should not be confused with the cause of PTB. Efforts should be made to exclude intrauterine infections and subclinical chorioamnionitis. Blood and amniotic tests for infections and abnormalities of fetal heart rate should be take into account. Tocolysis with Atosiban and bed rest may delay delivery by at least 48 hours, permitting the administration of corticosteroids to improve fetal lung maturity. In cases of severe infection, delivery may well be the best option combined with antibiotic therapy. Opinions about cervical cerclage vary.

10.5.6 Fetal Complications

Prematurity is the main cause of low birth weight, perinatal mortality, and the most frequent determinant of neonatal and infant mortality and morbidity. The following diseases are frequently associated with prematurity: transient tachypnea of the newborn, respiratory distress syndrome, persistent pulmonary hypertension, respiratory failure, temperature instability, jaundice, feeding difficulties, intraventricular hemorrhage, necrotizing enterocolitis and brain damage.

10.6 Monochorionic-Related Complications

10.6.1 Twin-to-twin Transfusion Syndrome

Twin-to-twin transfusion syndrome (TTTS) is the best-known complication of MC pregnancies, occurring in approximately 10–15% of cases. Although hormonal and hemodynamic mechanisms may be involved, the current interpretation of TTTS is that it is caused by an imbalance in the exchange of blood between one twin (the donor), and the other (the recipient) via placental anastomoses, due to a relative excess of unidirectional arterio-venous connections which is not compensated by reverse flow through other anastomoses. When a significant imbalance in blood flow occurs, the donor twin becomes hypovolemic and oliguric, develops severe oligohydramnios and Doppler signs of placental insufficiency. The recipient twin shows hypervolemia, polyuria and polyhydramnios, with cardiac overload, leading to hydrops in severe cases [10]. Without treatment, the prognosis is poor, with perinatal mortality up to 90%. In survivors, preterm birth due to polyhydramnios is a major cause of mortality and morbidity. In the case of intrauterine death of one twin, the surviving twin has a substantial risk of neurologic morbidity due to hemorrhage into the dead co-twin via placental anastomoses [11]. At 4 years follow-up, the incidence of cerebral palsy and abnormal mental development is 21% in surviving twins with TTTS [12].

The traditional neonatal criteria for diagnosing TTTS, based on an inter-twin hemoglobin difference (> 5 g/100 mL) and weight discordance (> 20%), do not apply in utero because similar discrepancies in hemoglobin and birthweight are also found in DC and MC twins without TTTS [13].

The diagnosis of TTTS is only made by ultrasound. In a twin pregnancy with a single placental mass, twins of the same gender, and a thin membrane dividing the twins (Fig. 10.3), the crucial ultrasound sign for the diagnosis of TTTS is the combined presence of polyuric polyhydramnios in one sac (deepest vertical pocket > 8 cm before 20 weeks' gestation, >10 cm after 20 weeks' gestation), and oligouric oligohydramnios in the other (deepest vertical pocket <2 cm) [14].

A classification system is divided into five stages based on ultrasound criteria. Stage I or II is when the donor bladder is still either visible or empty, in association with the polyhydramnios-oligohydramnios sequence. Stage III is when Doppler findings are abnormal for either twin. Stage IV and V is when there is congestive cardiac failure and hydrops in the recipient or the death of one or both twins [15]. This classification has created an impression of a disease with progressive deterioration and poorer outcome in the more advanced stages. However, clinical observations have demonstrated that the natural history of TTTS is variable and unpredictable. For this reason, this classification has recently been challenged because it fails to incorporate the cardiac function of the recipient twin, in whom there may be myocardial dysfunction even in Stage I and II in over 50% of cases, which represent advanced TTTS [16].

TTTS can manifest itself at any time during a pregnancy, but is more common in the second trimester. Considering the poor survival rate, and the risk of neurological complications due to antenatal or postnatal injury, treatment should undoubtedly be offered. The Eurofetus randomized trial which compared laser coagulation of placental anastomoses with serial amnioreduction, demonstrated that laser coagulation is the best first-line treatment for TTTS diagnosed before 26 weeks because it blocks the vascular connections which are assumed to be responsible for the syndrome [14].

10.7 Single Intrauterine Death

In MC twin pregnancies, the death of one twin, occurring in about 4% of these pregnancies, presents the co-twin with an increased risk of mortality and morbidity. The mechanism for this adverse outcome is blood loss from the dying twin through placental vascular anastomoses. This leads to hypovolemia, which may cause the death of the co-twin from hypovolemic shock, or parenchymal damage due to hypoperfusion. Sequelae include ischemic cerebral lesions, periventricular leukomalacia, renal cortical necrosis, and small bowel atresia. A review of the literature of 119 MC twin pregnancies complicated by the death of one of the fetuses showed 57% healthy survivors, 19% perinatal deaths, and 24% survivors with severe sequelae [11]. The risk of an adverse outcome for the surviving co-twin depends on the gestation at the time of intrauterine death, and the interval to delivery. In early pregnancy, the death of one twin frequently causes the death of the other fetus, but severe sequelae in the survivor are less common than at a more advanced gestation. The same review showed that in healthy survivors there was a longer interval to delivery (mean, 11.1 weeks) when compared to pregnancies with perinatal deaths or neurologic sequelae (mean, 5.3 weeks). Immediate delivery after a single intrauterine death only adds the risks of prematurity to the surviving twin. Indeed, damage may occur at the moment of death of the co-twin and therefore may not be preventable. Intrauterine transfusion can be a therapeutic solution but, if the critical moment preceding fetal death is missed, there

is no treatment and conservative management is recommended [17]. Ultrasound of the fetal brain and magnetic resonance imaging (MRI) 2–3 weeks after an intrauterine fetal death may provide useful information for predicting neurodevelopmental outcome in the surviving twin.

10.8 Twins Discordant for Fetal Anomalies

An excess of structural anomalies is observed in twins compared to singletons. While the frequency of malformations in a DZ pregnancy is similar to that for singletons (2–3%), it is two or three times higher than in a MZ pregnancy [18]. The reason for this is unknown, but might be considered to be part of teratogenic process during twinning.

MZ twins are considered identical, but recent observations have reported that this is not the rule, and a number of discordances have been observed for chromosomal anomalies (such as trisomy 21 and Turner syndrome), single gene disorders, X-linked diseases (such as Fragile-X, Aicardi's syndrome) and structural defects. These structural defects include malformations of the brain, abdominal wall anomalies, and cardiac disorders. The prevalence of cardiac defects has been reported as 2.3% in twins without TTTS, and 7% in those with TTTS, compared to 1% in the general population [19].

Structural malformations which are not genetically determined may of course affect only one of the two MZ twins. It has been estimated that both twins are affected in less than 20% of cases, whilst in the majority of cases only one twin is involved.

In approximately 1–2% of twin pregnancies a serious anomaly affects only one fetus and clinicians face the dilemma of choosing between expectant management or selective termination. The primary goal is to prevent the death of the normal twin. In monochorionic twin pregnancies, selective termination needs to be performed by ensuring complete and permanent occlusion of umbilical cord of the abnormal twin, in order to avoid acute hemorrhage from the co-twin into the dying fetus, a process which may lead to death or organ damage [20]. Bipolar cord occlusion under ultrasound guidance is still considered the best method for selective feticide in these cases.

Table 10.1 Type of discordant anomalies detected in a series of 84 monochorionic twins

Type of discordant anomaly	N. (%)
Central nervous system	37 (44.0)
Cardiovascular (without TTTS)	12 (14.3)
Abdominal wall	8 (9.5)
Urinary tract	8 (9.5)
Skeleton	3 (3.6)
Miscellaneous	10 (11.9)

Based on a cohort of 84 (9.6%) discordant anomalies detected by ultrasound or invasive prenatal diagnosis in 870 monochorionic twin pregnancies between 1999 and 2009, Table 10.1 shows the type of severe anomaly detected in one fetus that led to selective termination by bipolar cord coagulation in 51.2% of cases. During the same period, five twin pregnancies were complicated by concordant anomalies (trisomy 21, Apert's syndrome, cystic hygroma with hydrops, bilateral renal dysplasia) affecting both fetuses (0.6 %).

10.9 Twin Reversed Arterial Perfusion (TRAP) Syndrome

Twin reversed arterial perfusion (TRAP) sequence, also known as acardiac twinning, is a rare complication of MC pregnancies which can lead to an unfavorable outcome for the normal co-twin. The reported incidence is 1/35,000 deliveries, or 1% of MZ twins. In this condition there is a twin without any functional cardiac tissue and variable developmental disruption (the acardiac twin). This acardiac twin is perfused by the normal twin (the pump twin) by arterial blood flowing in a retrograde fashion through a single superficial artery-to-artery placental anastomosis. Poorly oxygenated blood bypasses the placenta, enters the acardiac twin's circulation at low pressure, and preferentially perfuses its lower part. The blood flow returns to the pump twin via a single vein-to-vein connection [4]. The acardiac twin acts as a parasite and space-occupying mass, being hemodynamically dependent on the other twin. Perinatal mortality rates reported for the pump twin range from 35–55%.

The primary causes leading to poor perinatal outcome are preterm delivery (because of the continuing growth of the acardiac fetus) and congestive heart failure (because of the volume of the acardiac twin's mass needing to be perfused by the normal heart). The deoxygenated blood circulating back to the pump may also cause chronic hypoxia, growth restriction, and hypoxic ischemic lesions.

In the case of rapid enlargement of the acardiac twin mass, or signs of cardiac overload in the pump twin, blockade of the vascular supply to the parasitic twin is recommended. Possible treatments include intrafetal ablation procedures such as radiofrequency and interstitial laser. Although no single technique has been conclusively shown to be the best, some form of antenatal treatment seems to be beneficial, because there is a reported overall pump twin survival rate of 76%.

In a series of 34 cases of TRAP sequence during the period 1999–2009, 15 cases were managed expectantly. In six cases, intrauterine death of both twins occurred before 18 weeks, while one pregnancy was terminated because of an abnormal pump twin. In eight cases, both twins were delivered near term. Two babies (where the acardiac fetus was very large, up to 1.5 kg) had a poor neurological outcome and periventricular leukomalacia probably because of the pathophysiology of the

condition. Apart from complications related to the invasive procedures (4/19), and one case of unexplained intrauterine late death of the pump twin, 14 of 19 cases (73.6%) who had in utero treatment are alive and well and free of neurological complications at postnatal follow-up.

10.10 Monoamniotic Twinning

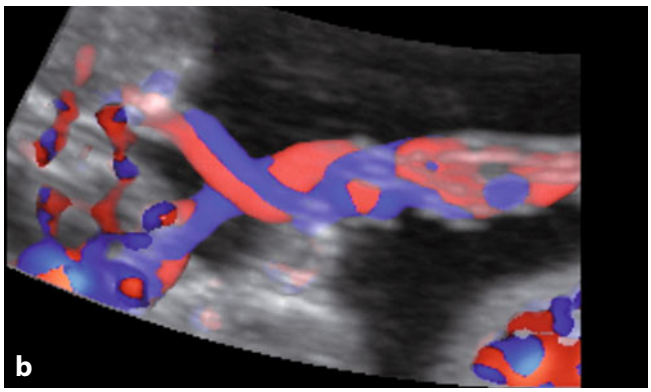
Monoamniotic (MA) twinning is rare, affecting 2% of all MZ pregnancies. MA twins share the placenta and the amniotic sac, and are at higher risk of structural anomalies, unexpected fetal death and perinatal death (ranging from 30 to 70%), compared with MCDA twins. The excess of fetal loss can be explained by umbilical cord entanglement (Fig. 10.4), and a crucial cofactor may be an acute exsanguination across large placental anastomoses. In the largest study reported in the literature (98 cases) there was a 17% perinatal mortality rate, and fetal death after 32 weeks occurred in 4% of pregnancies [21]. Thus the current perinatal mortality rate in MA twins appears to be lower than previously reported, but it remains high and occurs throughout pregnancy. Based on the observation that the risk of neonatal death associated with preterm birth at 32 weeks is 1 in 100, the risk for MA twins at this gestational age appears to be four times lower.

10.11 Laser Treatment In Twin-to-twin Transfusion Syndrome

Since the description of vascular anastomoses affecting all monochorionic twin placentae, the development of TTTS syndrome was explained by the hypothesis of unbalanced flow through arterio-venous anastomoses. Thus, the aim of researchers has been to treat TTTS by endoscopic laser coagulation of chorionic vessels in order to interrupt unwanted vascular connections. In the first description, De Lia photocoagulated all possible anastomotic vessels [22].

Due to a lack of anatomical markers for the identification of communicating vessels, this technique has been difficult to reproduce, and other approaches have been proposed. The non-selective technique requires coagulation of all vessels crossing the insertion of the inter-twin membrane. The selective technique interrupts only those vessels involved in blood exchange between twins, preserves normal cotyledons and is considered an important development in the treatment of TTTS [23].

The procedure is performed under local or regional maternal anesthesia. A 3 mm cannula is introduced in the amniotic sac of the recipient twin under ultrasound guidance using a percutaneous approach. A 2 mm fiberscope is then passed through the cannula, so that the operator can explore the fetal surface of the placenta to identify the vascular connections.



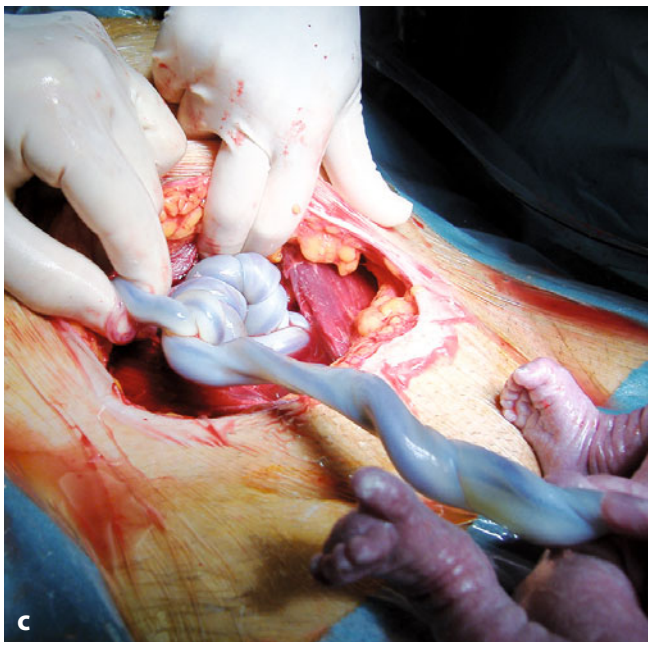


Fig. 10.4 Monochorionic monoamniotic pregnancy: twins floating in the same sac (**a**); entanglement of umbilical cords with colour Doppler (**b**); true knots between the two cords (**c**)

After identifying the anastomosis between an artery and a vein arising from the donor twin, coagulation is performed with a 400 μm laser fibre.

Until recently, serial amnioreduction (AR) was the most common treatment for TTTS. Amnioreduction works by reducing the risk of preterm delivery secondary to uterine distension, and possibly also by reopening compensatory placental vascular anastomosis. For MC twin pregnancies complicated by TTTS before 28 weeks, the International Amnioreduction Registry reported an overall survival rate at birth of 78%. In survivors, a central nervous system scan was abnormal in 25% of cases at 1 month of life [24].

In 2004, endoscopic laser coagulation of chorionic vessels was shown to result in a better neurological outcome than serial amniotic reduction. Periventricular leukomalacia (PVL) was 6% *vs* 14% (p = 0.002) [25]. This is why laser treatment is considered the best first line option in severe TTTS before 26 weeks' gestation, with 6 months' survival ranging from 50 to 70%. Complications that lead to a repeated procedure (laser or amniotic reduction are reported in less than 5% of cases, and reflect the evidence that there are deeper anastomoses, which cannot be coagulated. Preterm premature rupture of membranes (pPROM) has a significant impact on pregnancy when presenting before 24 weeks, since it may lead to miscarriage (7–23% of treated pregnancies) [26].

Perinatal survival rates vary from 50% in the first reported series to 80% in the most recently reported series (Table 10.2).

Postnatal complications have been described both in ex-recipient and in ex-donor twin after laser therapy. The recipient twin, which is hypervolemic, may develop right heart hypertrophy with a tricuspid valve regurgitation leading to valvular pulmonary stenosis. This cardiac abnormality may persist after successful laser treatment because myocardial tissue may have been already damaged by persistent overload. In selected cases, pulmonary stenosis may be so severe that balloon valvoplasty is required after birth. Similarly, severe hypovolemia may cause renal insufficiency. In this case, laser treatment can preserve kidney function in the surviving twin by establishing a normal circulating volume.

For both twins, neonatal morbidity is mainly related to neurological outcome. Most cerebral lesions result from hemorrhagic or ischemic injury. These lesions, which affect 10% of survivor twins after laser, are related to unbalanced blood flow and occur before laser treatment of TTTS [27]. Cerebral palsy affects nearly 6% of twins after laser; the risk of neurodevelopment impairment increases significantly with

Table 10.2 Endoscopic non selective laser coagulation of placental vessels: pregnancy outcome

prematurity. Neurological outcome worsens when laser treatment is performed at advanced gestational age and with a III/IV Quintero stage of TTTS. The reason is that the fetal brain may be more vulnerable to injury when the gestational age at the time of the procedure is higher. Indeed, the rate of neurological lesions in surviving twins after the intrauterine death (IUD) of one twin is considerably lower after laser therapy than after spontaneous IUD.

10.12 Cord Occlusion in Monochorionic Twins

Bidirectional flow through vascular anastomoses makes blood pressure in each twin dependent on both circulations: after the spontaneous IUD of one twin, acute hypotension in the other twin causes death or neurological damage in 50% of cases [11]. In complicated MC pregnancies, the risk of IUD of one twin is so high that selective termination of pregnancy (TOP) can be the last opportunity to save at least one fetus. There is often severe intrauterine growth restriction (IUGR) of one twin with an abnormal umbilical cord Doppler signal and TTTS that persists after treatment (amniotic reduction or laser), or there may be discordant abnormalities.

Intracardiac injection of chloride potassium cannot be used, as it would in dichorionic twin pregnancies because the toxic drug could reach the other fetus through anastomoses causing an unwanted fetal death. The safest way to terminate one MC fetus is occlusion of the umbilical cord of the selected twin. This can be done by ligation or by bipolar forceps coagulation, procedures that also prevent unwanted hypotension and hemodynamic changes in the co-twin. Bipolar cord coagulation appears to be a better option because of a higher overall survival rate [37]. With a local anesthesia, a 3.3 mm cannula is introduced in the uterine cavity under ultrasound guidance. Coagulation is obtained by a power of 50 W for 30–40 sec with the aim to reduce blood flow in the placenta of the selected fetus.

In a cohort of 113 pregnancies that underwent umbilical cord occlusion with bipolar coagulation, preterm delivery occurred in 33% of cases, with a procedure-to-delivery interval which varied between 1 to 22 weeks (median 11 weeks) (Table 10.3).

As for any other invasive procedure, pPROM before 24 weeks is the main complication (8%), and it is associated with abortion in 85% of cases if the procedure is performed before 18 weeks. A recent review reported a prevalence of 4–7% of severe neurological lesions in surviving MC twins [38]. This percentage is lower than expected if compared with neurological morbidity in surviving twins after the spontaneous IUD of the co-twin, which accounts for 22% of cases.

The main problems associated with any invasive intrauterine therapeutic procedures are abortion and prematurity following pPROM. The possibility of sealing the membrane damage caused by trocars and needles has recently been investigated by the introduction of an amniopatch made of platelets and cryoprecipitate. It seems that, if injected into the amniotic cavity, an amniopatch is able to seal ruptured membranes in 50–70% of spontaneous pPROM [39]. This level of success is not reached in cases of iatrogenic rupture of the membranes, where the origin of damage depends on many confounding factors (i.e., indication for the procedure, experience of the operator, gestational age at the time of the procedure).

Intrauterine Growth Restriction: Obstetric Aspects

Anna Maria Marconi and Frederick C. Battaglia

11.1 Etiology of Intrauterine Growth Restriction

Intrauterine growth restriction (IUGR) is not a specific condition, but represents the epiphenomenon of a variety of conditions. Traditionally, it is etiologically associated with maternal, fetal and placental disorders (Table 11.1). However, it is useful to make some distinctions within the group of IUGR pregnancies.

First, a clear definition of IUGR is needed. From a statistical viewpoint, the term "small for gestational age" (SGA) has been used to define newborns whose birth weight falls below the 10th percentile of gestational age specific birth weight standards [1]. This retrospective definition has been extremely useful in the past to provide a better understanding of perinatal outcomes. However, the widespread use of ultrasound in obstetrics has changed the traditional way of looking at fetal growth during pregnancy and specific intrauterine growth charts have been developed [2]. From an obstetrician's viewpoint, today the term IUGR indicates deviation from the intrauterine growth trajectory, based on intrauterine growth charts derived from formulae which take into account biometrical parameters measured in utero [2, 3]. Considerable differences have been reported between intrauterine and birth weight curves, especially at the lowest gestational ages [4, 5].

Although premature babies are often defined as low birth weight (LBW), very low birth weigth (VLBW) or extremely low birth rate (ELBW), IUGR is often a significant feature for these babies [6]. However it is important to distinguish babies who are premature because of spontaneous preterm delivery (most of these neonates are appropriate for gestational age) from babies who are premature because of iatrogenic preterm delivery, since the majority of the most severe IUGR infants will be delivered prematurely for clinical indications (Table 11.1). Thus, IUGR represents a risk factor for prematurity and not the opposite. Similarly, in most studies relating maternal malnutrition to IUGR, it is really an association with SGA that is reported [7].

A second important point is that the traditional list of risk factors for IUGR is misleading in separating mother, fetus and placenta as independent determinants of IUGR. Many risk factors share common factors and a distinction between placental and nonplacental causes of IUGR would be more appropriate.

A third point is that it is now widely recognized that severe IUGR is associated with arterial and/or venous Doppler abnormalities [8].

11.1.1 Placental Causes of IUGR

The placenta should always be analyzed when an IUGR fetus is born as there are few cases of IUGR where the placenta is macroscopically and/or microscopically normal.

Placental weight is often reduced, depending on the severity of the disease [5, 9, 10] and the reduction in placental mass is then inadequate to meet fetal needs throughout pregnancy. However, even when placental weight is normal and the fetus is IUGR, it is likely that the functional capacity of the placenta (measured as placental function per gram of tissue) may be impaired.

Several placental abnormalities have been reported in IUGR placentas [9]. Those associated with hypertension, either chronic, pregnancy induced or preeclampsia, are probably the most studied. A recent hypothesis suggests that there are two categories, placental and maternal [11]. Placental preeclampsia comprises placental vascular abnormalities, immunological and placental oxidative stress, which determine the maternal disease and growth restriction. In the maternal form, which often presents late, the placenta is normal (as is the growth of the fetus), but the maternal response is abnormal.

Table 11.1 Risk factors associated with intrauterine growth restriction

Maternal factors
Maternal diseases
– Hypertension/Preeclampsia
– Chronic hypertension
– Renal disease
– Pregestational diabetes
– Autoimmune syndromes (antiphospholipid, lupus erythematosus)
– Thrombophilia
– Cyanotic heart disease
– Asthma
– Hemoglobinopathy
– Phenylketonuria
– Uterine anomalies
– Therapeutic agents
Maternal life style
– Smoking
– Substance abuse (alcohol, drugs)
– Low socio economic status
– Short interpregnancy interval
– Infertility/ART
Environment
– Malnutrition
– Pollution
– Living at high altitude
– Living in developing countries
Fetal factors
Congenital anomalies
– Genetic diseases (aneuploidy, uniparental disomy, etc)
– Malformations
– Infections
Preterm birth
Multiple gestation
Unexplained elevated alpha-fetoprotein
Placental factors
Confined placental mosaic
Placenta previa
Abruption placentae
Infarction
Circumvallate placenta
Placenta accreta
Hemangioma
Cord abnormalities

Modified from [25].

Placental abnormalities have been demonstrated in cases involving maternal diabetes (hypervascularity of the villi/choriangiosis), maternal hypertensive disorders, maternal substance abuse (villus ischemic change/villus infarction) and maternal thrombophilia (villus ischemic change/infarction/thrombi). Abnormalities with SGA and LBW have also been reported [12].

Isolated abnormalities of the placenta and the umbilical cord can result in IUGR. Marginal/membranous insertion or hypercoiling of the umbilical cord have been found to be associated with vascular abnormalities [10], which may interfere with umbilical blood flow. The most common abnormalities seen in the placenta of IUGR are maternal vascular obstruction, fetal vascular obstruction, villitis of unknown etiology (either focal or patchy/diffuse), perivillous fibrin(oid) deposition and chronic abruption.

In summary, knowledge of the risk factors which have been reported to be associated with IUGR may impact considerably on clinical management both prospectively (when the risk factor is present and known at the beginning of the pregnancy and determines appropriate treatment) and retrospectively (for the thorough investigation of possible causes once an ultrasound diagnosis of intrauterine growth failure has been made). Histological examination of the placenta is mandatory whenever an IUGR baby is born (as with any obstetric adverse outcome) since it may reveal the presence of an underlying disease process which may have an impact on the long-term outcome of mother and child. However, prospective studies relating IUGR and its severity (as indicated by Doppler abnormalities) are needed to define the risk factors for this pathology, as most studies have been retrospective and related to neonatal birth weight.

11.2 Intrauterine Growth Restriction

Battaglia and Lubchenco [1] proposed that babies below the 10th percentile when born be considered SGA. These population data were based on birthweights of infants born at each gestational age. However, preterm delivery itself represents significant obstetric pathology. Later, as ultrasound was improved, biometry by ultrasound was found to be more reliable.

Studies have addressed which aspect of fetal body measurements provides the best estimate of fetal weight. These data led to the construction of fetal growth curves [2], which had the advantage that measurements could be made on normal pregnancies throughout gestation, including the 3 or 4 months before term delivery. Hence data from normal pregnancies were used to construct the fetal growth curves for early fetal development. This approach resulted in the calculation of the rate of fetal growth (from the slope of the estimated weight curve), instead of having to rely on a single body weight measurement obtained after birth.

The use of fetal growth data based on ultrasound measurements was a major advance in diagnosing and tracking fetal growth restriction. However, it still relied on population data to construct "norms" and, as many investigators pointed out, such an approach can lead to the misdiagnosis of "normal small" fetuses born to small parents. Gardosi [4] introduced standards to correct the fetal growth curve for parental size. Using this approach, the maternal size was the dominant determinant. While this was an improvement, it has largely been displaced by an approach that combines utilization of

biometric data obtained by ultrasound with velocimetry data obtained by power Doppler analysis [13]. Infants that are small by fetal growth data and have changes in the umbilical circulation indicating increased vascular resistance are clearly IUGR. This approach has several distinct advantages. Firstly, the two measurements, (ultrasound biometry and umbilical artery velocimetry) are both fairly routine in high risk obstetrical services. Secondly, the approach combines an assessment of fetal size with a functional assessment of the fetal circulation. This approach eliminates the misdiagnosis of small babies who are small for genetic or other reasons, and who have no obstetric pathology.

The disadvantage of this approach is that it is possible to miss babies whose fetal growth is restricted by placental or other pathology, but who have not yet developed the circulatory changes associated with increased vascular resistance in the umbilical circulation. This need not be a major clinical problem if reassessment of the umbilical circulation is repeated later during pregnancy.

Hence, at this time, the recommended approach is one which limits the diagnosis of IUGR to infants who have both reduced fetal size and elevated umbilical arterial pulsatility indices with the stipulation that the evaluation of umbilical arterial velocimetry be repeated several times during pregnancy.

11.2.1 Evaluation of Fetal Well-being

There have been major advances in monitoring the health of the fetus as pregnancy progresses. The most striking have been in the area of the evaluation of the circulation [14]. We will discuss this from a physiological basis, where velocimetry data are obtained from different fetal vessels. This approach is most widely used since power Doppler techniques permit the rapid collection of such information from different vessels. These approaches will be discussed first. However, it should be emphasized that absolute blood flow requires not only measurement of red cell velocity, but also measurement of the vessel's diameter.

11.2.2 Velocimetry Data

Studies began with measurements of umbilical artery velocimetry. In pregnancies complicated by IUGR, the umbilical arterial velocimetry pattern was different to that seen in uncomplicated normal pregnancies. They are characterized by a higher systolic peak and lower diastolic velocities, usually expressed as the Pulsatility Index (PI). The changes have been well described in many publications [15]. In the most severe cases, there is either no diastolic flow or reversed diastolic flow. The changes have been interpreted as indicating increased impedance in the umbilical circulation.

Since the umbilical circulation represents a large proportion of the fetal cardiac output, other studies followed, reporting changes in other part of the fetal circulation. Of special interest to neonatologists are the following changes which occur in some, but not all, IUGR pregnancies [16].

The fetal middle cerebral artery may show decreased pulsatility index, indicating vasodilatation. This has been interpreted as a physiologic response by the fetal cerebral circulation to a decrease in fetal oxygen tension.

As the condition of the fetus deteriorates in severe IUGR, the peak aortic and pulmonary artery flows may fall, indicating decreasing cardiac output. There are also changes in the ductus venosus with dilatation of the inlet of the vessel leading to flow velocity changes in the vessel [15, 16]. This will be discussed further under blood flow changes.

Pardi et al [13] proposed a classification of clinical severity of IUGR pregnancies which utilized fetal heart rate monitoring (FHR) and umbilical artery velocimetry data. This was a first attempt to define IUGR pregnancies according to the clinical impact on the fetus. The Pardi study showed that classification into three subgroups correlated with the incidence of fetal acidosis and hypoxia. Subsequent studies established that other metabolic parameters correlated with this rather crude clinical classification. For example, the transplacental glucose gradient, which is increased in IUGR pregnancies, was highest in Group 3 pregnancies and lowest in Group 1 pregnancies [17]. Because of the widespread use of FHR and umbilical artery velocimetry, this classification has continued to be useful.

More recently, Ferrazzi et al [15] examined the velocimetry changes at different points in the fetal circulation of IUGR pregnancies. Their work, as well as that of others, suggested that there is an orderly sequence of circulatory changes in IUGR pregnancies as physiologic conditions deteriorate with advancing pregnancy [15]. Specifically, the studies suggest that there are velocimetry changes which occur "early" in IUGR pregnancies; these include umbilical artery increased PI, dilatation of the middle cerebral artery, and absent umbilical artery diastolic flow.

Table 11.2 and Fig. 11.1 present a summary of these findings. It is likely that future studies of IUGR pregnancies will utilize such information to better determine clinical severity in these pregnancies than just the umbilical artery PI and FHR.

Table 11.2 Classification of clinical severity in IUGR

Early findings	Late findings
UA PI	DV S/a
MCA PI	UA RDF
UA AEDF	DV RF
	AO, PV ↓

UA umbilical artery, *MCA* middle cerebral artery, *DV* ductus venosus, *AO* aorta, *PI* pulsatility index, *AEDF* absent end diastolic flow, *RDF* reverse diastolic flow, *RF* reverse flow, *PV* peak velocity.

11.2.3 The Advent of Blood Flow Measurements

It has always been known to physiologists that the only important determinant from the viewpoint of tissue perfusion and oxygenation was not the speed of blood flow (velocimetry measurements) but actual (volume) blood flow. Such measurements became feasible through Doppler techniques which measured the speed of the blood and the diameter of the vessel. From these two measurements, the blood flow in the vessel can be calculated. This information is extremely important in IUGR pregnancies, for the following reasons.

It should be emphasized that blood flow alone, that is the flow in mL min^{-1}, cannot be properly interpreted without some reference point. The usual reference is per kg of tissue perfused, although an even better reference might be per unit O_2 consumption. The first measurements as they relate to perinatal medicine were of umbilical blood flow. Because of the size of the umbilical vein and the fact that it has little in the way of vessel pulsations, this measurement can be made very accurately in human pregnancies and these data have been reported from many centers [18, 19]. IUGR pregnancies have a striking reduction in umbilical blood flow, not only in absolute terms, but also when expressed per kg fetal weight [20]. Thus, in terms of fetal oxygenation, the IUGR fetus operates with a much smaller margin of safety and anything that might further adversely affect flow could lead to fetal hypoxia.

The reduced umbilical flow has another significance for neonatologists. A large fraction, (~60%) of the umbilical blood flow perfuses the fetal liver and the remainder is shunted through the ductus venosus into the inferior vena cava. In more severe IUGR pregnancies, the ductus venosus shunt can greatly increase [18]. The result of the combined effects of a reduced umbilical blood flow [21] and a larger shunt of this reduced flow through the ductus leaves the fetal liver with very little blood flow. This may explain neonatal cases of hepatocellular damage in IUGR infants without evidence of infection.

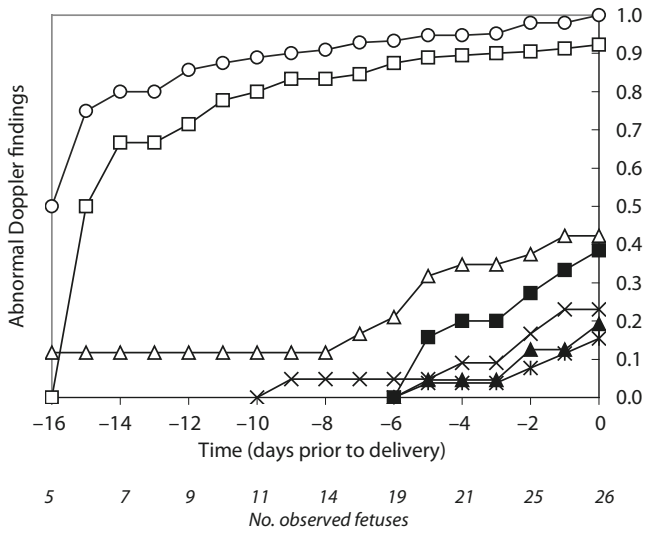

Fig. 11.1 Cumulative onset time curves of Doppler abnormalities for each fetal vessel examined. Time '0' refers to the date of delivery. ○ MCA PI; □ UA AEDF; △ DV S/a; ■ UA RF; × PA PV; ▲ DV RF; ✳ AO PV

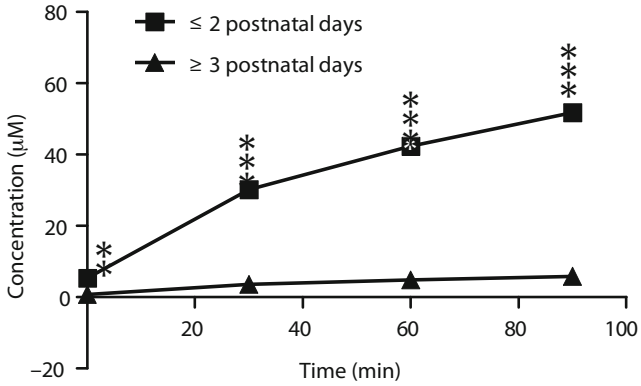

Fig. 11.2 Postprandial galactose concentrations are significantly higher after a milk feed in infants 2 days or less after birth than older infants. Data from [24]

It is now well established that the ductus venosus remains patent in many healthy infants born at term [22, 23] and IUGR infants who may have developed hypoxia and acidosis in utero may be prone to a persistent ductus venosus for a longer postnatal period of time. As a consequence of both the fetal hepatic injury from hypoperfusion and the persistent ductus venosus, galactose concentrations can be markedly elevated following a milk feed (Fig. 11.2) [24].

11.2.4 Fetal Hypoxia

It has been known for many years that pregnancies complicated by IUGR have a relatively high incidence of fetal hypoxia. This was also evident in the study of Pardi et al [13] where Group 3 pregnancies had an incidence of hypoxia and acidosis of approximately 70% compared to 0% in Group 1 pregnancies without velocimetry changes. From our previous discussion, it is clear that the high risk group could be further narrowed down to a group with "late" velocimetry changes. Persistent fetal hypoxia may also explain the increased incidence of neonatal polycythemia and hyperviscosity. The acidosis of clinical significance is metabolic. CO_2 crosses the placenta in both directions very rapidly. Transient changes in perfusion of the uterine and/or umbilical circulations at the time of delivery can lead to a very high PCO_2 in the fetus but as soon as neonatal ventilation is established, the PCO_2 is rapidly blown off and the pH corrected.

Intrauterine Growth Restriction: Neonatal Aspects

Enrico Bertino, Luciana Occhi and Claudio Fabris

12.1 Definitions

Although the terms *small for gestational age* and *intrauterine growth restriction* are often used as synonyms, they reflect two different concepts.

Small for gestational age (SGA) refers to a statistical definition, based on auxological cross-sectional measurements (prenatal or neonatal), and denotes a fetus or neonate whose anthropometric variables (usually weight) are lower than a given threshold value computed on a set of infants of the same gestational age. SGA includes infants who have not achieved their own growth potential because of maternal, uterine, placental and fetal factors as well as small but otherwise healthy infants [1].

Intrauterine growth restriction (IUGR) refers to a clinical and functional condition and denotes fetuses unable to achieve their own growth potential: a fetus with IUGR would have been larger, had no adverse environmental or genetic factors affected growth. IUGR can be recognized by ultrasonography during pregnancy by a longitudinal evaluation of fetal growth.

A neonate identified as SGA by neonatal anthropometric charts is not necessarily a case of IUGR and, conversely, a neonate identified as having IUGR during the fetal period by intrauterine growth charts may not be SGA (Figs. 12.1 and 12.2).

In addition, Doppler velocimetry can detect altered flow states in the fetal-placental and uterine-placental circulation. Among SGA fetuses, it may help to distinguish subjects with IUGR from constitutional SGA. In the first case Doppler flow patterns may be abnormal [2].

Consequently a comprehensive auxological evaluation of the neonate should consider not only anthropometric features at birth but also fetal ultrasound biometry and Doppler velocimetry.

12.2 Auxological Evaluation of the Newborn

12.2.1 Anthropometric Variables

Weight, length and head circumference at birth are indicators of the quality and quantity of growth. These variables must be evaluated using standardised instruments and following the techniques for accurate measurements described by Cameron [3]. Some anthropometric indexes have been proposed to identify intrauterine malnutrition. They compare variables such as body length and head circumference, which are less influenced by malnutrition, to variables which are more affected, such as body weight. The most well known is the Rörher ponderal index

$$\text{PI} = \text{body weight (g)} \times 100 / \text{length (cm)}^3$$

The normal PI for a full-term newborn lies between 2.2 and 3 (3rd and 97th percentile). This neonatal body proportionality index corresponds to the body mass index (BMI) used in children and adults

$$\text{BMI} = \text{body weight (kg)} / \text{length (m)}^2$$

and is an indirect measure of soft tissue and, by inference, of fat accumulation.

12.2.2 Gestational Age

The validity of neonatal auxological measurement relies on good estimates of gestational age. There is unanimous agreement that the best estimate is obtained by a combination of the reported last menstrual period and early ultrasound assessment [4].

12.2.3 Neonatal Classification

At birth, recognition of growth abnormalities or intrauterine malnutrition is of considerable importance for prognosis and

Fig. 12.2 Different fetal growth patterns of two AGA newborns of similar birthweight and gestational age respectively with and without IUGR

clinical practice. Neonatal anthropometric charts or curves are used to represent, at different gestational ages, either the percentile values or the mean and standard deviation of anthropometric variables computed from a reference population. A recent commentary defines the characteristics that a reliable anthropometric chart should possess to be of both epidemiological and clinical use (Table 12.1) [1].

Neonatal anthropometric charts enable the classification of newborns at different gestational ages based on weight as follows:

- SGA (small for gestational age): weight below the 10th centile for gestational age
- AGA (appropriate for gestational age): weight between 10th and 90th centile for gestational age
- LGA (large for gestational age): weight above 90th centile for gestational age.

Some Authors set down a cut-off of the 3rd and 97th centile among AGA, SGA, LGA newborns or equivalent limits of mean ± 2 SD [5].

Table 12.1 Characteristics suggested for a reliable neonatal anthropometric chart [1]

– Pre-planned multicentre ad hoc study
– Descriptive reference
– Mono-ethnic population
– Charts specific for gender
– Charts specific for single or multiple pregnancy
– Charts specific for parity
– Reliable gestational age assessment
– Reliable measuring techniques and instruments
– Range of GA from 42 to 24 weeks or less

The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists [4] recognize three groups of gestational age with the following definitions:

- Preterm: born before 37 completed weeks (less than 259 days)
- Full-term: born between 37 and 41 weeks + 6 days (from 259 to 293 days)
- Post-term: born 42 weeks or more after conception (294 or more days).

As a consequence, nine different classes of newborns can be defined.

The definition of small, appropriate and large newborn for gestational age is based on weight. However, similar classes may be defined by body length and head circumference, so that newborns can be defined as having small, appropriate and large body length or head circumference.

Consideration of weight, body length and head circumference traditionally allows for the identification, among the heterogeneous group of SGA newborns, of infants who are symmetrical (proportionate) or asymmetrical (disproportionate). Symmetrical SGA newborns have reduced weight, body length and head circumference.

The insult leading to reduced growth generally occurs early in pregnancy during the phase of growth primarily characterized by cellular hyperplasia with a consequent reduction in cell number (hypoplasia) that may limit subsequent catch-up of organ and tissue growth [2, 6]. Asymmetrical SGA newborns have reduced weight with body length and head circumference that is either normal or reduced to a lesser degree.

The insult causing reduced growth occurs later, interfering with the delivery of oxygen and nutrition during the phase of cellular hypertrophy, resulting in reduced cell size (hypotrophy) and the possibility of subsequent catch-up growth [2, 6]. The weight deficit is principally due to a reduction in fat deposition, particularly during the third trimester of pregnancy. The disproportion is due to the redistribution of blood flow during fetal development with preferential perfusion of the brain, heart and adrenal glands to the detriment of other organs, such as the liver, spleen, kidneys, thymus, and adipose tissue, and growth of the brain and body length are more compromised [7].

In the case of late insults the biggest reduction in fetal weight compared to body length may also be explained by the different dynamics of intrauterine growth: the velocity peak of length growth, about the 20th week, occurring earlier than the peak of weight growth [8]. At six months post conception the fetus reaches 70% of its full-term length, but only 25% of its weight. These newborns, once described as "dysmature", often appear to have clinical signs of intrauterine malnutrition, an appearance that has been likened to that of an "old man", wrinkled, with hypoelastic skin, with skinfolds that can be easily lifted, little subcutaneous tissue and muscle mass, with a thin umbilical cord. When meconium is passed in utero, there is yellow-green staining of fingernails, skin and umbilical cord (Fig. 12.3).

As a result of improved prenatal diagnosis and management of fetal growth restriction, newborn babies with all these features are uncommon these days. The main differences between symmetrical and asymmetrical SGA newborns are presented in Table 12.2.

Some studies have suggested that proportionate and disproportionate SGA newborns represent a continuum rather than distinct classes [9]. More recent data also suggest that both disproportionate and proportionate fetal growth restriction may start early in pregnancy (17–19 weeks of gestation) [10]. These observations have resulted in reconsideration of the causes, timing and risks of symmetric or asymmetric intrauterine growth restriction.

The recognition of specific causes of reduced fetal growth is more important than body proportionality at birth for predicting the short- and long-term outcomes of SGA children.

Growth of the fetus relative to the placenta also seems to be important. Babies born small but with a relatively large placenta are less likely to show catch-up growth during the 18 months after birth and have an increased risk of hypertension in adult life [11].

Fig. 12.3 Wrinkled and hypoelastic skin, easily liftable and pliable skinfolds in a IUGR newborn

12.3 Neonatal Outcome

12.3.1 Mortality

Small for gestational age newborns, both preterm and term, have an increased perinatal mortality risk [12, 13]. The increased risk of neonatal and infant mortality observed in late preterm (34–36 weeks) and early term (37–38 weeks) SGA infants persists even when infants with severe congenital anomalies are excluded. In addition to congenital conditions, birth hypoxic ischemia and infections have a relevant role in neonatal mortality whereas sudden infant death syndrome contribute to infant mortality [14].

A higher mortality rate is reported in SGA preterm infants with abnormal (absent or reversed end-diastolic flow) umbilical artery Doppler velocimetry [15].

12.3.2 Asphyxia (Hypoxic Ischemia)

Transient diminished placental blood flow during labor is poorly tolerated by growth-restricted fetuses. Intrauterine chronic hypoxia and limited carbohydrate reserves caused by placental insufficiency are more likely to predispose to perinatal hypoxic ischemia in SGA neonates than AGA newborns with an increased risk of all clinical sequelae of perinatal asphyxia [16].

12.3.3 Infections

Recent studies suggest possible interactions between immunological function and nutritional status. Thymic atrophy and prolonged impairment of cell immunity have been found in SGA infants and animal models of intrauterine growth restriction. These subjects also have a more pronounced hypogammaglobulinemia compared with AGA infants [17]. Neutropenia occurs frequently in infants born to mothers with preeclampsia. All these aspects result in an increased risk of neonatal infections.

Table 12.2 Symmetrical and asymmetrical SGA newborns

	Symmetric (20–30%)	Asymmetric (70–80%)
Onset of fetal growth restriction	Early in gestation	Late in gestation (late second trimester or third trimester)
Pathophysiology	Impaired cell hyperplasia Reduced cell number	Impaired cell hypertrophy Reduced cell size
Anthropometry	Small birth weight, length and head circumference, normal ponderal index	Small birth weight, but relative sparing of length and head circumference growth, low ponderal index
Major clinical problems	Malformations, congenital infections, increased risk of postnatal neurological and growth impairment	Asphyxia, meconium aspiration syndrome, hypoglycemia, polycythemia. Increased risk of type 2 diabetes
Causes	– Genetic disorders and syndromes – Congenital infections – Teratogens exposure – Substance abuse, fetal alcohol syndrome – Constitutional healthy SGA without IUGR	– Impaired uteroplacental function (i.e., preeclampsia, chronic hypertension, long standing maternal diabetes) – Maternal disease (i.e., renal or heart disease, collagen vascular disease, anemia) – Maternal malnutrition – Environmental factors (i.e., high altitude) – Multiple pregnancy – Substance abuse

12.3.4 Coagulation Disorders

The hepatic dysfunction that results from chronic intrauterine hypoxia may lead to hemostatic alterations, mainly concerning a reduction in vitamin-K dependent factors and thrombocytopenia. Such disorders are usually short-lived and respond to simple corrective measures. Occasionally severe bleeding, such as pulmonary hemorrhage, has been reported [18]. In a recent study, prolonged prothrombin time (PT) and international normalized ratio (INR) were observed in full-term healthy SGA neonates, indicating a predisposition to hemorrhagic events. However the newborns included in the study did not have clinical signs of altered hemostasis [19].

12.3.5 Thermoregulation

SGA are at increased risk of hypothermia because of their higher brain weight and body surface area in relation to weight as well as their lower subcutaneous adipose tissue stores, including diminished brown fat reserves that limit nonshivering thermogenesis [20].

12.3.6 Hypoglycemia

Reduced hepatic and skeletal muscle glycogen stores (the predominant source of glucose for the first hour after birth) and impaired glycogenolysis and gluconeogenesis are the main causes of hypoglycemia in IUGR infants. In addition, growth-restricted infants have limited fat stores and do not oxidize free fatty acids and triglycerides effectively, thus failing to spare tissue use of glucose. The risk of hypoglycemia is greatest during the first days of life as the newborn adapts to extrauterine life without a placental source of nutrients, although it may persist for several weeks [18, 21].

12.3.7 Polycythemia

Chronic fetal hypoxia results in increased erythropoietin production and release by the fetal kidney, causing excessive blood red cell production. In addition, a shift of blood from the placental compartment to the fetus during labor or fetal hypoxic ischemia constitute important causes of polycythemia in FGR fetuses [22]. Polycythemia adds to the risk of IUGR infants developing hypoglycaemia, hyperbilirubinaemia and necrotizing enterocolitis (NEC).

12.3.8 Respiratory Distress Syndrome (RDS) and Bronchopulmonary Dysplasia (BPD)

A commonly held view that intrauterine stress associated with IUGR enhances lung maturation has been challenged by reports that the incidence of RDS is inversely correlated with birth weight and gestational age [23], and that growth-restricted infants may have the same or greater [23, 24] incidence of RDS than AGA newborns of the same gestation.

An increased risk of chronic lung disease has also been reported in IUGR preterm infants [25–27]. Multiple etiologies have been implicated for the development of bronchopulmonary dysplasia in SGA. These include abnormal intrauterine lung development [25], oxygen free-radical mediated injury in utero, severe early lung disease with consequent

ventilator-induced lung injury, fetal and/or neonatal systemic inflammatory response due to chronic hypoxia [28].

12.3.9 Retinopathy of Prematurity (ROP)

SGA infants are at increased risk of developing ROP [29]. Changes in organ development due to fetal hypoxemia, nutrient restriction and an altered endocrine environment are all possible explanations [30]. SGA infants are often sicker than their AGA peers, requiring more intensive and prolonged hospital care [20]. They are therefore more likely to require supplementary oxygen, which is a well-documented risk factor for ROP. SGA infants have lower serum concentrations of insulin-like growth factor 1, and there is evidence of roles for this growth factor and for vascular endothelial growth factor in the pathogenesis of ROP [31].

12.3.10 Necrotizing Enterocolitis (NEC)

Infants with IUGR are at increased risk of developing NEC, especially if Doppler studies of flow in the fetal aorta or umbilical artery have identified absent or reversed end-diastolic flow velocities [32]. The underlying mechanism is unclear, but may be associated with alterations in blood flow in the viscera, particularly in the intestine and in the liver. Abnormalities of splanchnic blood flow may persist postnatally with some recovery during the first week, providing justification for delayed and slow introduction of enteral feeds [32]. Early postnatal evaluation of superior mesenteric arterial blood flow has been considered as a tool to identify infants at increased risk of developing NEC [33].

12.4 Long-Term Outcome

12.4.1 Postnatal Growth Impairment

Most term children born SGA experience catch-up growth and achieve a normal adult height, above –2 SD. Approximately 10% of them remain shorter than comparable AGA infants [5, 34]. Catch-up growth is typically an early postnatal process. Term SGA infants usually experience a period of accelerated linear growth during the first 12 months [35] and in most cases catch-up growth is complete by two years [5, 35].

It is has been suggested that SGA children aged 2–4 years with no evidence of catch-up growth and heights less than –2.5 SD should be referred for endocrine evaluation and eligibility for growth hormone (GH) treatment [5].

Preterm SGA infants can take 4 or more years to achieve heights in a normal range. Many preterm infants show a postnatal growth deficit at the time of hospital discharge, so-called extrauterine growth restriction (EUGR), which is defined as a centile at discharge lower than the birth centile. EUGR is largely due to an inadequate postnatal nutrient intake as well as postnatal morbidities, and it increases with decreased gestational age [36, 37].

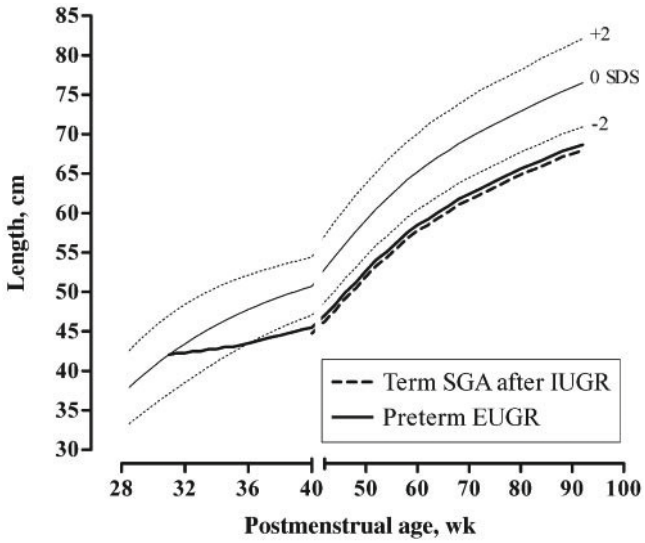

Fig. 12.4 Growth of a term SGA infant after IUGR and of a preterm AGA infant with EUGR. Reproduced from [36], with permission

Premature infants with EUGR also have metabolic abnormalities similar to those observed in term SGA children and these occur irrespectively of whether they are SGA or AGA at birth [38]. Approximately 10% of very preterm children have heights below –2 SD at 4 to 5 years of age. This percentage is similar to that of term SGA infants who do not show postnatal catch-up growth (Fig. 12.4) [36].

SGA term infants suffer from an adverse fetal environment during the last trimester of pregnancy, whereas very preterm infants suffer from an adverse postnatal environment during the first three months, a time biologically equivalent to the third trimester of fetal life.

Considering these similarities, an expert group has recently suggested that the indication of GH therapy should be expanded to preterm children with EUGR whose growth fails to normalize over time [36].

12.4.2 Neurological and Intellectual Risk

There is an increasing evidence that being born SGA is per se associated with mild to moderate learning difficulties in childhood and adolescence, lower psychological and intellectual performance in young adulthood, and low social competence and behavior problems when compared with AGA infants of the same gestation [39]. The most important predictor of subnormal performance is the absence of catch-up growth in height and/or head circumference [5, 16]. Long-term exclusive

breastfeeding could help to prevent some of the neurological sequelae of being born SGA. Overfeeding with an enriched formula could accelerate growth, but it does not seem to lead to an advantage for intellectual development and could increase metabolic and cardiovascular risks (see below) [40, 41]. It has been suggested that GH treatment may improve IQ in short SGA children, but additional data are required [5, 39].

The association between cerebral palsy and IUGR, which has been observed in both term and preterm infants, may be due to placental insufficiency. Reduced oxygen or nutrient delivery to the fetus may have adverse effects on brain development and differentiation [18, 39].

12.4.3 Metabolic Risk

Since the late 1980s, epidemiological studies have shown that impaired intrauterine growth is associated with later development of the metabolic syndrome (MetS) or one of its components (insulin resistance, hyperinsulinemia, impaired glucose tolerance or diabetes mellitus type 2, dyslipidemia, arterial hypertension, and obesity). Additionally, other morbidities have been connected with the syndrome, such as hypercoagulability, non-alcoholic fatty liver disease, renal dysfunction (micro- or macro- albuminuria), polycystic ovary syndrome, endothelial dysfunction, and atherosclerosis leading to increased cardiovascular morbidity and mortality [42].

A number of mechanisms for the development of MetS have been proposed. One hypothesis is that the fetus adapts to an adverse intrauterine environment "reprogramming" the endocrine-metabolic status with benefits for short-term survival. This process consists mainly of insulin resistance and reduced insulin secretion due to the impaired development of beta cells. As a result, blood glucose concentrations can be maintained to benefit brain development at the expense of less glucose being transported to peripheral tissue (e.g., muscle and fat) [43]. This reprogramming maintains glucose homeostasis in the short term when the intrauterine nutrient supply is deficient, but predisposes the child to metabolic syndrome in later life when nutrient supplies are plentiful [18, 35].

SGA newborns show accelerated postnatal growth with rapid weight gain, associated with later obesity, which is per se associated with the MetS [44]. A recent systematic review has shown that both low birth weight and postnatal catch-up growth are correlated with the later development of MetS [45]. Overweight former SGA children also are at increased risk of MetS compared with overweight former AGA children [46].

Poor postnatal growth is associated with later poor neurocognitive outcome. This detrimental effect should be weighed against the metabolic risk that results from promoting faster weight gain [47]. The next challenge for neonatal nutritionists will be achieving "healthy catch-up growth" in IUGR subjects, based on a nutritional strategy for improved neurodevelopmental outcome while minimizing long-term metabolic and cardiovascular adverse effects [45].

12.4.4 Chronic Kidney Disease

When intrauterine resources are restricted, renal development is impaired, possibly at the expense of appropriate development of the brain and heart [7]. The result of this trade-off during organogenesis is a diminished number of nephrons ("nephron underdosing"), predisposing these subjects to albuminuria and to the risk of chronic kidney disease and hypertension. Metabolic syndrome and type 2 diabetes may also cause renal complications [48].

12.4.5 Puberty and Reproductive Function

Girls born SGA have an increased risk of earlier pubertal development or normal timing with rapid progression [49]. These aberrations may result in reduced adult stature. Today there are insufficient data to define the risk of ovarian dysfunction, reduced fertility or early menopause in females born SGA. By contrast, most boys born SGA have normal pubertal timing, but are often short [49]. Although there is sparse information about the influence of fetal growth on gonadal function, most studies have shown that low birth weight is a risk factor for testicular cancer, hypospadias and cryptorchidism [50]. There is little evidence about the influence of fetal growth on adult male reproductive function.

Intrauterine Growth Restriction: Intervention Strategies

Victor K.M. Han, Maxim D. Seferovic, Caroline D. Albion and Madhulika B. Gupta

13.1 Introduction

Intrauterine growth restriction (IUGR) or fetal growth restriction (FGR) is defined as a pregnancy in which the fetus fails to achieve his/her genetically determined growth potential or optimal growth. Optimal fetal growth is defined as birth weight achieved in the absence of fetal, maternal or placental factors that can exert a pathological effect on growth [1]. Clinically, whether the fetus or newborn has achieved appropriate growth for gestation is inferred from gender-specific standardized growth charts. IUGR is diagnosed if the weight is below the 10th percentile for a given gestational age. During pregnancy, the diagnosis is made if the estimated fetal weight (EFW) has either fallen below the 10th percentile or if it is on a downward trajectory on consecutive measurements indicating that IUGR can be diagnosed even if the EFW is within the normal percentiles.

The outcome of the IUGR pregnancy is a small for gestational age (SGA) newborn [2]. Thus, IUGR and SGA are not synonymous. IUGR indicates a pregnancy associated with pathology, whereas SGA refers to a newborn whose birth weight is below expected for the gestational age. For both IUGR and SGA, an accurate assessment of the gestational age of the pregnancy is critical for the diagnosis. Although SGA newborns of 34 weeks or greater have mortality rates that are similar to appropriate for gestational age (AGA) newborns, the morbidity (perinatal asphyxia and neonatal transitional problems) remain. The outcomes of SGA preterm newborns (before 28 weeks) are worse than AGA preterm [3]. In addition, SGA infants are predisposed to developing diseases in adulthood including hypertension, coronary heart disease, stroke and type-2 diabetes [4]. This phenomenon, now called "Developmental Origins of Health and Disease (DOHaD)" or Developmental Programming, was first shown in the United Kingdom and has now been replicated among men and women in Europe, United States and India [5].

The interventions to improve birth weights in IUGR pregnancies have not been successful, and to date, delivery at an appropriate gestation is still the most important intervention. In this chapter, the possible diagnostic strategies based on new proteomic technologies and evidence for intervention strategies will be discussed.

13.2 Physiology of Fetal Growth

Normal fetal growth is a series of coordinated cellular processes in various organs and tissues that are regulated by an organism's genome, which is modulated by the cellular microenvironment (gene-environment interaction), which in turn, is determined by fetal, maternal and external environments. The placenta is the critical gatekeeper of the fetal environment and, under normal conditions, it functions to promote development. However, under conditions of limited availability, it may compete with the fetus for its own metabolism [6, 7]. As a target of both maternal (hypertension, renal, coagulopathies) and pregnancy diseases (preeclampsia) it may be damaged, leading to poor function (placental insufficiency).

The cellular processes of growth and differentiation are regulated by complex cell-cell and cell-matrix interactions, which are mediated by locally expressed soluble or structural peptide factors (growth factors, cytokines and matrix). The regulation of the expression of genes that control these intricate processes in various tissues of the embryo/fetus can be categorized into intrinsic (genomic and epigenomic) and extrinsic (environment). The genome of the developing embryo consists of all of the information that is needed to develop from a single cell zygote to a complex multi-cellular and multi-organ/tissue structure of the fetus/newborn and placenta. The epigenetic or epigenomic influence of gene expression is

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

defined as the heritable regulation independent of genomic sequence and includes DNA methylation, histone modification and non-coding RNAs. It is also the major mechanism by which the environment (nutrition, chemicals) regulates gene expression that may be long lasting and sometimes deleterious to the individual's health [8] and may be responsible for developmental programming [9].

13.3 Pathophysiology of IUGR and Intervention Strategies

IUGR remains prevalent (3–10%) in both developed and developing countries, albeit with different etiologies which can be categorized into embryonic/fetal, placental and maternal causes. Clinically, the causes can be categorized into potentially treatable or untreatable. The latter includes genetic (aneuploidy or single gene) and infective (viral or protozoal) causes. The former includes those that are either preventable or managed to reduce mortality and long-term adverse outcomes. In developed countries, placental insufficiency is the major cause, whereas in developing countries, inadequate maternal nutrition and infections (e.g., malaria) play a greater role. The multi-factorial causes of IUGR lead to three possible scenarios: (1) abnormal placental function, (2) inadequate maternal supply of oxygen and/or nutrients or removal of waste, and/or, (3) decreased ability of the fetus to use the supply. The placenta plays an integral role in the first two categories. Abnormal development, inadequate perfusion and dysfunction of the placental villi are often responsible for the development of IUGR, especially in the early onset type, such as seen in severe preeclampsia. Irrespective of the etiology, the final common biochemistry and several molecular pathways include: (1) hypoglycemia and/or hypoxemia; (2) altered insulin and IGF system expression [10]; (3) alterations in the expression or activity of placental transporters, particularly those that transfer amino acids; possibly, the placenta senses its own nutrient supply, alters its transport abilities accordingly, and regulates fetal growth [7].

The interventions depend on the diagnosis, the possible etiology (exclusion of untreatable causes), the assessment of prognosis (continuation of pregnancy to achieve growth and maturity *vs* delivery to prevent intrauterine death) and the effects of intervention.

13.4 Diagnosis and Monitoring

Due to many underlying etiologies of IUGR, a combination of detailed history and examination, fetal, placental and amniotic fluid assessment is required to arrive at the correct diagnosis and management planning. To identify those fetuses that are at risk for adverse outcomes, it is critical to exclude small but normal fetuses, and those in which intervention is not recommended (genetic or infective causes).

13.4.1 Clinical

The standard clinical anthropometric measurements of pre-pregnancy maternal weight and height, and weight gain during pregnancy are still of fundamental importance in the diagnosis of IUGR/FGR. The symphysis-fundal height (SFH) measurement (the distance from pubic-symphysis to the uterine fundus) is a simple, inexpensive and widely used screening tool to detect abnormal fetal growth [11]. The most important aim of SFH measurement is the detection of IUGR fetuses to prevent intrauterine death and the reported detection rate of IUGR ranges from 56 to 86%.

13.4.2 Ultrasound and Doppler

A complementary use of ultrasound (for fetal biometry) and Doppler (of fetal vasculature) methods provides the best assessment of IUGR for both diagnosis and clinical decision making. Detection of IUGR by ultrasound using fetal abdominal circumference or EFW less than the 10th percentile for gestational age and sex is still the most feasible and reliable method.

A detailed and thorough anatomic sonographic survey is essential. A careful study to detect potential aneuploidy markers (e.g., echogenic bowel, nuchal thickening, clinodactyly) and associated congenital anomalies (e.g., omphalocoele, congenital heart defect) can strongly suggest a genetic etiology, and echogenicity of liver or brain can suggest a viral etiology. Serial ultrasound measurements of the fetus and estimated fetal weight, as well as amniotic fluid volume (maximum vertical pocket or four-quadrant amniotic fluid volume estimation) [12] aid in the diagnosis and the timing of delivery.

Doppler assessment of the various fetal vasculature (umbilical vein, ductus venosus and carotid) provides important clinical information on the circulatory changes that are occurring within the fetus and also indirectly provides some evidence of fetal hypoxia or acidemia. The presence of an early diagnostic notch in the uterine arteries at 12–14 weeks is the earliest evidence of abnormal trophoblast invasion, and if present beyond 24 weeks, the diagnosis is almost certain. Reduced umbilical venous flow volume or increased placental blood flow resistance are the earliest signs of reduced villous perfusion. Absent or even reversal of umbilical artery end diastolic velocity indicates that 60–70% of the placental villous vasculature has been damaged with the risk of fetal hypoxemia and potentially acidemia. The late Doppler changes are indicative of advancing circulatory decompensation and potential

impending fetal demise. The pulsatility index of umbilical artery offers a valuable monitoring measurement even in the absence or reversal of the end-diastolic velocity [13].

13.4.3 Biophysical Profile

Biophysical profile is a composite score (fetal tone, fetal breathing movements, gross body movements, amniotic fluid volume and fetal heart rate analysis) that represents the fetal behavioral response to placental insufficiency. The biophysical profile score (BPS) shows a reliable and reproducible relationship with fetal pH [14], however the deterioration in BPS is a later manifestation compared to Doppler changes.

The diagnosis of deterioration of fetal health, using multiple modalities over time, gives the most reliable information. Of all the fetal biometric measurements, the abdominal circumference gives the best measurement with the highest sensitivity and negative predictive value for IUGR, which is further enhanced by serial measurements [15]. Estimated fetal weight (EFW) can also be used as an important monitoring tool, although less sensitive than abdominal circumference (AC) in diagnosing IUGR, it offers greater positive predictive value.

13.4.4 New Biomarkers

Using proteomic technologies, two potential proteins that may be useful as diagnostic and/or prognostic biomarkers – maternal haptoglobin α2 isoforms [16] and fetal site-specific hyperphosphorylated insulin-like growth factor binding protein-1 (IGFBP-1) isoforms have been described [17]. The latter protein is particularly promising as phosphorylation enhances IGF-1 binding and limits IGF-1 bioavailability, and therefore is potentially a biomarker with functional relevance. These markers were identified in IUGR pregnancies after the clinical diagnosis was established, and their usefulness as an early diagnostic or prognostic marker remains to be delineated.

13.5 Management During Pregnancy

13.5.1 Timing of Delivery

The critical decision of delivery of an IUGR fetus is usually made when tests of fetal health suggest that intrauterine risks exceed neonatal risks for adverse outcome. Once the diagnosis is made, the pregnancy is closely monitored for maternal and fetal health, and serial investigations are essential to confirm the diagnosis as well as to monitor for timing of delivery. The principles in management are to avoid fetal demise, ensure optimal fetal maturity, and conduct safest mode of delivery for the best outcome. Recent studies suggest that antenatal glucocorticoids should be used with caution as fetal endogenous glucocorticoids are already elevated in IUGR pregnancies and additional exogenous glucocorticoids may impede maturation [18].

13.5.2 Nutritional Supplementation

Once the diagnosis of IUGR is made, it is usually too late to intervene with any form of nutritional supplementation to enhance fetal growth in the majority of cases. Since the etiology is likely due to the inability of the fetus to grow or the placenta is diseased and is unable to transfer enough nutrients across, nutritional supplementation is usually ineffective. Even in developing countries where maternal malnutrition is the primary cause, nutritional supplementation during pregnancy has not shown to consistently reverse the outcome. Studies to supplement nutrition prior to or early in pregnancy have shown variable results. Nutritional advice to increase energy and protein intake improve gestational weight gain and outcome of pregnancy, but has no effect on the incidence of SGA [19]. Supplementation of micronutrients to pregnant mothers has shown some improvement in birth weight compared to caloric supplementation alone. A systematic review of five trials (1135 women) showed nutritional advice given to pregnant women to increase energy and protein intake improve birth weight, but not the pregnancy outcome [20]. In 13 trials (4665 women), balanced energy/protein supplementation was associated with modest increase in mean birth weight and a substantial reduction in SGA risk, stillbirth and neonatal death. Whether the impact is due to the improvement of maternal health (e.g., correction of anemia) or direct supplementation of fetal nutrition is still unclear. Protein supplementation has not shown to be of benefit, and on the contrary, high protein diet has shown significantly increased SGA risk and increase neonatal morbidity in three trials of 966 women [20].

Hypoglycemia and low insulin levels are common findings in IUGR. However, glucose infusion to achieve euglycemia and increase insulin levels in a fetal sheep IUGR model causes progressive hypoxia and acidosis with increased lactate without an increase in insulin or beta cell mass [21]. Thus, correction of fetal hypoglycemia in IUGR by glucose infusion will not be effective and may potentially be harmful.

Marine oil, which has been suggested to prolong pregnancy and increase birth weight, prolongs pregnancy slightly, by 2.6 days (WMD 2.55 days, 95% CI 1.03–4.07 days; 3 trials, 1621 women) and birth weight was slightly higher (WMD 47 g, 95% CI 1–93 g; 3 trials, 2440 women), but there was no overall change in the incidence of SGA [22]. Supplementation during pregnancy of folate, iron, magnesium, zinc and vitamin D do not improve birth weight or the incidence of SGA [13].

13.5.3 Oxygen Therapy

Fetal hypoxia is commonly present in IUGR pregnancies in which placental insufficiency is the cause and impaired fetal growth is thought to result from reduced oxidative metabolism. Continuous oxygen therapy to mothers from diagnosis until delivery may improve fetal growth and outcome. A systematic review of three studies involving 94 pregnancies indicates lower perinatal mortality rate (risk ratio 0.50, 95% CI 0.31–0.81) and higher birth weights [23]. However, the higher gestational age in the oxygenation group may have accounted for the difference. Further controlled studies are recommended due to the limitation in the number of pregnancies studied so far.

13.5.4 Growth Factors and Growth Hormone

Experimental IUGR in animals is associated with low levels of IGF-I [10]. To reverse the growth impairment, IGF-I has been administered IV or into the amniotic cavity of IUGR in fetal sheep. Both modes of administration significantly increased fetal growth rates, but only the intra-amniotic administration increased liver weight. Growth hormone administration of mothers partially reversed IUGR, however, there was increased the incidence of hydraencephaly [24]. No clinical studies have been performed to date to assess clinical applicability of either treatment.

13.5.5 Low Dose Aspirin and Other Pharmacologic Agents

Some cases of IUGR share placental pathology similar to preeclampsia, and low dose aspirin, which inactivates platelet cyclooxygenase, results in decreased thromboxane synthesis and improved uteroplacental blood flow. A meta-analysis of 13 randomized controlled trials (RCT) including 13,234 women showed a significant reduction in IUGR (OR 0.82, 95% CI 0.72–0.93) and a non-significant reduction in perinatal mortality (OR 0.84, 95% CI 0.66–1.08) [25]. Aspirin was effective at lower dose of 50–80 mg/d but the preventative effect was greater at a higher dose of 100–150 mg/d. However, a more recent meta-analysis of 38 trials showed no reduction in IUGR or perinatal mortality [26].

Other pharmacologic agents that have been proposed to be potentially useful by improving uteroplacental circulation include betamimetics and calcium channel blockers [13]. However, no consistent beneficial effects on birth weight or incidence of SGA have been demonstrated. Less well studied is L-arginine, a nitric oxide donor [27].

13.5.6 Bed Rest

Bed rest is commonly recommended to women with IUGR pregnancies to improve uteroplacental circulation and enhance fetal growth. A systematic review of RCTs revealed only one well conducted study comparing bed rest *vs* ambulation involving 107 women [28]. It showed no difference in birth weight or gestational age.

13.5.7 Exercise

A recent systematic review of regular aerobic exercise (at least 2–3 times/wk) for women during pregnancy included 472 women in 11 trials, although most trials were small and not of high methodologic quality. Exercise improved physical fitness and was associated with a statistically insignificant increased risk of preterm birth (relative risk 1.82, 95% CI 0.35–9.57) with absence of effect on mean gestational age, while effect on fetal growth was inconsistent [29]. Another systematic review of two small good quality trials of 45 women showed no effect on the incidence of preeclampsia (relative risk 0.31, 95% CI 0.01–7.09) [30]. SGA risk was noted in one trial as relative risk 3.0, 95% CI 0.14–64.26.

13.6 Conclusions

Intervention strategies to improve the immediate or long-term outcome of IUGR pregnancies have proven ineffective. The objective of management of such pregnancies is to determine the appropriate gestation and mode of delivery to achieve fetal maturity and avoid perinatal complications. SGA newborns should be closely followed up to determine long-term adverse outcomes. Intervention strategies in the newborn and childhood period are still under investigation.

Late Preterm Infants at Risk for Short-Term and Long-Term Morbidity and Mortality

Avroy A. Fanaroff

14.1 Introduction

Late preterm births were the first group of premature infants who neonatologists treated successfully. Over time with the very low birth weight infants surviving and demanding many resources, near-term infants were relatively ignored and unfortunately were no longer considered to be of high risk by many health care providers. The resurgence of interest in this group, and their renaming to late preterm resulted from the recognition that they were indeed the largest subpopulation of preterm infants, and had an increased mortality when compared to term infants and increased morbidity including transient tachypnea of newborn (TTN), respiratory distress syndrome (RDS), persistent pulmonary hypertension (PPHN), respiratory failure, apnea, temperature instability, jaundice, hypoglycemia, feeding difficulties and a prolonged neonatal intensive care unit (NICU) stay [1–5]. Furthermore, they have an increased prevalence of cognitive and neuro-developmental problems and a greater rate of readmission to hospital in the first weeks after discharge than term births. Escobar noted that many late preterm infants are never admitted to the NICU [6]. A possible explanation is that clinicians may be making clinical judgments based on infants' birth weight only rather than gestation and birth weight.

Preterm births are both emotionally and financially costly, taking a toll on the family and resulting in high direct health care costs due to longer hospital stays and hospital readmissions. Reducing the rate and toll from premature deliveries is both a national and international priority. Because late preterm deliveries, those between 34 and 37 weeks' gestation, account for about 70% of preterm births, they represent the low lying fruit, and are the logical initial target for prevention of prematurity.

14.2 The Late Preterm Infant

Until recently late preterm infants (those delivered between 34 weeks 0 days and 36 weeks plus 6 days) were regarded and treated as near-term infants. Consequently the considerable morbidity and mortality in this group of infants was largely unnoticed and disregarded. Recognizing that they indeed are the largest group of preterm infants with significant short and long-term morbidity and even mortality, the terminology has changed to emphasize the preterm birth, hence the terminology late preterm, and closer attention is being paid to this specific class of infant. As they account for over 70% of preterm births, utilize excessive resources and as many late preterm infants have no identifiable reasons for their early appearance, they present the best opportunity to substantially reduce the rate of preterm birth [1, 2].

14.2.1 Incidence and Prevention

In the United States, premature births have increased from 10.6% in 1990 to a high of 12.8% of all live births in 2006, declining to 12.7% in 2007 and 12.3% in 2008 [7]. Thirty five states reported a significant decline during the 2 year period. The rise of preterm births during the last three decades was primarily due to a rise in late preterm births from 7.3 to 9.1% of all live births in 2006. In 2006 there were 387,791 late preterm births in the United States, representing 9.1% of live births. Indeed between 1996 and 2006 the rate of infants born late preterm in the United States increased more than 18%. However, there was a slight decline of late preterm infants to 9% in 2007, perhaps reflecting progress in the prevention of late preterm delivery. Late preterm infants, more than 34 and less than 37 weeks' gestation, account for almost three quarters of preterm births (Fig. 14.1.) Almost half of these deliveries are by elective cesarean section. For sound medical reasons and in the best interest of both the mother and fetus/newborn,

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

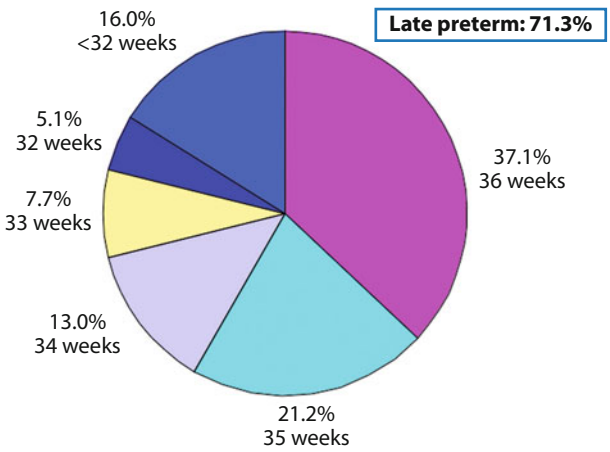

Fig. 14.1 Distribution of all preterm births, USA 2003

The American College of Obstetricians and Gynecologists has recommended that elective deliveries not be performed before 39 weeks of gestation [8].

Davidoff examined the changing epidemiology of gestational length among singleton births in the United States, from 1992 to 2002 [9]. Analyzing gestational age by mode of delivery, the distribution of spontaneous births shifted to the left, with 39 weeks becoming the most common length of gestation in 2002, compared with 40 weeks in 1992 ($P < 0.001$). Deliveries at greater or equal to 40 weeks gestation markedly decreased, accompanied by an increase in those at 34–39 weeks. Singleton births with premature/prolonged rupture of the membranes or medical interventions had similar trends. Changes in the distribution of all singleton births differed by race/ethnicity, with non-Hispanic white infants having the largest increase in late preterm births.

To quantify the adverse neonatal and maternal outcomes associated with elective term delivery at less than 39 completed weeks of gestation, Clark et al reviewed a cohort of 17,794 deliveries, including 14,955 (84%) at 37 weeks or greater. Remarkably, of these term deliveries, 6562 (44%) were planned, rather than spontaneous [10]. Among the planned deliveries, 4,645 (71%) were purely elective, and 17.8% of infants delivered electively without medical indication at 37–38 weeks and 8% of those delivered electively at 38–39 weeks required admission to a newborn special care unit compared with 4.6% of infants delivered at 39 weeks or beyond. Cesarean delivery rate in women undergoing induction of labor was not influenced by gestational age but was highly influenced by initial cervical dilatation and parity, ranging from 0% for parous women induced at 5 cm or greater to 50% for nulliparous women at 0 cm. They rightfully concluded that elective delivery before 39 weeks' gestation is associated with significant neonatal morbidity and is inappropriate.

Oshiro et al [11] reported that before initiation of a concerted system and multidisciplinary team effort (including administrators, information technology as well as bedside care providers such as physicians and nurses) with the goal of reducing elective births before 39 weeks, 28% of elective deliveries were occurring before 39 completed weeks of gestation. Within 6 months of introducing the program, the rate was down to 10% and 6 years later through continued education and a cultural change within the system, the rate is down to a very acceptable 3%.

Until 2007 the rate of preterm births has been increasing in the United States, especially for births at 34–weeks of gestation (late preterm). The causes for these trends remain unclear but significant contributors to these large numbers of late preterm births are elective inductions and cesarean deliveries prior to 37 weeks' gestation. This despite evidence and guidelines recommending against elective deliveries before 39 weeks without clinical indication [8].

Reddy et al [12] characterized the delivery indications for late preterm births and their potential impact on neonatal and infant mortality rates. Using the 2001 US Birth Cohort Linked birth/death files which contained over 3 million singleton births, they categorized delivery indications as follows: (1) maternal medical conditions; (2) obstetric complications; (3) major congenital anomalies; (4) isolated spontaneous labor: vaginal delivery without induction and without associated medical/obstetric factors; and (5) no recorded indication. They noted that among 292,627 late preterm births, the first four categories (those with indications and isolated spontaneous labor) accounted for 77%. The remaining 23% (67,909) were classified as deliveries with no recorded indication. Factors significantly increasing the chance of no recorded indication were older maternal age; race, multiparity; or previous macrosomic infant of more than 4000 g birth weight. The neonatal and infant mortality rates were significantly higher among deliveries with no recorded indication compared with deliveries secondary to isolated spontaneous labor but not surprisingly lower compared with deliveries with an obstetric indication or congenital anomaly. These 23% of late preterm births with no recorded indication for delivery noted on birth certificates present a prime opportunity for preventing late preterm births.

The potential for success in this regard is documented by the Ohio Perinatal Quality Collaborative Writing Committee [13]. They sought to reduce scheduled births between 36(0/7)–38(6/7) weeks that lack appropriate medical indication. They collected baseline data for 60 days from 20 Ohio maternity units and then mandated recording of an indication for scheduled births between 36(0/7)–38(6/7) weeks gestation. Deidentified birth data were analyzed centrally. Rates of scheduled births without a documented indication, birth certificate data, and implementation issues were shared regularly among sites. The rate of scheduled births between 36(0/7)–38(6/7) weeks without a documented medical indication declined significantly from 25% to less than 5% in participating hospitals. Birth certificate data showed inductions without an indication declined from a mean of 13 to

8%. Dating criteria were documented in 99% of charts. Thus merely by establishing and applying dating criteria for gestational age and requiring documentation of the reasons for scheduled birth, the number of late preterm deliveries were substantially reduced. If we can accomplish this beyond 36 weeks there is no reason to believe that it cannot be extrapolated to 34 weeks and beyond with a significant impact on reducing late preterm births. However, in order to sustain the success it will be necessary for scheduled births to be a part of the culture of safety and for mothers to be better educated regarding the risks of late preterm delivery.

Bailit et al [14], utilizing electronic health records, sought to determine maternal and neonatal outcomes by labor onset type and gestational age. They reviewed 115,528 deliveries from 2002 through 2008 categorized by labor onset type (spontaneous, elective induction, indicated induction, unlabored cesarean). Neonatal and maternal outcomes were calculated by labor onset type and gestational age.

Neonatal intensive care unit admissions, the need for assisted ventilation and sepsis improved with each week of gestational age until 39 weeks. The babies did better with elective induction, but there was increased risk of mothers requiring a hysterectomy in that group [14].

14.3 Mortality

In 2002, the neonatal mortality rate (deaths among infants 0–27 days chronologic age) for late preterm infants was 4.6 times higher than the rate for term infants (4.1 *vs* 0.9 per 1000 live births, respectively).This difference has actually widened when compared to 1995 data where there was a four-fold difference between late preterm and term infants (4.8 *vs* 1.2 per 1000 live births, respectively). This relationship also carries over into infant mortality. In 2002, the infant mortality rate, deaths during the first year of life, for late preterm infants was also greater than the infant mortality rate for term infants (7.7 *vs* 2.5 per 1000 live births, respectively) [9, 15].

This is most notable for late preterm small for gestational age (SGA) infants who are 44 times more likely than term appropriate for gestational age (AGA) newborns to die in their first month and 22 times more likely to die in their first year. Even excluding deaths from congenital conditions, including birth defects, the differences in mortality rate ratios persisted for SGA infants, especially those born in the late preterm period.

Thomasek [16] observed that late-preterm infants were particularly more likely to die in the early neonatal period compared with term infants from causes such as respiratory compromise, maternal complications of pregnancy, and congenital anomalies. They noted that infant mortality rates in 2002 were three times higher in late preterm infants than term infants (7.9 *vs* 2.4 deaths per 1000 live births) (Table 14.1). Because many of the deaths were caused by life threatening congenital malformations, which may have precipitated the preterm delivery, the plea for prospective documentation of the indications for late preterm deliveries is timely and appropriate.

Table 14.1 Complications of prematurity in late preterm *vs* term infants

Complication	Frequency late preterm	Frequency term
Jaundice	54%	38%
Sepsis evaluation	37%	13%
Feeding difficulties	32%	7%
Receive IV fluids	27%	5%
Hypoglycemia	16%	5%
Temp. instability	10%	<0.1%
Apnea	6%	<0.1%
Mechanical ventilation	3.4%	0.9%
Mortality (2002)	7.9/1000 Live births	2.4/1000 Live births

Kitsommart [17] compared data on 1193 late preterm, the majority of whom were 36 weeks (44%) followed by 35 weeks (29%) and 34 weeks (27%), respectively, and 8666 term infants. The prevalence of intensive care admission, respiratory support, pneumothorax, and mortality in late preterm infants was significantly higher compared with term infants. Although only 1% had positive cultures, almost 30% were treated with antibiotics. Despite a low overall mortality rate of 0.8%, the late preterm group had a 12-fold higher risk of death. The increased mortality and morbidity thus confirm the high-risk status of late-preterm infants.

14.4 Morbidity

It is estimated that nearly 50% of infants born at 34 weeks' gestation require intensive care, this number drops to 15% at 35 weeks and 8% at 36 weeks gestation. In order to identify infants at the highest risk for life threatening morbidity and those most likely to require specialized care Shapiro-Mendoza et al [15] classified a newborn as having a morbid condition during initial hospitalization when at least one of the following three criteria was met: (1) newborn hospital stay of 5 nights and any morbidity diagnostic code considered life-threatening, (2) newborn hospital stay of 5 nights and transfer to a higher level medical facility, and (3) infant death before hospital discharge. They reported that the risk for newborn morbidity increases two-fold with each earlier week of gestation, beginning at 38 weeks' gestation, until 34 weeks' gestation (Fig. 14.2). Late preterm infants are at greater risk for newborn morbidity than term infants, especially when maternal morbidity also is present. This risk seems to be particularly intensified when an infant has had prenatal maternal exposure to hypertensive disorders of pregnancy and antepartum hemorrhage.

Late-preterm infants were seven times more likely to have newborn morbidity than term infants (22 *vs* 3%) (Fig. 14.2).

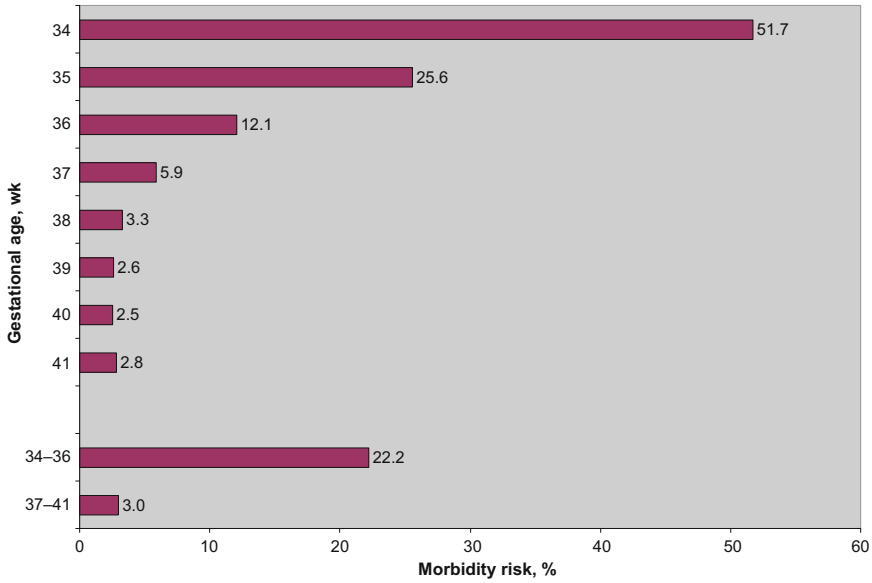

Fig. 14.2 Proportion with newborn morbidity during birth hospitalization according to gestational age. From [15], with permission

Late-preterm infants who were exposed to antepartum hemorrhage and hypertensive disorders of pregnancy (HDP) were especially vulnerable. Additionally HDP, diabetes, and asthma, are associated with an increased risk for indicated or spontaneous preterm birth (Table 14.2).

Decisions regarding the delivery of late preterm infants take into account the risks and benefits to both mother and fetus of prolonging the pregnancy. Specific standards of care and protocols are necessary for late preterm infants rather than applying those developed for term infants. Furthermore better anticipation, recognition and treatment of women with chronic and pregnancy-related health conditions may decrease the rates of newborn morbidity in all infants but especially in late preterm ones.

The major causes of morbidity encountered in late preterm infants include transient tachypnea of newborn (TTN), respiratory distress syndrome (RDS), persistent pulmonary hypertension (PPHN), respiratory failure, apnea, temperature instability, jaundice, hypoglycemia, feeding difficulties and a prolonged neonatal intensive care unit (NICU) stay [20]. In addition they have a higher prevalence of congenital malformations which, as noted above, may contribute to an increased mortality relative to term infants. They are also more likely to develop blood stream infections (Table 14.1).

Table 14.2 Risk for infant morbidity term *vs* late preterm [15]

Maternal condition	RR ratio LPT/Term
Hypertensive disease	6.1
Diabetes	5.4
Antepartum hemorrhage	5.1
Acute or chronic lung disease	6.1
Maternal infection	4.4
Cardiac disease	5.7
Renal disease	4.6
Genital herpes	10.0

14.5 Readmission

Escobar evaluated the large Kaiser Permanente data base which included 33,276 survivors of neonatal intensive care with 862 (2.6%) < 34 weeks' gestation, 2153 (6.5%) between 34 and 36 weeks, and 30,261 (90.9%) of more than 37 weeks [6]. Rehospitalization rates within 2 weeks after nursery discharge varied by gestational age range: 26/862 (3.0%) among babies <34 weeks, 94/2153 (4.4%) among babies 34–36 weeks, and 618/30 261 (2.0%) among babies 37+ weeks. Hence there is a two-fold risk of rehospitalization for late preterm infants compared with term infants and jaundice was the major reason for readmission. These data are substantiated by McLaurin, who reported readmission rates over the first year of life for late preterm infants were 15%, compared to 8% in term infants [19]. In particular, late preterm infants are three times more likely to be admitted within the first 15 days after discharge from the birth hospitalization (3.8 *vs* 1.3% [19]. The most common reasons for early readmission are jaundice, feeding difficulties, poor weight gain, dehydration, and apnea. Respiratory (including bronchiolitis) and gastrointestinal disorders are the most common diagnoses for late readmission (≥ 15 days after the date of discharge) during the first year of life. Underwood et al noted that the largest cohort of infants readmitted to the hospital at least once during the first month of life were infants born at 35 week's gestation, most commonly due to a respiratory illness [20]. The cost of hospital readmission for this cohort of infants approached 100 million dollars.

14.6 Thermal Instability

Whereas the late preterm infant is better equipped than the extremely low birth weight and premature infant, they are still vulnerable to cold exposure after delivery. Increasing amounts of fat are deposited in the final weeks of gestation so they have less white fat and brown fat accumulation and maturation, notably the controlling hormones surge at term. Late preterm infants often have temperature instability, which in turn leads to the consideration of sepsis, a sepsis evaluation and often the initiation of antibiotic therapy [21].

14.7 Transient Tachypnea of the Newborn

A major respiratory disorder in late preterm infants is transient tachypnea of the newborn (TTNB). TTNB is best described as the consequence of delayed and inadequate lung liquid clearance. This self-limiting disease, characterized by an increase in respiratory rate, occurs more frequently in infants delivered by elective cesarean section and is thought to result from delayed activation of liquid clearance in infants not subjected to the stress of labor. Gowen and others showed that newborn infants with TTNB had a transient decrease in amiloride sensitive nasal epithelial Na^+ transport compared with normal newborns, supporting the notion that suboptimal clearance of liquid is a cause of TTNB [22]. Infants with TTN were found to have low norepinephrine but normal epinephrine levels.

14.8 Respiratory Distress Syndrome

With more liberal use of antenatal corticosteroids commencing in 1994, and the introduction of surfactant in the early 1990s, infant deaths associated with respiratory distress syndrome decreased by 48% from 1989–1991 to 1995–1997 and then decreased by another 18% by 2002–2004 in the United States. The latter mortality reduction was evident at 28–32 weeks but not 33–36 weeks of gestation because these infants have not been optimally targeted to receive prenatal corticosteroid prophylaxis, despite evidence from randomized trials regarding the safety and efficacy of the treatment at this gestation. As corticosteroid use is infrequent beyond 33 weeks' gestation (15%) "addressing the knowledge practice gap in corticosteroid use at 33 and 34 weeks should reduce infant morbidity and mortality" [23].

Extrapolating the data from infants born at 24–32 weeks gestation, Joseph et al [26] concluded that the number needed to treat estimates for 35 weeks (n = 21) and 36 weeks (n = 64) of gestation are sufficient to warrant additional attention in terms of future research addressing efficacy at these more advanced gestational ages. However meta-analyses reveal non significant protective effects beyond 36 weeks [23].

Dudell et al [24] reviewed the ELSO Neonatal registry to study the indications for and outcomes of late preterm infants requiring extracorporeal membrane oxygenation (ECMO). The cohort comprised 2258 late preterm infants, representing 14.5% of 15,590 registered neonates. The primary etiology of hypoxic respiratory failure in late preterm infants treated with ECMO was RDS or sepsis as compared to term infants who were more likely to have aspiration syndromes. The overall survival (74%) has not improved over time, and was inferior for the late preterm infants as compared with 87% in the term population.

14.9 Apnea

Apnea occurs more frequently in late preterm infants (4–7%) than in term infants (1–2%) [25]. In the Collaborative Home Infant Monitoring study (CHIME), the recorded rate of apnea (obstructive and central apnea) and bradycardia events was greater in late preterm infants *vs* term infants [25, 26]. Late preterm infants may also be at increased risk for sudden infant death syndrome compared to term infants.

14.10 Feeding Difficulties

Late Preterm infants may have immature feeding mechanics with poor coordination of sucking and swallowing resulting in limited fluid intake and dehydration, often necessitating intravenous therapy. It is also more difficult to establish breast feeding and there may also be accentuated gastroesophageal reflux in late preterm infants. The American Academy of Pediatrics (AAP) has recommended that prior to discharge it is essential to establish successful feeding defined as coordinated sucking, swallowing, and breathing while feeding [2]. Weight loss should not exceed 7% of birth weight during birth hospitalization. If the infant is breast fed, twice daily documented observation by trained caregivers of successful position, latch, and milk transfer after birth also should be performed.

14.11 Jaundice

Hyperbilirubinemia is the most common clinical condition requiring hospital readmission during the first week of postnatal life. Late preterm infants are at substantially higher risk for severe hyperbilirubinemia than infants born at term. Infants born at 36 weeks' gestation have almost an eight-fold increased risk of developing a total serum bilirubin greater than 20 mg per 100 mL (5.2%) *vs* those born at 41 or 42 weeks gestation (0.7 and 0.6%, respectively) [27]. Approximately 1 in 650–1000 infants > 35 weeks' gestation develop total serum

bilirubin values greater than or equal to 25 mg per 100 mL and 1 in 10,000 have levels greater than 30 mg per 100 mL.

The risk factors for readmission are documented in Table 14.3 and are dominated by gestational age and breast feeding [28]. The jaundice may be attributed also to early discharge, inappropriate follow-up and monitoring as well as diminished fluid intake related to poor feeding. Late preterm infants accounted for 40% of kernicterus in a large series reported by Bhutani and Johnson [29]. All were discharged early and breast fed.

Most vaginal deliveries, including the late preterm infants, are discharged by 48 hours of life, well before the peak serum bilirubin that is observed in term infants on day 3–5 and later in preterm infants. The peak bilirubin thus occurs at home. It is therefore necessary to screen the bilirubin levels prior to discharge and arrange for early follow-up either at home or in the clinics to prevent catastrophic non monitored elevation of serum bilirubin. Decisions are made on the bilirubin levels according to age in hours and zones according to the Bhutani nomogram [29, 30].

It has long been accepted that jaundice progresses in a cephalo-caudal fashion as the total serum bilirubin (TSB) level increases. Kramer provided the first systematic study of this process by dividing the body into five zones ranging from zone 1 (jaundice restricted to the head and neck) to zone 5 (jaundice in the hands and feet) [1]. As the jaundice progressed from the head to the extremities, the TSB levels increased, although there was a wide range of bilirubin values in each zone [31]. To evaluate the visual assessment of jaundice Keren et al [32] utilized experienced well baby nursery nurses to visually evaluate newborns for jaundice at a mean age of 47 hours. The objective was to determine whether the pre discharge visual assessment would help to predict the subsequent risk of significant neonatal hyperbilirubinemia, defined as a bilirubin level that exceeded or came within 1 mg/dL of the AAP phototherapy treatment threshold [33]. Those whose pre discharge jaundice was seen in zones 4 and 5 were five times more likely to develop significant hyperbilirubinemia than those with no jaundice, or jaundice restricted to zone 1. Nevertheless, the correlation between cephalo-caudal progression and the ability to predict the risk of hyperbilirubinemia was highly erratic. An exception was the complete absence of jaundice (zone 0), which was present in only 17% of the population but had a powerful negative predictive value of 99%. The conclusion is that it is dangerous to rely on visual assessment of jaundice and if there is clinical evidence of jaundice then the bilirubin should be measured either chemically or by transcutaneous measurement. The AAP guidelines are directed at reducing the frequency of severe neonatal hyperbilirubinemia (levels >17 mg per 100 mL) and bilirubin encephalopathy, in addition to minimizing parental anxiety, discontinuation of breastfeeding and hoping to reduce costs. The key elements of the guidelines are presented in Table 14.4.

Table 14.3 Risk of being readmitted for phototherapy*

Risk factor	Odds ratio (*vs* 40 weeks)
35–36 wks	13.2
37–38 wks	7.5
Breast feeding	4.2
Jaundice in nursery	7.8
Length of stay < 72 h	3.2

* 30,000 discharges from well baby nursery 1988-1994; 4.2/1000 readmitted for phototherapy [28].

Table 14.4 AAP Jaundice Guideline The 10 key elements [33]

1. Promote and support successful breastfeeding
2. Establish nursery protocols – include circumstances in which nurses can order a bilirubin
3. Measure TSB or TcB if jaundiced in the first 24 hours
4. Visual estimation of jaundice can lead to errors, particularly in darkly pigmented infants
5. Interpret bilirubin levels according to the infant's age in hours
6. Infants < 38 weeks particularly if breast fed are at high risk
7. Perform risk assessment prior to discharge
8. Give parents written and oral information
9. Provide appropriate follow-up based on time of discharge and risk assessment
10. Treat newborns when indicated with phototherapy or exchange transfusion

14.12 Long-Term Outcomes

Until recently, the assumption was that late preterm infants carry minimal risk for long-term morbidities. Morse et al [34] refuted these assumptions when they compared prekindergarten and kindergarten outcomes among healthy late preterm infants, and healthy term infants. Outcomes were adjusted for 15 potential confounding maternal and infant variables. They observed that the risk for developmental delay or disability was 36% higher among late preterm infants compared with term infants. Furthermore the risk for retention and disability in kindergarten with need for special education was higher for late preterm infants. The assessment "not ready to start school" was borderline significant. Thus healthy late preterm infants compared with healthy term infants face a greater risk of developmental delay and school-related problems up through age 5 [35].

On the other hand Gurka et al [36] applied eleven standard outcomes measuring cognition, achievement, social skills, and behavioral/emotional problems using the Woodcock-Johnson Psycho-Educational Battery-Revised and the Child Behavior Checklist, administered repeatedly through age 15 years. They detected no consistent significant differences between late preterm and full-term children for these standard measures from ages 4–15 years. They concluded that late-preterm infants born otherwise healthy seem to have no real burdens regarding cognition, achievement, behavior, and socio-emotional development throughout childhood.

14.13 Discharge Planning

Clinicians who care for late preterm infants need to first recognize and establish that the infant is a late preterm infant. They must be aware of their increased risk for morbidity, mortality and potential neuro-developmental problems. They must anticipate, screen for and intervene in an appropriate and timely manner for the common problems encountered in these vulnerable infants. Prior to hospital discharge, parents need to be educated that their infant is at increased risk for jaundice, feeding difficulties, hypoglycemia and dehydration. Parents must be taught to recognize these conditions and promptly seek appropriate care following hospital discharge.

The AAP has established the following guidelines for discharge criteria for late preterm infants [2]:

- Determine the accurate gestational age, and ensure that there are no abnormalities or medical condition (i.e., hyperbilirubinemia) that requires further hospitalization.
- The infant demonstrates physiologic stability by demonstrating competency in the following:
  - Thermoregulation defined as an axillary temperature of 36.5–37.4ºC in an open crib.
  - Cardio-respiratory control with stable vital signs of a respiratory rate less than 60 breaths per minute and a heart rate between 100 to 160 beats per minute, and absence of medical illness.
  - Passed at least one stool spontaneously.
- Completed other routine newborn care. This includes screening tests (i.e., hearing and disorders that are threatening to life or long-term health), vaccinations (i.e., hepatitis B vaccine), and prophylactic treatment (i.e., vitamin K prophylaxis).
- Assessment of the family and home environment to identify any risk factors that may impact on the health of the infant.
- Successful training of the parents who have demonstrated competency in the care of their infant and the ability to assess for hyperbilirubinemia, feeding difficulties, and dehydration.
- A follow-up visit 24–48 hours after discharge is scheduled with an identified primary care provider.

14.14 Summary and Recommendations

In the United States, late preterm infants, defined as infants with a gestational age between 34 to 36 weeks and 6 days, account for 9% of all births.

Late preterm infants have a reported seven-fold increased risk of morbidity compared to term infants during birth hospitalization, which results in a longer hospital stay and higher medical costs. The most common causes of morbidity include hypothermia, hypoglycemia, respiratory distress, apnea, hyperbilirubinemia, and feeding difficulties. Late preterm infants have a higher mortality than term infants. Readmission rates are two to three times greater for late preterm compared to term infants. Early readmission (within 15 days of discharge from birth hospitalization) includes hyperbilirubinemia, feeding difficulties, poor weight gain, dehydration, and apnea. During the first year of life, respiratory and gastrointestinal disorders are the most common diagnoses for late readmission. Late preterm infants also have more neuro-developmental disabilities and school problems than their term born peers.

Ethical Problems

Otwin Linderkamp

15.1 Introduction

"I will prescribe regimens for the good of my patients according to my ability and my judgment and never do harm to anyone." The Hippocratic Oath expressed beneficence and non-maleficence as basic principles of medical ethics more than 2000 years ago. Beneficence in perinatal and neonatal medicine refers to the responsibility of the physicians to act in the "best interests" of the fetus and newborn infant. Non-maleficence relates to the avoidance of harm to the fetus and infant, but also to the mother. This implies that the benefit of treatments should outweigh the harm and risks of the treatment for the patient.

In the newborn infant, benefits are usefully defined as survival and the ability to live a self-determined life. For infants with no chance of survival, aggressive intensive care is not beneficial, but harmful and futile, and is, therefore, generally assumed to be unethical. However, in infants with uncertain prognosis (i.e., high risk of survival with poor quality of life), the decision is extremely difficult and requires clear ethical guidelines.

A recent meta-analysis on decision-making in the best interests of the newborn demonstrated that prejudices play an important role in the attitudes (and hence decisions) of caregivers [1]. Janvier et al [2] criticized that neonatal intensive care is usually far more scrutinized than intensive care of any older patient groups and that children and adults with a poor prognosis are more likely to be resuscitated than newborn infants with the same or a better prognosis. The authors explain the different attitudes by deficient knowledge about the actual outcomes or by irrational negative associations with low gestational ages. To avoid decision-making by prejudices and confirmation bias, evidence-based medical ethics applies research results (particularly epidemiology) in addition to ethical and legal principles to draw conclusions to ethical dilemmas in medicine.

Three groups of newborn infants are usually considered in end-of-life decisions: 1) infants at or below the gestational age limit of viability; 2) infants born with congenital anomalies incompatible with life; and 3) extremely ill preterm or full-term infants who might survive with severe damage of the brain or other vital organs after a long period of intensive care. This chapter focuses on the extremely preterm (EP) infant and reviews some of the important issues, such as outcome data, withdrawal and/or withholding life support, role of parents and health care providers, economics, and a framework for neonatal ethical issues.

15.2 Survival and Outcome of Extremely Preterm (EP) Infants

15.2.1 Survival of EP Infants

The knowledge of published survival and long-term outcome data is of great importance for antenatal and postnatal counseling of the parents and for the decision process in the care of EP infants. The prognosis depends on several factors such as gestational age, birth weight, gender, single or multiple births, prenatal and postnatal care, neonatal complications and morbidities, attitudes of the caregivers and parents, and on the individual maturity and resilience of the fetus and infant (Table 15.1).

Gestational age is accepted as major prenatal predictor of the prognosis of EP infants [3] since prenatal care (transfer to a perinatal center, corticosteroids) and antenatal counselling of the parents are mainly based on the gestational age. Most laws and guidelines on the limit of viability in EP infants use a defined gestational age as a limit. However, the estimated gestational age may deviate by ±7 days from the actual gestational age due to uncertain last menses and errors

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

Table 15.1 Determinants of the outcome of extremely preterm (EP) infants

Fetal factors
- Gestational age
- Body weight
- Gender
- Single or multiple births
- Social status and lifestyle of the mother
- Individual maturity and resilience of the fetus

Antenatal and intra-partum care of the fetus
- Maternal transfer to a level III centre
- Antenatal steroids, tocolysis, antibiotics, etc.
- Cesarean section on fetal indication
- Experience in "proactive care" of the mother and the EP fetus

Neonatal factors
- Individual maturity, strength and resilience of the infant
- Sufficient maturity of vital organs for survival (lungs) and for intact survival (brain, eyes)
- Condition of the EP infant at birth and response to resuscitation within 3–5–10 min
- Stability/instability in the first 12–24 postnatal hours
- Extent and required time of intensive care
- Neonatal complications and severe morbidities (IVH/PVL, ROP NEC, sepsis)

Neonatal and long-term care of EP infants
- Experience in resuscitation and neonatal intensive care of EP infants
- Availability of adequate equipment, resources and experienced staff around the clock
- Neonatal developmental care
- Specialized long-term care
- Socio-cognitive and learning support

Policies, attitudes and individual decisions
- Policies and guidelines concerning the care of EP infants
- Attitudes of the obstetrical and neonatal staff towards the care of EP infants
- Antenatal decisions of parents and caregivers (initiation and withholding of intensive care based on risk factors of death and long-term sequelae)
- Postnatal decisions of parents and caretakers (withdrawal of intensive care if the prognosis of the infant deteriorates)

of prenatal ultrasonography, unless the time of (*in vitro*) fertilization is precisely known [4].

A recent review of 20 published studies on survival rates of EP infants born between 1985 and 2008 [5] shows that live-born preterm infants with a gestational age of 22 weeks had an overall survival rate of 8% (145/1791) with no consistent trend to improvement with time. Survival rates ≥20% were noted in Japan [6–8] and in some single centre studies. In Japan, infants born at 22 weeks' gestation are principally considered viable and resuscitated. From 2004 to 2007, 1-year survival of infants born alive at 22 to 26 weeks of gestation in Sweden was 70% and ranged from 9.8% at 22 weeks to 85% at 26 weeks [9]. The overall survival rate of infants born at 23 weeks' gestation was 25% (1361/5383). Eight studies showed improvements and 6 showed decreases in the survival rates with time. Survival rates above 50% were reported for Sweden [9] and Japan [6–8].

Preterm infants born at 24 weeks' gestation showed an overall survival rate of 50% (3796/7555). A Japanese study on infants born in 2005 showed the highest survival rates in the whole-country studies (77%) [8], followed by Sweden in 2004–2007 (67%) [9], England and Wales in 2005 (56%) [10], and Norway in 1999–2000 (55%) [11]. In eleven time trend studies, a marked rise of the survival rates was observed with time. The overall survival rate of infants with 25 weeks' gestation was 68%. Japan, Sweden, Norway, and England and Wales reached again high survival rates of 85%, 81%, 77%, and 76%, respectively. Overall survival rates increased from 61% in infants born mainly in the 1990s to 74% in infants born mainly in the early 2000s. Infants born at 26 weeks' gestation had an overall survival rate of 80% [5].

15.2.2 Neonatal Morbidities and Long-Term Outcome in EP Infants

Seven recent studies on severe neonatal morbidity in surviving EP infants <27 weeks presenting week-by-week results have been reviewed elsewhere [5]. At 23 weeks' gestation the prevalence of intraventricular hemorrhage and/or periventricular leukomalacia ranged from 9 to 29%, at 24 weeks from 14 to 28% and at 25 weeks from 7 to 15%. Infants with 23 weeks' gestation had a high risk of severe retinopathy (17 to 62%) requiring surgical treatment. Blindness resulting from retinopathy of prematurity (ROP) has, however, become rare due to modern laser coagulation techniques.

The high risk of EP infants for neurodevelopmental impairments, such as cerebral palsy and cognitive or sensory deficits are of great concern to parents, caregivers and society. Only few national and regional studies present week-by-week outcomes in EP infants [5]. Severe disability was noted in 20–22%, 8–39%, and 11–27% of infants born at 23, 24 and 25 weeks', respectively. No disability was seen in 13–33%, 16–56% and 17–52% in infants born at 23, 24 and 25 weeks' gestation, respectively. Two Japanese studies showed relatively low rates of neurodevelopmental disability in infants born at 23 weeks' gestation (32–35%) [12, 13]. EP infants without visible disability in early years are at considerable risk for a variety of behavioral and educational deficits at school age.

There is concern that newly developed treatments and altered attitudes towards EP infants improve their survival rate, but that many of the additional surviving infants suffer from severe disability. A rising prevalence of long-term deficits such as cerebral palsy and poor cognitive outcome was indeed observed in several time-trend studies on EP infants born in the 70s and 80s and in some studies in the mid 1990s and the early 2000s [5, 14]. Recent studies showed both increasing survival rates and decreases in the rates of short- and long-term neurodevelopmental disabilities in EP infants [14]. The recent improvements of short- and long-term outcomes are probably the result of a comprehensive antenatal and postnatal care

philosophy including proactive antenatal care, optimal delivery procedure, competent neonatal care in the delivery room and the intensive care unit, better long-term care and a positive attitude of more caretakers towards these patients [15].

15.2.3 Prediction of the Outcome of Individual EP Infants

The prognosis of EP infants depends on several factors in addition to the gestational age. Although it is difficult to consider all of these factors in counseling the parents and in decision-making, obstetricians and neonatologists should be aware of the complex risk profile in individual infants. Several models have been developed that consider some or several of the factors influencing the short- and long-term prognosis of EP infants. Several guidelines include the option of withholding treatment if the infant's condition appears poor immediately after birth. This agrees with the attitude of many neonatologists who want "to see what the infant looks like" if the infant is born at the limit of viability [16]. However, several studies demonstrated that the infant's condition at birth (low Apgar scores and low heart rates at 1 and 5 min, need of cardiopulmonary resuscitation) did not predict poor outcome in EP infants [17, 18]. Thus, the condition at birth is an unreliable predictor of the prognosis of EP infants, unless resuscitation of more than 3–5 min is required to stabilize an EP infant.

Definitions of the limit of viability and of the "grey zone" in EP infants [19–22]:

a. Viability is defined as the possibility to live and survive outside the uterus independent of the risk for severe neurodevelopmental disability.
b. Viability is determined as a reasonable chance to survive without "severe and unacceptable" morbidity (usually defined as severe neurodevelopmental disability).
c. Viability is defined as the ability to grow and develop normally outside the uterus, the ability to communicate and to engage in meaningful relationships with others, to become a child and later achieve independent moral status and personhood.

The outcome of infants born at 22 weeks' gestation is actually extremely poor; infants born at 23–24 weeks' gestation have an uncertain prognosis, and infants born at 25 weeks' gestation have a reasonable chance to survive without severe disability. The lower limit of viability is currently set at 22–23 weeks, and the "grey zone" at 23 0/7 to 24 6/7 weeks. Infants born in the "grey zone" have an uncertain prognosis with high risk of death or survival with severe long-term deficits, but the individual prognosis depends on a variety of biologic and individual (maturity, strength and resilience), technologic and general care factors (including antenatal proactive care, attitudes of staff and developmental care in the NICU). The "grey zone" also considers the uncertainty of the assessment of gestational age by approximately ±7 days [4].

15.3 Laws and Guidelines for the Care at the Limit of Viability

The World Health Organisation (WHO) defines a life birth as "a fetus, whatever its gestational age, exits the maternal body and subsequently shows any sign of life, such as voluntary movement, heart beat, or pulsation of the umbilical cord, for however brief a time" [23]. The term "live birth" was defined by the WHO mainly for public health, legal and statistical purposes and should not be used synonymously with "viability". Signs of life may already be seen in extremely immature infants born at 20 weeks of gestation and no chance of survival.

The "Born-Alive Infant Protection Act" enacted by the US government in 2002 obliges the physician to "protect infants who are born alive at any stage of development". Enforcement guidelines to the law issued in 2005 requires the hospital and its medical staff "to perform a medical screening examination on that born-alive infant" and to treat the infant if signs of life are detected [24]. The legal conditions in the US may explain that the guidelines of the American Academy of Pediatrics [25, 26] recommend withholding life support in infants with 22 weeks' gestation, but do not give detailed recommendations for more mature infants. Similar guidelines have been issued in Spain [27]. In Italy, the National Bioethics Committee reccomends resuscitation of all babies born alive when a possibility of survival exists [28].

Some national laws define the limit of viability to address primarily the limit of legal abortion (e.g., Japan and Italy: 22 weeks; Netherlands, Singapore and UK: 24 weeks). In Japan the viability limit has been lowered from the previous 24 weeks' gestation to 22 completed weeks' gestation in 1991 (Motherhood Protection Act) based on surveys of survival rates in EP infants [6]. As a result of the legislation in Japan, intensive care is provided to all EP infants born at ≥22 weeks' gestations [13].

In most western countries, as well as in Japan and Australia, guidelines regarding the limit of viability have been established by medical organizations in agreement with national laws and court rulings [6, 22, 29–40]. The guidelines usually present recommendations for the care of infants with extremely poor, uncertain and fairly good prognosis. No country recommends resuscitation of infants with gestational age below 22 weeks. For infants of 22 weeks' gestation, guidelines of five countries recommend "comfort care only" [25, 30, 31, 34, 36]. The other guidelines propose individual decisions based on parental request or the infant's condition at birth. For infants with 23 weeks' gestation, three countries recommend "comfort care only" [31, 36, 39], while the other guidelines recommend individual decision or care according to parental request. At 24 weeks' gestation, four guidelines regard intensive care as due according with individual decisions [33–35, 40], four as generally indicated [6, 22, 37, 38]. At 25 weeks' gestation, most guidelines regard intensive care as "generally indicated". Resuscitation on the basis of gesta-

tional age has also been criticized [41]: The likelihood of a favorable outcome with intensive care can be better estimated by considering four factors in addition to gestational age: sex, exposure to antenatal corticosteroids, single or multiple birth, and birth weight [42].

15.4 Quality of Life and the Best Interests of the Infant

Assessments of the quality of life, the harm/benefit ratio and the best interests of the infant are often made to decide whether it is appropriate to begin or to continue intensive care. In the decision-making process the estimated quality of life corresponds to the probable benefit resulting from medical care and the best interests are deducted from the harm/benefit ratio. Parents and professionals caregivers are particularly concerned with the risk of "brain damage" and what it means for the child. In the newborn infant, quality of life is usually related to the estimated future health and development. There are several concerns with the definition of the future quality of life in preterm and severely sick neonates:

- The future quality of life is usually estimated from risk factors such as gestational age, birth weight, gender, signs of brain damage in ultrasound scans and other complications during intensive care. Quality of life is thus estimated from individual factors that are compared with statistical data studied in a cohort of infants with similar risk factors. The epidemiological approach is objective, but uncertain for the individual child.
- The meaning of an estimated future quality of life in infants cannot be judged by the infants themselves, but is estimated by the families, the caregivers and the society. It includes effects of the health status on lifestyle in the children and their families, the quality of life probably experienced by the child and the value placed by the public, the family and the child on compromised health states.
- The uncertainty of the estimation of the future quality of life is difficult to bear for many parents and caregivers, as the consequence of the judgment may be the death of the infant. This is admitted in some countries, but cannot avoid the suspect of a conflict of interests: some parents can overestimate babies' future disability or they cannot accept even a low-grade handicap that, on the other hand, the baby might bear.
- Life-and-death decisions based on the judgment of the quality of life have been regarded discriminatory against handicapped persons. Many disabled persons might consider their quality of life as good or acceptable. Some can argue that the decision to withhold or withdraw intensive care is only made in infants with anticipated disability that will probably lead to intolerable suffering and burden, and inability to interact with others, but some authors do not agree.

Several national laws, decrees, court rulings and guidelines request that any decision made on behalf of a person lacking decision-making capacity must be in the person's "best interests". Three major interests of the premature or sick neonate have been defined [43–45]:

- Interests in the neonate's health: reasonable care using recognized standards of care and appropriate individualized care measures have to be provided.
- Immediate (short-term) interests of the infant: pain and suffering, harm and indignity should be avoided by the selection of appropriate therapeutic measures (e.g., developmental care, pain treatment, comforting care).
- Long-term or future-potential interests of the infant: these are usually defined as good or acceptable long-term outcome.

In addition to the infant's interests, familial, communally, and public (moral and legal) interests play a role [43, 44]. The family members have their own interests and incorporate religious and cultural values. Communal or social interests consider cultural beliefs about the value of disabilities, concerns for dignity and respect. Public interests include protection of citizens from abuse or neglect. Medical care of newborn infants has to be compatible with moral and legal duties to incapacitated individuals.

Pain and suffering from intensive care procedures (present quality of life) are related to the risk for long-term suffering and burden (future quality of life). If the infant has no chance of survival, intensive care will merely prolong pain and suffering, and natural death may be in the best interests of the baby. If the outcome of the infant is uncertain, but most likely associated with poor health and development, the best interests will be judged from both the present pain and suffering (intensive care) and the estimated future suffering and burden.

Financial considerations should not play a role in the judgment of the best interests of an infant with uncertain prognosis by the caregivers and the society. The best interest concept is mainly applied in uncertain situations, but may be uncertain itself. What is the probability of survival of an individual infant? What is a reasonable, an acceptable and an unacceptable long-term outcome? Kipnis [46] defined three types of uncertainty in the estimation of the outcome: The vagueness of the definition of "intolerable deficits", the uncertainty of whether a baby will benefit from an intensive care intervention or be harmed by it, and the inability to determine the harm-to-benefit ratio of (sometimes aggressive and painful) intensive care measures. Moreover, the application of the best interest standards may be flawed by limited knowledge or lack of consensus about treatment choices, conflicts of interests, personal beliefs, bias and prejudice, lack of empathy, ignorance or disregard of persons' rights and duties [1, 44].

Critics of the "best interests" concept argue that it is vague, open to abuse, and permits decision-makers to do whatever they think is best. Decisions may be made in the interests of the parents and caregivers rather than in the best interests of the infant. To overcome the uncertainties of the best interests

of an invidual infant, it has been suggested that a best interests' standard should incorporate what a reasonable person of good will would want or consider acceptable in similar circumstances ("reasonable person standard" [43, 44]). Physicians and other health professionals should be aware that in clinical practise it is impossible to know the true best interests of an infant or to define the ideal best interests for an infant. The consideration of evidence-based facts, the clinical intuitions at predicting the outcome of an infant, has been found useful in one study [47]. In some countries the decision to withhold or withdraw intensive care in an infant is up to the parents. The best interests of the infant should be judged jointly by the parents and the physicians. The physicians do not make the final decision, but rather provide the parents with all the information they need do make an explicit decision. This information includes the probable outcome, the necessary intensive care procedures to achieve this outcome and the anticipated burden (including the social and financial burden).

Saigal and colleagues reported in a cohort of adults who were born extremely low birth weight, survivors had no difference in self ratings of health-related quality of life (HRQOL) when compared with normal birth weight controls [48, 49].

15.5 Attitudes Towards Extremely Preterm and Critically Sick Neonates

Attitudes of caregivers towards withholding and withdrawing intensive care of EP and critically sick infants with uncertain prognosis vary among different health professions, among different countries and regions, among various centres of a country or region, and among different caregivers in one centre [15, 50, 51]. Moreover, attitudes of caregivers and parents may deviate considerably. Attitudes of obstetricians and pediatricians were similar in most studies, while nurses in some countries tended to be more prone than physicians to withhold resuscitation in the delivery room and to consider parental opinion regarding subsequent treatment choices than physicians [35, 52, 53]. Nurses frequently underline the suffering of the newborn, whereas physicians often stress uncertainty in treatment outcome [54].

The EURONIC study group revealed that most caregivers in seven European countries would limit intensive care in EP infants with fatal/terminal illness, but that 45–60% of the responders from Germany, Italy and Spain would not set limits in case of poor neurological prognosis [51]. Moreover, the attitude towards "explicit involvement" of parents in decision-making varied between 10% (France) and > 90% (UK). If the physicians wished to discontinue intensive care of an infant with poor prognosis, approximately 50% would continue intensive care at parental request.

Bellieni and Buonocore [1] reviewed attitudes of caregivers concerning the best interests of the newborn. They conclude that several aspects of the personal (age, gender, having own children, fear of litigation), social, religious and professional background (position, experience, knowledge, number of cots) influence the attitudes of the caregivers. Religious convictions play an important role in the attitudes towards care of EP or severely critically infants independent of the denomination [50, 55].

Janvier and colleagues demonstrated that attitudes towards the care of EP or critically sick newborn infants deviate markedly from the attitudes towards older children and adults with similar or worse prognosis [2, 56]. Asked if they would resuscitate patients with identical outcome (50% risk of death and 50% risk of severe neurodevelopmental disability in survivors), 69% of the respondents would resuscitate an EP infant, 87% a full-term neonate and 97% a two-month-old infant. The authors conclude that EP infants are considered "morally different from older children" [57] and speculate that the majority of the respondents had either irrational negative associations with low gestational ages or they were unaware of actual outcomes [58].

Table 15.2 summarizes several indications that neonates, in particularly EP infants, are valued differently from older children and adults. A positive attitude of all prenatal and postnatal caregivers towards the care of a high-risk infant is

Table 15.2 Facts and causes of devaluation of the lives of preterm and full-term infants

- The fetus has almost no rights in utero, but suddenly becomes a citizen after birth
- Termination of pregnancy is legal in many countries even after the limit of a preterm's viability
- The extremely preterm infant is frequently described as "living fetus" or "fetal infant", thereby implying the same lack of rights for the newborn infant as for the fetus
- Infants of older mothers or mothers conceived by *in vitro* fertilization are often called "precious" or "irreplaceable" children in contrast to apparently less precious other infants (e.g., of very young mothers). This relativity of the value of a preterm infant is unthinkable for a critically sick child
- Some ethicists believe that newborn infants lack "personhood" (personality) and consciousness and are thus comparable with an animal rather than with a human child or adult
- There is widespread belief that bonding of infant and mother is less in newborn infants than in older infants and children and even less in premature infants
- Many caretakers are unaware of actual outcomes of extremely preterm infants and overestimate mortality and disability rates and the costs of care
- Irrational negative associations with low gestational ages are frequent in caregivers and the public. Confirmation bias results in the selection of arguments (and research results) that confirm the assumption of poor prognosis of extremely preterm infants
- Uncertainty of a prognosis (e.g., extreme prematurity, intracranial hemorrhage, severe asphyxia or malformations) may justify withholding and withdrawal of treatment in a neonate, but not in an older infant or child
- The informed decision process of the parents requires reliable information at a time when the caretakers themselves are still depending on subjective interpretation of benefits, risks and burdens of the infant

an important determinant of the prognosis. If some physicians or nurses think that an EP or severely sick infant is not viable, they might treat the baby that way, resulting in self-fulfilling prophecy. Education of all staff involved in prenatal and postnatal care of high-risk infants about the actual outcomes using valid epidemiological data, and elimination of irrational negative associations with low gestational age or other risk factors are important prerequisites for a good outcome of high-risk infants.

15.6 The Rights of the Newborn and the Parents

Mercurio distinguishes three rights of the newborn, the right to life, the right to mercy and the right to justice or fair treatment [59]. The right to life is part of many national constitutions and includes the right to appropriate medical treatment. He defined the right to mercy as "a right not to be subjected to pain or discomfort that is very unlikely to yield benefit". The right to justice or fair treatment includes the right to equal medical treatment independent of age, ethnicity, income, etc. Different attitudes to the care of preterm, full-term and older infants [58] violate this right, if they influence the care. The right to justice and equal treatment includes the use of proper epidemiological data in the decision to treat or not to treat an EP infant.

Most countries grant parents the legal rights to decide on behalf of their minor children including the general upbringing, the education, the religion and medical treatment decisions. The parents have the right to get all available information on the condition of their sick child and on therapeutic options for their child. After they have received all necessary information, the parents have the right to select from the therapeutic options, but also to refuse treatment or to have the infant transferred to another hospital. It would be inappropriate to override parents' wishes, since they are usually motivated by their infant's best interest, have natural authority over their child, express religious views in their opinion and bear the burden of treatment decisions [60].

On the other hand, the parents do not have the right to refuse necessary and reasonable treatment. Thus, parents' rights are rebuttable when their decisions pose a significant risk to the life or well-being of the infant [60]. "Parents have a right to make martyrs of themselves, but not of their children" [59]. Moreover, parents have no right to demand treatment that is of no benefit to the child. Without perceived benefit to the child, the parental right to decide is outweighed by the child's right to mercy [59]. These limitations of parental authority in decision-making for their preterm or sick infants do not justify to bar parents from accurate information about the long-term prognosis, resuscitation and treatment options. In many hospitals parents still have limited informed input, even if the infant is born in the "gray zone" of viability [51, 61].

15.7 Informing and Counselling Parents

Guidelines in many countries give parents the major responsibility for the decision-making in EP infants in the gray zone. This responsibility requires comprehensve and accurate information on the prognosis of the infant and treatment options before and after birth.

The major purposes of antenatal and postnatal counselling are: 1) to inform the parents accurately about the condition, the reasonable treatment options and the prognosis of the fetus or the newborn infant, and 2) to assist the parents with decision-making [19, 62, 63]. The consultations have to be honest, fair and compassionate, sensitive to the culture and religion, the level of understanding, the physical and psychological condition of the mother and the father. Translation services may be necessary for parents not proficient in the national language. Senior physicians together with other experienced staff should perform the consultations in a spirit of fairness and compassion. If the counseling physicians are sure that the parents have understood the information, options of care (inclusive withholding and withdrawing of intensive care) should be presented to the parents. Both parents should be present at the consultation, unless the father is legally or for other reasons not involved. In this case the mother should be given the possibility to have a confidant involved. If the mother is under-age or incapacitated, the mother's parents may share the authority with their daughter [64].

Antenatal counseling may be necessary for women with a high risk of delivering an EP or critically sick infants within days or weeks and for women with imminent delivery of a high-risk baby. The prenatal consultation is a collaborative process that should involve obstetricians and midwifes, neonatologists and neonatal nurses, and (if necessary) pediatric subspecialists, pediatric surgeons, and genetic counselors [65]. Communication among various specialists is of great importance to avoid inconsistent and contradictory information and counselling [62]. A shared decision between parents and physicians requires a trusting relationship between parents and caregivers. The parents should be encouraged to consult their family doctor or other health professionals outside the hospital, discuss their situation with relatives and friends, and be offered support by clergy, psychologist or social worker.

The first antenatal consultation is usually performed by the obstetrician and/or midwife and focuses on antenatal treatments (selection of hospital, tocolysis, corticosteroids, cesarean section). Parents should be given accurate information about the chance of their infant surviving and surviving without severe disability. Many physicians believe that the amount of specific medical information is too much for the parents. However, parents have the right to receive the same information as the physicians to make far-reaching decisions for their child. Framing of the information may influence the decision of the parents: Persons who were informed on the prognosis of an EP infant born at 23 weeks' gestation as having a chance of intact survival chose resuscitation of an EP

infant more often than parents who were given prognosis as risk of death and disability [66].

A neonatologist should become involved as early as possible to describe the anticipated immediate and long-term problems after birth, short-term and long-term prognosis, the expected extent of resuscitation and subsequent intensive care. Current information on outcome data of EP infants should include the prognostic relevance of the gestational age, birth weight, gender, multiple birth and prenatal care [42, 67]. Moreover, the parents should be informed on local care possibilities and on local outcome data in comparison with referral centres. Statistical outcome data presented in counseling should include risk of death and risk of survival with severe/moderate/mild impairments (including their meanings). It should also be mentioned that "normal" surviving infants are at risk of a variety of behavioral and educational deficits. Financial obligations are of little importance in counseling and resuscitation in most countries [68], but should be considered if the prognosis of the infant is poor and the financial costs for the family are high.

The anticipated quality of life, pain and suffering of the infant from intensive treatments, but also the burden for the family should be addressed. Moreover, the parents should be informed about the option to withdraw intensive care if the treatment becomes futile. During the consultation, the attitudes and preferences of the parents should be evaluated to assess the best interests of the infant as judged by the parents. An experienced neonatal nurse should explain nursing procedures in the NICU (including feeding of mother's milk, kangaroo care, developmental care) and (if possible) give the mother and/or the father a tour of the NICU. If possible, the consulting neonatologist(s) and neonatal nurse(s) should be part of the resuscitation team in the delivery room and the initial intensive care team for the infant. If this is not possible, the counselors have to make sure that the resuscitation team is informed on the decisions made before delivery and does not oppose to the decisions, unless the situation has changed considerably.

In countries where the decision is given to the parents, there is controversy as to whether counseling of parents should be directive or non-directive [63]. In non-directive counseling, information on outcome data is given (including the uncertainty of the data) without recommendation for the decision and parents are asked to decide whether they want their infant resuscitated after birth. This gives the parents full authority, but also the entire responsibility for a life-or-death decision. They might feel left alone with their decision, worries and emotions and may later regret their decision and feel guilty. Kaempf et al [69] demonstrated that shared authority of the staff and parents using clear guidelines for counseling are well accepted by the parents.

For many parents detailed information on the prognosis and discussion of treatment options are less important than religion, spirituality, and hope guided decision-making [70]. These parents may be reluctant to make a decision, but may prefer to leave "things in God's hands" and want everything done. Different moral and religious attitudes may be a source of conflicts between physicians and parents. Dunn [71] proposed to ask five questions, particularly if the views and decisions of the parents do not agree with the medical staff:

- Do the parents understand the clinical condition and prognosis of their child?
- Do they wish or should they consult others before finally making up their minds?
- Do they require more time?
- Is their decision a loving, caring one made in the interests of their child?
- Are they asking to pull life-saving treatment only for their baby's interest?
- Is their decision a reasonable one in the interests of their child and, if in doubt, is it so unreasonable as to request them to seek other medical advice or for me to take legal steps to take the child into care under the protection of the courts?

Breaking bad news is particularly challenging and requires the sensitivity and communication skills of the physician. If bad news is given with warmth and affection and parents are treated with respect and sensitivity, most parents will have positive memories and will be grateful to the staff involved [72].

15.8 Decision-making in EP Infants

Decisions concerning the care of EP infants may be required at three times:

1. Care of the mother and the fetus before birth. Parents and physicians have to decide whether antenatal proactive care is provided (transfer of the mother to a perinatal centre, tocolysis, antenatal corticosteroids, Cesaren section on fetal indication).
2. Initiation or withholding of resuscitation of the infant after birth. The decision as to whether the infant will be resuscitated is made before birth, but may be changed according to the infant's condition and the infant's response to resuscitation. The decision to provide proactive antenatal care is usually combined with the decision to resuscitate the infant and vice versa.
3. Continuation or withdrawal of neonatal intensive care. Reorientation of care may be considered if provisional care of an infant with assumed poor prognosis has been unsuccessful or if the prognosis deteriorated (e.g., large cerebral bleeding with inactive electric brain activity). The decision to withdraw intensive care in some countries should be made jointly by parents and staff.

The reasons for end-of-life decisions have to agree with national or hospital guidelines. Palliative care treatments (e.g., analgesic drugs) have to be compatible with national laws and court decisions. In most guidelines no or small chance of survival ("futility" of treatment) and no or small chance of survival without severe disability are recognized conditions. The

entire team (including subspecialists as pediatric neurologists, etc.) and (as required) the Ethical Committee should become involved in the end-of-life decision.

If the prognosis is uncertain, the harm-to-benefit ratio (i.e., pain and suffering from intensive care, suffering and burden from long-term impairments in relation to probable long-term outcome) should be estimated and considered in decision-making. Most guidelines consider only severe disability leading to intolerable suffering and burden and/or inability to interact with others as justification for withholding and withdrawal of life sustaining treatment. Whether suffering and burden resulting from intensive care and disability are intolerable has to be decided by the parents. However, the decision to withhold or withdraw intensive care is primarily a medical decision for which the doctor bears ultimate moral and legal responsibility.

The major concern of an end-of-life decision is that the outcome of an individual infant is estimated from statistical data determined in a group of (more or less) representative infants studied several years earlier. Because of the uncertainty of the prognosis, some authors are strictly against any end-of-life decision made before birth, but rather opt for an individualistic approach based on the infant's clinical condition and initial response to intervention at birth [28]. However, most authors agree that "extending intensive care to all of the most immature infants would entail considerable suffering, resource use, and cost in order to benefit only a small proportion of infants" [67]. This can be considered as a utilitarian viewpoint, but it is the logical consequence of dealing with an uncertain situation in which judgement and decision have to be made in the assumed best interests of the individual infant.

When parents are involved in end-of-life decision, the following scenarios may occur after birth in infants whose prognosis was uncertain before birth:

1. If a joint decision of parents and physicians has been made before birth to resuscitate the infant, resuscitation of the infant should usually be tried even when the condition of the infant is severely compromised at birth.
2. If a joint end-of-life decision of parents and physicians has been made before birth, resuscitation of the infant will usually not be attempted. If the infant appears viable (spontaneous respiration), resuscitation should be started within 1–2 minutes to avoid severe hypoxia.
3. If no joint decision of parents and physicians has been made before birth because the mother was already in active labour when admitted to the hospital or because of other reasons (e.g., language), the neonatologist must decide on behalf of the infant and should in case of doubt resuscitate the baby until the parents can be involved in the decision.

Parents differ in their request to be supported in their decision by the staff. Some parents want staff to suggest to them what to do, others wish to receive the necessary information but prefer to make decisions independently or with the support of family, friends, family doctor or religious adviser [72]. Although most parents wish support, the staff members have to avoid any devaluation of parental autonomy and self-worth. "Most parents want to feel guided, assisted and listened to, but not directed or controlled, and certainly not abandoned" [72]. Parents will usually make concerned and loving decisions in their infant's interests.

In countries where the decision to withhold or withdraw intensive care is taken with the essential statement of the parents, the main causes of conflicts between parents and physicians are different opinions of the condition and best interests of the infant, insensitive behavior and communication of the team, and religious convictions of the parents that forbid withdrawal of life-sustaining treatment [73, 74]. Parents usually make concerned and loving decisions in their infant's interests. A Dutch analysis of disagreements in end-of-life decisions demonstrated that conflicts within the team occurred in 4% and between the team and the parents in 12% of the cases. All conflicts were resolved by postponing the end-of-life decision until consensus was achieved [74]. When treatment is clearly futile, the physicians can decide to stop intensive care without decision of an Ethics Committee or court in some countries [75]. In case of conflict between parents and neonatologists that is the parents request to withdraw treatment, while the team sees a realistic chance of survival without severe disability and wishes to continue intensive care, intensive care should generally be continued.

15.9 Withholding and Withdrawing of Intensive Care

15.9.1 Withholding vs Withdrawing of Intensive Care

In various studies end-of-life decisions preceded death in 70–80% of dying newborn infants [76–77]. Principally three ways of ending or limiting intensive care are possible with the intention to shorten the life of a patient: 1) Withholding of resuscitation and intensive care after birth; 2) withdrawing of life-support; and 3) withholding of additional therapies (e.g., antibiotics, vasoactive drugs). The third way is preferred by many professionals and parents, but may result in survival with additional damage (e.g., from sepsis, hypoxia). Although probably not uncommon, withholding of additional therapies is rarely mentioned in reports on end-of-life decisions [76].

Several guidelines see no moral or ethical difference between withholding and withdrawing intensive care [19, 26, 32, 33, 40, 77]. Some authors explicitly opt for withdrawal rather than withholding life support, since "provisional" treatment allows for evaluation of the clinical condition of the infant, including the actual gestational age and body weight, and the reaction to resuscitation and intensive care [40, 77]. Boyle [78] describes the widespread American attitude: "If the treatment in question never is started, no one will benefit. If it is started, some may benefit, and it can be withdrawn from those

whom it does not benefit". During "provisional" intensive care a harm-to-benefit ratio can be estimated repeatedly to determine whether it is appropriate to continue or not. Some national guidelines (e.g., Swiss) recommend "provisional care" of EP infants born at a gestational age in the "gray zone" [40].

However, some religious convictions allow withholding, but not withdrawing of life support [73]. Furthermore, for many caregivers and parents it is psychologically more difficult to withdraw than to withhold intensive care measures. The EURONIC study demonstrated that neonatologists in Italy, Spain, France and Germany consider it more acceptable to withhold than to withdraw mechanical ventilation, whereas in the Netherlands, the UK and Sweden more than 93% of the neonatologists would withdraw intensive care in selected circumstances [51]. Reasons for reluctance to withdraw intensive care include fear of legal consequences, increasing emotional attachment of parents and infants with time, and feeling of active life-ending or even killing by extubation and application of pain and stress relieving drugs.

On the other hand, for some parents the death of their child may be more bearable if the neonatal team has "tried everything" and "gave him or her every chance" [59]. Moreover, a period of intensive care allows some time for the parents and siblings to meet the child, to perform baptism or other religious ceremonies, to touch and cuddle the baby. The infant may die in the arms of the parents and the family has time to grieve with their child and to mourn in dignity. Some parent-infant bonding may relief the mourning sorrow. These possible emotional benefits must be weighed against painful intensive care measures and the use of intensive care resources [79].

15.9.2 Withholding Proactive Antenatal Care and Resuscitation after Birth

Proactive antenatal care (transfer to a center, corticosteroids, cesarean section on fetal indication) improves the prognosis of an EP infant to the level of a 1–2 weeks more mature infant [8, 15, 40, 67]. It is therefore reasonable to decide either for both active antenatal care and postnatal resuscitation or for neither of these active approaches, unless the postnatal condition of the infant requires reorientation of the decision made before birth. Some parents might prefer a passive approach before delivery, but active life-support when the infant appears viable after birth. Even for preterm infants with a gestational age below the limit of viability, an experienced neonatologist should be present or immediately available at birth to confirm or to reorient the medical decision made before birth. However, a joint decision of the parents and physicians made before delivery should not be reversed after birth without marked change in the expected clinical situation.

When resuscitation is futile, compassionate care must be provided as for babies whose intensive care is discontinued. The baby may be placed on the breast of the mother and die in peace. If the baby suffers, an analgesic and/or sedative drug should be given. An appropriate religious ceremony should be offered and organized.

Since EP infants requiring more than 3–5 minutes of resuscitation have a poor prognosis [16–18, 80], the ILCOR guidelines [81] suggest to stop resuscitation "if there are no signs of life after 10 min of continuous and adequate resuscitative efforts". In clinical practice 10 minutes may, however, be a rather brief resuscitation time, since ventilation and other resuscitation measures are not always adquate [81]. A framework of care of extremely preterm infants derived from various guidelines and personal experience of the author is shown in Table 15.3.

Table 15.3 Framework of care of extremely preterm infants (< 26 weeks' gestation)

General considerations
– Extremely preterm infants deserve the best state-of-the-art care to attain the best possible outcomes. Withholding treatment because the hospital cannot provide the appropriate care is unacceptable. If experienced obstetricians and neonatologists are not available at the hospital, the mother has to be transferred to a specialized centre. If a transport is not possible, the most experienced local staff should be involved and get advice from a specialized centre
– Accurate estimation of gestational age (as a major determinant of the prognosis) is extremely important. Moreover, body weight, gender and multiple births influence the prognosis and should be considered in antenatal counseling of the parents
– Parents' rights to comprehensive information and explicit involvement in decisions about antenatal care (transfer to level III centre, tocolysis, corticosteroids, cesarean section) and postnatal care of their preterm infant born before or in the "gray zone" (23–24 weeks' gestation) have to be respected
– A decision before birth not to resuscitate or to resuscitate may have to be reconsidered after birth due to inaccurate prenatal estimation of gestational age and individual variation of the maturity and viability of the infant. The heart rate response of the baby to ventilation within 3–5(–10) minutes is a better indicator of the prognosis than the clinical condition at birth

15.9.3 Withdrawing of Intensive Care

The decision to withdraw intensive care is usually made in several steps.

1. The medical decision of treatment futility or intolerable long-term suffering is made collectively by the NICU team and other subspecialists (e.g., pediatric neurologist, cardiologist or surgeon).
2. The parents are informed on the prognosis of their infant and explicitly involved in the judgment of the best interests of their infant. Moreover, the parents are informed about options to prevent pain and suffering when their baby dies, and they are involved in the decision of appropriate pain and stress relieving treatment. Parents are supported in seeking advice by medical professionals outside the

hospital, friends and religious advisers. In some countries parents are requested to take an active role in this decision.
3. If parents and caregivers agree on the decision to withdraw intensive care, a time is set for ending intensive care (usually assisted ventilation). The parents decide whether they wish baptism or other religious rituals in correspondence to their faith.
4. Intensive care is reoriented to compassionate and palliative care. If possible, the baby is cared for in a private family room. Invasive procedures, blood sampling and any other painful or stressing interventions should be avoided or minimized. Maintaining dignity, warmth, skin contact (kangaroo care), relief of pain and stress are basic elements of palliative care [19, 82]. A family-centered care philosophy is an optimal basis for neonatal intensive care and for the care of a dying infant. Family members and friends are given time and opportunity to stay with the infant, to touch and cuddle the baby.
5. Withdrawal of life-sustaining treatment should take place in an unhurried, private and dignified manner. In the presence of the parents, tubes and electrodes are removed and the infant dies in the arms of the parents. Pain and stress relieving drugs should be given and the bronchial and gastric tube should be sucked to avoid vomiting and choking (if possible, before the parents enter the room). A nurse and a physician (with a good relationship to the parents and the child) should be present until the infant has died and should see the family from time to time thereafter.
6. The staff shows empathy and supports the family in their grief. Mementos of the infant such as photos and videorecordings, armbands, the clothes, a footprint and a strand of hair may be given to the parents. Parents should be supported with funeral arrangements and formalities as death certificate. Some countries allow taking the dead baby home for some time before the funeral. Further consultations (outside the NICU!) should be offered. Information about bereavement and parents groups should be provided.

15.9.4 Pain and Stress Relieving Drugs

For intensively treated newborn infants with a good prognosis, indications and dosages of pain reducing drugs are carefully adjusted to avoid serious side effects. After an end-of-life decision has been made, side effects are of little importance and the dosages can be increased to reach complete elimination of pain and stress. Moreover, pain and stress relieving drugs are indicated to minimize pain and suffering resulting from the removal of tubes, lines and electrodes and from dying itself. Several authors recommend administration of an adequate dose of opiate analgesia (morphine or analogues) together with a sedative (e.g., benzodiazepine) as part of humane care. Although the required high dosages of analgesics and sedatives may cause respiratory depression and shorten the life of the infant, their use is considered legal in most countries as long as the primary intention of the physicians is relief of pain and suffering and not shortening the life of the infant [83].

The administration of lethal dosages of drugs with the intention to hasten death is illegal in most countries. In The Netherlands, "non-voluntary euthanasia" is considered acceptable in selected infants for whom death appears to be in the infants' best interests, but who are presently not dependent on life-support. The Groningen Protocol for Euthanasia in Newborns gives detailed guidelines that are far more restricted than most guidelines and recommendations for withholding or withdrawing of intensive care [84]. In fact, only 4% of infants with end-of-life decision (born in The Netherlands from 2005–2006) died from drugs given with the intention to hasten death [84].

15.10 Severe Asphyxia

Stillborn infants do not breathe and show no other evidence of life (such as beating of the heart, pulsation of the umbilical cord, definite movement of voluntary muscles). If the infant shows signs of maceration, the infant has died at least 12 hours before birth. A fresh stillborn infant may have died hours or minutes before birth. If the fetal heartbeat was heard shortly before birth or fetal heartbeat was not monitored, resuscitation should be started.

Four studies on the outcome of infants with severe asphyxia defined by Apgar score 0 at 10 minutes following birth demonstrated that 69–98% died and all surviving infants developed severe (89–100%) or moderate neurodevelopmental disability [85]. This is why some justify cessation of resuscitation after 10 minutes [81], unless resuscitation was not adequate. If a baby develops signs of severe hypoxic-ischemic encephalopathy with poor long-term prognosis, a decision (jointly made by the parents and physicians) to withdraw intensive care is justified by some authors [78].

15.11 Malformations

Malformation may justify withholding of postnatal resuscitation if the malformation is not compatible with life or if there is a high risk of death or if therapy burden is not bearable. The

Table 15.4 Lethal malformations (according to the US American Birth Defect Center)

– Trisomy 13
– Trisomy 18
– Anencephaly
– Acranium
– Bilateral renal agenesis (Potter syndrome)
– Bart's hydrops fetalis

harm-to-benefit ratio (i.e., pain and suffering from early interventions in relation to the probable outcome) may be considered in the estimation of the best interests of the infant. Table 15.4 lists lethal malformations.

Termination of pregnancy for fetal malformation is liberally implemented in many countries. After birth the best interests of a viable infants with malformations have to be judged individually for each infant, each malformation and the probable long-term sequelae of the malformation. After birth, treatment decisions are primarily based on the best interests of the infant (and not primarily on the authority of the mother). This sudden change in authority is difficult to understand for many parents. Infants with Down syndrome pose particular dilemma for parents and physicians. On the one hand, the major purpose of prenatal screening is to detect trisomy 21 and to terminate pregnancy if the fetus suffers from Down syndrome, on the other hand there is general agreement that the diagnosis of Down syndrome is no indication for withholding resuscitation even if the infant suffers from severe cardiac or other malformations [86].

Basic Approach to the Care of Extremely Low Birth Weight Infants: an Outline

Costantino Romagnoli and Fabio Mosca

First hours of life of extremely low birth weight (ELBW) infants are crucial. Several problems can arise in this time:

- at the first hour of life
  - resuscitation
  - thermoregulation
  - cardio-respiratory stabilization
- on admission to Neonatal Intensive Care Unit (NICU)
  - vascular access
  - skin
  - respiratory
  - cardiovascular
  - neurologic
  - fluid, electrolyte and nutrition
  - infections
- special issues
  - hearing impairment
  - retinopathy of prematurity
  - osteopenia
  - neurodevelopment.

16.1 Delivery Room and the First Hour of Life

At birth, careful attention to the maintainance of body temperature is essential. The most effective interventions seem to be gentle drying and occlusive wraps (polyethylene wraps or polyurethane bags), associated with hats. In spite of these measures, low temperatures are common on admission and surveillance of temperatures in the delivery room and during transport should be identified as quality improvement initiatives [1].

ELBW infants need some form of assisted ventilation in the delivery room in order to achieve adequate lung expansion. It is important to avoid hyperdistension (using low inspiratory pressures) and to maintain an adequate lung volume (using positive end-expiratory pressure). Best practice for the ventilation of newborn babies it is still matter of some debate. The use of continuous positive airway pressure (CPAP) may be a practice that reduces the use of mechanical ventilation [2].

Careful monitoring of heart rate, oxygen saturation and pCO_2, as soon after birth as practicable, is recommended [3].

Adequate vascular access is important for ELBW infants. Catheterization of umbilical vessels is frequently used for the administration of fluids and drugs.

16.2 Admission to the NICU

On admission to the NICU body temperature and body weight should be measured to correct or to prevent hypothermia and to optimize fluid management.

16.2.1 Vascular Access

Sick ELBW infants need close monitoring of arterial blood pressure and gases, serum glucose and electrolytes. Insertion of an umbilical and/or arterial catheter is useful to avoid pain and discomfort. Arterial lines should be removed as soon as they are no longer necessary and a percutaneous central venous catheter should be dedicated to infusion of parenteral nutrition (PN). Often these infants require more than one central line and the use of a double lumen umbilical venous catheter may be useful for the administration of fluid, drugs and blood products.

16.2.2 Skin

Just after birth, the skin of ELBW infants is poorly effective as an epidermal barrier. Disturbances in temperature regulation and water balance, as well as an increased risk of infection, occur because of poor epidermal barrier function and the excessive use of adhesives. The routine prophylactic use of emollients is not recommended.

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

16.2.3 Respiratory

The goals of assisted ventilation should be: adequate oxygenation and ventilation avoiding barotrauma (due to high inspiratory pressures), stretching and rupture of the lung structures (due to volutrauma caused by high tidal volumes), and cyclical opening and closure of the closed alveolar zones (atelectrauma, caused by low positive end expiratory pressure).

In many centers, high frequency oscillatory ventilation (HFOV) is used as the initial ventilation strategy for the treatment of ELBW infants with acute pulmonary insufficiency in order to reduce the incidence of both early (e.g., air leaks) and late (e.g., bronchopulmonary dysplasia [BPD]) ventilatory complications [4]. Others prefer conventional pressure-cycled ventilation, synchronized intermittent mandatory ventilation (SIMV); hybrid forms of mechanical ventilation such as volume guarantee (VG), pressure regulated volume control (PRVC), and volume assured pressure support (VAPS) may be also used [5].

The optimal time for the administation of surfactant remains uncertain. It seems reasonable to administer surfactant as soon as oxygen requirements increase after birth. The timing of extubation is difficult because these infants are prone to severe apnea and frequent reintubations. Even if early extubation to nasal CPAP is possible for some because of methylxanthine administration (caffeine or theophylline), some require prolonged ventilation because of recurrent apnea or changes in lung dynamics (e.g., BPD), which may need different ventilatory strategies.

BPD is a major problem for these babies. Its frequency is variable.

16.2.4 Cardiovascular

The two major cardiovascular problems for ELBW infants are patent ductus arteriosus (PDA) and hypotension.

About 50% of ELBW infants show the effects of a hemodynamically significant PDA (left-to-right shunt) and the majority require pharmacological treatment with indomethacin or ibuprofen to close the ductus.

Although prophylaxis seems to be more efficacious than treatment for these infants, current best practice suggests a policy based on clinical and echographic evaluation of the ductus [6].

If clinically significant, or if the PDA fails to respond to pharmacological treatment, or if indomethacin or ibuprofen are contraindicated (about 20% of ELBW infants), surgical ligation should not be delayed.

When hypotension occurs in presence of hypovolemic shock volume replacement is required, while the use of plasma expanders and/or vasopressor drugs (dopamine or dobutamine) should be evaluated on the basis of infants attributes or blood arterial pressure and skin perfusion.

16.2.5 Neurologic

A cranial ultrasound scan should be done shortly after admission to NICU to document eventual developmental abnormalities. Careful monitoring using cranial ultrasound scans should be performed to diagnose both intraventricular hemorrhage (IVH) and its serious complications and periventricular echogenicities which are the antecedent of white matter injury (WMI) and of neurodevelopmental impairment. Although there is no question that magnetic resonance imaging (MRI) is superior to ultrasound for prognosis, ultrasound can give important early information and can be used to document the evolution of lesions, and is an important tool, particularly in many places where MRI is not available.

16.2.6 Fluids, Electrolytes and Nutrition

After birth, water and electrolytes should be supplied to ELBW infants to avoid dehydration and hypertonicity. There should be close monitoring of body weight (every 12–24 hours), urine output and osmolarity (every 12–24 hours) and plasma electrolytes (mainly sodium and potassium). Metabolic acidosis may become a problem with the progression of PN and its correction is still debated.

ELBW infants show limited nutritional reserves and immaturity of nutrient absorption in the face of high nutritional demands. For this reason, many ELBW infants experience postnatal growth retardation in spite of total PN and early enteral feeding. The main objectives of nutritional support are to maintain body stores and to assure adequate postnatal growth, avoiding metabolic complications and side effects.

ELBW infants should receive glucose and amino acid infusions soon after birth to maintain normoglycemia and protein levels. From the second day of life, lipids and electrolytes may be administered. Total PN should be associated with early enteral feeding to limit complications associated with PN, mainly cholestasis and sepsis.

Structural and functional immaturity of the gastrointestinal tract may limit early enteral feedings. Minimal enteral feeding (trophic feeding at 10–20 mL/kg/day) should be started as soon as possible after achieving clinical stability to stimulate normal functional development of the gastrointestinal tract. Its progression will be determined by feeding tolerance, which is normally reduced in ELBW infants. Feeding strategies depend on the experience of caregivers and should be aimed at the establishment of enteral feeding, avoiding feeding intolerance and necrotizing enterocolitis. Enteral volume (< 10 mL/kg/day) is increased gradually with close monitoring for abdominal distension, vomiting or increased volume of gastric aspirates, especially if bile-stained. When feeding intolerance is diagnosed, enteral feeding should be reduced or stopped. Breast milk is preferred to premature formulae for both trophic and enteral feeding, but when it is insufficient to

achieve normal postnatal growth, milk fortifiers can be added. Multicomponent fortification of human milk is associated with short-term improvements in weight gain, linear and head growth, but without evidence of long-term benefit.

16.2.7 Infections

Infection is a major cause of mortality and morbidity for ELBW infants. The incidence of early-onset sepsis (EOS) (<72 hours) is less than 5% with a mortality approaching 50%, mainly for ELBW infants born after premature rupture of membranes and/or chorioamnionitis. Prenatal treatment of chorioamnionitis and prevention of group B streptococcal infection has changed the distribution of pathogens of EOS with an increasing rate of gram-negative bacterial sepsis [7]. Taking a careful prenatal history, timely diagnosis (based on clinical signs, microbiological and biochemical tests) and therapy (empirical use of antibiotics) are important for the prevention and threatment of EOS and its complications.

Late-onset sepsis (LOS) affects 25 to 50% of ELBW infants and the mortality rate varies from 20 to 80%, depending on the causal pathogen. The main risk factors for LOS are the use of central lines, mechanical ventilation and parenteral nutrition. The clinical diagnosis of LOS is made more difficult in ELBW infants because of nonspecific clinical features and a lack of sensitive diagnostic tests. Thus, many of these infants receives several courses of antibiotics and antifungals during their hospital stay. Careful monitoring of a neonatal unit can help guide empirical antibiotic therapy and to limit antibiotic resistance [8]. Prophylactic intravenous administration of polyclonal immunoglobulins has been shown to reduce LOS, but was not associated with a reduction in other important outcomes or length of hospital stay and has not been widely adopted. Future use of monoclonal gamma-globulins for specific pathogens and of proteomics for diagnosis may offer new preventative and diagnostic opportunities [9].

16.2.8 Hematologic

Anemia is a frequent event for ELBW infants due to unavoidable multiple blood sampling, blood loss as a result of hemorrhage or hemolysis, rapid growth and low iron stores. Limitation of blood tests and the early administration of erythropoietin with iron supplementation may reduce the need for blood transfusions. Deficiency of vitamin K-dependent coagulation factors associated with low platelet count predispose ELBW infants to hemorrhage and should be promptly treated. Rarely disseminated intravascular coagulation may occur. All ELBW infants require phototherapy treatment for jaundice.

16.3 Special Issues

ELBW are also at high risk of hearing impairment because of illness and the use of ototoxic drugs, and require hearing screening in the neonatal period. Retinopathy of prematurity (ROP) is a special morbidity in ELBW infants.

Osteopenia occurs as a complication due to inadequate mineral intake, mainly phosphate and calcium. Its incidence increased when ELBW infants were feeded exclusively with human milk. Mineral support by total parenteral nutrition associated with preterm formulas or with fortified human milk have made osteopenia relatively unusual.

Recent observations suggest that ELBW infants are particularly vulnerable to external noxious stimuli: noise, light, pain, movements, frequent disturbances and manipulations. Neonatologists should pay particular attention to these problems and need to involve parents in individualized developmental care, practices to minimize stress and to optimize the neurodevelopment of each infant [10].

Finally, follow-up programs until adulthood have shown that about 20–30% of ELBW infants may have reduced growth patterns, severe neurological and physiological problems, neurosensory involvement, behavior and learning impairment.

The Process of Decision-Making

Endla K. Anday and Maria Delivoria-Papadopoulos

When one prevents one's emotions from overtaking one's rationality it is called reason.
When one prevents one's rationality from overtaking one's emotions it is called compassion.
When one can do both it is called wisdom.
Ancient Chinese saying

17.1 Introduction

In the past 40 years, tremendous progress has occurred in the care of the neonatal patient. An in-depth understanding of fetal and neonatal physiology and the molecular basis of pathological processes, concurrent with advancements in biomedical technology, have impacted favorably upon the survival of the newborn. However, extremely premature infants at the threshold of viability, infants diagnosed with potentially lethal congenital malformations, including chromosomal abnormalities, and neonates suffering from profound intrapartum and postnatal insults present difficult moral, ethical, cultural and social challenges for both families and caregivers in regard to providing or withholding life supportive measures. The decision to withhold or terminate treatment for an infant is based on defining the issues central to this process, including: the values and rights of the infant as an individual, the values of the family and the medical caregivers and the cultural influences and societal values that shape the moral arguments that affect one's judgment. Part of the challenge resides in the complexity of defining *who is* or *should be* responsible for making difficult decisions resulting in the death of a newborn since fundamentally this type of decision is at odds with human nature even in situations where the end of life would mean no further suffering for the infant.

St. Christopher's Hospital for Children, Philadelphia, USA

The goal of this chapter is to consider some of the issues confronting the clinician charged with practicing the art of medicine in the context of a certain degree of medical uncertainty and the implications for medical decision-making. In-depth discussions of ethical problems and guidelines for the care of the extremely low birth weight infant (ELBWI) will be covered in other chapters of this book.

17.2 The Neuroscience of Decision-Making

Viner has stated that "Human behavior, in general is not under the constant and detailed guidance of careful and accurate hedonic calculations, but is the product of an unstable and irrational complex of reflex actions, impulses, instincts, habits, customs, fashion, and hysteria" [1]. Clearly, one would hope and expect that Viner's perspective of human behavior is not relevant to the process involved in making decisions to provide or withhold treatment for infants. Cognitive neuroscience supports that a variety of processes are essential to integrate novel incoming stimuli for decision-making in situations of uncertainty such as those pertaining to life-sustaining medical treatment. When considering options about incoming information, the key individuals involved must demonstrate flexibility to account for various outcomes, constantly monitor incoming information as it relates to the ultimate goal-state or decision and evaluate the risk-benefit ratio for various decision making options [2]. But medical decisions are not simply the rational calculation of benefit versus burden. The individuals involved often consider past experience and values as well as future outcomes of their decisions as part of the basis for that choice. As such, a certain degree of individuality is defined that contributes to decision-making, particularly when one considers the emotional influences on this process. In humans, emotions influence decision-making. Internal cues and external contextual information can positively or negatively impact the emotional state surrounding the decision-making process. The emotional evaluation of an action's consequences

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

guide the individual who must be able to provide a basis for making certain choices [3]. Social neuroscience supports that the neuroanatomical substrate involved in complex decision-making in humans involves the integration of contextual social knowledge represented as event knowledge in the prefrontal cortex (PFC); social semantic knowledge, stored in the anterior and posterior temporal cortex; and motivational and basic emotional states, which depend on cortical-limbic circuits [4, 5]. While certain perceptual and emotional abilities have been shown to be shared by humans and other animals, morality and moral decision-making is a product of evolutionary pressures specific to the human species that have shaped social cognitive and motivational mechanisms into uniquely human forms of experience and behavior [6]. Experiments using functional magnetic resonance imaging (MRI) in humans have identified that decision-making involving intelligence and complex resolution activates the ventral and medial aspect of the prefrontal cortex (VMPFC) [7]. Activation of the VMPFC appears to signify that wisdom required in the decision-making process comes from categorizing and organizing past experiences from many situations, and involves options for actions, deciding what actions to take and factual emotional outcomes [8].

Thus, the evolution of the human PFC is intimately related to the emergence of human morality, allowing for the motivational mechanisms to be integrated with an exceptional power to predict outcomes from a large repository of experiential wisdom. Coupled to semantic knowledge, cultural and situational factors become integrated into the neural substrate to weigh the motivational relevance of different behavioral choices in social situations. Clearly then, through a complex interaction of biological and cultural factors, the human moral mind emerges and integrates cognition to emotion and motivation, forming the framework for decision-making.

17.3 Steps in Decision-Making

17.3.1 Recognize the Moral Dimension

From a philosophical approach, Neonatal Medicine has been practiced to provide specialized and intensive care measures aimed at improving the health and survival of premature and critically ill newborns. But how are these goals affected when the curative model is inadequate, such as with infants diagnosed with anencephaly or with the delivery of a 22 week gestational age infant; what do the goals become? And why is decision-making in this context so difficult? Consider the situation wherein prenatally a mother is diagnosed as carrying a fetus with severe potentially lethal congenital anomalies; the physician is put into a unique situation in medicine in which he/she contemplates withholding support in a human being *that the physician has never even seen*! Or contemplate the situation of the 23 week gestational age infant with bilateral Grade III intracranial bleeds and pneumoperitoneum trapped in NICU biomedical technology, hanging on to life by a thread and without reasonable expectation for improvement without incurring unnecessary pain and suffering; when is enough really enough? Compound the dilemma with both parental and physicians' attitudes toward life-saving technology and death, which have been shown in numerous studies to vary with race and ethnicity, and are thought to result from complex interactions of factors including: access to medical care, communication styles, family involvement in decision-making, trust in physicians and religious background [9].

Each healthcare dilemma reminds caregivers of their limitations, including uncertainty, the human predicament, lack of knowledge, and decision-making abilities. All of these are tempered by the moral constraints under which we act. These are the difficult situations which, based on individual social, cultural, ethical and moral differences, make it highly unlikely that we will all agree. Nevertheless, within the context of providing care to the high-risk neonate, the best interest of the child must be kept foremost in the minds of the caretakers and the professional staff and form the basis for decisions related to the care of that infant.

17.4 Recognize the Parties Involved

17.4.1 The Infant in His/Her Own Right as an Individual

The infant born at the threshold of viability or one who has potentially lethal congenital anomalies has no voice of its own; it depends on decisions made by a surrogate, most often its mother and/or family members to advocate on its behalf. Under ideal circumstances, prenatal diagnosis and counseling allows for effective communication between parents and physicians and a reasonable approach to initiating or withholding resuscitation can be achieved based on the prognosis and risk versus benefit of treatment. During this decision-making process, the value of the infant's life is being judged. However, there may be disagreements between the medical care providers and surrogates where, in the opinion of the provider, the infant's best interest is not being served and in which the surrogate's decision should be over-ridden [10]. In 2001, the Senate and House of Representatives of the United States Congress passed the "Born Alive Infant Protection Act". Specifically, the Act provides that any "member of the species *homo sapiens at any stage of development* that is expelled or extracted from the mother who then breathes or has a beating heart or movement of voluntary muscles is to be considered a person and granted full protection under the U.S. Constitution" [11]. The Act provides that even a fertilized ovum, embryo and fetus of any gestation are to be considered co-equal with regard to protection from harm. While it was widely understood to be an anti-abortion legislation, the Act

altered the definition of the words "person", "human being", "child", and "individual". Although the law did not impose a new standard of medical care upon physicians, nor change existing law, it altered the physician norm of deferring to parental discretion regarding the initiation or discontinuation of medical treatment for the extremely premature infant. However, the American Academy of Pediatrics (AAP) and the Neonatal Resuscitation Program Steering Committee issued an opinion that it would not affect day-to-day neonatal medical practice and standards. In fact, the Committee clearly stated that "decisions about withholding or discontinuing medical treatment that is considered futile may be considered by the medical care providers in conjunction with the parents… Those newly born infants who are deemed appropriate to not resuscitate or to have medical support withdrawn should be treated with dignity and respect, and provided with 'comfort care' measures" [12].

Consider the Baby Doe Law, passed in 1984 in the United States that sets forth specific guidelines for the treatment of seriously ill or disabled newborns and dictates what must be done for a child regardless of the wishes of the parents [13]. Withholding treatment is considered neglectful unless an infant is irreversibly comatose or the treatment is futile in terms of the infant's survival, but "quality of life" is not a reason for withholding medical care. As a result of this law, hotlines were set up for anonymous reporting of alleged abuse such as withholding of medical care to seriously ill newborns leading to intrusions into the hospitals that were disruptive and ultimately found unwarranted. This Act was overturned in the Federal Courts in 1987.

Two laws, each illustrating potential conflicts between two or more values and the rights of the child as a distinct entity contrasted to the rights of parental decision-making as the surrogate for the infant. Even more intriguing is the observation that, in spite of legal and ethical standards requiring resuscitation when it is considered to be in a patient's best interest, the newborn infant and particularly the preterm baby is devalued in comparison to older patients with comparable survival and morbidity outcomes [14]. In a questionnaire describing eight neurologically incompetent patients with potentially equivalent adverse neurological outcomes who required resuscitation (24 week preterm, term infant, 2 month old infant, 7 year old child, 14 year old, 35 year old, 50 year old patient and an 80 year old subject), respondents were asked whether they would comply with the families' wishes if resuscitation was refused. The families' refusal of resuscitation was accepted most frequently for the 80 year old subject and the 24 week premature infant, even though the majority of the respondents thought that resuscitation was indicated for the 24 week infant but not the 80 year old patient. Since the decision was not made on the basis of outcome or what was perceived to be in the infant's best interest, there seems to be a different value placed on life at the extremes. While the root of this devaluation is not clear, it may be attributable to anthropologic, cultural, social and evolutionary factors.

17.4.2 Parental Decision-Making

Regardless of the concept of provision of care, it is essential that parents understand the implications of the nature of aggressive care in situations where they "want everything done" for their infant and physicians must be willing and prepared to recommend withdrawal of support in futile situations. Throughout this process, the infant must be afforded compassion and comfort. What is good for critically ill newborns and who determines this? The presence of numerous voices in deliberations about newborn patient care presses this question. What we as health care professionals think may be quite different from what the family or child might choose.

In the face of uncertainty and inability to predict outcome for an individual infant, there will usually be differences of opinion regarding outcome, viability and treatment futility. Those who bear the ultimate burden of the decision ought to have the major role in the decision making when outcomes are very uncertain. Simply put, once a physician has determined that an infant has no realistic expectation of survival based on the evidence at hand, parents should be informed and given the opportunity to withhold initiating treatment (e.g., prenatally diagnosed infant with trisomy 18 and complex congenital heart disease) or given the option of withdrawing the life-supporting interventions (e.g., 23 week gestational age ELBWI with bilateral Grade IV IVH and necrotizing enterocolitis totalis). When faced with such a difficult moral decision, parents often will look to the physician for advice and counseling. The Committee on Bioethics of the American Academy of Pediatrics has advocated for a shared decision-making model whereby the physician has an ethical duty to seek and respect information regarding parental preferences and values in exchange for providing the parent with medical information [15]. A nondirective approach to counseling parents is advocated to allow parents to choose a course of action based on their own personal values. While the transfer of information from physician to parent should be unbiased, the manner in which information is communicated may have a framing effect on the parental decision. The recent study by Haward et al [16] examined message framing and perinatal decisions and demonstrated that the manner in which parents received prognostic information, i.e., framed as mortality data versus survival data, affected their treatment preference independent of religiousness, parental status and beliefs regarding the sanctity of life [16]. In subtle ways, framing bias can inadvertently affect the process of parental decision-making at a time when decisions dependent on moral values that deal with the consequences of life and death occur in close proximity to physician counseling.

However, for some parents non-initiation of or withholding life-sustaining treatment is a psychologically and morally impossible choice; they may want treatment withdrawn or not initiated so their child does not suffer, but do not want the responsibility of making that decision because they do not want to give up hope. Under these circumstances, a "left unasked

but not unaddressed" approach may allow transition of aggressive, futile care to care that is based upon medical indications [17]. For example, instead of asking a parent if they want to initiate dopamine infusion for their infant with bilateral Grade IV intraventricular hemorrhage (IVH) and refractory hypotension, and giving them false hope, one can explain that everything reasonable has been done for their baby, that keeping their infant comfortable now and holding their baby is the best one can do at this time. In this manner, the parents are not tormented with decisions fraught with anguish, ambiguity, doubt and guilt. There comes a time when "there is no need to compound the suffering of the patient by prolonging it, nor that of the parents by insisting they must make a decision as fate has already decreed" [17].

17.4.3 The Physician's Role

At the time of delivery of an extremely premature infant or one with potentially lethal congenital anomalies, it may be difficult for a physician to predict for parents what the outcome will be: possibilities range from death soon after delivery to survival with severe disabilities to intact survival. Similarly, an infant might have an initial postnatal course that would favor a reasonable outcome, only to suffer a devastating event in the NICU where prognosis is poor. The physician is placed in a situation of weighing the benefits and burdens of ongoing support for the infant under conditions of medical uncertainty and communicating information in an effective manner to the parents, keeping in mind that the decision is in keeping with legal and organizational guidelines. The roles of authoritative statements, professional policies, and recommendations can be helpful in the decision-making process for the physician, however, most decisions are not based purely on a utilitarian approach.

During the course of refining the practice of neonatal medicine, a wealth of information relating to the care of the critically ill newborn has been accumulated, not only in the United States, but world-wide. A number of NICU guidelines and statements have been developed to establish norms and reference points in an effort to assist physicians in day-to-day management of difficult situations including withholding or terminating life-sustaining therapy, but these may at times be of limited use in the discussion of risks, benefits and other options with the parents and families [18, 19]. Although objective outcome data are available to many clinical populations, for a given infant and in many situations, the chance of a certain outcome may be either 0 or 100% [20, 21]. The recommendations by the International Liaison Committee on Resuscitation for guidelines on neonatal resuscitation supports the "do-not-resuscitate" order on evidence-based justification for the extremely low birth weight infant < 23 weeks and < 400 grams and confirmed trisomy 13, 16 and 18 [22]. However, upon review of incorrect information, diagnosis or prognosis about a specific situation, the guidelines provide for the opportunity of a trial of therapy with the option of subsequent withdrawal of support. The Groningen protocol considered euthanasia under strict protocol in situations where there was severe and sustained suffering without relief [23]. Newborns are classified into three categories depending on the severity of their condition: Group 1 is infants who are expected to die in spite of invasive medical care and are actively removed from support to be held by the parent(s); Group 2 are infants who survive birth but are expected to have poor quality of life and who cannot survive without the assistance of invasive technology; and Group 3 are patients who could eventually survive without technology but who suffer severe, sustained pain and a life without hope of improvement. Of the three groups, Group 1 is least likely to present a dilemma. In Group 2 patients, quality of life issues form the basis for the decision-making and in this situation, it is critical to maintain the best interest of the child in consideration and involve the opinion of the parent(s). However, the decision should not rest solely with the parent; discontinuation of support must be in concert with the physician together with the parent(s). At all times, the infant should be kept comfortable and without pain. The last group presents the most difficult situation because it is a judgment call that death would be more humane than continuation of life. A passive approach to allowing "nature to take its course" and withhold creature comforts, such as nutrition, can lead to a period of severe suffering until death Alternatively, deliberate termination of life, or euthanasia with the use of medications to end the suffering is considered illegal. The recent article by Verhagen and Sauer [23] discussed the Groningen protocol in regard to strict reporting and review of each case of proposed active termination of life to ensure that acceptance of this practice will not allow erosion of moral norms where other undesirable qualities in newborns can be used as justification to end their lives.

Physicians and parents may have different interpretations of what is discussed and what decisions are made during prenatal counseling, in the delivery room and following the delivery of an infant. Studies support that it is the parents' perception that physicians do not always address values that parents consider important in the counseling they provide [24–26]. Specific parental values such as hope, spirituality and religion are often not incorporated in the discussions and may contribute to confusion about what has been discussed and what decisions have been made [27]. To ignore these questions is to fail to recognize the significant influence that these values and cultural influences have had in shaping individual professional lives and human interactions.

17.5 Summary

Ours is a global society in which one must be increasingly aware of the different value systems in multicultural societies across nations. While a deeper understanding of the cognitive

and brain mechanisms that guide human behavior is of general interest, the moral and ethical decisions that are made regarding withholding or withdrawing care to an infant provoke anxiety and guilt that come with responsibility for making difficult decisions. In the end, the goal of care for the newborn must be focused upon the best interests of the child. Parents generally should be considered the spokesperson for determining what is in the best interest of the child; therefore, the medical team should seek the opinions of the parent(s), both prior to and following delivery of a child identified as extremely high risk for adverse outcome.

A period of transition to extrauterine life, allowing for stabilization and evaluation of the infant to assess the degree of significant intervention and determine the likelihood of reversal of acute processes should be offered. When evidence-based guidelines are available as a frame of reference, one may choose to work within a set of guidelines; however, these must be individualized for each circumstance. Prognosis can change rapidly, from the time of birth, to the delivery room resuscitation; the likelihood of "reasonable outcome" should be reevaluated at each junction. Implicit in the decision-making is the assumption that parental counseling has occurred. Parental wishes regarding extent of intervention initially should almost always be honored until further determination by the medical team supports the futility of further care. In the absence of a reasonable expectation of steady improvement and in the presence of significant pain and suffering, withdrawal or withholding life-sustaining medical or surgical treatment is a decision that takes the best interest of the baby in consideration.

In the Hippocratic Corpus, medicine is defined as having three roles: "To do away with the suffering of the sick, to lessen the violence of their diseases, and to refuse to treat those overmastered by their diseases, realizing that in such cases medicine is powerless" [28]. In the end, perhaps decision-making may best be summarized by the Jesuit ethicist, Father John Paris, "The best one can do is to make a human judgment based on probabilities" (personal communication).

Follow-up Outcomes of High Risk Infants

Maureen Hack and Deanne Wilson-Costello

18.1 Introduction

Advances in obstetric and neonatal care following the introduction of methods of neonatal intensive care in the 1960s resulted in a progressive improvement in the survival of high-risk neonates until the mid to late 1990s [1]. However, the survival of acutely ill preterm infants who previously would have died together with iatrogenic factors, such as the use of postnatal steroids, resulted in an increase in neurodevelopomental impairments during the 1990s [2]. Since 2000, the rates of mortality of preterm infants have remained fairly stable and there has been an encouraging decrease in the rates of cerebral palsy. This has contributed to an overall decrease in neurodevelopmental impairments, especially for extremely preterm infants (Fig. 18.1) [3–5].

Follow-up of high risk newborns is important for many reasons. Firstly from a clinical care perspective, there is a need to provide ongoing surveillance of the growth and development of the survivors of neonatal intensive care and to provide specialized care for those who develop complications of prematurity such as bronchopulmonary dysplasia or perinatal brain injury with resultant neurosensory inpairments. Surveillance of the outcomes of neonatal intensive care is also necessary in order for each perinatal center to be able to monitor the overall quality of care in their neonatal intensive care nursery as well as the specific effects of new therapeutic interventions on outcomes. Such information is also necessary in order to be able to council parents as to the potential outcomes of their infants. These may be birth weight or gestational age specific outcomes or the outcomes of specific neonatal complications, for example periventricular leucomalacia or severe periventricular hemorrhage. From a research perspective, follow-up of infants until at least into the second year of life has become an integral part of randomized controlled trials of perinatal intervention and of cohort studies which monitor changes in outcomes over time. Outcomes examined usually include measures of growth, neurosensory impairments including rates of cerebral palsy, blindness and deafness and cognitive function, as well as specific health care needs. Cerebral palsy is the most common of the neurosensory deficits among preterm children. The outcomes of preterm children are usually reported as rates of neurosensory deficits and developmental outcomes, which include early childhood cognitive assessments such as the Bayley Scales of Infant Development or intelligence tests at school age [6].

The organization of follow-up programs of high risk newborns depends on the health care system of the specific region. In most countries the majority of clinical follow-up care of neonatal intensive care graduates is undertaken by pediatricians or the family physician, with referral to subspecialists for specific complications. National data bases, when they exist, may be used in such instances to provide data on the outcomes. Academic tertiary care centers, however, usually organize follow-up programs as an integral part of their neonatal care intensive care unit. These follow-up programs serve not only to provide surveilance of growth and development of selected groups of survivors but also coordinate and undertake the follow-up of subjects who have participated in randomized controlled research trials. Such programs also serve to educate medical students, pediatric residents and neonatal fellowship trainees in the potential outcomes of the children they have treated in the intensive care unit and in the essential skills required to assess growth and development of high risk neonates. A minimal requirement for the clinical monitoring of outcomes is a periodic assessment of growth and neurosensory development during the first 2 years of life. The ideal is a comprehensive program including all aspects of care, including well-baby care, evaluation of outcome, social and educational intervention, and therapy when needed.

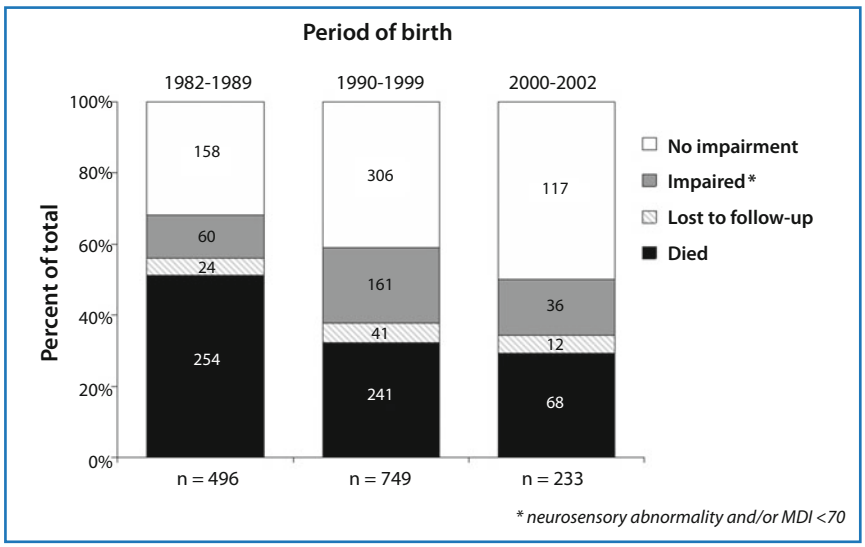

Fig. 18.1 Comparison of death and survival with and without neurodevelopmental impairment at 20 months corrected age for 500–999 gram birth weight infants born during 3 periods: 1982–1989; 1990–1999 and 2000–2002. Impaired: neurosensory abnormality and/or MDI <70 (MDI Mental Developmental Index). Reproduced from [5], with permission

Children at highest risk for poor health and developmental outcomes include those born at extremely low birth weight (<1 kg) and gestational age (<28 weeks) who have high rates of neonatal complications such as bronchopulmonary dysplasia and cerebral hemorrhage, infarction or periventricular leukomalacia (Table 18.1). However, there is a gestational age gradient in outcomes and even late preterm infants born at 34–36 weeks gestation have higher rates of health and developmental problems than term born children. Problems that predispose to poor outcomes among term born children include severe birth depression, severe respiratory failure including persistant fetal circulation, meningitis, severe intrauterine growth failure, intrauterine infections, severe hypoglycemia and kernicterus following severe hyperbilirubinemia. The majority of these problems can also affect the preterm and late preterm infant.

Perinatal outcomes are influenced by the demographic and socioeconomic profile of the family, the incidence of extreme prematurity, a selective treatment or admission policy, the percentage of inborn patients at any center, and the rate of follow-up [7]. Intercenter differences in neonatal sequelae and outcome are well described [8, 9]. Regional results therefore reflect a more accurate picture of outcome because they include all infants born in an area. Other factors to be considered are the rate of loss of infants to follow-up, the neonatal and post-discharge death rate, the age at follow-up, and the method of follow-up (Table 18.2) [10]. Two years is the earliest age to get a fairly reliable assessment of neurodevelopmental outcome. Follow-up to school age allows for a more stable assessment of cognitive function and for the indentification of subtle neurologic and behavioral dysfunction. Other important measures at school age include tests of academic achievement (spelling, reading, math) and school failure or need for special education. Parent questionnaires may also provide information on the behavior and social functioning of the child, quality of life, special health care needs the child may have and impact on the family. Similar measures may be obtained during adolescence at which time the child can also be interviewed.

Table 18.1 Factors affecting outcome of the preterm infant *

- Birth weight <750 g or <25 weeks' gestation
- Periventricular hemorrhage (grades III and IV) or infarction
- Periventricular leukomalacia
- Persistent ventricular dilation
- Neonatal seizures
- Bronchopulmonary dysplasia
- Neonatal meningitis
- Subnormal head circumference at discharge
- Poverty and parental deprivation
- Coexisting congenital malformation

18.2 Health and Medical Problems

Respiratory problems especially during the first year of life, during the winter months and among infants who suffered from bronchopulmonary dysplasia, include frequent wheezing, upper and lower respiratory infections and a susceptibility to the respiratory syncitial virus. These may result in increased rates of rehospitalization. The respiratory problems diminish during the second year of life although asthma and airway reactivity may persist.

Children with neurologic sequelae such as cerebral palsy and hydrocephalus may also require rehospitalization for shunt complications, surgical correction of spasticity and eye surgery for strabismus.

18.2.1 Growth

Intrauterine growth failure occurs commonly among preterm infants and may be associated with maternal complications such as preeclampsia or fetal conditions such as multiple birth. Studies of the postnatal growth of extremely low birth weight and gestational age children born in the 1990s, who were born approprite for gestational age, revealed that the majority developed growth failure during the neonatal period. This was related to a conservative approach to early parenteral and oral nutrition and to the development of chronic conditions of prematurity including necrotizing enterocolitis, bronchopulmonary dysplasia and repeat episodes of late onset sepsis. Poor growth among infants with bronchopulmonary dysplasia and those with neurologic impairment may occur both during the neonatal and post-discharge periods and be associated with swallowing dysfunction, oral aversion and gastroesophageal reflux. A more aggressive approach to early parenteral and oral nutrition together with increased caloric formulae during the neonatal period and after discharge has improved the growth of preterm children during infancy, however, whether this advantage persists later in childhood is as yet unknown [11].

Growth, weight, length and head circumference should be measured serially during the first 2 years of life to assess both catch-up growth in infants who suffered previous intrauterine or neonatal growth failure and to monitor for fall off in growth which may occur following discharge from the intensive care unit, especially in neurologically impaired infants and those who suffered from bronchopulmonary dysplasia. Fluctuations in growth may also occur in healthy children although this needs to be closely monitored. The majortiy of catch-up growth occurs during the first 2 years of life, however, catch-up growth may occur later during childhood and during the adolescent growth spurt. The genetic effects of parental size on length/height usually influence the growth of children after the first year of life [12].

Growth of the child should ideally be compared to local growth norms. Alternatively, the Center for Disease Control (CDC) growth norms may be used [13] or the World Health Organization (WHO) growth norms [14]. Weight during infancy and early chidhood should be measured with the child undressed. Recumbant length should be measured using a pediatric stadiometer and the maximal frontal occipital head circumference with a non stretch measuring tape. Other measures of growth may include the Body Mass Index after the age of 2 years.

18.2.2 Neurodevelopmental Outcomes

The neurologic examination during infancy is largely based on changes in muscle tone that occur during the first year of life. The examination developed by Amiel-Tison, which is

commonly used, measures the progressive increase in active muscle tone (head control, back support, sitting, standing, walking) together with the concomitant decrease in passive muscle tone. This also documents visual and auditory responses and some primitive reflexes. This method gives a qualitative assessment of neurologic integrity, which is defined as normal, suspect, or abnormal. A conventional neurologic examination should be performed thereafter, together with the Amiel-Tison method for early childhood [15, 16].

18.2.3 Transient Neurological Abnormalities

Transient abnormalities of muscle tone during the the first year of life include abnormalities of muscle tone such as hypotonia or hypertonia (occurring as poor head control at 40 weeks' post-conceptional age, poor back support at 4–8 months, or a slight increase in muscle tone of the upper extremities). The increase in muscle tone is often termed dystonia. Although transient neurologic abnormallities may resolve during the second year of life, they may indicate later subtle neurologic dysfunction which is not measurable during early childhood, or school learning difficulties [17].

18.2.4 Major Neurologic Sequelae

Major neurologic disability is usually classified as cerebral palsy, hydrocephalus (with or without accompanying cerebral palsy or sensory deficits), blindness (usually caused by retinopathy of prematurity), seizures, or deafness. The type of cerebral palsy mostly seen among preterm children pertains to the spastic type which includes bilateral (diplegia, quadruplegia) or unilateral (hemiplegia) spasticity. The athetotic and dyskinetic types of cerebral palsy are usually seen among term born children.

Cerebral palsy is the best clinical marker available to monitor the effects of perinatal and neonatal complications and therapies on the long-term outcomes of preterm children, as measures of cognition and intelligence are highy influenced by sociodemographic, environmental and genetic family effects. Until the 1990s cerebral palsy was defined as a non-progressive disorder of movement, posture or both [18]. When function was considered, cerebral palsy was defined as mild, with no loss of function and independent walking; moderate with functional disabilities requiring assistance for walking with aids or walkers; and severe, nonambulatory, requiring a wheelchair. Cerebral palsy was alternatively labeled "disabling" or "nondisabling" [19].

In 1997, Palisano et al [20] developed a reliable functional classification system to quantitatively measure gross motor function in children with cerebral palsy. This Gross Motor Function Classification System (GMFCS) defines motor function on the basis of self-initiated movement with particular emphasis on sitting, walking and mobility using a five level classification system. Distinctions are based on functional limitations, the need for hand-held mobility devices such as walkers, crutches or wheeled mobility, and to a much lesser extent, quality of movement. Since classification of motor function is dependent on age, separate descriptions are applied over a variety of age ranges. An example of the classification system used for toddlers is presented in Fig. 18.2. In 2004, an international workshop on the definition and classification of cerebral palsy proposed inclusion not

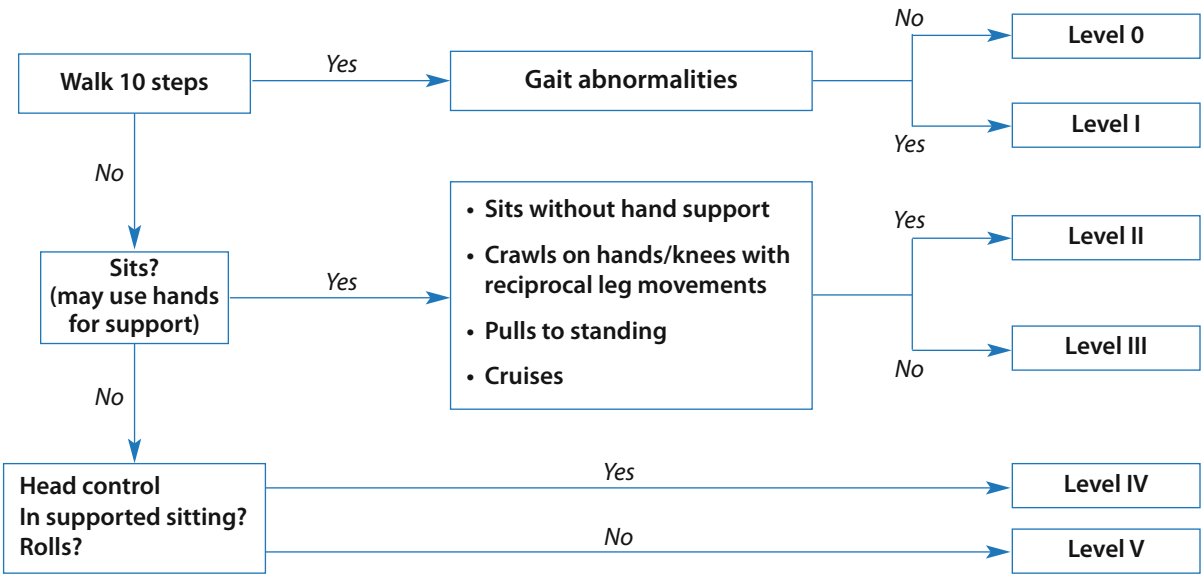

Fig. 18.2 Gross motor classification system for toddlers. Data from [20]

only of motor disorders but the functional abilites of the child and other associated deficits which may coexist including seizures and cognitive, perceptual, sensory (visual and hearing), and behavioral impairments [21]. The classification also includes anatomic and radiologic findings and causation and timing of the lesion. Its use should improve the classification of children with cerebral palsy and facilitate studies of trends in the rates of cerebral palsy and its correlates.

When examining rates of cerebral palsy in a population it is important to differentiate between the rates per live births, that is the total population at risk, including those who die, as compared to the rates of survivors only. Although many studies report rates of cerebral palsy at age 18–24 months, a definitive diagnosis should not be made prior to 3 years of age and preferably 5 years. This is due to the fact that some cases diagnosed at age 2–3 years may not be considered as cerebral palsy at age 5 years [22].

18.3 Timing of Clinical Follow-up Visits

For clinical purposes, the initial follow-up visit should be 7–10 days after discharge from the neonatal nursery. This is important in order to evaluate how the child is adapting to the home environment. A clinic visit at about 4–6 months of corrected age is important to document problems of inadequate catch-up growth and severe neurologic abnormality that might require intervention or occupational and physical therapy. Eight to twelve months of corrected age is a good time to identify signs of developing cerebral palsy or other neurologic abnormalities. For research purposes 18–24 months of age is the earliest age to obtain a fairly reliable assessment of both neurologic outcome and early cognitive function. By 3 years of age, other measures of cognitive function can be performed that better validate the child's mental abilities. Language is well measurable at this age. From 4 years of age more subtle neurologic, visuomotor, and behavioral difficulties are measurable.

18.3.1 Developmental Testing

The Bayley Scales of Infant Development are the most commonly used tools for monitoring early cognitive and motor development for high risk infants. The scales were developed for children aged one month to 3.5 years of age. The first and second editions of the Bayley Scales (BSID and BSID-II) were divided into three subtests or scales: mental, motor and behavior and provided a Mental Developmental Index (MDI) and Psychomotor Developmental Index (PDI) with a mean of 100 and a standard deviation of 15 [23, 24]. The 1992 revision yielded lower scores for survivors than those described for children born during the 1980s and early 1990s and tested with the original BSID. The MDI and PDI were 12 and 7 points lower respectively than the original version of the Bayley Scales. In 2006, the most recent iteration of the Bayley Scales, the third edition (BSID III) was introduced [25]. This revision includes five major areas of development for early childhood assessment from birth through 3 years of age. The five scales include cognitive, language, motor, social-emotional and adaptive behavior, the latter two in the form of parent questionnaires. Thus BSID III does not generate a "mental developmental index" but rather separate cognitive and language scores. The cognitive composite of the Bayley III is 6 points higher than the previous MDI and the motor composite is 8 points higher than that of BSID II [26]. These differences need to be considered when comparing outcomes of high risk children over time. Infant tests prior to 2 years of age measure simple cognitive functions. They cannot be considered as tests of intelligence and have poor predicitve validity for tests of intelligence at school age [27].

Parent questionnaires may also be used for developmental screening. The Ages and Stages Questionnaire is one such questionnaire that may be used as a screening tool for children age 3 months–5 years in order to identify developmental delays [28]. However, it does not give a quantitative assessment and thus cannot be used to quantify outcome in specific high-risk populations.

18.3.2 School Age Outcome

Measures at school age should include growth, a neurologic exam, gross and fine motor function, intelligence both verbal and non-verbal, neuropsychologic functioning including executive function, memory and learning and tests of academic achievement including reading spelling and math as well as measures of behavior.

For intelligence the Wechsler Scales (WPPSI-III and WISC-III) may be used with prekindergarten and school-age children. The WISC-III is probably the most commonly used instrument for school age assessment. The Kaufman Test was standardized on a 2 1/2 to 10 year old population and is less heavily weighted by verbal items than other tests. Although the mean IQ of preterm children falls within the low normal range, the rates of borderline (70–84 IQ) and subnormal (<70 IQ) are significantly higher when compared to term born children of normal birth weight.

A recent meta-analysis of the neurobehavioral outcomes of very preterm or very low birth weight children at school age reveals significant differences between preterm children and controls in academic achievement (including mathematics, reading and spelling), in executive function (verbal fluency, working memory and cognitive flexiblity and congitive flexibility) and in behavior, including poor attention, hyperactivity and internalizing symptoms, which includes withdrawn, anxious and depressed behavior. These school age problems are associated with the need for special education and poor social functioning [29].

18.4 Functional Limitations and Special Health Care Needs

Children with special health care needs are defined as those who have, or are at risk for having a physical, developmental, behavioral, or emotional condition and require health or related services of a type or amount beyond that required by children generally. In the United States this definition is used for the identification and planning of federal aid and services for children which thus includes many preterm children [30]. Due to their higher rates of medical, neurologic and developmental problems, extremely preterm children have many more functional limitations, compensatory dependency needs and require many more services above routine than term born children (Figs. 18.3 and 18.4). A parent questionnaire, the Questionnaire for Identifying Children with Chronic Conditions (QUICCC) was utilized for a study in Cleveland of <1 kg birth weight children born 1992–1995 [31, 32]. Results revealed that 64% of the children had one or more functional limitations, as compared to 20% of normal birth weight children. Functional limitations included limitations in activities of daily living such as physical and social activities and difficulties in feeding dressing and toileting; 48% had compensatory dependency needs which included need for special medications, special equipment to see, hear or walk and help or equipment to feed, dress, wash or toilet compared to 23% of normal birth weight children. Sixty five percent of the children required special services for chronic conditions, as compared to 27% of normal birth weight children. These included physical or occupational therapy, nursing care, rehospitalizations, and special education or extra help at school. These differences remained significant even when children with neurosensory impairments were excluded. However, with the exception of a small minority of children with severe disabilities, the majority of services pertain to special education services for school learning problems.

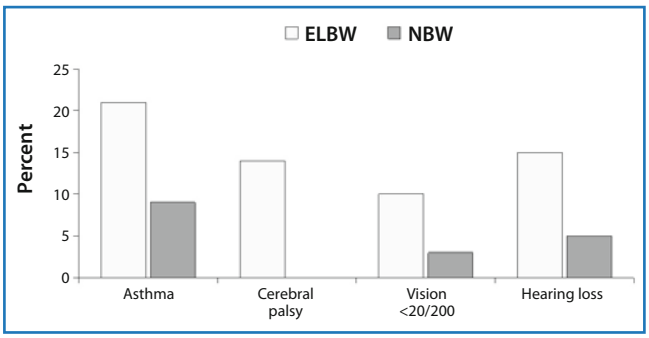

Fig. 18.3 Rates of asthma, cerebral palsy, vision < 20/200 and mild hearing loss (unilateral or bilateral hearing loss of more than 25 dB in at least 2 frequencies) of extremely low birth weight (ELBW, < 1kg birth weight compared to normal birth weight (NBW) children at age 8 years. Data from [32]

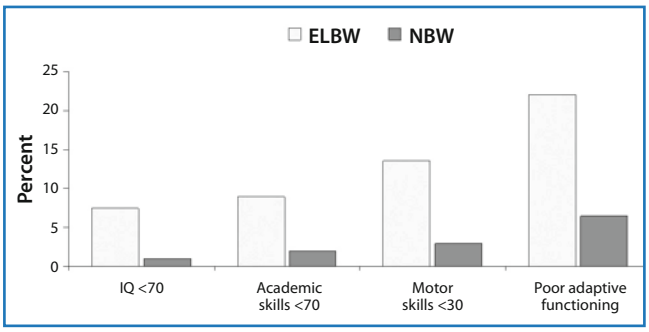

Fig. 18.4 Rates of subnormal IQ, academic skills, motor skills and poor adaptive functioning of extremely low birth weight infants (ELBW, <1kg birth weight) compared to normal birth weight (NBW) children at age 8 years. Data from [32]

18.5 Outcomes of Extremely Preterm Infants

Two European regional studies reported important information about the poor school age outcomes of extremely preterm children. The Epicure study of infants born between 20–25 weeks gestation in the United Kingdon and Ireland in 1995 revealed that at age 6 years 21% of children had cognitive disability defined as more than 2SD below the mean. However, when compared to classmates, this value rose to 41%. Disabling cerebral palsy occurred in 12% of the children. Only 20% of the children had no disability including cognitive, neurologic, hearing and vision problems, 34% had mild disablity, 24% moderate and 22% had severe disabilites. Severe disabilities were defined as non-ambulant cerebal palsy, an IQ score 3SD below the mean, blindness and profound hearing loss [33]. The Epipage study of 22–32 week gestation infants born in nine regions in France revealed that at age 5 years 9% of children had cerebral palsy, 32% had a cognitive score < 85 and 12% had a cognitve score < 70. Disability was highest for the children born at the lowest gestational ages (24–28 weeks gestation). Special health care resources were used for 42% of children born at 24–28 weeks gestation and 31% born at 29–32 weeks compared to only 16% born at term [34]. When the 23–25 week gestation children of the Epicure study were compared to those of the Epipage study the rates of cerebral palsy were similar at age 2 years (21% *vs* 16%), as were the rates of cognitive score < 70 at age 5 years (10% *vs* 14%, respectively) [35].

Analyses of outcomes by birth weight rather than gestational age similarly reveal that < 1 kg birth weight children and especially those of 500–750 gram birth weight have significantlly poorer outcomes than normal birth weight controls [36–38]. Impact on the family of having a preterm child which includes financial impact, as well as caretaker and family burden is significantly higher than that of normal birth

weight controls. However it is related mainly to the chronic and neurodevelopmental problems the child may have [39, 40]. Despite the increase in chronic conditions and associated functional disablity which persist among extremely low birth weight adolescents, both parents and the adolescents themselves rate their health related quality of life, in general, similar to that of normal birth weight controls [41]. The findings of a self perceived health related quality of life similar to that of controls persists in young adulthood [42].

18.6 Late Preterm Children

Late preterm children are defined as those born between 34 and 36 weeks gestation. Due to their physiologic and metabolic immaturity they are at higher risk of neonatal morbidities than term born children. These include respiratory problems, temperature instability, hypoglycemia, jaundice and poor feeding. Although information about the later development of the late preterm infant is sparse, these children have been noted to require early intervention services during infancy similar to those of <32 week gestation infants [43]. At school age they have have lower reading and math skills and higher rates of enrollment in special education than term born children. These differences are gestational age dependent with 32–33 week gestation infants having poorer outcomes than those born at 34–36 weeks [44].

18.7 Young Adult Outcomes

The adult outcomes described to date pertain mainly to preterm infants born in the 1970s and early 1980s, a time when neonatal mortality was high and few extremely immature infants survived [45]. The studies suggest that the neurodevelopmental and growth sequelae of prematurity identified during the school age and adolescent years persist into young adulthood. The two major predictors of adult outcomes are lower gestational age, which reflects perinatal injury, and family sociodemographic status, which refects both genetic and environmental effects. When compared to normal birth weight controls, very low birth weight young adults have poorer educational achievement, more chronic illnesses such as asthma or cerebral palsy and less physical activity. Pregnancy and childbirth rates are lower for young adult women. There is also evidence that the young women have higher rates of anxious, depressed and withdrawn symptomatology than controls. However, despite the significant differences, the vast majority of preterm survivors born during the early years of neonatal intensive care do well and live fairly normal lives. Of interest also is the fact that very low birth weight young adults demonstrate less risk-taking than controls including alcohol and drug abuse.

18.8 Early Intervention

Enrichment programs for low birth weight children have included neonatal in-hospital infant and parent focused programs as well as infant educational enrichment and parent support programs during infancy and early childhood [46, 47]. However, long-term beneficial effects have not been demonstrated. A recent meta-analysis of the effectiveness of early developmental intervention programs on cognitive and motor development of preterm children revealed improved cognitive outcomes in infancy and preschool, but no significant impact at school age. There was also no improvement in motor outcomes during infancy or the school age periods [48]. Studies of early physical therapy have similary not been found to have an effect on the rates of cerebral palsy. The longest follow-up to date of early intervention of preterm infants is that of the Infant Health and Development Program in the United States that followed a cohort of low birth weight infants to age 18 years. At this age, although slight improvements in mathematics, behavior and vocabulary were noted for those who participated in the intervention, they were only evident in larger birthweight preterm children with birth weights of 2–2.5 kg. There had been earlier improvements in outcome for the <2 kg birth weight infants suggesting that the long-term effects of early educational enrichment programs may be less effective for infants of lower birth weight and gestation [49, 50].

Early Markers of Poor Outcome

Fabrizio Ferrari, Licia Lugli, Isotta Guidotti and Marisa Pugliese

A major issue for neonatologists and developmental neurologists is the identification of those infants who are at risk of subsequent neurodevelopment disability and who may benefit from neurological follow-up and early intervention strategies.

Currently brain ultrasound (US) is the most widely used imaging technique in neonatal intensive care: serial US have been used in large population-based studies to monitor the rate of cerebral palsy and to investigate the type of brain injury. It is a cheap, useful and relatively easy to use method for the detection of hemorrhagic and cystic lesions, but it is not sensitive enough for diffuse white matter (WM) abnormalities or basal ganglia/thalami (BGT) lesions.

Magnetic resonance imaging (MRI) can offer more detailed information about white matter (WM) and gray matter abnormalities and is the gold standard for neuroimaging techniques during the newborn period. However, it is not easy to perform in the sick neonate and experience in interpretation of the results is limited to a few centers [1]. A large proportion of infants with brain abnormalities seen on MRI do not develop cerebral palsy or major developmental disabilities. Neuroimaging needs to be accompanied by an accurate clinical assessment of the functional repertoire of the infant, which varies according to the stage of development.

A thorough neurological assessment in the neonatal period and during the first two years of life is mandatory in to evaluate neurological deficit and functional impairment due to the brain injury (or a brain defect).

19.1 Poor Outcome

Outcome can be categorized into severe and moderate-to-mild deficits. Severe deficits comprise CP, mental retardation (developmental quotient of less than 70), and severe visual or hearing impairment. Severe deficits can be detected within the first two years of life. Moderate to mild deficits, however, are often not detected until school-age [2].

19.1.1 Cerebral Palsy

Cerebral palsy (CP) is a major disability which is defined as a group of disorders of movement and postural control caused by a nonprogressive defect or lesion of the developing brain. The leading prenatal and perinatal risk factors for CP are birth weight and gestational age, but other risk factors include neonatal encephalopathy, multiple pregnancy, infection and inflammation, and a variety of genetic factors.

CP is in part a developmental diagnosis, and it is based on the description of motor signs that are disabling; such a clinical diagnosis is not easy to make, especially early in development. CP is divided into three major types to describe different movement impairments; this classification also reflects the areas of the brain that are damaged [3]. The three major type are:

- *Spastic CP*: Children with this type of CP are hypertonic and have a neuromuscular condition stemming from damage to the corticospinal tract or the motor cortex. Spastic CP is further classified by topography dependent on the region of the body affected: spastic hemiplegia with one side being affected; spastic diplegia with the lower extremities affected and less upper-body spasticity; spastic tetraplegia with all four limbs affected equally. Monoplegia, paraplegia, triplegia may be used to refer to specific manifestations of the spasticity.
- *Ataxic CP*: Symptoms can be caused by damage to the cerebellum; some individuals have hypotonia and tremors, motor skills might be affected, as well as balance, especially while walking.
- *Athetoid/dyskinetic CP*: This is characterized by mixed tone and sometimes by hypotonia (hypotonia will usually

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

occur before 1 year of age; the muscle tone will be increased with age and progress to hypertonia). People with athetoid CP have trouble holding themselves in an upright, steady position for sitting or walking, and often show involuntary movements. The damage occurs to the extrapyramidal motor system and/or pyramidal tract and to the basal ganglia (BG) [3, 4].

In the 2004 an international meeting on the definition and classification of CP was held in Bethesda. The major addition to the classic Bax and Mutch et al [3] definitions involved emphasis on the accompanying developmental disturbances that accompany neurodevelopment disabilities: these are often functionally more important than the developmental motor disorders that are, by definition, the hallmark of CP [3]. The severity of CP is nowadays classified according to the Gross Motor Function Classification System for Cerebral Palsy (GMFCS): it is a reliable and predictive internationally adopted method of scoring gross motor function in children with CP [4].

19.1.2 Mental Retardation

Mental retardation (MR) or intellectual disability is defined as a disability that involves significant limitations both in intellectual functioning and in adaptive behaviour, which covers many everyday social and practical skills. This disability originates before the age of 18 years and encompasses a wide range of conditions, types, and levels.

19.1.2.1 Visual Disability and Hearing Impairment

Visual disability is the impairment of visual functioning even after treatment and/or standard refractive correction, with a visual acuity in the better eye of less than 6/18 for low vision and 3/60 for blindness or with a visual field of less than 10 degrees from the point of fixation (according to the WHO definition).

A hearing impairment or deafness is a full or partial decrease in the ability to detect or understand sounds. It can be classified as conductive or sensorineural hearing loss [6].

19.2 Traditional Neurological Examination

A variety of standardized examination tools have been developed to estimate gestational age, detect neurological abnormalities and determine their course during the neonatal period and later on during the first 2 years of life [5]. Infants at high risk of brain damage may be included in follow-up programs comprising serial neurological examinations in order to identify early indicators of abnormal neurological development. A simple and scorable neurological examination for infants between 2 and 24 months of age was developed in the Paediatric Department of the Hammersmith Hospital in London (the Infant Neurological Examination [HINE]) [3]. The assessment consists of different items assessing cranial nerve function, posture, movements, tone, reflexes, the development of motor function and the state of behaviour [5]. For details, see Chapter 130.

The prognostic power of the HINE optimality score was explored in very preterm infants between 9 and 18 months of age: 48% had suboptimal scores, the scores were not associated with the degree of prematurity and had a very high accuracy to predict walking at 2 years. The scores were also not invariably associated with the pattern of ultra-sonogram findings: cystic periventricular leukomalacia (PVL) was associated with low scores, other ultra-sonogram abnormalities with both optimal and suboptimal scores. This is not surprising because hemorrhages and periventricular densities can be associated with both normal and abnormal neurodevelopment. A high correlation between the HINE at 3 months and the developmental quotient at 24 months was found. The high predictive value of the HINE across the first year of life was probably granted by the effective combination of different groups of items for each age period. Indeed, although a number of items were found to be consistently among the most predictive ones (movement quality, quantity and lateral tilting), other items changed across time. Tone items (ventral suspension, arm pronation/supination and scarf sign), tended to be more predictive at 3 and 6 months post-term, while maturational items, such as arm protection, vertical suspension and forward parachute, were highly predictive only after 9 months. Therefore these studies demonstrated that a standardized neurological examination performed from 3 to 12 months can be used reliably in very preterm infants to predict motor outcome [6].

The predictive value of the HINE examination was also evaluated in infants with other neurodevelopmental risks, like infants with hypoxic-ischemic encephalopathy (HIE) (see Chapter 136).

Follow-up studies have demonstrated that the outcome cannot be always predicted by the severity of HIE. Although HIE stage 1 is usually associated with a normal outcome and HIE stage 3 with severe neurodevelopmental abnormalities, the outcome in infants with HIE stage 2 can be quite variable, ranging from normal to CP and severe MR. Several studies have reported that neurodevelopmental outcome is best predicted by the pattern of lesions observed on neonatal MRI (see Chapter 132). The HINE was used in a group of infants with HIE at age 9 to 14 months to evaluate the correlation between the scores and early MRI findings, and whether the scores can be used to predict locomotor function at 2 and 4 years. Approximately 40% of the infants had suboptimal scores on neurological examination and the magnitude of the suboptimal scores was related to the pattern of the MRI lesion. Severe BG lesions, diffuse brain injuries, or both were associated with the most severe outcome [7].

The use of the optimality score gave prognostic information on the severity of the functional motor outcome. Although neonatal MRI can identify early infants who will have CP, the neurologic examination can provide information on the severity of the functional motor impairment and distinguish infants who will walk from those who will only sit or not even acquire the sitting posture. It is interesting, however, that few children who were able to walk without restrictions at 4 years had an abnormal gait, associated with a mild hemiplegia or with mild movement disorders, which suggested that mild neurologic abnormalities can also occur in the absence of widespread lesions or severe abnormalities. Further studies evaluating follow-up at school age are required to evaluate whether these minor neurologic abnormalities are related to any difficulty in everyday life [7].

19.3 Early Markers of Cerebral Palsy: the Role of General Movements

The type of brain injuries most frequently occurring in term infants are hypoxic-ischemic injury to the BGT, parasagittal injury; and in preterm infants PVL, intraventricular hemorrhages (IVH) and persistent flare.

CP occurs in 8–10% of very preterm babies and approximately 40% of all children with CP are born preterm. In preterm infants spastic diplegia prevails, followed by hemiplegia. In full-term infants tetraplegia and hemiplegia are by far the most common forms; dyskinetic CP is more common in full-term infants [2].

The early prediction of CP will lead to the child receiving neurological follow-up and earlier enrolment in rehabilitation program. It is generally reported that CP cannot be diagnosed before several months after birth or even before the age of 2 years. A so-called silent period, lasting up to few months has also been described.

The neurological signs observed during the first months after birth in preterm infants who will develop CP are neither sensitive nor specific enough to allow for a reliable prognosis. Irritability, abnormal finger position, spontaneous Babinski reflex, weakness of the lower limbs, transient abnormalities of tone and delay in achieving motor milestones are some of the neurological signs that have been described in these high risk preterm infants. All of them may be encountered before the onset of CP or during transient dystonia, dissociated motor development, and other transient neurological disturbances that vanish during the first or second year of life.

In the last two decades a technique for assessing spontaneous motor activity has been introduced and evaluated, namely Prechtl's assessment of general movements (GMs). This approach, which involves observation of the infant without direct physical examination, has proved a reliable and sensitive method in the neonatal period and early infancy for predicting normal and abnormal motor outcome, particularly CP [8]. It requires video-recording of a few minutes of spontaneous motility and off-line observation of the quality of GMs. Serial assessments of GMs from preterm birth until 3–5 months post-term age define the developmental trajectory. Assessment based on developmental trajectory predicts CP at a much earlier age than other neurological assessment.

19.3.1 Diplegia and Tetraplegia

Early specific markers for spastic cerebral palsy are cramped-synchronized (CS) GMs and abnormal fidgety GMs. As far as CS GMs, the movements of limbs and trunk appear rigid and lack normal smooth and fluent character. Limb and trunk muscle contract and relax almost simultaneously. All infants who show consistent and prolonged CS GMs later develop CP. The earlier consistent CS GMs occur, the worse the later motor impairment of preterm infants. If the CS character is transient and followed by normal fidgety GMs the infant may have a normal outcome [9]. The second specific marker for CP is absent fidgety movements (FMs). Almost all infants who never had FMs developed CP. Absence of FMs can be preceded either by CS GMs or by poor repertoire (PR) GMs. Both abnormal qualities of GMs, i.e., CS GMs and/or absence of FMs, are seen within 3–5 months post-term, thus much earlier than with other neurological assessment [9].

19.3.2 Hemiplegia

Hemiplegia (HE) is usually due to focal one sided lesions, either ischemic or hemorrhagic infarction, more rarely to cystic lesions due to focal or unilateral PVL.. Brain US and MRI detect site and severity of the focal lesions: the neurological follow-up of these infants aims to detect (or exclude) early signs of HE. Traditional neonatal neurological examination is of low predictive value for such patients.

The studies carried on with the GMs method have shown that all babies with a focal lesion have an abnormal quality of GMs (PR or CS) from term, and, a silent window is not observed. Asymmetrical segmental movements can be recognized from as early as 3 months post-term in preterm infants and from 3–6 weeks post-term in full-term infants with neonatal cerebral infarction. Segmental movements are distinct wrist movements, occurring either in isolation or as a part of GMs.

In term infants who later develop HE asymmetry in wrist movements, a lower frequency of independent digit movements are seen as early as 12 weeks and predict later HE. It is important to note that only infants with concomitant ipsilateral involvement of a cerebral hemisphere, BG and the internal capsule on the MRI brain scan later develop HE. Early recognition of subtle motor asymmetries is not easy with unaided eyes; it is easier when videorecording of spontaneous motor behavior is available [10].

19.3.3 Dyskinetic CP

Dyskinetic CP has a frequency of only 10–15% of all CP forms. The dyskinetic form of CP comprises two subtypes: a syndrome of choreatetosis (infants showing mainly massive, purposeless involuntary movements) and a dystonic form, characterized by sudden shifts of muscle contraction and infantile reflex activity. This second subtype is more common. During the first two months, infants who will develop a dyskinetic form, display a PR of GMs, arm movements in circles and finger spreading. Abnormal arm and finger movements remain until at least 5 months and are associated with lack of arm and leg movements towards the midline (particularly foot-foot contact) and with lack of FMs. The abnormal unilateral or bilateral circular arm movements are monotonous, slow forward rotations from the shoulder. The monotony in speed and amplitude is the most characteristic quality of circular arm movements.

An early differential diagnosis of dyskinetic versus spastic later CP is not easy: later dyskinetic infants share the absence of FMs and antigravity movements, i.e., leg lifting in infants with later spastic form. Moreover, circular arm movements can be mistaken for wind-milling arm movements seen during the first year of life and with cycling movements described in infants with HIE. Choreo-athetoid movements are easy to recognize but the sudden shifts of muscle contraction are difficult to differentiate from the abnormal muscle tone of spastic forms. Dystonic and spastic features are quite commonly mixed in the same infant [11].

19.4 Neuroimaging Predictors

Besides neurologic assessment of the infant with neonatal brain injury or at risk for neurodevelopmental disturbances, neuroimaging can provide predictors of neurodevelopmental outcome. Two main imaging techniques have been used for the prediction of neurodevelopmental outcome in the neonatal period: US and MRI (see Chapter 132).

19.4.1 Cerebral Ultrasound

US is a simple bedside tool and when used repeatedly, its sensitivity and specificity can be very high, expecially in the preterm infant. US lesions can be detected in the majority of infants born below 32 weeks of gestation who develop CP. IVH grade III and IV, PVL and focal infarctions are major cerebral lesions detected by US in the preterm population. Also infants with a grade I-II IVH are at an almost two times higher risk of developing neurodevelopmental impairments at 20 months compared with those without any hemorrhage. The degree of milder US findings (grade I or II PVL) and size of the corpus callosum are also related to neuromotor function in school-age children without CP. New techniques such as transmastoidal access have improved the representation of the cerebellum, a structure that can also be injured in very low birth weight (VLBW) infants. Cerebellar injuries may contribute to long-term neurocognitive disabilities, independent of associated supratentorial parenchymal lesions [2].

Cerebral US is useful in the critically ill newborn who cannot be studied with MRI. During the first hours after asphyxia, US may give little information on the severity of lesions and prediction of outcome. Arterial Doppler studies (measurement of the pulsatility index) may better predict outcome, but in most cases it is still normal 6–12 hours after the insult. The most frequent lesion observed by US in asphyxia is BGT hyper-echogenicity while parasagittal ischemia is more difficult to detect, because the distance between brain lesions and the acoustic window is high.

19.4.2 MRI Abnormalities and Outcome

MRI of the preterm infant is best done at term equivalent age when the myelination of the posterior limb of the internal capsule may be used as a predictor of motor outcome. MRI lesions in the full-term infant are best seen after the first week.

In the preterm infant, MRI has been used to detect diffuse WM abnormalities and gray matter changes. Gray matter abnormalities are also associated with the same risks but to a lesser extent than WM abnormalities. WM abnormalities can be detected in more than 50% of VLBW children and are predictive of CP and psychomotor delay in early childhood and neurosensory impairment. Recently it has been shown that HIE, typically described in in full-term infants, can also be observed in pretem infants. These infants have a high incidence of severe BGT and brainstem involvement and the lesions are associated with significant mortality and neurologic morbidity. Advanced MRI techniques such as volumetry and morphometry, diffusion tensor imaging and tractography have been used to better determine the full spectrum of brain injury. In infants born preterm and examined at term, abnormalities in the cortex and deep nuclear structures are related to the degree of immaturity at birth and concomitant WM injury. Volumetric changes in the sensorimotor, premotor, midtemporal and parieto-occipital regions may be related to intellectual performance at school-age. Recent findings indicate that the hippocampal volume may be reduced in preterm infants and that it is associated with reduced working memory, cognitive and motor performance at 2 years of age. However, the significance of subtle abnormalities detected on MRI regarding long-term functioning has not yet been fully resolved [2].

HIE and BGT are often associated with abnormal signal intensity in the posterior limb of the internal capsule (PLIC), brainstem, hippocampal region and cortex, particularly around

the central fissure and insula. Loss of the normal signal intensity from the PLIC is associated with adjacent BGT injury. The motor correlate is a spastic or dyskinetic CP. BGT lesions are the imaging signature of an acute and profound hypoxic ischemic event. BGT lesions associated with severe WM damage, conversely, suggest a more prolonged hypoxic-ischemic insult. WM damage is proved by a loss of gray matter/WM differentiation, consistent with an overt infarction: in these infants a very poor outcome can be expected.

When the predominant lesion involves the WM and cortex but spares the BG and PLIC, the pattern probably results from prolonged partial hypoxia-ischemia: the motor outcome is often good but there may be cognitive and behavioral impairments that are proportionate to the extent of WM and cortical injury. Severe BGT lesions are associated with a high risk of developing CP and severe cognitive impairment regardless of the additional associated WM lesions [12].

19.4.3 Cognitive Evaluation

The most widely used standardized developmental scales to assess mental development, in the first two years after birth are the Bayley Scales of Infant Development (BSID) and the Griffiths Mental Developmental Scales.

The new Bayley Scales of Infant and Toddler Development, third edition, include updated items and modernized stimulus materials and manipulatives, and yield mental assessment results as separate cognitive and language scores rather than as separate scores for Cognitive, Language and Motor scales and separate scores for Expressive and Receptive Communication and for Fine and Gross Motor skills. The associated Adaptive-Behavior parent questionnaire is an excellent addition to the new Bayley scales, giving functional information that can be used to support a tested significant mental delay. On the other hand, the Griffiths Mental Development Scales for children from birth to 24 months, reviewed in 1996, comprises items to assess locomotor, personal-social, hearing and language, eye and hand coordination, and performance domain. Domain raw scores are obtained and converted to standardized sub-quotients, percentiles and developmental age, the sum of which is the General Quotient, a score for an overall developmental level.

The purpose of developmental standardized scales is to assess a child's development at the time of observation, to determine developmental delay or impairment, in order to implement early habilitation interventions. Despite the wide use of standardized scales to determine the extent of developmental delay or impairment, major concern remains about their accuracy in discriminating cognitive function. To evaluate specific cognitive deficits, it is essential to use neuropsychological tests and to continue cognitive follow-up at least until school age. Developmental scales are not intelligence tests and developmental quotients (DQ) calculated in the first two years are not as reliable as the intelligence quotient (IQ) measurement, calculated after the first 3 years of life, nor do they have as good a predictive value for later IQ. However, in preterm populations, a score of 2 standard deviations (SD) below the normative mean has been used as a cut-off to identify abnormalities. Currently, following a consensus statement, many authors suggest that a cut-off of 3 SD is more appropriate and may be more predictive of later poor performance [2].

19.5 Visual Evaluation

Subcortical visual pathways have a major role in neonatal vision while cortical visual modules progressively emerge during the first months of postnatal life. Abnormal visual function occurs in infants with brain lesions even in the absence of ocular abnormalities (cortical blindness). Blindness affects early motor development, especially self-initiated postures and locomotion.

Term infants with HIE can show visual abnormalities (reduction in visual acuity, fixation shift or visual fields in the first years of life. Occipital cortex and optic radiation injury have been found in infants with visual impairement, but cortical and WM lesions sparing the BG are not always associated with abnormal visual findings. Cortical and BG lesions are always associated with severe abnormalities of visual function during the first year of life, confirming the role of BG in human visual development. Poor acuity, weak stereopsis and delayed visual maturation can occur in chidren with focal BG lesion [13].

VLBW infants are at risk of visual, visuocognitive and visuomotor impairment. Vision loss for preterm infants is given as visual impairment with the best vision after correction of < 20/60, or legal blindness with the best corrected vision of < 20/200 (< 6/60). Severe visual impairment occurs in 1–3% of ELBW and 2–6% in children with gestational ages below 27 weeks.

Retinopathy of prematurity (ROP), is one of the main causes of poor visual function and blindness; prevention is based on ophthalmic screening to identify cases requiring treatment. Less severe visual impairments include refractive errors, reduced visual acuity, strabismus and nystagmus. IVH and PVL are other causes of visual impairment [14]. Severity of visual impairment is also related to the extent of basal ganglia, lateral geniculate nuclei and optic radiation involvement. Fractional anisotropy of the optic radiation was related to visual assessment scores, independent of WM maturation.

Assessment of visual function at term corrected age includes: ability to fix and follow a target, preferential looking, attention at distance, color and stripe discrimination. Measures of early visual cortical function are orientation reversal visual event-related potentials (OR-VERP) and fixation shifts under competition. Both measures correlate with the severity

of brain abnormalities and are sensitive predictors of neurodevelopmental outcome at 2 years.

Post-discharge eye examinations until preschool are useful to monitor refractive errors and to prevent amblyopia.

19.6 Hearing Evaluation

Hearing loss (HL) is one of the most common birth defects (3/1000) and is associated with language and perception disorders. Genetic factors, prematurity, low birth weight, hyperbilirubinemia, pharmacologic ototoxicity and noise exposure are the main causes of HL. The introduction of universal screening resulted in a significant decrease of HL.

Otoacoustic emissions (OAE) and auditory brainstem response (ABR) are employed in newborn hearing screening programs. The OAE measures the inner ear response to sound by placing a microphone in the ear canal. The ABR records the brain's response to sound by placing electrodes on the head.

Auditory steady-state responses have been reported as a reliable and objective technique for evaluating the hearing threshold. ABR and auditory steady-state responses in infants with perinatal brain injury show a high sensitivity of auditory steady-state responses for detecting hearing impairment.

In term infants much hearing impairment is due to specific gene abnormalities, including the connexin mutation. Some authors state that hypoxia-ischemia damages cochlear hair cells, causing hearing impairment. Infants carrying genetic mutations for hearing loss may coincidentally experience perinatal stress, but prevalence of hearing impairment in children born with HIE is not significantly increased.

In preterm infants, sensorineural HL has been associated with prolonged ventilation, ligation of patent ductus, hypotension and ototoxicity, infections, craniofacial abnormalities and family history. All extremely low birth weight (ELBW) infants are considered at high risk for HL, and in most centers hearing testing is done prior to intensive care discharge, either as OAE or full diagnostic testing with ABR. Occasionally, this test defines auditory neuropathy with abnormal auditory brainstem function and a strong cochlear microphonic with normal OAE.

Although as many as 6% of children with gestational age below 26–27 weeks have severe to profound hearing impairment, many function well after the early placement of cochlear implants.

Children with undiagnosed HL can experience delays in the development of language, social, and academic skills. Besides the degree of hearing loss and age at onset of deafness, environmental factors (parental support and education methods) seem to play an important role in the cognitive development and academic success. As language development begins within the first months of life, it is important for parents to be aware of normal language and communication developmental milestones beginning when their baby is very young so that they can discuss development with their child's healthcare provider [15].

Quality of Neonatal Intensive Care and Outcome for High Risk Newborn Infants

Liz McKechnie, Kathryn Johnson and Malcolm Levene

It is generally accepted that outcome is related at least in part to the quality of care and therefore the quality of care delivered to babies should be closely monitored in order to improve outcome. Quality in neonatal care is a complex subject, but improving and developing the quality of care is a goal to which all neonatologists should aspire. In order to achieve incremental improvement in quality of care, these outcomes need to be monitored ongoing interim measures need to be implemented in order to improve care such as audit, benchmarking and confidential enquiries, which are discussed below. Traditional measures of outcome such as death, neurodevelopmental status and chronic lung disease are also discussed in detail later in this chapter. Improving quality of care can additionally be achieved by implementing modern, effective, evidence based methods of knowledge translation in order to increase the use of evidenced based health care.

20.1 What Is Quality in Neonatal Care?

The quality of the care that we provide to all newborn babies has gained increasing prominence in the last decade or so. Quality in healthcare has been defined in many different ways and by many different authors. However, appertaining to neonatal care it has recently been defined as:

> [...] providing an appropriate level of care to well newborn babies while providing a good quality of more specialised care to the few babies that need it. This should be done while obtaining the best medical neonatal outcome and satisfying parents and families as well as providers. This should be delivered in the context of sound managerial and financial performance and whilst developing perinatal services to further raise standards of care. [1]

M. Levene (✉)
Academic Unit of Paediatrics and Child Health
University of Leeds and Department of Neonatal Medicine
Leeds Teaching Hospitals Trust, Leeds, United Kingdom

This definition clearly demonstrates the complexity of measuring quality in neonatal care; not only do we need to consider the care that the baby has received and the effects of that care, but also the effect on the family, parents and health care professionals surrounding that baby. Compounding these factors with the complexities of healthcare management and economics makes measurement of this highly complicated entity very difficult.

20.1.1 Measuring Quality in Neonatal Health Care

The assessment of quality in neonatal care is evolving and the framework around which quality can be measured is that of clinical governance. This encompasses many different processes by which care can be measured.

In the past, outcome studies have been used for reflecting the quality of care, but more recently other methods have become more commonplace such as auditing, benchmarking and confidential enquiries. Subsequently, increasing amounts of work are being published on ways in which to improve quality of care, based on the published literature.

When measuring quality it is important to recognize and differentiate the discrete aspects of healthcare – the structure or organization of care that is provided, the process of providing that care and the outcome of the care that has been provided [2]. These different aspects may be assessed individually to measure quality.

20.1.2 Outcome Studies

In the past much of the neonatal literature has been focused on different aspects of care and their effect on outcome for a baby. Outcome can mean many different things, such as later neurodevelopmental attainment, and the presence or absence

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

of chronic lung disease. These outcome measures can be used as a proxy for the quality of care.

One of the problems with using studies reporting outcome as a marker for quality of care is that there are frequently differences in results between similarly designed studies. These differences can be in part accounted for by differences in clinical practice or in the demographics of the study populations. However, it has been shown that these differences in clinical practice and in demographics are not enough to explain the variation in results. It has been suggested that the differences may therefore be due to a difference in outcome in quality of care [3].

20.1.3 Audit

Clinical audit is a quality improvement process that seeks to improve the patient care and outcomes through the systematic review of care against explicit standards and subsequently the implementation of change. Where indicated, changes are implemented and further monitoring is used to confirm improvement in healthcare delivery. It is a continuous circular process. Therefore, audit does not define what optimal care is, but whether perceived optimal care is actually provided.

In the UK the National Neonatal Audit Programme (NNAP) was set up in 2006 and uses the audit method to capture information on current practice measured against previously defined standards. The first annual report highlighted many of the problems encountered when auditing such a complex process as healthcare [4]. Three years data has now been reported. In light of the results of the first period, changes were made to the questionnaire and also to data ascertainment. However, there continue to be issues with interpreting the data and ensuring that the questions asked give the information required.

The report highlights examples of difficulties in the analysis of data as a result of imprecise questions. One standard set by consensus of the NNAP Board was "of those receiving surfactant, 90% should receive it within 1 hour of birth". In answer to the audit question of whether this standard was achieved, there was data missing from 173/647 babies. Of all eligible babies 64% received surfactant in the first hour (87% of babies with complete data) showing that the standard was not achieved. However, the question could not distinguish those babies who did not receive surfactant in the first hour because they were not intubated, following the increasingly common occurrence of babies of this gestation going directly onto nasal continuous positive airways pressure (nCPAP) after birth. Similar issues were highlighted with the remaining questions. However, despite the problems encountered the quality of early surfactant administration is clearly not up to the expected standard and so changes can be made to improve this.

Within Europe, the Euronatal Study [5] investigated differences in perinatal mortality rate by looking at quality of care in a geographical region within 10 individual countries. Differences were demonstrated between different health care systems. Suboptimal care factors occurred significantly less in Finnish and Swedish regions than in the remaining participating regions (Spain, the Netherlands, Scotland, Belgium, Denmark, Norway, Greece and England). Sixty seven per cent of neonatal deaths ≥ 34 weeks were graded by an expert panel to have had suboptimal care factors that were likely or might have contributed to the fatal outcome. Clearly, this study showed that improvements in quality of care should be possible but no re-audit has been carried out to date.

When auditing a standard of care if the expected standard has not been met change should be implemented to achieve that standard. Re-audit is then imperative in order to demonstrate that change has been beneficial and the quality of care has improved.

20.1.4 Benchmarking

Benchmarking is a process whereby aspects of health care practice are evaluated against known best practice. It is a helpful way to compare activity and performance in different areas with other organizations and to provide an evidence base for further review and action planning. Benchmarking is a commonly used technique across a wide range of different sectors and industries to review and improve performance. It is one of the most widely applied management techniques used to improve organizational performance.

A useful definition of benchmarking is provided by The NHS Benchmarking Club [6], who define the process as "Making evidence-based comparisons of practice, drawing conclusions and implementing improvements".

Benchmarking has many benefits. It is an evidence based quality improvement tool. It can provide the means to compare practice with similar organizations and thereby identify outliers from the standard of care, i.e., good and bad performers. It can assess whether current performance achieves practice standards and can provide the catalyst for organizational change to improve quality of care. Sharing benchmarking data can share good practice and motivate the need for change. The first large benchmarking collaboration in neonatal medicine was within the Vermont-Oxford Network (VON) and now provides benchmarking data for participating units internationally. The UK Managed Clinical Networks (see below) can provide a group of similar units that can benchmark both internally and externally.

20.1.5 Confidential Enquiries

Standard methods of measurement (e.g., audit) may not be sufficiently powerful to capture the complexity of neonatal

health care. A more focused approach may sometimes be needed such as that used in Project 27/28 [7], which was carried out in England, Wales and Northern Ireland in the 2 year period between September 1998 and August 2000. The aim was to identify variations in the standards of care that might have contributed to the deaths of infants born at 27 and 28 weeks gestation during this period. Anonymized medical records were scrutinised by a panel of experts for deficiencies in the standards of care provided to the infants that died. Having highlighted consistent deficiencies in the standards of care the working party published recommendations for changes to practice in order to improve the quality of care. Their main findings and recommendations were based upon early thermal, ventilatory and cardiovascular care.

20.2 How Can Quality be Improved in Neonatal Care?

20.2.1 National and International Groups

Different groups whose aim is to improve quality within neonatal care have been set up. The largest organization is the Vermont Oxford Network (VON). This is an international collaborative of neonatal units with the objective of integrating research and clinical practice in order to improve the quality of neonatal care [8]. Other organizations such as the Neonatal Survey (UK) and Australian and New Zealand Neonatal Network (ANZNN) collect data and use this to provide information on outcome. Contibutors to these databases are then able use the information provided for developing and enhancing their quality of care.

20.2.2 Managed Clinical Networks

Managed Clinical Networks are a way of delivering high quality care to a population across a large geographical area. A Managed Clinical Network has been defined as:

> Linked groups of health professionals from primary, secondary and tertiary care, working in a co-ordinated manner, unconstrained by existing professional and Trust/Health Authority boundaries, to ensure equitable provision of high quality and clinically effective services. [9]

Managed Clinical Networks in the UK were set up after a government initiative called "The NHS Plan". The aim was to create a more effective and efficient service. The network should ensure appropriate access for patients to the right care delivered in the most relevant setting. Access to specialist knowledge and care should be streamlined and quality of care should be consistent [10].

The network can play a central role in the maintenance of national standards for neonatal care but can also develop and implement local quality improvement measures such as taking a leading role in the development of education, audit and guidelines [11]. The networks can also provide support and advice for individual units about both clinical and non-clinical matters. All these network roles clearly can improve quality.

20.2.3 Education and Knowledge Translation

It is well described that there are major gaps between routine practice and what the evidence shows is optimal practice [12]. An example of this is nicely demonstrated by the work done by Ligand in the early 1970s that showed the improvement in respiratory function of newborn premature lambs and later human preterm infants after antenatal maternal steroid administration. Although the benefit was clearly demonstrated it took until the late 1990s to reach routine antenatal care.

Translating audit and research findings into best practice is hampered by many barriers and obstacles at all levels of care delivery. This has been addressed in several studies that show that using active methods of information dissemination (e.g., audit, feedback, multidimensional workshops, ongoing support) knowledge translation can be far more effective than traditional methods of learning such as lectures and seminars [13, 14].

20.3 Short-Term and Long-Term Morbidity and Mortality in High Risk Infants

Infants born prematurely are at significant risk of both increased morbidity and mortality compared with babies born at term [15]. They represent one of the leading causes of perinatal morbidity and mortality in the developed world [15–17].

Reported rates of preterm delivery (<37 weeks) in North America are 12–13% [17], compared with 5–9% in Europe [18]. The highest morbidity and mortality not surprisingly is seen in the smallest, most premature infants [16, 19–23]. These figures are considerably higher in the developing world [24].

Premature delivery therefore continues to be a significant problem worldwide and rates show no evidence of declining; in contrast there are many reports worldwide of increasing rates of preterm birth [15, 16, 25–27]. A variety of factors have contributed to the increasing preterm birth rate, including increased use of assisted reproduction techniques and the associated increase in multiple births [15, 16, 18]. Increases have also been seen in the rates of singleton preterm birth particularly amongst medically induced preterm births rather than those born following the spontaneous onset of labour [15, 18]. In addition singletons born following assisted

reproduction are more likely to be preterm than their spontaneously conceived counterparts [28]. Socio-economic status is well described to have a significant effect on preterm birth; however this effect has been shown to be static over time [26]. Racial origin also impacts on rates of preterm birth; changes in racial demographics over time may therefore have influenced rates of preterm birth [22, 29, 30]. Reported rates of preterm birth may have also have been influenced by changing attitudes in delivery units over time with more infants being classed as live births or offered resuscitation [31, 32], however this may not be the case at all gestational ages [33].

20.3.1 Mortality

Major advances in antenatal, delivery suite and neonatal management of preterm infants led to major advances in survival up until the mid to late 1990s when compared with the 1980s or earlier [20, 25, 34–36]. Contributors to improved survival include the increasing and now widespread use of antenatal corticosteroids [20, 23, 25, 36, 37], changes in attitude in delivery units to the management of extremely preterm infants and widespread postnatal use of surfactant [36, 38]. There is now a wide range of international data from the mid to late 1990s following widespread introduction of antenatal corticosteroids and postnatal surfactant reporting mortality for the preterm infant for geographically based studies.

More recently in the late 1990s and into the 21st century the changes in survival have been less convincing [20, 36, 39]. Recent large studies in the UK show some improvement in survival in extremely preterm infants born after 24 weeks but not at lower gestational ages [33, 40]. However in other European countries the trends towards increased survival have continued into the 21st century [41].

Table 20.1 shows the reported survival for extremely preterm infants from three international cohorts.

Preterm birth at 34–36 weeks of gestational age accounts for 75% of all preterm births [42, 43] and whilst such infants have a lower morbidity and mortality than those born extremely prematurely, they still have a significant mortality and morbidity when compared with those infants born at term [42]. Mortality rates were significantly higher at 34 (1.1/1000 live births), 35 (1.5/1000) and 36 (0.5/1000) weeks gestation when compared with the term infants (0.2/1000).

Although the number of infants born at < 32 weeks represent < 5% of all babies born, most mortality is seen in this group, particularly the 0.4% of all infants born at less than 28 weeks. Infants born at 25 weeks are 32 times more likely to die than if born at 31 weeks [44]. Within this highest risk group separate data is available for the smallest most premature infants. Multicenter data from the UK for births in 2006 shows 25% mortality for infants born at 22–23 completed weeks (of those admitted) [41]. Higher rates of survival of 40% of live births for those born at 23 weeks have been shown in a multicenter Swedish study [45]. Data from a single centre in the USA gives a survival (as a percentage of all births) of 1.8% at 22 weeks increasing to 34% at 23 weeks [19].

20.3.1.1 Multiple Births

As a result of the well described increase in multiple birth rate over the last 20 years, concerns have been raised regarding the potential for increased mortality and morbidity in such infants compared with their singleton counterparts. In a large, nationwide Canadian study of infants < 32 weeks, there was no increase in mortality in those infants born following multiple births when compared with gestationally matched singletons [46]. These findings are supported by other large studies [47–49]. In addition, different measures of morbidity were comparable apart from a higher rate of respiratory distress syndrome (RDS) in those infants born following multiple birth [46]. This effect was seen only in the second twin in one large study [48].

20.3.1.2 Gender Effects

Male infants born extremely preterm are consistently shown to have a higher mortality than their female counterparts [20, 40], with some authors reporting females showing generally a week's additional maturity and a birth weight heavier than 100 g than their male counterparts [50]. This negative effect of male sex is pervasive into early childhood with higher rates of neurological and developmental disability when compared with females of the same age [51].

Table 20.1 Survival at limits of viability from three large cohorts

	Survival 22+0–22+6 wks	Survival 23+0–23+6 wks	Survival at 24+0–24+6 wks
Sweden [45]	Not available	(at 180 days) 40% of live born infants	(at 180 days) 50% of live born infants
United Kingdom [38]	(to discharge) 9% of admitted infants	(to discharge) 20% of admitted infants	(to discharge) 33% of admitted infants
United States [19]	(to discharge) 4.5% of live born infants	(to discharge) 46% of live born infants	(to discharge) 59% of live born infants

Table 20.2 Major variations in mortality data for different developed countries

Country	Type	Date	Number	Gestation	Survival
Belgium [47]	National	1999–2000	322 (liveborn)	22–26	54% liveborn to discharge
Denmark [62]	National	1994–1995	407 (actively treated)	22–27+6 +/– <1 kg	56% actively treated
Norway [23]	National	1999–2000	636 (all births)	22–27+6 or 500–999 g	59% of all births
Finland [56]	National	1996–1997	529 (all births)	22 weeks, <1000 g	55% of all birth including still births
France [54]	National	1997	4395 (all births)	22–32 weeks	85% of all births
UK & Ireland [38]	National	1995	4004 (all births)	20–25+6	39% of admissions
USA [72]	Regional	1995–1996	4438 (all births)	501–1500 g	84% of all births by d28
Australia [34]	Regional	1991–1992	401 (live births)	23–27 weeks	56% of live births to 2 years

20.3.1.3 Geographical Variations

There are notable inter-country and inter-regional variations in overall mortality of extremely preterm infants. Frequent comparisons are made between different regions/countries, but such comparisons can be misleading. Crude perinatal mortality rate used alone will be significantly influenced by the rate of preterm birth [52] which varies considerably between regions within Europe [53]. Despite using mortality specific for preterm infants there will remain major variations which may not be a reflection of true mortality [44]. Table 20.2 highlights major variations in simple crude mortality data. Denominators vary for all infants including those terminated, to those admitted to the neonatal unit for ongoing care following delivery suite resuscitation. Such variations were highlighted by the French EPIPAGE study which showed an overall survival rate of 67% for all births < 32 weeks, but 85% for live births and 89% admitted to intensive care [54]. Mortality will also be influenced by the attitude and approach of staff at the time of delivery [31, 32]. Such proactive delivery suite policies, whilst resulting in low mortality, have not necessarily been associated with increasing burden of short or long-term morbidity [32].

20.3.2 Morbidity

As with mortality the smallest most immature infants are at highest risk of adverse outcome [21, 55, 56]. With the increased rate of survival seen in the 1990s following extremely preterm birth, it was anticipated that a significant increase in survivors with morbidity would be seen. Many authors have shown morbidity in survivors to be static over time rather than increasing, but with the increase in total numbers of survivors the absolute numbers of those with morbidity will undoubtedly have increased [20, 25, 35].

When interpreting the wide range of studies examining morbidity in the preterm infant, one must be cautious with the interpretation of results, as the denominator used clearly will affect the results: the proportion of infants with a particular clinical condition may be a percentage of the total number of infants born, the total number admitted for intensive care and for longer term morbidities may be a percentage of the total survivors.

Morbidity in moderately preterm infants (30–36 weeks) is less than those born most preterm, but as these deliveries occur in much higher numbers than extremely preterm deliveries, absolute numbers are much higher and therefore such infants do impact significantly on neonatal intensive care units. As infants then become more mature towards term, morbidities gradually decrease [42, 57, 58].

20.3.2.1 Lung Disease

Respiratory distress syndrome is a frequent early marker of respiratory morbidity in preterm infants. This may then evolve into chronic respiratory symptoms termed bronchopulmonary dysplasia (BPD) or chronic lung disease (CLD). Definitions of BPD/CLD generally define this as either oxygen dependence at 36 weeks' post menstrual age (PMA) or at 28 days after birth. More recently definitions of BPD have been refined in order to provide more useful information and have been subclassified into mild, moderate and severe BPD [59].

As with mortality and other morbidities the highest rates of respiratory disease are seen in the smallest most immature infants with over 90% of infants < 500g having RDS [55]. As birth weight increases from 500 g to1500 g, reducing rates of RDS are well described [20]. In infants born prior to 28 weeks' gestation rates of RDS range from 80–90% [38, 47, 54].

Whilst such morbidities are seen less frequently in the less premature group (30–36 weeks), they are still seen more frequently in this group as compared to term infants. Rates of respiratory distress in infants born at 34 weeks are 5–6% with a step-wise reduction at each gestational week to a risk of below 1% at term [42]. Within the less mature group aged 30–34 weeks, respiratory distress syndrome again reduces at each gestational age week with rates of > 40% at 30 weeks as compared to < 3% at 34 weeks [57].

The now widespread use of antenatal steroids (ANS) has significantly reduced the risk of the need for respiratory support and respiratory distress syndrome in the premature infant [60]. Postnatal surfactant therapy also improves survival and reduces risk of pneumothorax [36]. Despite this, RDS rates over time are frequently reported as static despite significant

increase in the use of both ANS and surfactant. For example, rates of RDS in 1991 through to 1999 in a large multicenter USA study in infants 501–1500 g were static [36]. In other temporal comparisons of population cohorts, RDS rates have been shown to increase in more recent years [39]. RDS has a wide clinical phenotype and it may be that cases over recent years following the widespread use of ANS and surfactant may be less severe, with fewer infants requiring invasive respiratory support and less associated mortality [36], but this may then result in more BPD [25].

Rates of BPD/CLD across Europe vary somewhat, but in infants born at < 32 weeks the rates range from 10–20% in survivors to discharge [53]. Rates of CLD as high as 74% are reported in the smallest infants with birth weights of 401–500 g [55]. Between 23 and 25 weeks, rates of CLD significantly decrease from 65% at 23 weeks to around 30% at 24 and 25 weeks [19]. If birth weight is used, rates decrease significantly from nearly 50% in those infants 501–750 g to 6% in those infants of birthweight 1251–1500 g. Overall, in this population of infants weighing 501–1500 g, BPD develops in 22% [20].

Of infants born at less than 26 completed weeks in the 2006 UK EPICure cohort, 75% were oxygen dependent at 36 weeks corrected age [40]. Disappointingly, this figure is not significantly different to the previous EPICure cohort from the 1990s [38]. A comparison of two cohorts from the late 1990s and early 2000s also showed little difference in the rates of BPD with rates of just over 50% (< 1 kg, < 28 weeks), despite increased ANS and postnatal surfactant use over the 2 time periods [61]. Some authors have shown rises in rates of BPD despite significant increases in the use of ANS and surfactant [25]. Over recent years the timing of surfactant administration has been optimized, with early prophylactic use in the extremely preterm infant and this optimal practice may be reflected in improvements in respiratory morbidity over coming years. Lack of improvement may also be explained by a different causative pathology as compared with the pre-surfactant era and as such current infants with BPD/CLD have a different pathogenesis and hence disease than those in previous eras. Pathological findings of the "new" BPD have shown fewer and larger alveoli, indicating a possible defect of septation as compared with previous findings of inflammation and fibrosis seen pre surfactant [59].

The choice of ventilatory support may influence rates of subsequent chronic lung disease. A large multicenter study of infants <1 kg and <28 weeks in Denmark showed rates of chronic lung disease of 16% in those infants managed with CPAP and permissive hypercapnia [62]. In the recently published multicenter trial of CPAP *vs* intubation in infants <29 weeks there was no difference in BPD or death in the two groups [63]. BPD may then act as a predictor of other poor outcomes. At 2.5 years those infants with CLD have an odds ratio of > 2 for cerebral palsy [51]. These findings are supported by other studies showing an odds ratio of 2.5 for death or neurosensory impairment at 18 months if BPD is present at 26 weeks corrected gestational age [64].

20.3.2.2 Brain Pathology

Early neurodevelopmental morbidity can arguably be monitored by rates of intraventricular hemorrhage (IVH) and/or cystic periventricular leukomalacia (PVL) detected on cranial ultrasound scan (CUSS). The incidence of CUSS abnormalities vary significantly between countries and within regions of Europe [53]. Some variation will be seen as a result of user variability differences in the denominator; higher rates being seen in non-surviving infants [65]. In those infants with more severe IVH, intra-observer variability has been shown to be less when compared with minor abnormalities [66]. This intra-observer variability in the more minor abnormalities may explain some of the increases in less severe IVH described recently by some authors [25]. Modern equipment with higher resolution may also influence detection rates of minor IVH detection.

Following improved perinatal care in recent decades and specifically the widespread introduction of antenatal steroids, a reduction in the rates of IVH has been reported [36, 65, 67]. Other reports show static rates of IVH over time [35, 40, 56, 61] or possibly a trend towards a higher incidence of less serious IVH [25]. However, whilst antenatal corticosteroids may reduce the risk of IVH, subsequent neurodevelopmental outcome may not be affected [37]. Other authors describe a neuroprotective effect of ANS, with a protective effect against more severe motor disability at 2.5 years [51].

Within Europe the rate of severe IVH/cystic PVL in preterm infants (< 32 weeks) varies widely from 2.6% to 10% [53]. Comparisons of individual data sets can be difficult as definitions of abnormality and inclusion criteria vary. Data from 2008 in the UK shows a 15% rate of abnormal CUSS in survivors born at 26 weeks or less, which is unchanged from 1995 [38, 40]. Multicenter French data for infants born < 32 weeks reported a rate of 3% for IVH with dilatation, rising to 20% for minor IVH without dilatation and 21% for any white matter damage including both those with the most severe cystic PVL and those with minor persisting echodensities [68]. Comparable multicenter data from Belgium showed that 11% of infants < 27 weeks had major IVH, 25% had a minor IVH and 10% cystic PVL [47]. Multicenter data from Denmark showed a comparable figure for severe IVH/PVL in survivors < 28 weeks [62].

In keeping with all morbidities associated with extreme prematurity, rates of IVH/PVL increase with decreasing gestational age. Those at the limits of viability with the lowest birth weights are most affected, with rates of IVH/PVL as high as 84% at 23 weeks [19]. Other series report rates of white matter damage (WMD) of 37% at 23/24 weeks decreasing to 17% at 30 weeks. Minor IVH shows a similar trend with a rate of 40% at 23/24 weeks decreasing to 22% at 30 weeks. Between 30 and 34 weeks there is a statistically significant decreasing trend for IVH/PVL. In those more mature preterm infants, IVH is < 1% (all grades) in 34–36 week infants, but still significantly greater than the rate seen in term infants [41].

The effect of early abnormalities seen on cranial ultrasound scan on long-term neurodevelopmental outcome is variable. Abnormal last CUSS in the large EPICure 1 cohort gave an odds ratio of 4.95 for cerebral palsy. However this was not a sensitive marker of long-term disability with less than 50% of infants with cerebral palsy at 2.5 years having white matter changes on cranial ultrasound scan on the neonatal unit [51]. However a significantly abnormal final cranial ultrasound scan independently increased the risk of cerebral palsy [51]. Follow-up of the large multicenter French cohort showed that 25% of those with white matter damage on CUSS had cerebral palsy at 2 years versus 4% of those with a normal CUSS. One third of children with cerebral palsy had a normal CUSS [69].

20.3.3 Longer-Term Outcome

Neurological and developmental morbidity data from discharge up into later childhood and adulthood is now available from some of the large multicenter studies. The large UK EPICure cohort (22–25 completed weeks) showed rates of severe disability at 2.5 years of 23% with an additional 25% having some disability including abnormalities of sensory and communication function, mental and psychomotor development. Nineteen percent of these infants born at 25 completed weeks or less had cerebral palsy at 2.5 years [51]. Lower rates of cerebral palsy of 8% are seen at 2 years in a large French cohort, however, this cohort included infants up to a gestational age of 32 weeks [69].

At 5 years, 9% of children born very preterm in the large cohort reported from France had cerebral palsy, 39% had some disability with 5% being classified as severe, 9% moderate and 25% minor. Not surprisingly the risk of disability was highest in the 24–28 week group but absolute numbers were greater in the more mature infants up to 32 weeks [70]. In keeping with these findings, the risk of disability at 5 years in the less premature infants (30–34 weeks) reduces with a rate of 6% for cerebral palsy in infants born at 30 weeks and further decreasing significantly to < 1% in babies born at 34 weeks [57].

Significant long-term neurodevelopmental effects of prematurity have been described well into adulthood. A large population based study of babies born at less than 27 weeks had a relative risk of 10.3 for mental retardation when compared to their contemporaries born at term. The same group had a relative risk of 7.5 of receiving a disability pension when compared with those born at term [71]. In addition, the gestational age of adults in this large population study was associated with their educational attainment, income and receipt of social security benefits. Those born preterm achieved a lower educational level, income and were significantly more likely to be in receipt of social security benefits. These findings highlight the pervasive effects of prematurity well in adulthood.

20.3.3.1 Visual Disorders

Retinopathy of prematurity (ROP) is frequently used as a marker for morbidity in the high risk preterm infant. It can be challenging to report comparable figures as studies report different outcomes including all ROP, severe ROP only or treatment for ROP. As infants become more mature rates of ROP reduce gradually with infants of higher gestations being very unlikely to need treatment for ROP [40, 47, 56]. In infants born at less than 29 weeks almost one third had some ROP with 14% requiring treatment for this 23. Other studies of infants <27 weeks reported 20% requiring treatment for ROP [47]. In the smallest most preterm infants (401–500 g) rates of ROP reach as high as 89% with one thirds of all infants in this cohort having severe ROP. Treatment for ROP in the 2 Epicure cohorts (1995 versus 2006) showed a significant increase from 13 to 21%, but it is likely that this increase represents a lower threshold for treatment rather than a true increase in morbidity [38, 40]. When ROP is combined with two other morbidities, BPD and brain injury, not surprisingly the three together were strongly predictive of death or neurosensory impairment at 18 months [64].

20.3.3.2 Other Outcome Measures

Significant additional morbidity is seen in preterm infants influencing both their short- and long-term clinical course and outcome. Necrotising enterocolitis (NEC) continues to be a significant risk to the extremely preterm infant and a source of significant mortality and short- and long-term morbidity. Some temporal comparisons have shown a slight but insignificant decrease in rates of NEC over time [35, 56], but generally rates remain static at between 5 and 10% for extremely preterm infants [20, 25, 36]. The highest rates tend to be seen in the smallest infants [72] and decrease with increasing maturity to rates of less than 0.1% at 34 weeks, but such rates remain significantly higher than those seen in term infants [42].

Sepsis in the preterm also continues to be a significant source of morbidity and mortality. Early onset sepsis is seen in up to 15% of infants born extremely preterm [20, 47] with a mortality of 37% in these infants as compared with 13% in those infants in the cohort without early onset sepsis [20]. Some authors have suggested an increase in sepsis in such infants over time [35], but late onset sepsis appears to have remained static over time with rates of around 20% for infants 501–1500 g [20]. The smallest preterm infants (401–500 g) had very high rates of sepsis, with over half having at least one episode and late sepsis reported in one quarter [55]. Again, as with other morbidities those less premature infants whilst at less risk of sepsis than their extremely preterm counterparts are at greater risk than their term equivalents, with rates at 34 weeks of 0.5% versus 0.1% at term [42]. Episodes of sepsis can then be subsequently associated with other morbidities, for example early sepsis has been shown to increase the risk of IVH [67] and chronic lung disease [62].

Cerebral Plasticity and Functional Reorganization in Children with Congenital Brain Lesions

Giovanni Cioni, Andrea Guzzetta and Giulia D'Acunto

21.1 Introduction

Cerebral plasticity plays an important role during brain development. For example, children learn a new language or achieve complex skills, such as playing a musical instrument, faster than adults. In a classic experiment on string players, the extent of the cortical representation of the left digits was found to be inversely correlated with the age at which the person had begun to play, indicating a larger amount of cerebral plasticity in subjects with earlier exposure to training [1]. Similarly, children lacking proper environmental inputs early in life are more likely to have abnormal development of the functions related to those inputs (the concept of critical periods) [2].

The presence of mechanisms for neuronal plasticity during early phases of development should mean that recovery from brain damage is better for early lesions compared to similar lesions acquired later in life. This principle was first suggested by Paul Broca in 1865 [3] and then systematically explored by Margaret Kennard in the late 1930s [4]. Since then, studies carried out in different species have not refuted this general principle. The picture appears, however, to be more complex. Account needs to be taken of factors other than the timing of the insult; these include the location and extent of injury (e.g., focal or diffuse), the clinical correlates (e.g., presence of seizures), and the genetic susceptibility of the subject [5].

One of the most important predictors of the efficacy of functional reorganization seems to be the distribution of the damage, i.e., whether diffuse or focal [6, 7]. Strikingly, children with early unilateral left hemisphere damage may develop normal language, while lesions at a similar site and of similar extent in the adult brain result in aphasia [8]. Even if an entire hemisphere is removed at an early stage of development (for instance for the treatment of severe epilepsy), children can develop normal language and cognitive function [9]. Also, children with unilateral ischemic stroke are able to develop normal cognitive functions, which they maintain over time [10].

By contrast, children who sustain an early generalized cerebral insult (e.g., global hypoxia or traumatic brain injury) recover slower with a poorer outcome, compared to adults with similar lesions [11]. The mechanism most often invoked for this greater vulnerability to early damage is that, at an early stage, cognitive development is highly dependent on the integrity of diffuse neural networks; thus the transient disruption of developing attention, memory, and learning functions undermines the effective acquisition of new abilities [7]. Conversely, at an older age, cognitive abilities, which have already been acquired, may be spared and impairment is limited to functions directly related to the final area of damage.

The aim of this chapter is to outline recent discoveries relating to mechanisms of functional reorganization in the young brain, in view of future possible non-pharmacological therapeutic interventions.

21.2 How Early is Early?

The time boundaries of early brain damage have never been clearly defined. This is due to the complexity of the task rather than to lack of effort. Cerebral plasticity, which influences the effects of brain damage, has a gradual effect during development and vulnerable periods are now known to be different for the various functional sub-systems [2]. The types of brain insults vary during development and affect the nervous system in ways that depend on the level of maturity at the time they occur. The boundaries between early and late lesions are therefore necessarily fuzzy. This chapter explores the differences of the young brain's response to damage and focuses on lesions occurring before or around birth (also called congenital lesions), which are more frequent and have been more extensively studied than later ones.

A relevant aspect of the pathophysiology of congenital brain injury is the stage of cerebral development at the time of

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

the insult, which may be either prenatal or perinatal. Because of the complexity and speed of maturation during pregnancy, the response to a harmful event varies with gestational age with different neuropathological and clinical outcomes. Our understanding has been enhanced by non-invasive neuroimaging techniques, first ultrasonography, and, more recently, computerised tomography (CT) and magnetic resonance imaging (MRI). These new methods, increasingly applied to children, allow *in vivo* investigation of cerebral lesions by monitoring their evolution and providing further insight about the relationship between lesion and its effect on function.

In broad terms, types of congenital brain damage can be grouped according to timing (Fig. 21.1). Lesions occurring during the first half of gestation (and in particular the first trimester) give rise to cortical malformations. These lesions can vary in size, location and distribution, resulting in different clinical pictures. The underlying mechanisms of cerebral plasticity are likely to be similarly variable. The second group of lesions are those occurring around the early third trimester of gestation (approx. 25–34 weeks of gestation). The most typical of this group are periventricular leukomalacia and intra-ventricular hemorrhage. The first is a diffuse lesion due to ischemia or infection-inflammation, while the second is a hemorrhagic lesion, usually limited to within the ventricles, but sometimes developing into a periventricular parenchymal infarction, usually unilateral. The third group includes lesions around term (typically lesions affecting the term infant at around birth). The most relevant are hypoxic-ischemic encephalopathy (HIE) and focal cerebral stroke. HIE is a bilateral and diffuse ischemic lesion, while a stroke is a focal lesion of arterial origin, with similar neuropathology to the stroke observed in adults.

The distribution of the lesion, i.e., focal unilateral compared with diffuse bilateral, appears to be the single most important factor that influences the effectiveness of the plastic reorganization of brain function. Congenital lesions therefore provide an interesting model for studying cerebral reorganization because they include different combinations of distribution (focal, diffuse) and timing (early gestation, late gestation and term).

21.3 Cerebral Plasticity and the Different Systems

The effects of a cerebral lesion are related to the site of the lesion. This implies different involvement of the various systems in different subjects, with complex and heterogeneous functional correlates. Although subjects with cerebral damage that is acquired early show a clinical phenotype consisting of impairment of language, sensori-motor and visual systems, we will consider each system independently, focusing on cerebral plasticity and differentiating the effects of early and late lesions.

21.3.1 Language

Language processing generally (i.e., in 95% and 98% of adults) occurs in the left hemisphere of the brain. How this special ability develops, its nature and what happens when the left hemisphere is damaged by a cerebral injury during early development are still matters of debate. More than 30 years ago, invasive techniques such as the Wada test demonstrated that language developed in the right hemisphere of patients with early left hemispheric brain lesions [12]. How this happens and the consequences for brain function are starting to be clarified by the application of advanced functional neuroimaging techniques, such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI).

An important aspect relates to where (and indirectly how) in the right hemisphere language function is organized. In 2002, Martin Staudt and coworkers used fMRI and a language task to explore the topography of right-hemispheric language organization after early left brain injury by unilateral periventricular lesions. They showed a remarkable similarity between activation in the left hemisphere in normal controls and activation in the right hemisphere in brain injured patients, with identical distribution of the known cortical areas of the language circuit [13]. These findings indicated that reorganization of language in the right hemisphere occurs in areas that are homotopic (i.e., in the same location) to those

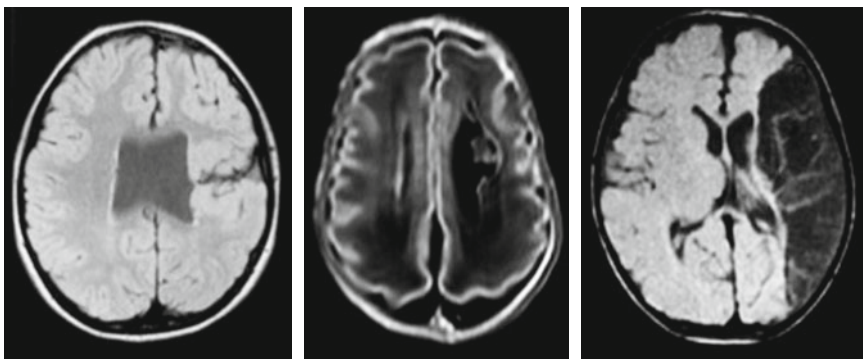

Fig. 21.1 Correlation between timing of insult and type of brain injury. Three examples are shown of typical congenital brain lesions on MRI; the correlation between timing and characteristics of the lesion are clear. In the *left column*, a case of schizencephalia, a malformation of cortical development secondary to an insult acquired during the early phases of brain development. In the *central column*, a case of periventricular white matter injury, secondary to an intraventricular hemorrhage, occurred at the beginning of the third trimester of gestation. In the right column, a case of ischemic infarction in the territory of the middle cerebral artery, occurred around birth in an infant born at term

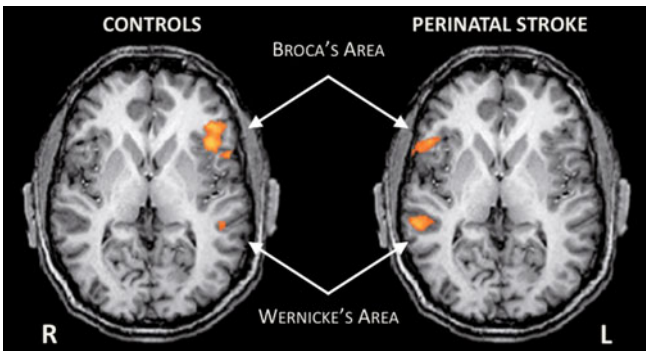

Fig. 21.2 Language representation in patients with left perinatal stroke and right hemispheric reorganization of language. fMRI shows the activation of regions in the right hemisphere which are contralateral and homotopic to the regions of the language area, activated in normal controls (a group analysis was performed on 8 patients and 10 controls). Data from [16]

normally involved, strongly suggesting a near-equipotentiality of the two hemispheres at birth as far as the ability to develop language control is concerned.

Similar findings were found in patients with malformations of cortical development [14, 15]. In those subjects, however, epileptic seizures, which are known to alter cerebral reorganization, were almost invariably present. This made it hard to explore whether shifting language processing could also happen in the absence of seizures and/or with later damage (early third trimester). More recently, Guzzetta et al demonstrated a similar pattern of contralateral homotopic reorganization in patients with arterial stroke at term (Fig. 21.2) [16]. The study also showed that a shift of language function after a stroke at term is more common than for earlier lesions, suggesting a direct influence of timing on the pattern of reorganization. If this pattern is confirmed, it might suggest that, as for other systems (see below), the hemispheric specialization of language develops because of competition between the two hemispheres. If a left (non-epileptogenic) lesion occurs during the early third trimester when cerebral plasticity is highly active, the affected hemisphere is more likely to maintain its genetic advantage over the contralateral hemisphere and eventually develop control over language. When a left lesion occurs at term or during early development when the potential for plasticity is reduced, the non-affected hemisphere might take over language development. This possibility becomes progressively less available during later development, with later lesions invariably resulting in an intra-hemispheric reorganization of function and different degrees of language disturbance.

21.3.2 The Sensori-Motor (SM) System

When a cerebral cortical or subcortical lesion involves the motor system, neuroplastic mechanisms should be able to drive recovery of voluntary movements, restoring an adequate cortical impulse to the spinal motor neurons and inter-neurons. In the case of a cerebral lesion, two major mechanisms are available for restoring an efficient re-connection of the motor cortex with the spinal cord. The first involves reorganisation of the ipsilateral cortex within the primary motor cortex or in non-primary motor areas. The second mechanism is specific for lesions during early development. It is based on the existence of bilateral motor projections originating in the primary motor areas during the first weeks of life post-term; these connect each hemisphere with both sides of the body. These fibres withdraw during later development, but may persist in the case of cerebral damage, giving rise to a contralesional reorganization of motor function, but this mechanism is limited to early brain damage (Fig. 21.3).

fMRI is able to provide relevant information on the type of reorganization occurring in each patient. Integration with other techniques to provide temporal resolution, such as Transcranial Magnetic Stimulation (TMS), demonstrates the existence of cortical-spinal monosynaptic connections. TMS has shown that in subjects with early lesions of the motor cortex, there is significant bilateral corticospinal innervation of spinal motoneuron pools and that these persist in the healthy hemisphere. In these subjects, activation of the intact motor cortex elicits large responses in both ipsi- and contra- lateral muscles, with similar latencies and thresholds.

But what are the consequences of having found this specific type of motor reorganization after early damage? It appears that this pattern of SM reorganization (contralesional reorganization) is determined during the first year of life, and possibly even within the first few months [17]. This is not only a consequence of the size and site of the lesion, but is strongly influenced by what happens after damage (action

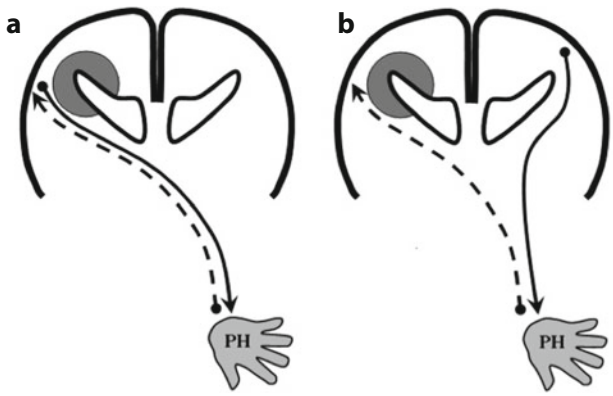

Fig. 21.3 Main types of reorganization of sensori-motor function following early brain damage. **a** Ipsi-lesional reorganization of motor and sensory function. Both functions are reorganized in the affected hemisphere, in regions around the lesion. In this case, functional impairment was mainly related to the extent of damage to the sensori-motor system. **b** Contra-lesional reorganization of motor function and ipsi-lesional reorganization of sensory function. Motor and sensory functions of the affected limb are processed by different hemispheres. In this case, functional impairment is related not only to the extent to which the sensori-motor system has been damaged, but also to the presence of a functional dissociation

dependent reorganization): there is a complex interaction between the residual motor output from the affected hemisphere and a somato-sensory feedback from the affected limb – the hypothesis has been called "amblyopia of the corticospinal system" [17]. Confirmation of this hypothesis would emphasise the importance of an early time window (the first months of life) for therapeutic intervention. This is especially true when considering that children with contra-lesional reorganization, i.e., when the unaffected hemisphere directly controlling both hands, achieve less good hand-motor performance, making this pattern of reorganization potentially maladaptive [18, 19].

Cerebral lesions affecting the motor system often involve the sensory system as well, and may lead to a functional deficit. These functions can be studied *in vivo* with techniques like somato-sensory evoked potentials, magnetoencephalography and fMRI with sensory stimulation. These approaches have demonstrated that, by contrast with the motor system, the intra-hemispheric (ipsilesional) reorganization of primary sensory function is the principal, if not the only, compensatory mechanism for brain damage of the sensory system, even when this occurs very early during development [19].

The mechanisms underlying this phenomenon are not fully understood. However, two elements seem to be of special relevance. The first is the lack of an anatomical substrate for contralesional reorganization, even during the early stages of development, in contrast to what happens to the motor system. The second is the possibility that at least for some types of early lesions, thalamo-cortical fibres are still developing when the insult occurs, thus allowing a bypass of the lesion and reconnection with the sensory cortex [20].

It is of considerable interest that the different reorganizational potentials of the sensory and the motor systems often result in an inter-hemispheric dissociation of these functions, with the sensory system being reorganised in the affected hemisphere and the motor system being shifted contralaterally (Fig. 21.3b). There is some evidence to support the hypothesis that such a dissociation could lead to functional deficits in tasks requiring good sensory-motor integration (such as stereognosia). In light of these findings, a specific target of early therapeutic intervention might be activation of the sensori-motor cortex of the affected hemisphere to enhance the competitive ability of a damaged corticospinal system during development and, by so doing, to mitigate the consequences of injury on motor function.

21.3.3 The Visual System

There have been few investigations of reorganization of the visual system after early lesions in humans. However, visual function has been more studied in animals, especially the cat, than any other system. The sparse scientific evidence from humans on the specificity of reorganizational mechanisms after early damage is summarized below (Fig. 21.4).

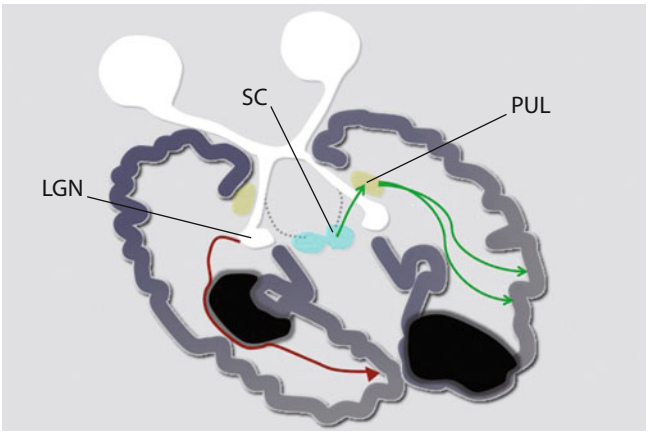

Fig. 21.4 Main types of reorganization of visual function following early brain damage. On the left, a possible type of reorganization following early damage of the optic radiations. The thalamo-cortical connections are able to bypass the lesion and reach the final cortical target (primary visual cortex). A full recovery of conscious vision can be achieved. On the right, the reorganization mechanisms following early damage to the primary visual cortex. Circuits connecting the retina with extrastriatal visual structures are expanded, in particular involving the superior colliculus and the pulvinar. A full recovery of conscious vison cannot be achieved, but a high degree of functional compensation is obtained, consisting of near normal exploratory visual behaviour and navigation. *LGN* Lateral Geniculate Nucleus, *SC* Superior Colliculus, *PUL* Pulvinar

The correlation between damage to the optic radiations or the occipital cortex and the corresponding visual field deficit is far less strong in the case of an early lesion than for a lesion occurring later in life. This might be a direct expression of greater cerebral plasticity in the young child. It may, at least in part, have a similar neurophysiological basis to that observed for the somato-sensory system; in particular there is a possibility that thalamo-cortical fibres develop after the injury and so bypass it. The precise characteristics and limits for plasticity involving thalamo-cortical connections are not fully understood. Some data suggest that up to term, structural modifications of the geniculo-striate pathway enable functional reorganization of the visual system. A combination of fMRI and diffusion tensor tractography was used in a recent longitudinal study of an infant with a perinatal left arterial stroke [21, 22]. The stroke spared the primary visual cortex but involved the optic radiations. At 3 months, cortical activation could only be observed in the unaffected side; diffusion tensor imaging (DTI) was unable to show the presence of optical radiations in the affected hemisphere. At 20 months, the infant was re-tested using the same protocol and surprisingly showed definite fMRI activation, an indirect sign of functional reorganization. This was further supported by clear structural modifications on diffusion tractography [22]. Unfortunately, assessment of visual fields could not be performed because of the subject's young age. However, regardless of the possible presence of functional impairment, the imaging data seem to support the existence of a process of reorganization at the level of the thalamocortical pathway, and an ability to restore at least

partially a functional connection between the lateral geniculate body and the occipital cortex.

Even when there is a visual field deficit, patients with early damage seem to have fewer difficulties in environmental navigation and exploration. These data are in line with findings from animal models, which showed clearly that ablation of the whole primary visual cortex in the newborn animal did not affect visual orientation, which, by contrast, was massively impaired after a similar lesion in adult animals. Studies on cats showed that this phenomenon is linked to reorganization of the pathways connecting subcortical visual structures (the lateral geniculate nucleus, superior colliculus and pulvinar) directly to the extrastriatal ipsi- and contra- lateral visual centers [23]. This could also apply to humans in some certain degree, as shown, for example, by increased activation on fMRI of extrastriatal structures after stimulation of the affected hemifield. Reorganization of visual function appears to be more effective after early brain damage. This may be due either to reconnection with targeted structures or to the use of compensating circuits. Even if such circuits are not able to restore conscious visual perception on the contralesional hemifield, they seem to allow for good compensation in spatial orientation and localisation. These conclusions are being confirmed by a study in progress at the Stella Maris Scientific Institute; this is aimed at demonstrating how, in a visual search task, congenital hemianopic subjects perform normally, whereas patients with acquired hemianopia are significantly compromised.

21.4 Conclusions

How can we summarize present knowledge on cerebral plasticity and reorganization following early brain damage? The emerging concept, based on studies on both human and non-human subjects, is that functional reorganization in children is similar to that in adults, but there are differences. An understanding of the specific mechanisms of cerebral plasticity in infancy is far from complete. Such knowledge will, however, be essential for the definition and development of therapies based on sound neurobiological and neurophysiological principles. Information is needed about not only the type of treatment, but also its timing, dosage, and means of administration. Brain mapping techniques, and in particular fMRI, have provided answers to many questions. Implementations of other technologies, for example Ultra High Field MRI tomography, will doubtless provide further insights.

Organization of Perinatal Care

Neil Marlow

22.1 Overview

Medical and nursing care for the newborn is organized differently in different health systems. Whereas general support in terms of screening and routine care is provided for a large number of babies in a maternity setting, neonatal intensive care for sick and immature babies is a low throughput high cost service. The development of neonatal intensive care has undoubtedly been one of the success stories of modern medicine. Its rapid evolution since the early 1970s has led to dramatic changes in mortality at low gestational ages and a reduction in immediate and later morbidities. Nonetheless, babies born at "borderline viability" (gestations with >50% mortality) have consistently demonstrated a very high morbidity rate, even though the "borderline" gestational age is reduced and currently sits at around 23–25 weeks in most developed countries.

The extent to which different models of organization of neonatal services have contributed to this is hotly debated. Services evolve as the technical aspects of care change and are rarely planned on a geographic basis. However, there is a general agreement that a sick neonate needs to be treated in a specialist neonatal unit. Thus, a neonatal transport system must be a basic element for any regional program that aims at reducing morbidity and mortality (see Chapter 24).

Organization is very dependent on how the healthcare system is financed and managed and on the regulatory framework of a particular country. In this chapter we describe the recent changes in organization within the United Kingdom healthcare system to illustrate the thinking and evidence base on which service changes may be planned and from which the reader may derive concepts relevant to their own local health system.

Briefly, in the UK, healthcare is organized independently in each of the four constituent countries. Within the UK, the majority of births occur in hospital (approximately 600,000 out of 680,000 annually) and healthcare is organized under the auspices of the National Health Service. The NHS is regionalized into 12 Strategic Health Authorities and they are responsible for "purchasing" health services for their population from Hospital and Primary Care Trusts (the "providers"). Low volume services such as neonatal intensive care are "commissioned" (purchased or contracted) centrally.

Neonatal care is delivered in maternity hospital settings within the UK, except for highly specialist areas, for example such as cardiac surgery. Over recent years, hospitals have become increasingly focused on the areas of neonatal care they undertake based around a three tier model, where some units provide only basic non-invasive care, some more invasive care (usually including short periods of intensive care) and other hospitals provide a full neonatal intensive care service; more specialist services – surgery, extracorporeal membrane oxygenation, cardiac surgery – are provided in only a few centers around England to optimize efficiency and maximize quality outcomes.

22.2 Models of Care

Neonatal care cannot take place in isolation from other services. In particular pediatric, obstetric and fetal medicine services are interdependent so it makes sense that these are co-located. In many non-UK systems, however, neonatal intensive care takes place within a children's hospital setting, which has implications for family integrity and support but may provide optimal support for the highly technical aspects of care and management. In contrast there are increasing moves in some countries to enhance the concept of family-centered care by co-locating maternal and neonatal care for mother and child in the same area. This model does allow for some separation for the periods of necessary intensive care but optimizes the family experience and is designed to minimize psychological morbidity. Neonatal care should be

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

organized in a manner appropriate to the societal setting and resources available.

The issue of centralized versus dispersed services has been the subject of much debate. Apart from research carried out in the UK [1], studies in other health systems have seen advantages in terms of mortality and morbidity where services are centralized to provide care for the sickest and smallest infants in large "tertiary" units [2]. It has been suggested that the reason that this has not been shown in England relates to under-capacity within the large neonatal services [3, 4], as there is evidence that mortality is related to the number of nurses available each shift [5].

To address this problem we have developed a series of "managed clinical networks" of neonatal care. A managed clinical network may be defined as linked groups of health professionals and organizations from primary, secondary and tertiary care working in a coordinated manner to ensure equitable provision of high-quality clinically effective services, unconstrained by existing professional and Health Board boundaries. Further description of the roles and responsibilities of Managed Neonatal Networks is available [2], but in essence all hospitals serving a population agree to work together to deliver the whole range of care. Where possible this is carried out as close to the mother's area of residence but where specialist care (i.e., intensive care) is required then the mother and baby are transferred to the appropriate centre. This way hospitals that provide different levels of care act together to make sure that the baby and family are appropriately supported. To date these networks of care are variously effective but recent developments have been undertaken to formalize their function [6].

22.3 Care of High-Risk Newborn Infants

Within a neonatal service a range of areas require planning and monitoring:

- antenatal counseling and support
- delivery room care and resuscitation
- screening and acute care following "normal" births
- care in the neonatal unit
- discharge care and support
- follow-up of at-risk children.

22.3.1 Antenatal Counseling and Support

Central to good perinatal care is the availability of neonatal staff to discuss forthcoming deliveries with women and their partners. This is a key role for the neonatologist and the neonatal nurse. Discussions may simply include information about the process of birth for an at-risk child and a pre-delivery visit to the neonatal unit. In other situations the neonatologist must be involved in discussions of prognosis where delivery is anticipated very prematurely or where fetal anomaly has been detected and on occasions must be part of the decision-making process as to where a baby is best delivered to receive optimal care. Most fetal medicine services now involve the relevant pediatric specialist, where a fetal problem has been identified to help develop a delivery plan, but of equal importance is the neonatal team who will often have a different perspective on the early management of the baby, which may alter the initial proposal.

22.3.2 Delivery Room Care and Resuscitation

Neonatal staff are usually responsible for the organization and training of all obstetric, midwifery and neonatal staff in neonatal stabilization and resuscitation. In most countries formalized training is available through nationally accredited neonatal life support courses and all staff that are likely to be involved in neonatal stabilization should be properly accredited [7, 8]. Clear written arrangements for checking that resuscitation apparatus is always available and for calling appropriate staff when necessary should be agreed. Management plans where comfort or palliative care is anticipated need to be agreed and, given the ethical difficulties that surround, in particular, birth at extremely low gestations each neonatal unit should agree with their obstetric and midwifery colleagues a policy for communicating risk to prospective parents facing such deliveries.

22.3.3 Screening and Acute Care Following "Normal" Births

Within our health system the neonatologist is responsible for carrying out a screening examination for the newborn baby and troubleshooting where the midwife has identified potential postnatal problems. This involves identifying babies who are at high risk of particular conditions such as neonatal infection, hip dysplasia, and congenital heart disease. Screening for metabolic disease is also undertaken in most countries.

In most hospitals the screening examination is delegated to trainees or to specifically trained midwifery staff, although in some settings it may be undertaken by the family pediatrician. A single neonatal examination is usually sufficient to identify major anomalies, although problems, which become apparent later in the neonatal period such as duct or pressure dependent congenital heart disease and jaundice, may need separate assessments [9]. Screening with saturation monitors for heart disease may enhance the detection rate of screening examinations [10]. Hospitals need to ensure that they have a range of protocols for treating babies at risk of infection [11] and babies who develop new problems after birth [12].

22.3.4 Care in the Neonatal Unit

22.3.4.1 Designation of Neonatal Care and Services

Neonatal units have a range of service available to them that differ from hospital to hospital. Often the quanta of care that is provided depend upon staffing levels and co-located facilities. In many countries a three level system operates formally or informally with a fourth level designating those hospitals which provide "super-specialist" care such as cardiac surgery, neonatal surgery etc. The detail will vary from one health system to another. The British Association of Perinatal Medicine (BAPM) grading [13] is shown in Table 22.1.

Within these designations it is important that we define what activity occurs within each service. Again these definitions will vary widely between health systems. The BAPM definitions of normal, special, high dependency and intensive care are shown in Table 22.2. One of the key features about the use of definitions such as these is that they dictate the level of support required by the baby and that this is independent of the setting in which the care is delivered. For example if a baby required intensive care whilst awaiting transfer to a neonatal unit, the referring hospital should be able to provide the equipment and manpower immediately available to cope with the baby's needs. This may cause problems in that if the staff are needed for an emergency elsewhere in the hospital; other staff members should be available to deal with that leaving experienced staff to care for the baby who needs intensive care. Similarly, often babies who fall into the category "special care" are cared for alongside their mothers. This requires enhanced nursing support but may occur outside the confines of a neonatal unit. Sometimes this is known as "transitional care". Neonatal units have used transitional care as a means of enhancing the care they give (promoting mother-baby contact) and also of enhancing the capacity of their neonatal unit, but need extra resources to do it properly. In our system the nursing requirements also follow the care category as indicated in Table 22.2. Because staff costs are the greater proportion of total unit costs this allows re-imbursement to be made for care on a bed day basis.

Table 22.1 Designation of neonatal services within a neonatal network

Level 1 or *Special Care Units* – provide special care but do not aim to provide any continuing high dependency or intensive care; this includes units with or without resident medical staff
Level 2 or *Local Neonatal Units* – provide high dependency care and some short-term intensive care as agreed within the network; medical staffing at middle grade and consultant level is shared with a general pediatric service
Level 3 or *Neonatal Intensive Care Units* – provide the whole range of medical neonatal care but not necessarily all specialist services such as neonatal surgery; medical staffing at all grades is dedicated to the neonatal service

Adapted from [13].

Table 22.2 Definitions of categories of neonatal care

Intensive care

These babies have the most complex problems. They need 1:1 care by a nurse with a neonatal qualification. The possibility of acute deterioration is such that there should be the constant availability of a competent doctor.

1. Receiving any respiratory support via a tracheal tube and in the first 24 hours after its withdrawal
2. Receiving NCPAP for any part of the day and less than five days old
3. Below 1000 g current weight and receiving NCPAP for any part of the day and for 24 hours after withdrawal
4. Less than 29 weeks gestational age and less than 48 hours old
5. Requiring major emergency surgery, for the pre-operative period and post-operatively for 24 hours
6. Requiring complex clinical procedures:
   - Full exchange transfusion
   - Peritoneal dialysis
   - Infusion of an inotrope, pulmonary vasodilator or prostaglandin and for 24 hours afterwards
7. Any other very unstable baby considered by the nurse-in-charge to need 1:1 nursing: *for audit, a register should be kept of the clinical details of babies recorded in this category*
8. A baby on the day of death

High dependency care

A nurse should not be responsible for the care of more than two babies in this category

1. Receiving NCPAP for any part of the day and not fulfilling any of the criteria for intensive care
2. Below 1000 g current weight and not fulfilling any of the criteria for intensive care
3. Receiving parenteral nutrition
4. Having convulsions
5. Receiving oxygen therapy and below 1500 g current weight
6. Requiring treatment for neonatal abstinence syndrome
7. Requiring specified procedures that do not fulfill any criteria for intensive care:
   - Care of an intra-arterial catheter or chest drain
   - Partial exchange transfusion
   - Tracheostomy care until supervised by a parent
8. Requiring frequent stimulation for severe apnea

Special care

A nurse should not be responsible for the care of more than four babies receiving Special or Normal Care

- Special care is provided for all other babies who could not reasonably be expected to be looked after at home by their mother

Routine care

- Is provided for babies who themselves have no medical indication to be in hospital

Adapted from [13].

22.3.4.2 Family-Centered Neonatal Care

Traditionally parents were observers whilst medical and nursing experts assumed responsibility for care. Indeed many units were designed with viewing galleries or corridors to prevent contact. With the advent of more enlightened views of the role

Table 22.3 Examples of family-friendly standards for NICU

1. Where admission to a neonatal unit is predicted, a pre-natal opportunity to visit the neonatal unit and meet key personnel should be offered to the family
2. All parents should be introduced to facilities, routines, staff and equipment on admission to a neonatal unit
3. Every parent should have unrestricted access to his or her baby, unless individual restrictions can be justified in the baby's best interest
4. Parents should be encouraged and supported to participate in decision-making about the care and treatment of their baby. Written and regularly updated care plans should be shared with parents. Clinical care decisions, including end of life decisions, should be made by experienced staff in partnership with the parents and discussions held in an appropriate setting
5. Parents are encouraged and supported to participate in their baby's care at the earliest opportunity, including:
   - Regular skin to skin care
   - Providing comforting touch, comfort holding, particularly during painful procedures
   - Feeding
   - Day-to-day care, such as nappy changing
6. Every baby should be treated with dignity and respect:
   - Appropriate positioning is promoted and encouraged
   - Clinical interventions are managed to minimize stress, avoid pain and conserve energy
   - Noise and light levels are managed to minimize stress
   - Appropriate clothing is used at all times, taking into account parents' choice
   - Privacy is respected and promoted as appropriate to the baby's condition
7. Every parent will have the opportunity to discuss their baby's diagnoses and care with a senior clinician within 24 hours following admission or a significant change in condition.
8. Written information should be available (in languages and formats appropriate to the local community) to all users of the service on medical and surgical treatments, to permit early and effective communication with parents covering at least:
   - Condition/diagnosis
   - Treatment options available
   - Likely outcomes/benefits of treatment
   - Possible complications/risks
   - Possible tests and investigations
   - Who to contact with queries or for advice
   - Where to go for further information, including useful websites
   - Circumstances requiring consent (written and verbal)
9. Maternity and neonatal services should encourage breastfeeding and the expression of milk through the provision of information and dedicated support, including:
   - whenever possible, initiation of breast feeding as soon as possible after birth
   - when necessary, support to start expression as soon after delivery as the mother's condition allows to maximize the benefit of colostrum
   - the availability of a comfortable, dedicated and discrete area
   - the facility to express discretely at the cotside
   - the availability of breast pumps and associated equipment for every mother who requires them
   - supporting breastfeeding as part of the discharge process
   - promotion of safe and hygienic handling and storage of breast milk
   - possible availability of donor breast milk

Adapted from [11] and [14].

of the parent in enhancing the baby's progress through the neonatal period, parents are now welcomed into the neonatal unit and encouraged to participate in their child's care. The advantages of this in engendering better psychological support for parents are clear and there is evidence that skin-to-skin contact is of great importance in promoting infant stability and well-being. Encouraging close parental involvement in their child's care demands organizational changes in the way neonatal services are run, the facilities available for parents such as sitting rooms and overnight bedrooms, and for privacy when they are with their child [6]. Some units have developed the concept of single cubicle care to accommodate this more appropriately but staffing, space and cost constraints make this an expensive if desirable option.

Within a neonatal service it is possible to draw up a range of standards for family-friendly care to ensure that a baby and his family are afforded due respect and that communication and involvement occur. An example of one such set of standards is included in Table 22.3. Importantly these should be auditable so that the neonatal service should be able to demonstrate its commitment to this important area.

Further organizational issues centre around the discharge of the baby home at the completion of the episode of perinatal care. The process of taking a baby home is highly stressful for parents. Units need to develop expertise and clear arrangements for preparing families for home and if possible supporting them in the transition. Information packs, training in resuscitation techniques and supportive outpatient follow-up are important steps in the discharge process.

22.3.4.3 Nurse Staffing

The provision of recommended neonatal nurse staffing levels again will vary between health systems, depending on the roles that are undertaken by nurses and the availability of other professionals, such as respiratory therapists. Within the UK system there have been few studies of nursing input on which to base the recommendations set out in Table 22.2. Nonetheless it is apparent that adequacy of nurse staffing is a key issue within neonatal units in relation to mortality [15]. Further research is needed to support recommendations in this area.

In systems where nurses take on more technical roles (cannulation, intubation, ventilator management), enhanced nursing support is required. With appropriate training many units have developed the role of Advanced Nurse Practitioner; such individuals form an intermediate tier between junior and senior resident doctors and assume many of the roles previously taken on by medical staff (at least in the UK) and may contribute to on call rosters [16]. In some settings they may act without medical staff in supporting low risk deliveries, whereas in other settings they provide intensive care activity. Both these and other roles require different and bespoke training.

22.3.4.4 Medical Staffing

Medical staffing is equally dependent upon the health service model. In the UK, medical trainees and Advanced Neonatal Nurse Practitioners support neonatal intensive care services at a technical grade (junior resident) and as experienced senior resident support. The number of staff neonatologists in this system is relatively few and they have more of an executive and managerial role. Changes to working hours (for example the European Working Time Directive) and availability of resident staff to work in these high intensity settings mean that such systems are under threat. In many other settings, staff neonatologists (nationally-qualified doctors) provide medical care.

Research into the numbers of neonatologists required to staff a neonatal service is unusual. One epidemiologic approach determined that mortality rose in areas of the USA where there was a very low supply of neonatologists (<4.3 doctors per 10,000 births) but that increasing the number did not result in further reductions [17]. In the UK the number of consultants was not related to mortality or nosocomial infection rates [18].

22.3.4.5 Clinical Governance

Within any neonatal service a strong clinical governance framework is required in order to maximize safety and efficiency. Clinical governance comprises a range of organizational structures which we use as professionals in order to quality assure the care we provide, the most useful of which are:

- the clinical audit process
- the use of standards, guidelines and perinatal audit tools
- benchmarking and the application of evidence based care.

Although all three are interwoven they merit consideration separately.

Clinical Audit

The key to the process or cycle of audit is the setting of standards, the appraisal of your service against the standard and the revision of your standard consequent upon the audit, to be followed by a re-audit to make sure it is appropriate. The areas that are amenable to audit cover the range of activities of a neonatal service and include the structure of the service (people/facilities available); the process of care (are we consistently doing what we think we are?); and the outcome of care (Is our prophylactic indomethacin effective?; Is our mortality rate appropriate for our population?).

Clinical audit is a key part of assessing the service we are giving and audit of structure and outcome can provide valuable information when bidding for resources and re-designing services. It also helps to confirm that we are achieving what we aim to achieve in terms of outcomes and activity. More information on the use of clinical audit in neonatal care is to be found elsewhere.

Standards and Guidelines

Part of the way in which we develop our service is to provide a range of policy that is based around the best evidence we have. In the USA, the Fetus and Newborn Committee of the American Academy of Pediatrics produces regular guidance based on best evidence. In the UK, guidance on aspects of clinical care is sometimes available from professional organizations and may be specified as part of the process of resourcing the service. The series of Green-top guidelines produced by the Royal College of Obstetricians and Gynaecologists, for example, contain much of relevance to neonatal care and guide practice widely in the UK. The Royal College of Paediatrics and Child Health publishes a range of documents, which although not primarily aimed at neonatal care are of great importance in neonatal practice, for example, Withholding or Withdrawing Life Sustaining Treatment in Children: A Framework for Practice (2004), which guides practice around end-of-life decisions. The British Association of Perinatal Medicine (BAPM) also produces a range of practical guidance, for example:

- Management of extremely preterm babies (2008)
- Acute in-utero transfers (2008)
- Screening and treatment of retinopathy of prematurity (2008)
- Classification of Health Status at 2 years as a perinatal outcome (2008)
- Early care of the newborn (2005)
- Consent in neonatal clinical care (2004).

Further guidance is published on an ad hoc basis, for example, the recent European Guidance on the Management of Respiratory Distress Syndrome [19].

Most neonatal intensive care units are busy places and it is helpful to have a range of guidance easily assessable to staff. It is also helpful to work to protocols so that audit of care is more meaningful. Key aspects of guidelines are that they should:

- be evidence based
- explain in principle why a treatment/process is preferred
- be auditable to ensure they are working.

Within the UK neonatal networks, guidelines are usually shared for key areas of practice: referral, transfer and early care for very preterm babies, for example, and shared between units via their websites. Within the Trent Neonatal Network (www.trentperinatal.nhs.uk), for example, the following guidelines are available:

- Neonatal transport
- Surgical referral
- In-utero transfer
- Early care.

Benchmarking

Comparing the performance of one unit with another is fraught with difficulty. Population risks are different and can lead to erroneous conclusions (see Chapter 143).

Table 22.4 Recommended format for reporting perinatal outcomes at 2 years [21]

Gestational age at birth		22 w	23 w	…	31 w
Number of births (exclude terminations of pregnancy)[1]					
Number of live births					
Number of admissions for intensive care					
Number of survivors discharged home					
No. of deaths between discharge and 2y					
No. of survivors evaluated at 2y					
No. with cerebral palsy					
No. with motor impairment GMFCS 2 *					
No. with motor impairment GMFCS 3-5 **					
No. with Cognitive score <–2 SD *					
No. with Cognitive score <–3 SD **					
No. with hearing aids but not severe hearing impairment *					
No. with severe hearing impairment **					
No. with speech and language impairment *					
No. with severe speech and language disability **					
No. with visual impairment but not severe visual impairment *					
No. with severe visual impairment **					
Total with neurodevelopmental impairment (moderate or severe) *					
No. with moderate disability					
No. with severe neurodevelopmental disability (SND) **					
Moderate impairment	% survivors evaluated				
	% admissions for NIC				
	% births *				
Death or moderate impairment	% admissions for NIC				
	% births *				
Severe impairment	% survivors evaluated				
	% admissions for NIC				
	% births *				
Death or severe impairment	% admissions for NIC				
	% births *				
No. with other disability					
Describe					

[1] "Births" may be total births or particular groups (e.g., gestational age) in a defined population – this could be hospital based, network based or population based depending upon the need.
* Components of moderate disability – a child with an impairment in any category (but none in the severe category) is classified as having moderate disability.
** Components of severe disability – a child with any one severe disability or impairment in any category is classified as having severe impairment.
GMFCS Gross motor function classification system.

However, it is important to establish an external reference for the performance of a neonatal service and there are important resources available to support this – such as EuroNeoNet (www.euroneostat.org) and the Vermont Oxford Network (www.vtoxford.org), in addition to national or local benchmarking systems. Whereas the exact ranking in such datasets is not really helpful, progress against the reference population and the identification of areas where a service is an outlier are invaluable pieces of information. The most valuable benchmarking process in the UK is the national Centre for Maternal

and Child Enquiries (CMACE) process (formerly known as Confidential Enquiry into Maternal and Child Health (CEMACH) and Confidential Inquiry Into Stillbirth and Death in Infancy [CESDI]), whereby there is national monitoring of perinatal and maternal mortality with focused confidential enquiries and other audit projects (www.cmace.org.uk).

Alongside the benchmarking process, the Vermont Oxford Network offers a range of quality improvement programs, which serve to help a service deliver state of the art care and minimize morbidity, in areas such as nosocomial infection, chronic lung disease and intraventricular hemorrhage through a process of audit.

Data Collection

The key to all aspects of clinical governance is the collection of robust and accurate information about the unit and the babies it looks after. There is a range of datasets available but all require close attention to details to ensure that what is collected is accurate and useful. BAPM has produced a UK national dataset [20] and the international benchmarking groups require similar datasets. The recent National Health Service Neonatal Taskforce has recently published a series of Principles for Quality Neonatal Care that will form the basis for development of the UK dataset further [11].

22.3.5 Follow-up after Discharge

Most neonatal services now provide follow-up for groups who are at high risk of disability. In the UK, a recent working party has revisited the criteria for defining health status as an outcome measure for perinatal care, recommending a formal assessment and recoding of data at 2 years of age [21]. These are similar to those used within the The Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD) Neonatal Network in North America. Target groups for follow-up are very preterm or very low birth weight children, children who have been encephalopathic and any that are identified by other routes to be at risk. Combined with mortality data, this powerful information is useful in terms of monitoring outcomes and providing centre based information for parents. An example of the output from such a service is shown in Table 22.4.

Training of Doctors and Nurses in Perinatology

Franco Macagno and Alfred Tenore

A consideration and comparison of the training of neonatologists in developing and developed countries would be beyond the scope of this chapter because the vast differences which exist would compile enough material to be a book in itself. The reason for this, as one would expect, is that there is hardly anything which may be referred to as a unifying standard of training in developing countries [1]. Unfortunately what is more un-consoling is that there is no unifying standard in developed countries as well.

23.1 Comparison of Some Exemplary Training Systems

The educational track to a career in neonatology in the United States, regardless of the State where the training takes place, goes through an initial three year pediatric training program, or "residency", comprised of time in the clinic, inpatient wards, and emergency department under the guidance of pediatric faculty. During this training, the resident takes care of patients in a closely supervised environment, goes to daily lectures and teaching conferences, and works night shifts to handle pediatric emergencies in the hospital. The resident is also exposed to a broad range of pediatric subspecialties (including pediatric and neonatal intensive care). Subsequent to pediatric training, an additional 3 years of training called a "neonatal fellowship" is required to become a neonatologist. This time is typically divided between taking care of sick babies in a neonatal intensive care unit, under the constant supervision of experienced neonatologists, and usually, clinical or basic science research. The neonatology trainee is required to learn to handle the full spectrum of neonatal problems and diseases as well as writing an article about a research project related to newborn care.

F. Macagno (✉)
Department of Perinatal Medicine, Azienda Ospedaliero-Universitaria Santa Maria della Misericordia, Udine, Italy

One big difference between United States and united Europe, is that Europe, in many things, particularly medical and specialty training, is not yet "united". The same can be said for an attempt to compare programs throughout the world. It is for this very reason that one of the major concerns of the UEMS (European Union of Medical Specialists), since its creation in 1958, has been to harmonize the different training programs for the different specialties in order to ensure the highest possible health care for European citizens. Unfortunately, after 50 years this still has not been achieved even though assuring the highest and uniform possible health care for its citizens should be of primary and vital importance.

Needless to say, the formation of the European Union (EU) has had many positive political and economic consequences through the enforcing of *standards* which member states are required to follow. However, it has also allowed many problems to surface, especially in the field of medicine where, paradoxically, no such standards have been enforced even though EU guarantees the recognition of medical education and training programs as valid in all member states as well as the free movement of physicians throughout Europe. This European directive allows doctors to work wherever they like, even though training programs in Europe both at the medical or specialist graduate level are not comparable in quality or content. In order to achieve high standards of patient care, high quality post-graduate training programs are indispensable. The European Academy of Paediatrics (EAP), the Paediatric Section of UEMS, along with the European Board of Paediatrics, a standing committee of the EAP, has the specific objectives to standardize training throughout EU.

The European example is only one of many that exist throughout the world which reveal great variations in training. In fact, key indicators of health, such as neonatal, infant and under 5 yrs mortality rates as well as disease morbidity, reveal dramatic differences between children living in developed and developing nations. Although many socio-economical factors are responsible for these differences, an important, although rarely emphasized disparity in quality of life for children, is the lack of access to trained pediatricians, let alone neonatologists.

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

Pediatric training in developing countries can range from well-organized programs to very informal ones; however, even where standards for training have been delineated, these alone are frequently inadequate for a variety of reasons (Chapter 22).

Neonatology is a highly technical and rapidly evolving area of pediatric medicine. In the USA, most but not all neonatologists are *board certified* in the specialty of pediatrics by the American Board of Pediatrics (ABP), and in the sub-specialty of neonatal-perinatal medicine also by the ABP. Most countries now run similar programs for fellowship training in neonatology. A doctorate of medicine in neonatology, referred to as a DM (Neonatology), from India is one such highly regarded program. In most EU countries, like in the USA, neonatology is established as an independent specialty following post-core training in pediatrics. Although it is emphasized that the curriculum be delivered over a minimum of two years it is highly recommend that individual EU countries move to deliver this curriculum over three years in the interest of training competent practitioners in neonatal medicine and to provide consistency. However, the form and duration of training, as well as the process for accrediting training centers and monitoring the quality of training, vary markedly from country to country.

23.2 Recommendations for Appropriate Training Programs in Neonatology

The amount of time necessary to form a competent neonatologist is somewhat difficult to standardize because it depends on a variety of factors among which the degree of expertise and the necessary material educational resources available. Because of this fact, the emphasis must be placed on establishing clearly defined standards of training aimed to equip the pediatrician with the necessary knowledge, skills and attitudes required to practice high quality neonatal medicine. Appropriate *formation* requires the acceptance of a standardized *core curriculum* elaborated by some of the world's leaders in neonatal education. The essential elements of the core curriculum include (a) a "syllabus", or a detailed listing of the knowledge that needs to be covered during training, (b) a number of clinical skills and procedures that need to be mastered during training, and (c) an "accredited" structure where the training will take place.

The trainee neonatologist should acquire detailed knowledge in the following categories: (a) epidemiology, (b) patho-

Table 23.1 Knowledge-based content of core curriculum

Epidemiology	Mortality and morbidity rates in the perinatal period and factors which influence mortality and morbidity; methods of data collection, including birth and death notification systems and audits aimed at quality assessment.
Pathophysiology of the fetus	Fetal growth and development and the means of its assessment; impact of the major diseases of pregnancy on the fetus (i.e. hypertensive disease, maternal medical conditions, antepartum hemorrhage, and preterm labor); detection of fetal anomalies and collaborative prenatal counseling.
Physiology of postnatal adaptation	Respiratory, cardiovascular and other physiological changes at birth; development of organ systems and physiological changes after birth; physiology of breastfeeding.
Pathophysiology of prematurity	Respiratory development and pathology including surfactant deficiency and its sequelae; cardiovascular problems including patent ductus arteriosus and persisting pulmonary hypertension; gastrointestinal development and feeding, renal maturation and fluid balance; neurological problems, including pathogenesis of intraventricular hemorrhage and periventricular leukomalacia.
Pathophysiology of conditions encountered in premature and mature infants	Congenital abnormalities and their management; perinatal hypoxia and consequences of hypoxia and ischemia; metabolic adaptation to postnatal life; inborn errors of metabolism including screening programs for their detection; neonatal immunity and pathogenesis of perinatal/neonatal infection.
Pharmacology in the perinatal/neonatal period	Pharmacokinetics in the term and preterm newborn; drug toxicity and interactions; influence and effects of maternal medications and drug abuse on the fetus and newborn infant; transmission of drugs via breast milk.
Principles of neonatal care	Theory and organization of resuscitation; respiratory care and mechanical ventilation, endotracheal intubation and delivery of respiratory support; management of complications and long-term sequelae of prolonged neonatal ventilation; cardiovascular support, assessment of cardiovascular system and of patent arterial duct; postnatal growth, breastfeeding, composition and use of neonatal formulae and supplements; parenteral nutrition, prescription, administration and indications; assessment, diagnosis and management of severe enteral diseases; neonatal skin and thermal care; assessment of fluid balance and nutritional requirements; assessment of bone mineralization; assessment of structural and functional integrity of the brain using clinical examination and special investigations; prognosis of major neuropathology, screening preterm and "at risk" babies for retinopathy and hearing loss; diagnosis and assessment of congenital abnormality and dysmorphology; investigation of suspected inborn errors of metabolism; use of genetic investigations and diagnostic aids; routine care of the newborn in relation to jaundice, breastfeeding, infections; screening for neonatal disease by examination and investigation: early, medium term and late sequelae of neonatal and perinatal events and ethical issues in neonatal care.
Follow-up of high risk infants	Outcomes associated with perinatal high risk groups, e.g., prematurity, fetal growth restriction and intrapartum hypoxia; diagnosis and counseling associated with cerebral palsy, visual and hearing defects, chronic respiratory problems and an understanding of the importance of other neurocognitive outcomes.
Ethical issues and legal problems	

Table 23.2 Skills-based content of core curriculum

Practical procedures	Resuscitation of the newborn, tracheal intubation and techniques of artificial ventilation; insertion of umbilical and peripheral arterial catheters; establishment of intravenous infusion and long intravenous lines; blood transfusion and exchange transfusion; arterial puncture, pleural drainage of pneumothorax, suprapubic aspiration of urine, lumbar and ventricular puncture.
Diagnosis	Interpretation of neonatal chest and abdominal radiological investigations; role of specialized investigations, e.g., MRI, CT; experience in interpreting results of ultrasound examination of the nervous system, the abdominal organs, and of congenital hip dysplasia; ordering and interpretation of common laboratory and microbiological investigations; use and interpretation of the results of EEG, cortical evoked responses and neuromuscular electro-physiological tests.
Clinical practice	Clinical examination of sick and healthy newborn babies; recognition of specific neonatal problems including deformation and malformation; assessment of gestational age; developmental and neurological assessment of the older infant and child and the assessment of disability.
Communication	Counseling and communication skills including appropriate approach to distressed and bereaved parents, disclosure of "bad news", handling of autopsy reports; staff support and team dynamics; co-operation and consultation with other medical specialists.
Technology	Understanding basic mechanical and electrical function of radiant heaters, incubators, ventilators, and monitoring equipment.
Teaching	Training and involvement in teaching activities including teaching programs for doctors and nurses.

physiology of the fetus, (c) physiology of postnatal adaptation, (d) pathophysiology of prematurity, (e) pathophysiology of various conditions encountered in premature and mature infants, (f) pharmacology in the perinatal/neonatal period, (g) principles of neonatal care, (h) follow-up of high risk infants and (i) ethical issues and legal problems. Table 23.1 reports a more detailed list of the major topics of each of the points listed above and which represent the knowledge-based content of the core curriculum.

Trainees will also be expected to have acquired extensive skills in the following domains: (a) practical procedures, (b) diagnostic related studies, (c) clinical practice, (d) communication, (e) technology and (f) teaching (Table 23.2). In addition, Table 23.3 describes competencies which may be considered key elements in the training of the neonatologist and the efficient and competent practice of neonatology. The neonatal specialist's role also includes emphasis on personal development in leadership within the clinical team.

Furthermore, since today's neonatologists undertake important management roles within the team and within their host organization (usually their Hospital or University), training programs must also equip the trainee with the personal skills necessary to fulfill these roles, which include: (a) counselor, (b) manager, (c) leader and (d) teacher. In addition, the trainee must also have acquired experience in clinical governance and audit as well as in the field of statistics where he should be skilled to appropriately interpret statistical data.

Worldwide, about 98% of neonatal deaths occur in developing countries where maternal risk during pregnancy and at delivery is very high. Major improvements in neonatal and infant mortality and quality of life can be achieved by reducing causative factors. In these areas, the application of a regional organization, comprising a three level perinatal service, may not be considered the main priority. Furthermore, the establishment of a network coordinated by a regional center may also be difficult because of unfavorable geography, which will add to the problems of establishing an efficient transport system that ensures the timely and safe transport of the pregnant woman and high risk newborn [2]. In these situations, maternal and neonatal care receive minimal government funding. Furthermore, thousands of first level hospitals and improved neonatal intensive care units would be required. Basic problems should first be addressed and training of personnel attending pregnant women and neonates should be the main priority. Great distances between regional centers constitute a problem not only for maternal and neonatal transport but also for the education of physicians, nurses and midwives.

In most areas, the main educational aim should be good quality home-based neonatal care post hospital discharge. Midwives and caregivers should be trained to identify normal and sick neonates, to resuscitate hypoxic newborns, to support breastfeeding, to prevent and treat neonatal infections, to satisfy the basic needs of preterm babies and to recognize malformations.

Perinatal care programs based on a three level organization should only be considered when mortality in a region falls below 15/1000 live newborns. The effect of local differences is that there is no single program or strategy that can be universally applied to developing countries. Decisions should be made on the basis of the local background, economic resources, number and educational status of personnel, geographic, social and demographic conditions.

In developing countries with high neonatal morbidity and mortality, efforts should be directed at improving primary care models. In order to strengthen primary care services, an education program aimed particularly at midwives is effective in reducing neonatal mortality rate. Thus, each region should establish a program that is appropriate to its own requirements, depending on resources, local conditions, personnel and the availability of outreach education [3].

Table 23.3 Key competencies in neonatology that trainees must be capable of demonstrating

Resuscitation	Be able to institute and lead neonatal resuscitation both of the term and preterm baby and demonstrate a full understanding of the physiology and treatments involved.
Neurology	Proficiency at clinical assessment; investigation, including cerebral ultrasound scanning, and management of a range of neurological disorders, including preterm and term brain injury, congenital malformations, intracranial trauma and seizures.
Communication skills and counseling	Increasing skills in communication with parents and staff, both individually and as part of a team, during their training; this includes experience at breaking bad news, handling perinatal death and discussing prognosis with parents.
Congenital anomalies and genetic disease	Able to recognize common congenital anomalies, to investigate babies with such lesions and to use literature and database searches to identify rare conditions and communicate such information to parents.
Cardiorespiratory intensive care	Be able to plan for the care of the baby with chronic respiratory disease and be aware of the potential long-term complications. Be able to institute and maintain full cardiorespiratory intensive care for preterm and sick term newborn babies demonstrating a full working knowledge of the principles and application of a range of ventilatory modalities and of circulatory support.
Fluid balance, thermoregulation and renal failure	Be able to initiate and manage the thermal environment of preterm and term babies, and manage fluid balance in such babies, demonstrating a full understanding and knowledge of the underlying physiology – with special reference to the rapid postnatal changes in body water distribution and transepidermal water loss. The trainee should be able to diagnose and initiate treatment of renal failure.
Hematology and transfusion	Be able to diagnose and manage the range of hematological disorders found in newborn babies and be conversant with the full range of blood products available for transfusion and the appropriate use of each.
Metabolism and endocrine disorders	Proficiency in the recognition, assessment, investigation and management of the more common and important metabolic and endocrine disorders.
Nutrition, feeding, gastrointestinal and hepatic disease	Understanding of the importance and principles of neonatal nutrition and be able to provide comprehensive nutritional support to well and sick newborn babies, including the recognition and treatment of common complications; be able to recognize both common congenital gastrointestinal and hepatic anomalies and acquired neonatal disease.
Immunity and infection	Understanding the development of immunity and the vulnerability of the newborn to infection.
Family care and care of the well newborn baby	Acquisition of a wide knowledge of normal development, common minor problems and morphological variation and the importance of communication with other health care professionals and the parents.
Transport of the newborn baby	Be competent at retrieval and transport of the sick newborn baby and be able to teach others to carry out transfers.

23.3 Conclusions

Given the enormous diversity that exists throughout the world in the formation of a neonatologist related to the duration of the training as well as the structure of the training program, the object of this chapter was not to attempt to compare the various programs but to give information regarding the common knowledge, skills and competencies that are needed to be acquired by a trained pediatrician in order to become a neonatologist. The EAP has published a syllabus for trainees in neonatal medicine which details the range of subjects that trainees should cover during the neonatal sub-specialist training. The syllabus can be downloaded from the EAP website (http://www.EAPaediatrics.eu). However, since knowledge, skill acquisition, training, and general competence occur in a continuum of lifelong learning, trained neonatologists should be committed to a continual state of learning and evaluation in order to remain up-to-date with advances in medicine and to provide evidence to the public that they remain competent to practice their specialty [4, 5].

Neonatal Transport Services

Rocco Agostino and Roberto Aufieri

24.1 Introduction

Neonatal transfer is necessary when a newborn baby needs care that cannot be provided in the referral centre. Since it represents an additional risk factor for a critically ill neonate [1, 2], it should be performed, when possible, by a well-organized neonatal transport service.

In a network, aimed at the regionalization of perinatal care, high-risk pregnancies should be transferred "in utero" in order to minimize risks for both mother and neonate [1, 3]. However, there will always be a number of neonates who need to be transferred for unpredicted or unpredictable reasons [4]. Every maternity unit should therefore be able to provide effective neonatal resuscitation in the delivery room, be able to maintain a sick baby in a stable condition in the short-term and have access to a Neonatal Emergency Transport Service (NETS) for the provision of neonatal intensive care when appropriate. Thus, NETS provides a bridge between birth centers and Neonatal Intensive Care Units (NICUs).

24.2 NETS: a Mission Statement

NETS should aim to guarantee:

- optimal care for every neonate in the most appropriate location
- safe and quick transport with minimization of risk
- good communication between transport team, parents and the centers involved
- rational resource use with optimized cost-benefit ratio
- an outreach education program relating to resuscitation and pre-transport stabilization
- guidelines for referral centers and transport personnel.

R. Agostino (✉)
Department for Maternal and Child Health
S. Giovanni Calibita Hospital Fatebenefratelli, Rome, Italy

The establishment of a NETS therefore requires planning and organization. There should be regular auditing to monitor its efficiency and effectiveness (see Chapter 22).

24.3 Organization

The organization of a NETS should be appropriate to the needs and characteristics of the region covered and resources available. Account should be taken of:

- demography (birth rate and distribution)
- place, number and levels of perinatal units
- number of transports per year and patient flow between centers
- neonatal transport index (NTI, see below)
- available economic resources, personnel, vehicles and equipment
- regular clinical audits.

There are different models of perinatal networks for the provision of the most appropriate service. The choice between the two models in terms of cost-benefit ratio depends mainly on the number of transports per year and on the referral area [6], as follows.

- *Dedicated service*: all transports carried out by a team devoted full-time to this service. The optimal number of transports per year is 400-600. Fewer than 400 increases costs and more than 600 decreases efficiency.
- *On-call service*: in this organizational model, transport is integrated into the overall activity of an individual NICU and carried out by "in-house" personnel. The optimal number of transports per year to minimize costs and maximize efficiency is 150-200.

The characteristics of each model are summarized in Table 24.1. In Europe, the most usual models for regional networks are dedicated or on-call NETS [5].

The NTI is an expression of the number of neonates transferred per 100 live births. This index can be used to compare the flow of newborns between facilities in each area. A low

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

Table 24.1 Characteristics of the two NETS models

	Dedicated	On-call
Activation times	Usually shorter	Usually longer
Availability	Around the clock	Available on-call
Distances covered	Longer	Shorter
Area covered	Usually larger	Usually smaller
Receiving centre	All NICUs (interfacility transports)	Only NICU where NETS is based
Individual specific transport expertise	More, because mainly appointed to transport service	Less, because temporarily detached from NICU
Costs	More expensive	Less expensive

NTI (around 1%) indicates a good distribution of perinatal facilities and well-organized maternal-neonatal transport services. Where high-risk perinatal care has been regionalized, as in the UK, the NTI is about 1% [7, 8], whereas in areas with heterogeneous distribution of obstetric units, the NTI can reach 10%, e.g. the Loire–Atlantique region in France [9].

To account for regional diversity, it is also possible to organize a network with more than one type of NETS.

24.3.1 NETS Coordinating Centre

Each regional network should ideally have a NETS coordinating centre. Its role is to:

- triage requests for transfers
- monitor cot availability and find appropriate cots
- activate the appropriate transport team and co-ordinate the transfer
- prioritize simultaneous requests
- give advice to referring clinicians and to the transport team
- supervise staff, plan audits and education
- ensure the provision of appropriate resources.

24.4 Types of Transfers

Transfers can be classified on basis of the degree of emergency and destination:

- *acute*
  - primary transfers: to a NICU or a higher level centre, depending on the requirement for intensive or high dependency care;
  - intertertiary: between NICUs, if there is a lack of cots or the need for surgical or specialized care;
- *elective*
  - back-transports: usually from a NICU to the local hospital, when a neonate is stable, to maintain the availability NICU cots, and minimize costs and discomfort for families [10];
  - return transfers: for diagnostic investigations (e.g. MRI) or procedures (laser treatment for ROP).

24.5 Transport Process

The transport process (Table 24.2) starts with a request for transfer by the referring centre. Each transport should be coordinated by the coordinating centre, or by a senior neonatologist at the admitting center.

24.5.1 Patient Stabilization

It is important that staff at the referring hospital should be able to perform basic resuscitation and stabilization before the arrival of the transport team. The baby's clinical condition should be carefully evaluated to establish the initial diagnosis and a therapeutic plan. Stabilization involves basic physiological support and is defined as the treatment or correction of those processes which, if not addressed, may lead to deterioration in the baby's condition. After stabilization, preparations for transfer are started. These include ensuring that physiological parameters are satisfactory, that airway and vascular access are secure and that appropriate monitoring is in place. Insufficient attention to resuscitation and stabilization may result in clinical deterioration during the transfer and the environment during transport (limited space, vibration, noise, etc) is not conducive to optimal patient care. Good communication between team members and between the team and the referring staff and the patient's family is essential.

24.5.2 Personnel

The choice of personnel for a transport team varies widely between NETS, depending on organizational preferences, budgets and availability of professional groups [6, 11]. The traditional view that a neonatologist and a nurse should constitute a neonatal transport team is no longer generally accepted. Retrieval teams with different professional backgrounds do not appear to affect the outcome of transports [12, 13].

The nature of the professional background of transport team members is less important than training in transport practice with specific core competencies [14]. Poor transport

Table 24.2 Transport process

Events	Operative approach
Request for transfer	Discussion, triage, advice and support for referring centre, plan of action
Cot search	Finding the most appropriate cot and activation of the transport team
Transport team departs from base hospital	Continuing advice and support for the referring centre, which is responsible for pre-transport stabilization
Transport team at the referring hospital	Assessment and further stabilization prior to transport
Transfer of the baby to admitting hospital	Monitoring, continuous assessment, specific treatment if needed
Transport team at the admitting hospital	Final assessment, handover to admitting team
Transport team return to base hospital	Check and replacement of used equipment and medical gases, communicate new availability

experience reduces quality of NETS [15, 16]. Time devoted to stabilization of the neonate prior to transport increases with operator experience [17].

There should be regular rotation of personnel between NICU and the transport service to prevent burnout and allow for professional updating.

24.5.3 Equipment

Equipment taken on transfer needs to be suitable for a variety of babies, from the extremely low birth weight to term, and for the range of medical or surgical problems that require different therapies in transit. The transport itself requires a transport incubator system with a mechanical ventilator, infusion pumps, suction pump and monitors. A neonatal resuscitation kit, including drugs should be carried in a separate bag.

Equipment should be dedicated exclusively for neonatal transport, to ensure its ready availability and that the battery is fully charged. Some recommendations have been provided by the European Committee for Standardization [18, 19]. Difficult working conditions and mechanical stresses, caused by vibrations and sudden forceful impact, mean that equipment should be checked and tested regularly. Staff should be trained in their use and should be aware of the more frequent minor causes of malfunctioning so they are able to fix them.

24.5.4 Road and Vehicles

The choice of road and vehicle should aim to guarantee the quickest, safest and most comfortable transport for the baby, taking account of clinical conditions, regional geography, weather, road and traffic conditions [20]. Different scenarios should be considered and guidelines prepared to determine the choice of vehicle and appropriate response to emergency situations. Vehicles that can be used by NETS are ambulance, helicopter and fixed wing aircraft. Ambulances are most commonly used because of lower costs, universal availability, short activation times and the possibility of reaching hospitals directly. Dedicated vehicles guarantee shorter activation times and better compatibility between equipment.

Air transport, including by helicopter, is indicated for longer distances and for regions with poor weather conditions during winter or peculiar geographic characteristics (e.g. mountain regions). Account should also be taken of the possible need for an additional ambulance journey, depending on whether there are facilities for landing at the hospital. Air transport is characterized by the presence of high noise and vibration levels, changing of gas pressures, temperatures, humidity and gravitational forces that may affect care and possibly worsen the condition of the critically ill neonate and, for these reasons, should only be performed by specifically trained personnel [21].

24.6 Quality Evaluation and Costs

Audit is essential for the evaluation and improvement of the service [22, 23]. Data collection should include demographics, staffing and pre- and intra- transport times, as well as clinical parameters.

NETS availability and time required can be considered as indicators of efficiency [24]. Time investment includes:

1. the response time (period between call for transport and departure for referring hospital);
2. the waiting time (time between call for transport and arrival at referring hospital);
3. the stabilization time (time required to assist neonate at referring hospital);
4. "on the road" time (time with baby in transport between departure from referring unit to admission at receiving hospital);
5. the total transfer time (from departure towards referring hospital to availability of the team for another transfer).

Measures of effectiveness can be based on changes in the infant's core temperature during transfer, validated transport scores [25, 26, 27] and monitoring complications during transport.

The annual budget for running a NETS includes fixed and variable costs. Fixed costs are independent of the number of the transports and include equipment amortization, insurance cover, training and education, organization and communication. Variable costs depend on the number of transports and include supplies, equipment maintenance, and ambulance

expenses. Personnel salaries depend on the type of NETS: in the "dedicated" model, this is a fixed cost, whereas in the "on call" model it affects both fixed costs (depending on availability) and variable costs (actual hours). The total cost of the NETS and the average cost of each transport depend on the fixed and variable costs, which in turn depend on the organizational model adopted and the load of scheduled jobs [6].

24.7 Training and Outreach Education

Continued improvement of perinatal outcomes depends on all health professionals recognizing their responsibility to keep up-to-date with recent advances in perinatal care, by updating their knowledge and clinical skills.

Transport personnel must receive appropriate training and supervision. Core competencies include clinical, procedural, communication and teamwork skills, and the ability to work in the transport environment [14].

Continuing education in neonatal transport involves training and supervision of all members of the transport team. It relates not only to clinical care but also to safety and communication, as well as to administrative and other relevant topics. Extending continuing education throughout the referral region (outreach education) is also important for the healthcare professionals responsible for referring and stabilizing infants for transport [6].

Problems of Discharge and Home Care of Newborns

Fabio Mosca and Monica Fumagalli

Improved obstetric and neonatal care has increased the survival of very preterm babies and very ill newborns who are often discharged with unresolved medical problems or special health care needs. A close follow-up and an individualized home-care plan have to be developed for these babies before discharge from NICU.

High-risk newborns include premature infants, babies requiring special care and technology dependent infants, defined as those needing ventilatory or nutritional support.

25.1 Timing of Home Discharge

According to the guidelines of the American Academy of Pediatrics [1] timing of home discharge should be based on physiologic criteria rather than body weight.

Physiologic stability and the acquisition of the following competencies are considered essential to allow home discharge: 1) respiratory control; 2) thermal stability in home environment; 3) competent oral feeding (by breast or bottle) for an appropriate growth.

25.1.1 Respiratory Control

Significant apneas of prematurity can persist up to 43 weeks' postmenstrual age (PMA). After stopping methylxanthines administration, babies who have experienced problematic apneas should have an event-free period of 5–7 days before discharge. It is known that the prone position improves oxygenation, while the nonprone position decreases the incidence of sudden infant death syndrome (SIDS) [2, 3]. The association between prone sleeping and SIDS among low birth weight infants is equal to or even stronger than the association among those born at term. Therefore, prior to discharge, babies should spend a period of weeks in the supine position monitoring the occurrence of desaturation events and mothers should be strongly advised by caregivers during hospitalization to maintain supine sleeping position when at home.

25.1.2 Immunization

Preterm infants should receive routine recommended vaccines at a chronological age consistent with the schedule recommended for full-term infants [4].

During the respiratory syncytial virus (RSV) season palivizumab should be given before discharge to high-risk neonates according to the national recommendations [5].

25.1.3 Neonatal Screening Programs

Newborn metabolic screening should be completed and reviewed before discharge. Research data have shown that infants in the NICU are at highest risk of having neural hearing loss. Therefore, a hearing test should be performed before discharge in high-risk babies and a long-term careful monitoring for hearing loss, with subsequent appropriate audiological management, is essential after discharge.

25.1.4 Parental Education

An active program of parental involvement in the infant's care should be established by caregivers as soon as possible during the hospital stay in order to teach parents to handle the

baby and let them acquire skills and competence needed to take care of their infant at home.

Breast milk should be strongly promoted as the optimal diet also for high-risk infants and soon after birth mothers should be encouraged to provide milk for their own infants. After discharge, mothers should be supported to continue breastfeeding or to give their own expressed milk; considerable psychological benefits of breastfeeding have been also described.

Before discharge a planned follow-up program should be offered to the parents by an identified primary care physician who will take the responsibility of the baby's care after discharge. Individualized discharge and follow-up plans are important to assure safe and effective care at home and to minimize avoidable hospital readmissions. In order to help parents to cope with the baby's needs at home additional support may be provided by home nursing care.

25.2 Special Care Needs

25.2.1 Ventilatory Support

Babies with chronic lung disease (CLD) may require long-term oxygen supplementation to maintain oxygen saturation at an acceptable level and avoid growth failure. In order to shorten hospital stay home oxygen therapy should be considered for these babies with increased inspired oxygen need. Some infants may require oxygen supplementation for months or even years and weaning from supplemental oxygen should be gradual to avoid worsening of pulmonary hypertension.

For infants who cannot be weaned from assisted ventilation or infants with upper airway abnormalities home ventilation may be necessary. In this case a tracheostomy has to be performed before discharge and a special education for parents and qualified home care are needed.

High-risk newborns may require pulse oximetry or apnea monitoring after discharge. Although criteria to home apnea monitoring vary widely among NICUs, recommendations for home monitoring include babies presenting mild episodes of apnea not requiring stimulation, having a feeding tube in situ and requiring oxygen supplementation or ventilatory assistance.

The use of home monitoring is not indicated to prematurely discharge babies who do not demonstrate maturity of respiratory control.

25.2.2 Nutritional Support

Competent breast or bottle feeding supporting appropriate growth is advocated before discharge. Nevertheless, the use of a feeding tube at home may be considered when feeding is the last issue precluding home discharge. A safe home management of feeding tube can be assessed for a limited time period by well educated parents; when the baby does not improve in oral feeding skills a gastrostomy should be performed to guarantee safe and effective gastric nutrition. During gastrostomy feeding oral nutrition must be stimulated as removal of naso/orogastric tube reduces discomfort during suction and may improve oral feeding skills.

Infants with short bowel syndrome due to pre- or postnatal damage of the gut usually require total parenteral nutrition (TPN) when less than 40 cm of small intestine remains. If TPN is likely to be needed long-term, home administration has to be planned to give these children a better quality of life. Home TPN requires medical devices and intense home nursing for surveillance of central venous catheter related problems until parents achieve competency and independency.

25.3 Late Preterm Infants

Infants born at 34+0 through 36+6 weeks gestation were previously referred to as "near-term" babies. A change in terminology from "near-term" to "late-preterm" is now recommended based on the evidence that these infants are less physiologically and metabolically mature than term infants.

The population of "late preterm" is at increased risk of developing medical complications during hospital stay and has a higher rate of hospital readmission during neonatal period (for jaundice, feeding difficulties, dehydration and suspected sepsis) [6] and later in infancy.

In a large national US study 15.2% of late-preterm infants were rehospitalized in the first year of age, compared to 7.9% of term infants [7].

Moreover, late preterm infants seem to be more likely to have a diagnosis of developmental delay within the first 3 years of life and to be referred for special needs preschool resources [8]. This observation highlights the importance of understanding the inherent risk of this subgroup of patients in order to design appropriate discharge planning.

25.4 Rehospitalization

Preterm infants have a high rate of readmission in the first year of life (about 15%), mainly due to respiratory illness, with the highest incidence in babies <25 weeks' gestation (31%), with CLD, living with other children, first discharged during the RSV season or belonging to socially disadvantaged groups [9]. The identification of associated risk factors can be useful to define high-risk groups of babies at discharge needing close follow-up and surveillance.

25.5 Safe Transportation

When positioned in a safety car seat premature babies and low birth weight infants have an increased risk of airway obstruction [10]. The potential risk of respiratory compromise is strictly related to anthropometric parameters (weight and length) and neurologic maturity as well as to the associated medical conditions, especially CLD. A car seat evaluation should be performed before discharge in newborns at risk for obstructive apnea, including babies with hypotonia (related to genetic or neuromuscular disorders), micrognathia or previous cardiac surgery. Parental education about the proper infant's position in the car seat is necessary to minimize the risk of respiratory impairment. A car bed may be indicated for infants who present apnea or decrease in oxygen saturation when positioned semi-reclined, unless evidence is not clear.

Risk Management

Isabelle Ligi, Sophie Tardieu, Véronique Millet and Umberto Simeoni

26.1 Introduction

Rapid advances in neonatal medicine have caused a substantial reduction in neonatal mortality, especially in low birth weight babies. However, caring for newborn infants in the neonatal intensive care unit (NICU) exposes them to invasive therapies and therefore to iatrogenic damage. Moreover, NICU is a complex system with an environment of continuous and emergency care prone to error. Iatrogenesis is defined as an unintended harm or suffering arising from any aspect of health care management [1]. The report *To Err is Human* by the Institute of Medicine revealed the importance of medical errors in terms of patient harm, death and cost in USA [2].

Despite the fact that newborn infants constitute a high-risk population, data are still scarce. Incidence of iatrogenesis varies strongly between studies according to the methods of data collection and the definition used but recent prospective studies have reported high incidences of 0.4 to 0.74 iatrogenic events (IEs) per patient [3–6]. Many iatrogenic events result in permanent harm and more than a third are considered to be preventable [3–5]. They have huge financial, human and medico legal costs for the patient, their families and the staff [2, 7].

In response to a focus on improving patient safety, the concepts and practice of risk management have evolved during the last decade. Clinical risk management can be defined as organizational systems or processes that aim to improve the quality of health care and maintain safe systems of care [8]. It is based on a system approach, rather than an individual approach to error, taking account that human beings are fallible and that IE occurrence is a consequence of a successive lost of protective defenses, barriers and safeguards [9]. That is why risk management is an ongoing process based on an attitude (awareness of potential risk and liability), the knowledge and understanding of hazards, skills and commitment.

26.2 Epidemiology of Iatrogenesis in Neonatology

26.2.1 Definitions of Patient Safety Terms

Many definitions are commonly used in the patient safety literature. Using precise definitions helps interpret the findings of studies, as there is no standardized nomenclature.
Error: a failure of a planned action to be completed as intended or use of the wrong plan to achieve an aim [2].
Serious medical error: a medical error that could harm or injure a vulnerable patient if it reached the patient uninterrupted [10].
Adverse (medical) event: an injury caused by medical management rather than the underlying condition of the patient [2].
IE: any event that compromises the safety of the patient in the presence or the absence of harm. It may or may not be preventable and may or may not involve an error by the health-care team [3].
Critical incident: any event which could reduce, or does reduce, the safety margin for the patient [6].
Severe IE: any unintended injury or complication that results in disability, death, or an extended hospital stay, caused by health-care management.
Preventable IE: any avoidable iatrogenic event based on available knowledge and accepted practices [11].
A near-miss event: an event that could result in an injury, fatality, or property damage if not prevented.
Adverse drug event: any injury resulting from medical intervention related to a drug.
Medication error (ME): any preventable event that occurs in the process of ordering, transcribing, dispensing, administering, or monitoring a drug, irrespective of whether an injury occurred or the potential for injury was present [12].

26.2.2 General Epidemiology of Iatrogenesis: Frequency, Severity, Preventability and Type

Data on epidemiology of iatrogenesis in neonatology are scarce and heterogeneous depending of definitions and methodology used. Table 26.1 shows data of seven reviewed studies. Undoubtedly, retrospective chart reviews broadly underestimate rates of iatrogenesis, with the estimate being that medical errors affect between 1.2 and 1.5% of admitted neonates [13, 14]. Actually, recent studies highlight the importance of iatrogenesis among neonates, as expected, in terms of frequency and severity. These studies (most of them based on a prospective, anonymous, voluntary and non-punitive system) reported high incidences of 0.4 to 1.25 events per patient [3–6, 15]. Two studies reported rates of 20 to 25 IEs‰ patient-days [3, 5]. As 30 to 50% of the incidents were judged to be severe and harmful, the impact on patient morbidity is considerable [3–6]. Preventability is often high from 35 to 83% of events [3–5].

Frequency of incident by category is heterogeneous, varying with local environments and patterns of problems. Nosocomial infections and respiratory events are reported to be common and often severe events. Particularly, unplanned extubations are a frequent (1.5 to 4.8 per 100 ventilation days), severe but largely preventable incident [16]. MEs and cutaneous injuries (Fig. 26.1) occur frequently in NICU but are often minor. ME rates vary widely between studies, partly due to differences in the definitions of an error and the methodology used for their identification. Kaushal and colleagues found an incidence as high as 5.7 MEs per 100 NICU prescriptions (91 MEs per 100 admissions) but included near miss events [12]. With near miss events excluded, Raju and colleagues reported a rate of 15 MEs per 100 admissions [17]. Dose errors, occurring during the prescribing and particularly the administration stage, are reported to be the most common type [18]. Ten-fold MEs are common and mainly related to errors in programming of flow rates of electric infusion pumps. Lastly, cutaneous injuries were found to be a frequent incident. Although skin necrosis was rare, scars constituted a severe and significant event with esthetic and sometimes functional troubles.

Table 26.1 Epidemiology of iatrogenesis in neonatal intensive care

Reference	Study design	Population	Characteristics of reporting	Definition	Results		
					Incidence/n reports	Severe	Preventable
Frey et al Switzerland 2000 [6]	Prospective 1 year	467 admissions (56% neonates)	Comprehensive, anonymous, non punitive	Critical incident	0.45 CI per admission	30%	Not described
Suresh et al USA 2004 [21]	Prospective Period 1: 17 months Period 2: 10 months	54 NICU	Non punitive, anonymous, voluntary, externally, internet based, free text (period 1) or structured form (period 2)	Medical errors near-miss, adverse events	1230 reports	27%	Not described

Snidjers et al Netherlands 2009 [15]	Prospective 12 months	8 NICU, 1 PICU 3859 neonates	Anonymous, voluntary, non-punitive	Critical incident	1.25 CI per admission	1.4%	Not described

Fig. 26.1 Skin necrosis related to extravasation of fluids from peripheral venous catheter

As expected, the major risk factors of iatrogenesis are low birth weight and use of invasive procedures (central venous line and mechanical ventilation). Moreover, iatrogenesis is independently associated with an increased length of hospital stay [3-5].

26.3 Learning from Iatrogenic Events

Four steps are fundamental in developing risk management policy: identification, analysis, assessment and graduation, control of the risk.

26.3.1 Factors Contributing to Iatrogenic Event Occurrence

Multiple factors are invariably involved in the sequence of events that results in iatrogenesis occurrence. As described by James Reason in the "Swiss cheese" model of iatrogenic event occurrence, a set of circumstances coincide both in time and space to cause an event [9]. Human errors can contribute or cause events in an active or a latent way. Active failures comprise the unintentional lapses or slips (misinterpretation, error of attention or memory or selection) and the intentional mistakes (rule or knowledge based) or procedural violations. Active failures are immediate causes of an iatrogenic event. Latent failures are local and organizational conditions that facilitate event occurrence by providing a point of weakness. Factors include individual (training, health, awareness, fatigue) and team (communication, supervision) conditions, institutional (financial resources, safety culture) and environmental (staffing levels, equipment) factors, task conditions (workload, protocols) and patients attributes (age, language, personality, general health, social conditions).

26.3.2 Incident Reporting Systems

Incident reporting systems [19] refer to structured reporting, collation and analysis of iatrogenic events. Reporting systems are a key strategy for learning from errors. Mandatory reporting systems, on the basis of retrospective chart reviews, focus on errors associated with serious injuries or death. But errors resulting in serious harm are only part of the problem, and iatrogenesis is certainly underestimated by these systems. However, Sharek and colleagues recently described a trigger tool chart review that identifies efficiently adverse events in NICU [4]. By contrast, voluntary reporting systems focus on incidents that often result in slight injury, no harm or even those that are intercepted (so-called near-miss events). The intent is to identify and remedy vulnerabilities in systems to improve patient safety. Leape and colleagues emphasize the importance of a non-punitive, anonymous, and timely reporting system to effectively monitor adverse events. This approach has been shown to be effective in improving reporting [6, 20, 21]. Reporting can be facilitated by adding a trigger list of key incidents that reflect the nature of local clinical practice and areas of concern. Moreover, prospective methods of data collection demonstrate their superiority to cross sectional or retrospective methods [22]. Indeed, they seem more appropriate to identify preventable events, to assess the impact of error-prevention strategies, to study organizational and human factors and to assess the consequences of incidents. Furthermore, prospective incident reporting can be used as an educational process to convince clinical teams that errors contribute significantly to adverse events.

26.3.3 Investigation and Causation Analysis of Incidents

Investigations are needed for serious incidents or for recurrent ones. Debriefing (root causes analysis) is a key process to understand incident genesis and to learn from the incident to improve patient safety. The debriefing process has to be confidential, non-threatening, structured and timely. It is a collaborative process used to dissect events. The objectives are to determine what happened, to identify why it happened (underlying causative human and system factors) and to pinpoint lessons learned to make recommendations for improvement in a blame-free way. The lessons learned need to be fed back in a timely manner to the staff via meetings and/or a monthly bulletin.

26.3.4 Risk Assessment

Assessment and graduation of medical risk in terms of probability of occurrence or recurrence and harm potential is important for organizations in healthcare. Incidents can be reviewed retrospectively to rate the preventability and the severity. An alternative is to take a prospective approach in the technique of failure mode and effect analysis. The reliability and potential failures of any new system, process, equipment or service is systematically evaluated prior to exposure of patients and staff. Even if it is time-consuming, the proactive analysis facilitates assessment of potential risk prior to its implementation.

26.3.5 Limitations of Incident Reporting Systems

The prospective incident reporting systems are time-consuming in reporting and investigating incidents. Moreover, voluntary reporting can be inadvertently perceived as a means to blame and can paradoxically encourage defensive clinical practices. Another bias that is important to bear in mind is the underestimation of incidents by under-reporting or detecting.

26.3.6 Our Local Experience of Iatrogenic Event Reporting

Since 2005, we have used an anonymous, non-punitive and voluntary incident reporting system. The reporting form has been composed by a working group, which consists of neonatologists, one epidemiologist and referent nurses, on the basis of published work, professional expert devices and a pilot study in 2003. The form consists of three sections: administrative data (neonatal unit, patient identification, date of birth, discharge date, hospital length of stay or death), patient characteristics (birthweight, gestational age, sex, mechanical and/or continuous positive pressure support, central venous line) and narrative sections about incidents (date, age and weight, description, causative mechanisms). At the back of the form, a trigger list of 53 potential incidents was established to help reporting. Before the introduction of the form, several tutorial sessions and group discussions were held to familiarize nursing and medical staff with the incident report. The form was placed in the baby's chart from the time of admission until the discharge or death. Every month, two pediatricians independently review the reported incidents to confirm the diagnosis and to rate severity and preventability of each event. A monthly meeting is held by the working group to discuss rates and to enact preventive measures. A monthly bulletin composed of general data (number of admissions, activity level), of a summary of IE reports and nosocomial infections and of clinical lessons or guidelines is posted in units for feedback. Every 4 months, a staff meeting is organized with the nursing and medical team to discuss the rates and measures [3].

26.4 Strategies to Reduce the Risk: Components of Risk Management

Leadership and Safety Culture Leadership and safety culture (Fig. 26.2) are critical to convince staff that hazard and risk are not inevitable and can be managed to improve patient safety. Leaders must sensitize and encourage the entire staff in a collaborative and non-hierarchical process. The objectives are to convince that patient safety is a primary goal, that the system can be improved and the risk reduced. Leaders should emphasize the importance of blame-free incident monitoring as a positive means to improve quality, empower changes and allow development of targeted interventions. Leaders should also organize feedback, communication and promotion of patient safety.

Communication Communication with the parents is a major issue to help limit claims and complaints. Parent consent and information are key areas. Transparency is capital in the case of iatrogenic event occurrence. Communication between professionals is also essential to reduce risk and hazards.

Training, Induction and Competence As inexperience and unfamiliarity are key factors in error occurrence, continuous training is needed. Moreover, turnover is high in NICU and new staff are usual. All new staff must be aware of guidelines, policies and procedure.

Guidelines and Protocols Standards developed from evidence-based medicine are useful to assist professionals in decision in every steps of the care.

Audits Independent assessment of care and risk can be useful to implement preventive measures and to assess their effect during re-audit.

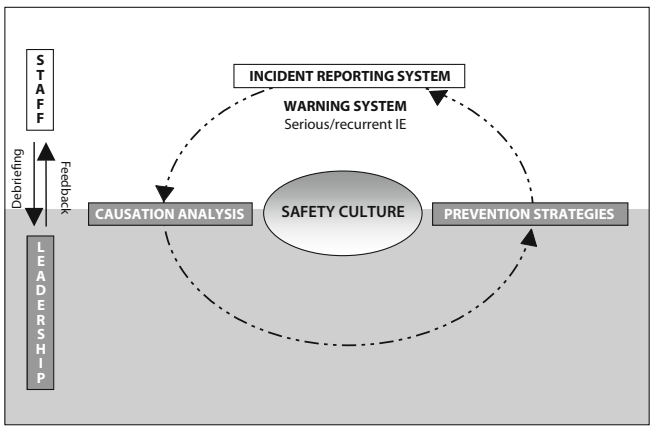

Fig. 26.2 Organization of risk management

Prevention of MEs: An Example of Risk Management MEs occur frequently in NICU with a real potential for harm. Prescription and administration, in particular smart pump programming, are two high-risk stages. Inexperience and intensity of workload are the major risk factor for occurrence. Even though medication management is a complex and multifaceted system, studies show that risk can be efficiently reduced and MEs prevented. First, the involvement of a NICU based pharmacist significantly reduces dosing errors [23]. Strategies to reduce error at the prescribing stage include: clinical staff education (indication documentation, formulation and dose regimen information), improving environment conditions at the time of prescription, implementation of standardized dosing references and perhaps use of computerized provider order entry (CPOE). CPOE could prevent 66% of MEs. However, CPOE may contribute to new types of errors and more studies are needed to assess the impact of such technology on MEs as CPOE systems are expensive [18]. Strategies to reduce errors at the administration stage include: use of standard concentrations for infusion, restriction of verbal orders to emergency situations, limitation of handwritten orders, requirement of double-checking at each step of the medication process especially for high-alert drugs (opiates, sedatives, insulin, anticoagulants, concentrated electrolyte solutions), storage of these drugs separate from ward stock, strict identification of syringes, handoff verification check. These measures have demonstrated their efficiency in reducing MEs.

Guidelines and Protocols

Rinaldo Zanini

27.1 Introduction

Medicine nowadays offers many more services than ever. Progress in perinatal medicine through technology is a good example, although better living conditions for the population in general and for pregnant women in particular have also had a significant effect.

The complexities of modern medical procedures, joining different branches of medicine (Obstetrics and Neonatology to make Perinatology), and increased knowledge and available technology have contributed to today's good results. However, this has also imposed new behavioral and organizational models on physicians and healthcare workers to ensure that all these opportunities result in improved and consistent clinical outcomes for patients.

Organizational processes to promote team work are needed to facilitate the support and management of a healthcare process that is no longer in the hands of a single physician. The costs of health care have increased enormously because of advancing technology, the complexity of interventions and a continuing demand for better outcomes. These increased costs affect the healthcare systems of all industrialized countries and there is a risk that they will stunt medical progress in future years. Increased costs have tended to reduce the fairness of the healthcare system, making access less easy and decreasing its availability to users.

Because guidelines (GL) are systematic, repeatable, sharing and transparent, their use can contribute to a response to both control of costs and easy of access [1].

Complexity and cost are linked by the increasingly pressing need to provide high quality treatment with six fundamental attributes: safety, appropriateness, efficacy, efficiency, fairness and centrality for the user and his/her family.

27.2 The Guidelines

A definition of GL has been agreed by the Institute of Medicine, USA:

> Guidelines are recommendations for clinical lines of conduct produced by way of a systematic process for the purpose of helping physicians and patients to decide on the most appropriate healthcare procedures in specific clinical circumstances [2].

Rather than being an imposition, GL are an aid to obtaining the most appropriate healthcare results, through clearly defined criteria of scientific validity (systematicity), which take into account the viewpoints of different stakeholders and which must therefore balance the interests of patients (clinical outcomes), physicians and healthcare providers (availability of resources).

The increasing use of GL has highlighted several problems, mainly related to the non-univocity of definitions and to not observing essential methodological prerequisites. The spread of low quality GL and GL that give contradictory recommendations are of growing concern [3–4].

GL require validity, which can be defined as the capacity to obtain an improvement in health. Validity in this sense is measurable. It is analogous to the efficacy of a drug, which can be evaluated for specific, determinable interventions, for example by way of randomized clinical trials, or of a diagnostic procedure, which can be characterized in terms of sensitivity, specificity, predictive value and probability ratio. The validity of the diffusion and implementation of a GL may then be evaluated in terms of the outcomes it produces [5].

Systematic reviews of these studies showed that in some contexts GL can change the behavior of healthcare practitioners and in some cases they can lead to significant improvements in clinical outcomes for patients [4–6]. These systematic reviews showed how a greater chance of obtaining positive results was associated with certain characteristics of GL. These include simplicity, local adaptability and the involvement of relevant professionals in their development.

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

An important problem highlighted by systematic reviews was the identification of methodological weakness of the available studies. This limited the ability to draw definitive conclusions about the validity of some treatments [6].

Assessment of the validity of a set of GL should be based on the positive changes its implementation induces on a specific pathological process. Such an assessment is made difficult by numerous confusing elements and by the complexity of the studies required. The concept of the validity of a GL has therefore shifted towards evaluation of adherence of a specific GL to the reference methodology, which is considered a guarantee of achieving the desired results.

GL may also be considered as tools for reducing the gap between current practice and alternative practices. They are therefore supporting tools to help make decisions for individual patients and for organizations by spelling out the benefits, risks and costs of different healthcare choices.

Based on these assumptions, the following methodological criteria have been identified:

1. The development of a GL and its evaluation must be oriented towards the results of the healthcare: the start of the process of forming (or using) a GL must always start from a precise healthcare context which is seen (or better still, evaluated) as problematic and therefore subject to improvement.
2. The GL must be based on the best evidence available.
3. The method used to summarize the available evidence must be rigorous, and follow a series of agreed steps: definition of the topic, formation of the writing group, definition of the method of bibliographical research and evaluation of the studies, dissemination and implementation.
4. The GL must contain an explicit classification of the strength of the recommendation: this is crucial and requires the need to give a "strength" to the various recommendations, based not only on the opinion of individual experts, but also on criteria arising directly from the quality of the studies which support the different recommendations of a GL.
5. The process of developing a GL must be multidisciplinary and involve users and patients. Experts in a discipline must not be the only ones to deal with a certain topic and others, who are in some way involved with the clinical management, including the patients, must also be included.
6. A GL must be adapted to the specific local circumstances.
7. A GL must take into consideration the available resources. This bridges the gap between experimental situations and the actual clinical context in which the individual practitioners work.
8. Once produced, GL must be disseminated and implemented in an appropriate manner. The simple act of publishing a set of GL in journals or congresses is not an effective way of promulgating their use in clinical practice.
9. The implementation of GL must be carefully monitored.
10. A GL must be regularly updated.

The main steps required for the formulation of GL are:

1. Formation of the work group.
2. An evaluation of the literature, aimed at establishing the best available research-based evidence for practice and researching GL already in existence.
3. Drafting the GL:
   - Systematic search of the literature;
   - Evaluation of the methodology of the studies;
   - Evaluation of the quality of the studies;
   - Production of a table of evidence, setting out the results of each study in terms of its conclusions and level of evidence. This step is the most difficult methodologically, as it assumes knowledge of epidemiology and the methodology of research; this step can be performed by persons outside the work group if there is nobody with the appropriate skills within it. The table of evidence should state the strength of evidence on which the GL is based, using a system such as that of the Scottish Intercollegiate Guidelines Network (SIGN) [7] (Table 27.1);

Table 27.1 Levels of evidence

1++	High quality meta-analysis. Systematic review of RCTs or RCTs with very low risk of bias
1+	Well conducted meta-analysis. Systematic review or RCTs with low risk of bias
1–	Meta-analyses. Systematic review or RCTs with risk of bias
2++	High quality systematic reviews of case-control or cohort studies High quality case-control or cohort studies with a low risk of confounding or bias and with a high probability that the relationship is causal
2+	Well conducted case-control or cohort studies with a low risk of confounding or bias and a moderate probability that the relationship is causal
2–	Case-control or cohort studies with a high risk of confounding or bias and a significant probability that the relationship is causal
3	Non-analytic studies (e.g., case reports, case series)
4	Expert opinions

Table 27.2 Strength of recommendations according to MERGE and SIGN criteria

A	At least one meta-analysis or a systematic review or an RCT classified as 1++ and directly applicable to the population, or a systematic review of RCT or a body of evidence consisting mainly of studies rated as 1+, directly applicable to the target population and with an overall consistency of results
B	A body of evidence consisting mainly of studies rated as 2++, directly applicable to the target population and with an overall consistency of results, or evidence extrapolated from studies rated as 1++ or l+
C	A body of evidence consisting mainly of studies evaluated as 2+, directly applicable to the target population and with an overall consistency of results, or evidence extrapolated from studies rated as 2++
D	Evidence level 3 or 4, or evidence extrapolated from studies rated as 2+

– Formulation of recommendations. On the basis of identified studies, recommendations for best practice can be made. These are then graded, according to the criteria listed in Table 27.2. This classification is drawn from the MERGE (Method for Evaluating Research and Guideline Evidence) [8] project and was adopted in 2000 by the SIGN. It partly changes a previous classification formulated by the AHCPR in 1993 [9] and has the advantage of incorporating quality aspects of the studies directly into the graded recommendations. It also gives appropriate weighting to randomized clinical trials, particularly for those issues (diagnosis, prognosis, etc.) for which other types of study (e.g., a cohort study), may be more appropriate.

4. Dissemination and implementation. These steps are an integral part of creating a set of GL. This section covers the identification of problems that may arise during the application of the GL and approaches for their resolution (e.g., incentivizing initiatives, structural and organizational changes, the use of specific tools such as reminders [paper or electronic] etc.) which can reach the site where the clinician actually makes the healthcare decisions [10].

By conducting an analysis of 431 sets of GL produced by international scientific societies between 1988 and 1998, evaluating them on the basis of essential criteria, such as their multidisciplinary applicability, completeness of the systematic review of the literature and gradation of the evidence, Grilli [3] demonstrated that 67% did not provide information

Table 27.3 Criteria for evaluating the validity of the guidelines' production process

	N/A	Yes	No
Responsibility and support for the development of the guidelines			
1. Do the guidelines identify the Institute/Organization responsible for the development and approval?	____	____	____
2. Do the guidelines give the source of finance and other support for the development?	____	____	____
3. If funds were received from commercial parties (e.g., pharmaceutical industries), do the guidelines give explicit details on the nature and level of the client?	____	____	____
4. Have any potential conflicts of interest of the parties providing finance or support been taken into consideration in a satisfactory way?	____	____	____
Composition of the guideline development group			
5. Is there a description of the individuals (professionals, interest groups including the patients) involved in the development of the guidelines?	____	____	____
6. Have all those involved made a formal declaration of interest?	____	____	____
7. Does the group contain representatives of all key disciplines?	____	____	____
8. Does the group include patients or their representatives?	____	____	____
9. Have each individual participant's potential conflicts of interest been taken into consideration in a satisfactory way?	____	____	____
Evidence identification and summary			
10. Is there a description of the methods used to collect the evidence on which the recommendations are based?	____	____	____
11. Are the methods of collecting the scientific evidence adequate?	____	____	____
12. Are the sources of information used to develop the guidelines adequately referenced?	____	____	____
13. Is there a description of the methods used to obtain the opinion of possible interested parties not included in the group developing the guidelines?	____	____	____
Assessing the strength of the scientific evidence			
14. Is there a description of the methods used to assess the strength of the evidence?	____	____	____
15. Do the guidelines make explicit links between the recommendations and the strength of the supporting evidence?	____	____	____
16. Overall, are the methods used to rate or weigh up the scientific evidence satisfactory?	____	____	____
Pre-test and external evaluation			
17. Have the guidelines been submitted to an Independent external review by experts or by an external panel?	____	____	____
18. Have the guidelines been pilot tested?	____	____	____
19. If the guidelines were pilot tested, has explicit information been given on the methods adopted and the results?	____	____	____
Review			
20. Do the guidelines provide explicit details on how they will be subjected to review and updating?	____	____	____
21. Do the guidelines identify the parties responsible for the review and updating?	____	____	____
22. Do the guidelines give a date scheduled for the review or an expiry date?	____	____	____
Global assessment of the validity of the guideline development process			
23. In the guidelines, is there an accurate summary of the methods, content and recommendations?	____	____	____
24. Overall, have the problems of potential bias and conflicts of interest been adequately dealt with?	____	____	____

Table 27.4 Criteria for the assessment of the validity of the guidelines' content and format

	N/A	Yes	No
Clinical applicability/flexibility			
1. Is there a description of the patient population(s) to which the guidelines are considered to be applicable?			
2. Is there a description of the professional groups for which the guidelines are considered to be applicable?			
3. Is there a description of the circumstances (clinical and non-clinical) in which exceptions can be made in the use of the guidelines?			
4. Is there a description of the ethical issues likely to arise in the using the guidelines?			
5. Is there an explicit description of how the patients' preferences must be taken into consideration in the application of the guidelines?			
6. Overall, do the recommendations cover all the significant clinical circumstances (including the diagnostic processes, clinical treatment and consultations)?			
7. Are the guideline recommendations consistent with each other?			
Clarity			
8. Are the main topics presented clearly?			
9. Do the guidelines describe the conditions to be diagnosed, treated or prevented in unambiguous terms?			
10. Do the guidelines describe in unambiguous terms the various options for the decisions on the condition?			
11. Do the guidelines identify current unacceptable or ineffective practices?			
12. Are the recommendations written in unambiguous terms?			
13. Can the main recommendations be found easily?			
Description of the likely costs and benefits			
14. Is there an adequate description of the health benefits that are likely to be gained from the application of the clinical recommendations?			
15. Is there a description of the potential harms or risks that may occur as a result of specific clinical recommendations?			
16. Is there an adequate description of the costs and expenditure likely to be incurred for specific recommended clinical lines of conduct?			
17. Have the potential costs and benefits been estimated appropriately?			
18. Are the issues regarding administrative/managerial competence clearly identified?			
19. Are the recommendations supported by the estimated benefits and possible harms and risks of the intervention (with the relevant strength of the evidence)?			
Development of local healthcare protocol, dissemination and implementation			
20. Do the guidelines describe recommended methods for the development of local healthcare protocols?			
21. Do the guidelines identify which professional groups should be involved in the development of local healthcare protocols?			
22. Do the guidelines identify key elements to be considered in local healthcare protocols?			
23. Do the guidelines identify key elements for which information should be provided to patients?			
24. Are there examples of reminders for individual patients?			
Clinical Audit			
25. Do the guidelines identify specific clinical outcome indicators for the areas covered by the guidelines?			
26. Are core targets and standards identified?			
27. Do the guidelines define the core data for reporting the relevant clinical care results?			
28. Does the core data for clinical care include key indicators of a) risk b) severity?			

on the staff involved, 88% did not provide information on the bibliographic search strategies, and 82% did not grade the evidence. Only 5% of GL reviewed satisfied all the criteria. However, there was an improvement with time, especially in respect of the search strategy (from 2% to 18%) and grading of the evidence (from 6% to 27%). Similar studies revealed the same problems, meaning that tracking down good quality GL cannot be taken for granted.

If it is possible to find GL with good validity, what strategies can be used to identify valid GL? It might be possible to adopt GL that have already produced positive results in terms of health outcomes. However, such experiences are relatively scarce and cannot be reproduced in different contexts. Account needs to be taken therefore of the local situation, ensuring the relevance of GL, which may lead to recommendations that are different to the originals.

An alternative strategy is to adopt stringent, validated methodological criteria to assess the available GL, or to construct evaluation "grids", which can be used by clinicians and by the final users. A recent systematic review analyzed available studies on this topic. It came to the conclusion that more than one of the tools had characteristics of such validity as to be of practical use, the one developed within the context of the European project AGREE [11], being one of the most widespread and useful. This evaluation tool focuses attention on the methodological and formal aspects described above, structuring the analysis and the evaluation of them in a format that is easily understood and usable (Tables. 27.3 and 27.4). In this way it is possible to evaluate a set of GL, adhere to a good development process and therefore, by inference, achieve the desired health effect. Thus, the tool is based on theoretical assumptions (the best available at the time) rather than on empirical evidence, which it is hoped can be accumulated with a wider diffusion of this type of evaluation.

Physical Environment: the Thermal Environment

Gunnar Sedin

28.1 Overview

During intrauterine life, heat production by the fetus results in a fetal temperature that is about 0.5°C higher than the maternal temperature [1]. After birth, the newborn infant is exposed to air and surfaces, which have a much lower temperature than that previously experienced in utero. The skin surface at birth is covered with amniotic fluid, causing heat loss through evaporation in an environment with a low vapor pressure [2]. As a result the body temperature of the infant is lowered, and the rate of this reduction is influenced by the temperature of the environmental air in the delivery room and the delivery of its flow. This gives rise to thermogenic responses that increase basal heat production [1, 3] and the skin circulation may decrease to lower the heat losses [4].

Heat balance in newborn infants depends on the heat transfer between the infant and the environment [5–8]. This transfer is related to the temperature and humidity of the environmental air (the vapor pressure), the flow velocity of that air (which causes a sense of cooling of the skin) and the temperatures of the surfaces facing the infant (ceiling, walls of room or incubator or bedding material) and the temperature of the surfaces in direct contact with the infant [5, 6, 8, 9].

After birth, the immediate interventions required to avoid body cooling are to carefully wipe off the amniotic fluid from the skin surface with cotton fabrics to lower the loss of heat through evaporation, and to cover the infant with a warm, dry towel or blanket, or both, to lessen the exposure of the infant's skin to the environment [2, 6]. The infant born at term or moderately preterm can be covered with a blanket and then placed on the mother's chest [10–12], but extremely preterm infants usually need other types of measures to maintain their body temperature, usually placement in an incubator or under a radiant heater [5, 6, 13–16] and, if necessary, mechanical ventilation with warm and humidified gas [7, 17–19].

28.2 Routes of Heat Exchange

Heat exchange between the infant and its environment occurs through the skin and through the respiratory tract. It has previously been difficult to estimate the heat exchange between the infant and the environment. The introduction of new techniques to measure the evaporation rate from the skin [6, 14, 20, 21] and from the respiratory tract [7, 21, 22] has permitted the heat loss through evaporation to be determined [6]. It is also possible to calculate the heat loss through other modes of heat exchange, such as radiation, convection (air movements), and conduction (in direct contact with a piece of material or skin) and to determine the heat loss per unit surface area and from the total body surface area [8], and also to take into consideration the proportions of surface area of the body participating in the different modes of heat exchange [5, 6]. In addition, the modes of heat exchange between the infant's respiratory tract and the environment can be determined.

28.3 Water and Heat Exchange Between the Infant's Body Surface and the Environment

Heat exchange through evaporation, radiation, convection and conduction can be calculated with knowledge of the transepidermal water loss (loss of water through the skin), the temperature of the infant's skin (T_{skin}), the temperature of the walls facing the infant (T_{wall}), the temperature of the ambient air (T_{amb}), the temperature of the material on which the infant is placed (T_{bed}), and characteristics of the material in the infant's environment, using the equations given in the following [2, 5].

28.3.1 Determination of Water Loss from the Skin

In the absence of forced convection (air movements), and if the effect of thermal diffusion is disregarded, the process of water exchange through a stationary water-permeable surface can be expressed in terms of the vapor pressure gradient immediately adjacent to the surface [20].

The evaporation rate (ER; g/m^2 h) from the infant's skin can thus be determined by a method based on calculation of the water vapor pressure in the layer of air immediately adjacent to the vapor pressure and the distance from the evaporating surface [20]. In this zone, the relationship between the vapor pressure and the distance from the evaporating surface is linear [20]. If the gradient in this layer is known, the amount of water evaporated per unit time (transepidermal water loss, TEWL; g/m^2h, which is a mean value of cutaneous water loss) can be calculated [20] according to the following equation:

$$TEWL = 0.92 \times ER_{(a,b,c)} + 1.37$$

where $ER_{(a,b,c)}$ is the arithmetic mean of ER measured from the chest, an interscapular area and a buttock [8, 9, 21, 22].

The gradient method (Evaporimeter, Servomed AB, 511 21 Varberg, Sweden), allows quick measurements of free evaporation without disturbing the infant [20, 22].

28.3.2 Calculations of Heat Exchange Between the Infant and the Environment

28.3.2.1 Exchange at the Surface

Heat exchange through evaporation (H_{evap}), can be calculated if TEWL is known [8, 9, 20–22] according to the equation:

$$H_{evap} = k_1 \times TEWL\ (3.6 \times 103)^{-1} \qquad (W/m^2)$$

where k_1 is the latent heat of evaporation (2.4×10^3 J/g), and 3.6×10^3 is the correction factor for time (s).

Heat exchange through radiation (H_{rad}) can be determined if the mean temperature of the skin (T_1; K) and the mean temperature of the surrounding walls (T_2; K) are known:

$$H_{rad} = S_0 \times e_1 \times e_2 \times (T_1^4 - T_2^4) \qquad (W/m^2)$$

where S_0 is Stefan-Boltzman's constant (5.7×10^{-8} W/m^2 K^4), e_1 is the emissivity of the skin, and e_2 is the emissivity of the surrounding walls (0.97).

Heat exchange through convection (H_{conv}) can be calculated if the mean temperature of the skin (T_1; K) and the mean temperature of the ambient air (T_3; K) are known:

$$H_{conv} = K_2\ (T_1 - T_3) \qquad (W/m^2)$$

where K_2 is the convection coefficient (2.7 W/m^2 K). The coefficient for convection given above and used in many studies referred to in this chapter has usually been determined in measurements on adult human skin [23]. A convection coefficient suggested as being more valid for newborn infants [24] can alternatively be used and Hconv will then be 48 % higher.

Heat exchange through conduction (H_{cond}) can be determined if the temperature of the skin (T_{skin}; K) and the temperature of the bed (T_{bed}; K) are known:

$$H_{cond} = k_0\ (T_{skin} - T_{bed}) \qquad (W/m^2)$$

In this equation k_0 is a conductive heat transfer coefficient. With the thermal conductivity characteristics of most regular mattresses the heat loss through conduction is very low.

The extent of heat exchange between the body surface area and the environment thus depends on the type of heat exchange, on the position and geometry of the body [6, 8] and on the magnitude and frequency of body movements. As different modes of heat exchange are unequally influenced by changes in the body position, the relative contribution of different modes of heat exchange might vary with time. Heat exchange is often presented per unit area of body surface exposed to the ambient air or facing the walls of the incubator.

28.3.2.2 Heat Exchange Between the Infant's Respiratory Tract and the Environment

The expired air is usually more humid, than the inspired air, and has a higher water vapor pressure. This implies that evaporative loss of water and heat takes place from the respiratory tract. Convective heat transfer, usually of low degree, also occurs in the respiratory tract. In research, these two processes are considered together [25]. In the newborn, heat can also be gained through the respiratory tract if the infant inspires very warm air with a high humidity. Because of the alternating displacement of air during the respiratory cycle, convective and evaporative heat transfer in the respiratory tract is complex. When ambient air, which is cooler than the body, passes along the mucosa of the infant during inspiration, it gains heat by convection and gains water vapor by evaporation from the mucosa. On reaching the alveoli, the air is at thermal equilibrium with the central body temperature and is saturated with water. During expiration, the expired air may become a little cooler than the body temperature before it leaves the infant [7, 21].

28.3.2.3 Determination of Water Loss from the Airway

Respiratory water loss (RWL) is usually included in measurements of total insensible water loss when these are performed

with ventilated chambers, but it can be estimated separately [26, 27]. Hey and Katz [26] and Sulyok and colleagues [27] found that the respiratory water loss was higher at a low ambient humidity than at a high humidity. In other studies, data on respiratory water loss, oxygen consumption and carbon dioxide production were provided [7, 17, 18, 21, 28–32].

28.3.2.4 Calculation of Heat Exchange Between the Infant's Respiratory Tract and the Environment

The exchange of heat through convection in the respiratory tract, H_{conv-r}, is calculated from the air volume ventilated per unit time (V = ventilation volume) and from the temperature difference between expired and inspired air ($T_E - T_I$) according to the following relationship:

$$H_{conv-r} = V \times r \times c\ (T_E - T_I)\ m^{-1} \qquad (W/kg)$$

where V is ventilation volume per unit time, r is density (1 g = 0.880 L), c is the specific heat (1 J × g^{-1} × $°C^{-1}$), m is the body weight (kg) [8].

Because of the alternating inspiratory warming and expiratory cooling of the air, the convective heat exchange in the respiratory tract depends mainly on the temperature of the inspired air. In human infants nursed in incubators there is a very small difference between the temperatures of the inspired and of the expired air, and convective losses are small.

Evaporative heat exchange from the airway (H_{evap-r}) depends on the difference in water content between the expired and the inspired air. This is the respiratory water loss [17, 19, 33]. As the formation of water vapor in the respiratory tract requires thermal energy, the amount of heat exchange by evaporation per unit time is expressed by the following equation:

$$H_{evap-r} = k_1 \times RWL\ (3.6 \times 10^3)^{-1} \qquad (W/kg)$$

where k_1 is the latent heat of evaporation of water (2.4×10^3 J/g), RWL is the respiratory water loss (mg/kg min) and $(3.6 \times 10^3)^{-1}$ is the correction factor for time.

28.4 Heat Exchange in Incubators, under Radiant Heaters and in Heated Beds

When it was realized that a good thermal environment increases the chances of survival of newborn infants, attempts were made to provide them with a warm environment. The ambient temperature influences the survival rate and oxygen consumption in newborn infants [3, 26, 33] and a body temperature of around 37°C is appropriate for newborn infants at rest [31]. At a high ambient temperature full-term infants start to sweat, and if they are fed cold glucose through a gastric tube, sweating is inhibited [34].

28.4.1 Incubators

In a convectively heated incubator, the warm air supplied should be directed so that both the air temperature of the incubator and the incubator walls are kept warm. If the air flow velocity is lower than 0.1 m/s, the convective heat transfer will depend on the gradient between the skin and the air temperature, and the vapor pressure gradient close to the skin surface will be maintained, avoiding an increased evaporative rate due to increased air flow velocity [8, 23, 24].

An evaluation of environmental and climate control in incubators has shown that the air flow velocities and capacity for humidification vary markedly between different types of incubators. Also, the wall temperatures vary considerably between different incubators [32] and it is therefore necessary to determine the air flow velocities, humidity and wall temperatures carefully before calculating heat exchange. With air flows higher than 0.2 m/s, there will be a forced convection.

28.4.2 Radiant Heaters

A radiant warmer placed over an open bed platform provides good accessibility and visibility for the care of the newborn infant and has therefore become widely used in neonatal intensive care.

Infants nursed under a radiant heater gain heat, but they may also have extensive heat losses through evaporation and convection, and also, from some surfaces, through radiation [14, 15, 35–38], making it difficult to estimate the relative contributions of different modes of heat exchange. Because of the free movements of air above the infant's body surface, both evaporative and convective heat loss may increase as a result of a high air velocity.

28.4.3 Heated Beds

In the 1990s, Sarman and co-workers found that infants weighing 1000 g or more can be kept warm by placing them on a heated water-filled mattress [39] early after birth. By covering most parts of the body except the face, direct heat exchange between the infant's skin and the environment through other modes can be almost eliminated in a large proportion of the body surface.

Preterm and term infants can maintain a normal body temperature during skin-to-skin care, if they are placed lying naked except for a diaper on the mother's or father's chest, and are covered with the mother's clothing or a blanket [10–12].

Only parts of the head are exposed to the environmental air [10–12] and will exchange heat with the environment.

28.5 Water and Heat Exchange Between the Skin and the Environment

In a series of studies, water evaporation from the skin surface of infants nursed in incubators has been determined by use of the gradient method (the ServoMed Evaporimeter), and transepidermal water loss (TEWL) [13, 21, 22, 40] and heat exchange have been calculated [2, 5, 6]. In these studies the body temperature has been maintained at 36-37°C, except when the effect of warming has been investigated, and the ambient humidity has been kept at 50% except when the effects of different humidities have been analyzed. Evaporative heat loss is usually insensible, but might become sensible when term infants are nursed in a warm environment and start to sweat [34]. Some infants born at term and nursed in a warm environment do not begin to sweat [34], and if they do, the sweating is preceded by an increase in skin blood flow. In preterm infants the sweat glands are non-functional [26].

28.5.1 Heat Exchange During the First Hours after Birth

Immediately after birth, when the infant's skin is covered with amniotic fluid, there is an enormous evaporative heat loss from the skin surface. This evaporative heat loss decreases gradually during the first hours, whether the infant is nursed in the delivery room or in an incubator [2], (Fig. 28.1, top two diagrams). Heat loss through radiation is high if the infant's skin is facing the walls of the delivery room and is much lower if it is facing the inner walls of the incubator [2] (Fig. 28.1, middle diagrams). The heat loss through convection is lower than that through radiation but is much higher when the infant is nursed in room air (Fig. 28.1, lower left diagram) than when nursed in the incubator (Fig. 28.1 lower, right diagram).

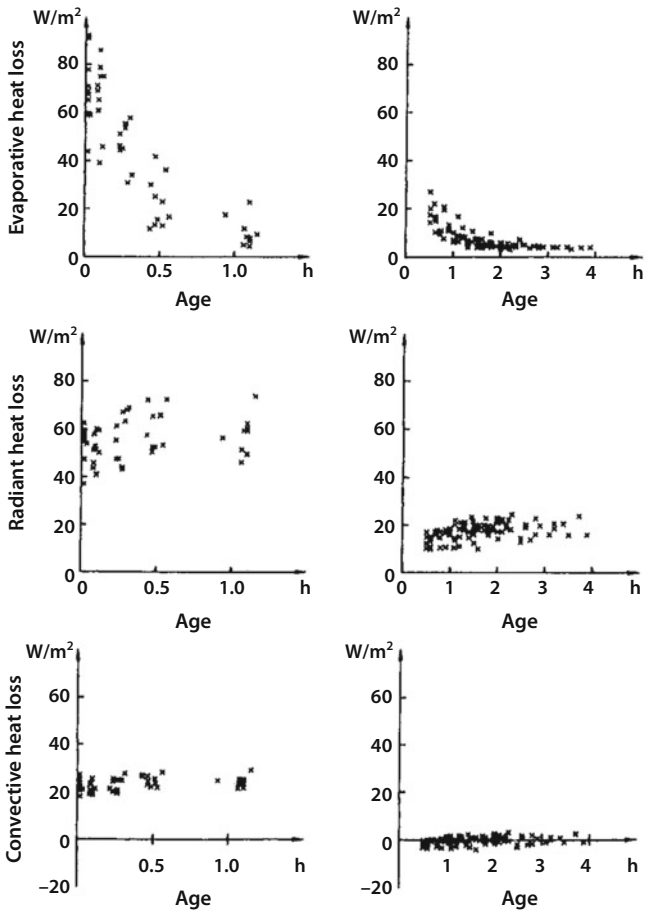

Fig. 28.1 Heat exchange between the skin of full-term infants and the environment immediately after birth and during the first 1 to 4 hours postnatally. The infants were not washed or wiped. Data presented in the left-hand scatter diagrams are based on measurements in infants initially placed at the delivery bed or at the mother's chest and later in a cot. After the measurements made 1 and 5 minutes after birth, the infants were covered with a towel between the measurements. Data in the right-hand diagrams are based on measurements in infants who were covered with a towel after birth and until they were placed in an incubator [2]

28.5.2 Transepidermal Water Loss During the First 4 Postnatal Weeks

The transepidermal water loss from the skin surface of the newborn infant depends primarily on the gestational age (GA) at birth [13], but it is also influenced by the postnatal age [40]. The transepidermal water loss in newborn infants is also lower in small for gestational age (SGA) [21] than in appropriate for gestational age (AGA) [13, 21, 40] infants. There is an exponential relationship between TEWL and gestational age in AGA infants when measurements are made during the first day after birth [13]. This relationship prevails over the first 4 weeks after birth, even though the difference in TEWL between the most preterm and the full-term AGA infants gradually diminishes with increasing age. The evaporation rate and TEWL both depend on the ambient relative humidity or ambient vapor pressure [13, 21]. This relationship seems to be valid for all gestational ages and is also valid for all postnatal ages studied [13, 21, 40, 41].

28.5.3 Heat Exchange During the First Day after Birth

The evaporative heat exchange is directly proportional to the amount of water that evaporates from the infant's skin, and shows the same type of relationship to GA as TEWL [5, 21]. When infants are nursed in an ambient humidity of 50%, the evaporative heat exchange may reach 50 W/m^2 of the body surface area in the most preterm infants [5], whereas in term

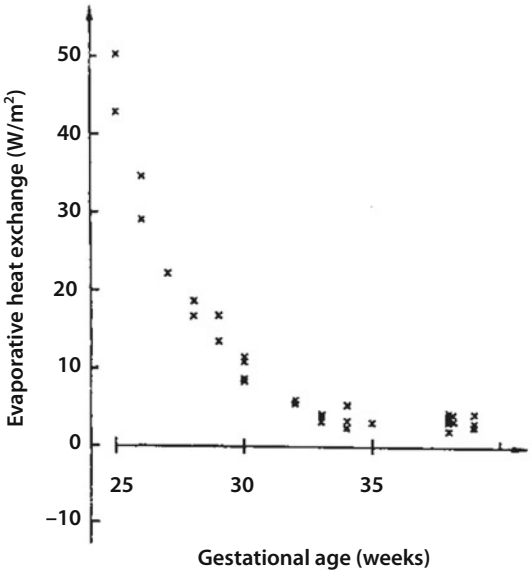

Fig. 28.2 Heat exchange through evaporation at ambient humidity of 50% in relationship to gestational age. Measurements were made during the first 24 hours after birth in preterm infants and during the first 30 hours in term infants [5]

infants it is close to 5 W/m^2 (Fig. 28.2). The high evaporative heat loss in very preterm infants makes it necessary to have a very high ambient temperature in the incubator to maintain a normal body temperature of 36.0°-37.0°C in these infants.

The servocontrol system of the incubator that controls the skin temperature, regulates the temperature of the air, which also leads to changes in the temperature of the incubator walls and thereby influences the heat exchange through convection and radiation.

The most preterm infants can even gain heat through these modes of heat exchange. Preterm infants were nursed in an incubator with a relative humidity of 50%, at a higher ambient vapor pressure than the more mature infants need [21, 40]. This means that the heat exchange between the very preterm infants and their environment could have been even greater, if comparisons had been made at equal ambient vapor pressures instead of at equal ambient humidities.

In studies of the effects of different ambient humidities, it was found that infants born at a GA of less than 28 weeks need a T_{amb} of around 40°C to maintain a normal body temperature at an ambient humidity of 20%, whereas full-term infants need a T_{amb} of around 34°C at this ambient humidity (Fig. 28.3). Nursing very preterm infants at a higher ambient humidity means that a lower ambient temperature can be sufficient to maintain a normal body temperature [5].

28.5.4 Heat Exchange at Different Ambient Humidities

Evaporative heat exchange between the skin of very preterm infants and the environment is highest at a low humidity [5],

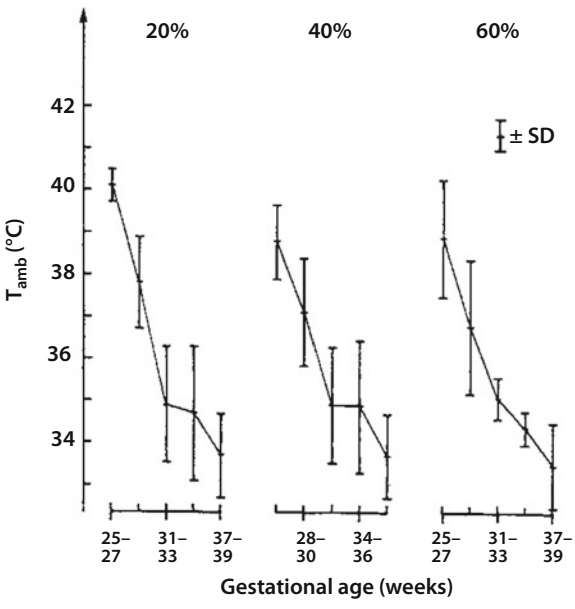

Fig. 28.3 The relationship between gestational age and the ambient temperature needed to maintain a normal body temperature at three different humidities of 20%, 40% and 60%. Measurements were made during the first 24 hours after birth in preterm infants and during the first 30 hours in term infants [5]

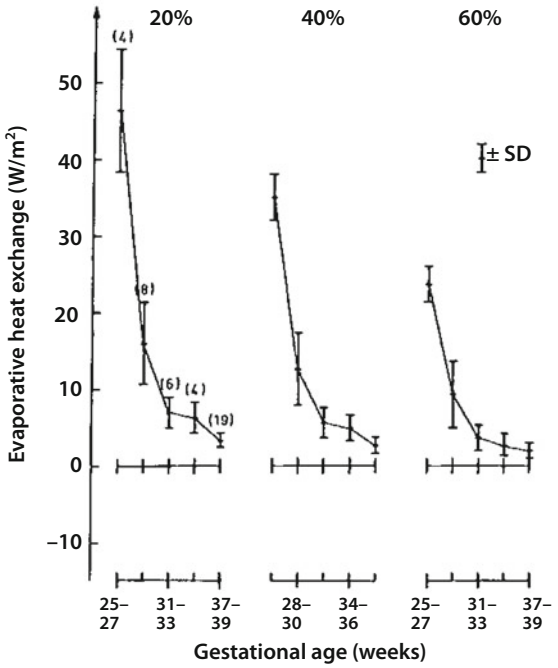

Fig. 28.4 Heat exchange through evaporation in relation to gestational age at relative ambient humidities of 20%, 40% and 60%. *SD*, standard deviation [5]

and lower at higher ambient humidity. In fact, heat exchange through evaporation in the most preterm infants is twice as high at 20% as at 60% ambient humidity. Other modes of heat exchange are all influenced by the ambient humidity (Fig. 28.4). The sum of the different modes of heat exchange, in the different GA groups is almost the same, but the total heat loss cannot be calculated in this way, as the proportions of the body surface area exchanging heat in different ways are not known.

28.5.5 Heat Exchange During the First Weeks after Birth

The high evaporative losses of heat from the infant's skin that are seen in the most preterm infants during the first days after birth will gradually decrease with increasing postnatal age [6]. Heat loss through radiation is low early after birth in the most preterm infants born at 25–27 weeks of gestation. Heat loss from radiation will, however, be the most important mode of heat exchange after the first postnatal week. In infants born at a GA of 28 or more weeks, the radiative heat exchange is the most important mode of heat exchange from birth and it gradually increases with age. The heat exchange through convection is low in infants nursed in incubators. Initially there is a gain of heat through convection in the most preterm infants early after birth.

During the first weeks after birth the relative magnitude of the different modes of heat exchange markedly depend on the ambient humidity (Fig. 28.5). In infants born at 25–27 weeks of gestation and nursed in a dry environment, evaporative heat exchange will be the most important mode of heat exchange for more than 10 days after birth. At an ambient humidity of 60% this mode of exchange is the highest only during the first 5 days. Thereafter, the radiative heat exchange is the most important mode of heat loss [6].

The total heat exchange between the infant's skin and the environment can be calculated if the body surface area of the infant and the fractions of this area that participate in the different modes of heat exchange are known [6, 21, 26]. This is very difficult with available methods, especially if estimations are to be made over a longer period of time [6]. The total heat exchange is basically dependent on the metabolic rate.

28.5.6 Heat Exchange Between the Infant's Skin and the Environment During Care under Radiant Heaters

Several authors have considered that a lower vapor pressure in the ambient air [42] and more convective air currents under the radiant heater [35] cause an increase in evaporative water loss and heat exchange. More recent determination of the evaporation rate from the skin of term, moderately preterm and very preterm infants nursed in incubators with 50% ambient humidity and under a radiant heater, have shown that the evaporation rate from the skin surface of full-term infants is significantly higher under a radiant heater than in an incubator [14]. In moderately preterm infants born at 30 to 34 weeks of gestation, the evaporation rate from the skin is significantly higher at an environmental humidity of 30% than at 50%, and in very preterm infants with a GA of less than 30 weeks, the evaporation rate is higher under a radiant heater than in an incubator at an environmental humidity of 50%.

A transparent heat shield positioned over the infant can lower the heat exchange, (occurring through both convection and evaporation) between the infant and its environment, decrease convective air currents and increase humidification

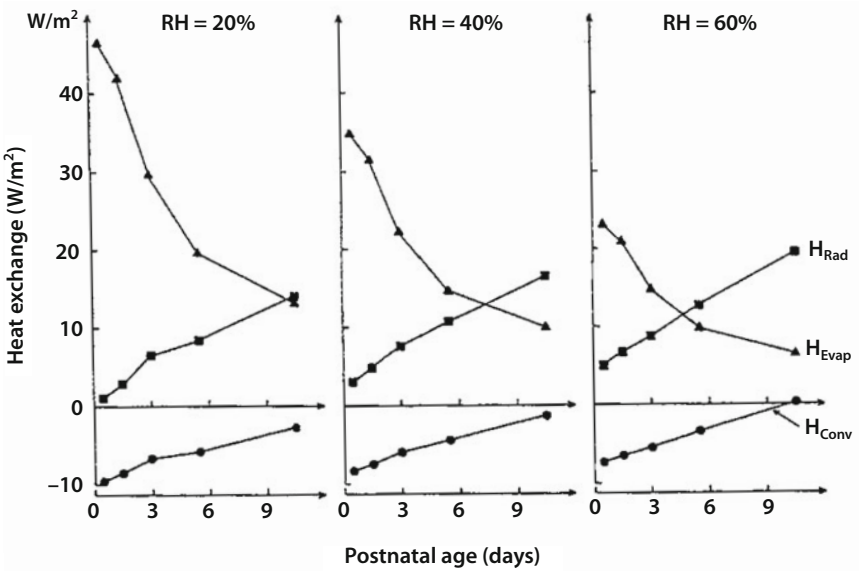

Fig. 28.5 Heat exchange between the infant and the environment in relation to postnatal age at relative ambient humidities (RH) of 20%, 40% and 60% in infants born at 25 to 27 weeks of gestation [6]

[35] and diminish the water loss [42–44]. It has been suggested that a bed platform that can be used with a radiant heater or with a hood might make it easier to adapt to the mode of care that such an infant needs [45].

28.5.7 Ambient Humidity Influence on the Rate of Skin Barrier Maturation in Extremely Preterm Infants

In infants born at 24–25 completed weeks of gestation, and nursed in incubators at 50% ambient humidity, water loss was higher than that previously found in infants born at 25-27 weeks of gestation [46].

To investigate if the level of radiant heaters (RH) in which the preterm infants are nursed, might influence their postnatal skin maturation, TEWL was determined in twenty preterm infants (GA 23–27 weeks) nursed at postnatal ages (PNA) of 0, 3, 7, 14 and 28 days [47]. The results indicate that the level of RH influences skin barrier development, with more rapid barrier formation in infants nursed at a lower RH. The findings have an impact for promoting skin barrier integrity in extremely preterm infants (Fig. 28.6) [47]. The individual decrease in $TEWL_{50}$ was consistently more pronounced in the RH_{50} group than in the RH_{75} group. There were no differences in body temperature, skin temperature, or ambient temperatures (T_{amb} and T_{wall}) between the 2 study groups. The total fluid intake and serum sodium levels during the period 0–14 days of PNA are presented in Fig. 28.6.

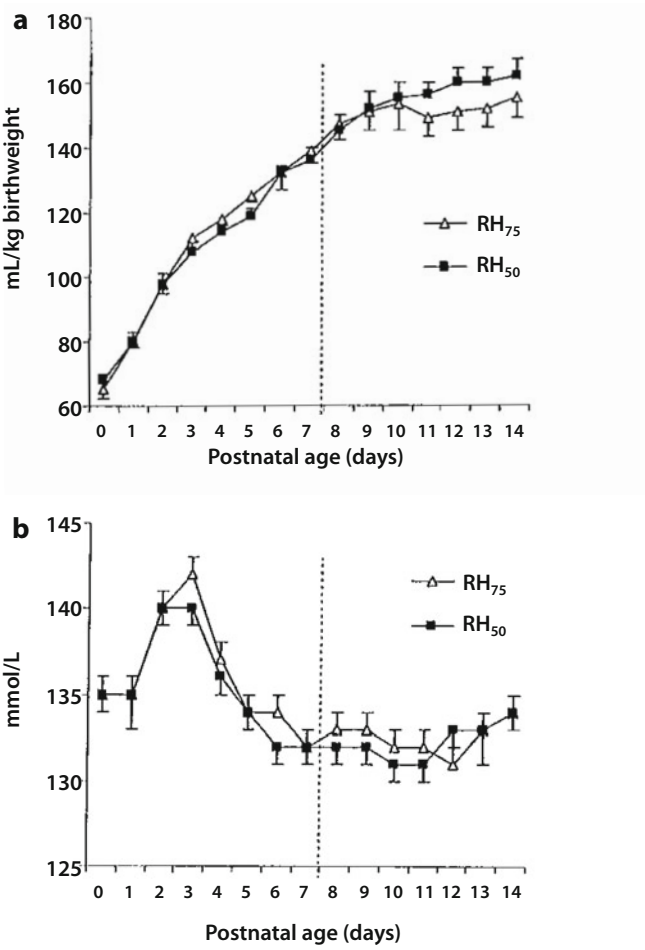

Fig. 28.6 Daily total fluid intake (**a**) and serum sodium levels (**b**) at postnatal ages (PNA) of 0 to 14 days in infants nursed at RH_{75} or RH_{50} from PNA 7 days (*indicated by dotted lines*). There are no statistically significant differences between study groups [46]

Table 28.1 Effect of activity level on insensible water loss and oxygen consumption

Activity level	IWL_S	IWL_R	IWL_T	VO_2
0	6	6	12	8
1		8		9
2		9		10
3		10		11
4		12		12
5	7	16	23	13

Insensible water loss from the skin (IWL_S) and from the respiratory tract (IWL_R) and their sum (IWL_T) in g/kg/24 h, and oxygen consumption (VO_2; L/kg/24 h), in full-term appropriate for gestational age infants at different levels of activity. From [29].

Table 28.1 further documents that there are no significant differences between the group of infants that were nursed at a RH of 75% and those nursed at a RH of 50% (Table 28.1).

28.5.8 Heat Exchange Between the Infant's Skin and the Environment During Phototherapy

Phototherapy has been reported to increase insensible water loss in newborn infants [35, 42]. This loss of water and heat might be caused by altered barrier properties in the skin or by increased respiratory water loss. However, other studies have indicated that in thermally stable term and preterm infants [36] there is no increase in the evaporation rate from the skin surface during phototherapy.

28.5.9 Heat Exchange Between the Infant's Skin and the Environment During Care on a Heated Bed

An infant on a heated bed gains heat through conduction. Some losses of water and heat from the airway will take place, depending on the vapor pressure of the room air. Sarman and colleagues showed that infants weighting ≤1000 g

could be kept warm when nursed on a heated water–filled mattress [39]. In a 2 week trial with infants whose birthweights were between 1300 and 1500 g, Gray and Flenady found that that weight gain was lower and body temperature higher in those who were cot-nursed with warming than in those who were nursed in an incubator [48].

28.5.10 Heat Exchange Between the Infant's Skin and the Environment During Skin-to-Skin Care

After the introduction of skin-to-skin care for newborn infants [12], Bauer and colleagues showed that preterm infants less than 1 week of age and with a birthweight of less then 1500 g were not exposed to cold stress during 60 minutes skin-to-skin care in stable preterm infants [10]. Similarly, preterm infants born at 28 to 30 weeks of gestation and studied during the first and second week after birth increased their body temperature during 1 hour of skin-to-skin contact with no significant change in oxygen consumption [11]. More immature infants, born at 25 to 27 weeks of gestation, showed no increase in oxygen consumption but a decrease in rectal temperature during the same duration of skin-to skin contact during the first week after birth.

During the second postnatal week, the body temperature did not change in infants born at 25 to 27 weeks of gestation during skin-to-skin care [11]. It has been suggested that infants born at 25 to 27 weeks of gestation might have a very high evaporative heat loss during the first week after birth, causing cold stress [6, 13].

28.5.11 Keeping the Very Preterm Infant Warm Early after Birth: the Effect of Thin Clothing

Newborn infants are at risk of losing heat soon after birth. It is therefore of great importance to wipe off amniotic fluid from the skin surface, remove wet linen, and to wrap the infant in pre-warmed blankets or alternatively, placing the infant skin to skin on the mothers chest to use her body as a heat source [12].

When an infant is placed in an environment where the temperature and humidity is low, the evaporative heat and water exchange will be high and air movements in the environment may further increase the loss of heat through evaporation, conduction, convection and radiation. It is therefore of outmost importance to keep the infant warm. In a laboratory setting we present data on the evaporation rate from a semi-permeable membrane positioned above a membrane [2, 5, 13, 49].

28.6 Water and Heat Exchange Between the Respiratory Tract and Environment

Water and heat exchange from the respiratory tract takes place with each expiration. Using indirect methods, it has been shown that respiratory water loss depends on the humidity of the inspired air, with lower losses occurring at a high humidity [26, 38]. The respiratory water loss (mg/kg min) can be determined using a flow-through system with a mass spectrometer for measurements of gas concentrations [7–9, 17, 18, 28–30, 32]. In an environment with an ambient humidity of 50% the evaporative heat loss from the airway will be moderate [28], i.e., in term AGA infants the insensible water loss from the respiratory tract (IWL_R) and that from the skin (IWL_S) will be of equal magnitude [28]. The evaporative heat loss from the respiratory tract ($H_{evap–r}$) and the evaporative heat loss (H_{evap-s}) from the skin will also be of equal magnitude under these conditions.

The evaporative loss of water and heat from the airway depends on the ambient humidity both in lambs [7] and infants [28], with lower losses at a high than at a low humidity. Whereas IWL_S decreased from 9 to 2g/kg/24h in term infants when the ambient humidity was increased from 20 to 80%, the corresponding change in IWL_R was much smaller, i.e., from 9 to 5g/kg/24h [28]. In infants placed in a calorimeter, Solyok et al [27] found that the respiratory heat loss was between 0.07 and 0.22 W/kg, or 3-10% of the total heat production from metabolism and about 40% of the insensible heat loss. In term infants, RW_L and H_{evap-r} may increase during activity by up to 140% of the values at rest [29].

In Table 28.2, data are presented on IWL_S and IWL_R. During moderate heat stress both lambs and infants can increase their RWL and H_{evap-r} without increasing their oxygen consumption and CO_2 production [17, 30]. Exposure to radiant heat can alter the respiratory water loss in a lamb while leaving the oxygen consumption and CO_2 production unchanged. RWL is directly proportional to the rate of breathing [17, 30, 31], which means that lambs and infants will lose more water and heat when they have a high rate of breathing (Fig. 28.7). The oxygen consumption will increase if the heat stress induces bodily movements with higher levels of activity [29].

28.6.1 Respiratory Water and Evaporative Heat Exchange before and after Intubation

In non-intubated lambs, exposed to a radiant heat source, RWL increased from 10.5 to 33.4 mg/kg/min, while the respiratory rate increased from 54 to 161 breaths/min and the oxygen consumption and CO_2 production were unaltered [21]. During exposure to the same heat source, intubated lambs increased their respiratory water loss from 8.1 to 18.7

Table 28.2 Effects of phototherapy on respiratory values in neonates

	n	RWL (mg/kg/min)	VO_2 (mL/kg/min)	VCO_2 (mL/kg/min)	RR (breaths/min)
Before	11	4.4 ± 0.7	5.9 ± 0.9	4.0 ± 0.7	48 ± 7
12 min	11	4.4 ± 0.6	5.9 ± 1.0	3.9 ± 0.6	
24 min	10	4.1 ± 0.8	5.5 ± 1.1	3.8 ± 0.7	
36 min	9	4.2 ± 1.0	5.4 ± 1.0	3.6 ± 0.6	
48 min	11	4.4 ± 0.7	5.9 ± 1.1	3.9 ± 0.7	51 ± 11
60 min	9	4.6 ± 0.9	5.9 ± 1.1	4.1 ± 0.8	
After	9	4.8 ± 0.8	6.1 ± 0.9	4.1 ± 0.4	

Respiratory water loss (RWL), oxygen consumption (VO_2), carbon dioxide production (VCO_2; mean ± SD) and respiratory rate (RR) in full-term infants before, during, and after 60 min of phototherapy. From [22].

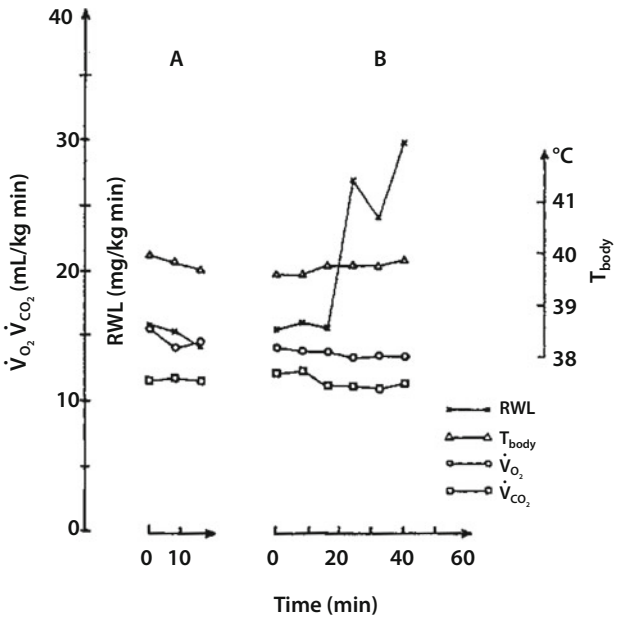

Fig. 28.7 Respiratory water loss (RWL), body temperature (T_{body}), oxygen consumption (VO_2) and CO_2 production (VCO_2) in a 6-day-old lamb before (A) and during (B) heat stress. From [30]

mg/kg/min and their rate of breathing from 46 to 125 breaths/min. In intubated lambs both the oxygen consumption and CO_2 production increased significantly [21].

28.6.2 Respiratory Water and Evaporative Heat Loss in Relation to GA

RWL was found to be highest in the most preterm infants and lower in more mature infants; they were usually asleep during the measurements [18]. Studies were performed in incubators with 50% ambient relative humidity and an ambient temperature that allowed the infant to maintain a normal and stable body temperature. RWL per breath (mg/kg) was almost the same at all gestational ages and the higher RWL values found in the most preterm infants as compared to the more mature ones was thus due to the higher rate of breathing [46].

28.6.3 Respiratory Water and Evaporative Heat Exchange During Phototherapy

When term and preterm infants [22] were exposed to phototherapy in the absence of heat stress, there were no significant changes in RWL, oxygen consumption, CO_2 production or rate of breathing [22] (Table 28.2).

28.6.4 Respiratory Water and Heat Exchange During Mechanical Ventilation

In clinical neonatal care with a warm and humid environment or with warm and humidified gas supplied from a respirator, heat exchange through evaporation and convection between the respiratory tract and the environment is low [7, 27, 28]. Infants who inspire cold air with a low water vapor pressure will have high evaporative loss from the respiratory tract and will also lose heat through convection. These losses may become clinically significant, for instance during transport in a cold climate [19].

The concept of an optimum thermal environment for newborn infants evolved during the 1960s [50]. This idealized setting, called the neutral thermal environment, is characterized as the range of environmental temperature within which the metabolic rate is at a minimum and within which temperature regulation is achieved by non-evaporative physical processes alone. There is no reason to believe that the normal temperature of infants is different from that of adults. An infant's internal temperature within the range of 36.5° to 37.5 °C (with a diurnal variation of ±0.5°C) is probably normal. Because body temperature is a measure of only the balance between heat production and net heat loss, a normal body

temperature should not be confused with a "normal" metabolic rate [50].

A cold-stressed infant depends primarily on mechanisms that cause chemical thermogenesis. When an infant is stimulated by cold, norepinephrine [51] is released, inducing lipolysis in brown fat stores principally found in the interscapular, paraspinal and perirenal areas. Because of the protein thermogenin, brown fat can decouple oxidative phosphorylation and break down fats to produce heat, without the inhibitory feedback loop of adenosine triphosphate (ATP) production. Triglycerides in the fat are broken down to fatty acids and glycerol. The fatty acids enter thermogenic metabolic paths that end in the common pool of metabolic acids. Brown fat is turned on in response to skin thermoreceptors prior to a decrease in core temperature, and shivering is initiated by a decrease in core temperature.

Glycolysis may also be stimulated during severe stress when epinephrine released from the adrenals activates glycogen stores, which may result in transient hyperglycemia [52]. Lowered blood sugars in cold-stressed infants also have been reported [53], possibly caused by inhibition of glycolysis, by lipolysis, or by exhaustion of glycogen stores.

28.7 Summary

The exchange of heat between the infant's skin and the environment is influenced by the insulation provided by the skin, the permeability of the skin, and environmental factors such as the ambient temperature and humidity, air-flow velocity, and the temperature and characteristics of the incubator surfaces facing the infant. Evaporative heat loss from the skin is the major component of heat exchange in the most preterm infants early after birth, and these infants gain heat through convection and, in a very dry environment, possibly also through radiation when they are nursed in an incubator. As water loss from the skin surface of the most preterm infants decreases with postnatal age, heat loss through evaporation from the skin also decreases. Their need for a high ambient temperature also diminishes, and with the lower temperature of the incubator walls, the heat loss through radiation then increases and the heat gain by convection is changed to a low loss of heat during the first weeks after birth.

Infants nursed under a radiant heater gain heat through radiation and, as a result of the low ambient humidity, evaporative loss of water and heat may be high in very preterm infants. The loss of heat through convection greatly depends on how the infant is protected from high air velocities by arrangements made under the radiant heater, and also on the magnitude of movements in the nursery.

In term infants nursed in incubators with an ambient humidity of 50%, the evaporative water and heat loss from the respiratory tract and from the skin are about the same magnitude. Respiratory water and evaporative heat loss is thus low in term infants. The respiratory evaporative water loss and heat loss per breath are of about the same magnitude in calm preterm and term infants. In preterm infants, the evaporative heat losses from the skin are much more important than such heat losses from the respiratory tract. The evaporative heat loss from the airway might be considered important only in infants with high motor activity or with tachypnea, especially if they are nursed in a very dry environment. Mechanical ventilation with dry and cold air also results in high loss of heat from the respiratory tract through evaporation and convection.

Information and Psychosocial Intervention in Neonatology

Massimo Agosti

29.1 Introduction

Maternity is a unique experience calling for shared responsibility in protecting the baby, the parents and their environment. Mood disorders (stress, depression) can occur and sometimes interfere with the complex network of relationships that lead to satisfactory family and infant relationships.

Women with antenatal psychosocial risk factors are more likely to have postnatal depression [1]. Various investigations have supported routine antenatal and postnatal screening for psychological mood disorders. An assessment screening questionnaire developed by Matthey and colleagues was used to collect information on the frequency of psychosocial risk factors in over 2000 pregnant women in Australia, as well as the impact on clinical caseloads. The most common risk factors were personality and life stresses (24%), followed by psychiatric history (20%), current mood (12%), childhood abuse (9%), family violence (5%: interestingly, more women reported being violent toward their partner than their partner being violent toward them); the least frequent risk factor was lack of support (3%) [2].

Even hospitalization of the premature infant in the neonatal intensive care unit (NICU) is considered as a "psychological crisis" in the family, causing feelings of powerlessness and stress, especially for mothers.

29.2 Preterm Birth and Family Stress

In Italy approximately 6000 very low birth weight (VLBW, less than 1500 g) births occur annually. Survival rates for small preterm infants have improved, especially those of VLBW. Although the birth of an infant with VLBW poses a considerable challenge to parents, there is little information about how it affects family stress. For an event like preterm birth, different sources of parental stress have been identified. One of the most important is early separation of the mother and infant, which may adversely affect attachment between the mother-child dyad [3]. Consequently, feelings of anxiety and depression are frequent in mothers of preterm infants and appear to be more intense during the hospitalization of the child in the neonatal intensive care unit. Maternal depression has been associated with impairment of child cognitive, emotional, and behavioral development. Early maternal depression or other psychological symptoms may have varying effects on preterm infants. The relationship of maternal mental health on parenting behavior is important for preterm populations because maternal psychological status and other social factors (e.g., socioeconomic status, maternal substance abuse, multiple birth, or other life stressors) have been found to correlate with childhood emotional and mental well-being in children of school age, who were of low-birth-weight or preterm. Signs of parental distress can emerge during hospitalization, which is why staff should adopt a holistic approach to understanding the uniqueness of each family and provide appropriate support.

If a problem is diagnosed during pregnancy, parents should be forewarned. If this does not occur, most women and their partners will not give serious consideration to the possibility of preterm delivery or illness in their newborn baby and admission to a neonatal unit. Parents are unfamiliar with the potentially complex problems their infant faces and there is uncertainty about the future. A lack of understanding and uncertainty are major sources of stress. In addition, maternal health is often compromised at this time. Mother and baby are separated when the infant is admitted to the neonatal unit, and this may last many months. Although in some hospitals a visit to the neonatal unit is a routine part of antenatal care, the neonatal unit is generally an alien environment for most parents. Units are often noisy, bright, and hot. They can be overcrowded and parts will be "high tech." Parents rarely know the neonatal unit staff before their baby is admitted, and the language and behaviors they encounter can contribute to

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

an overwhelming feeling of isolation. The sickest preterm infants may be in hospital for many months, and visiting can be difficult, exhausting, and a financial drain for parents, especially as neonatal services become more centralized. All these factors put strain on the parents' relationship: a relationship is more likely to breakdown during the months after preterm delivery. Some couples, however, feel the experience makes their relationship closer, at least initially. Generally, stress and anxiety are higher in mothers than in fathers, and lessen with the passage of time. For some parents, the stress experienced is similar to that seen in adults diagnosed with post-traumatic stress disorder. High levels of stress may last beyond the first year of their infant's life, and the level and duration of stress may not be directly related to how preterm or how sick their baby was. In addition to high levels of stress and anxiety, these parents are more prone to clinical depression, which may be difficult to recognize.

Responses and feelings similar to those of a classic grief reaction can be encountered: shock, denial, anger, guilt, acceptance, and adjustment. Several models have explored how parents cope with having their baby in the neonatal unit. Various mechanisms are seen, however, and a single is not appropriate for all parents. Some coping strategies include trying to gain a deeper understanding of the problems, establishing a degree of control over the situation, seeking social support from other people, and escaping from or minimizing the apparent severity of the situation. These mechanisms are used to varying degrees by individual parents. There is a systematic difference between mothers and fathers. Mothers tend to look for support from others and to search for an explanation for what has happened, whereas fathers are more likely to try to minimize the situation, often by concentrating on supporting their partner.

29.3 Interventions

A better understanding of the sources of stress and how parents try to cope allows appropriate interventions for the family. A complex network of structural, practical, social and psychological interventions can promote acceptance by mothers and fathers of this challenging event. When designing neonatal units, great emphasis is placed on effective layout, lighting, and noise reduction. Facilities for families to stay close to their baby are usually provided, and rooms for parents allow mothers and fathers to relax and meet other parents. Play areas for siblings have been incorporated into some units. This more "family-orientated" approach to care is helped by less restrictive visiting policies in neonatal units. Most units allow parents and siblings open access if they comply with local infection control measures. Thus a more sensitive approach could affect faster bonding between mother and sick newborn (i.e., 24/24 open access to NICU, kangaroo mother-care, promotion of maternal/human milk).

Prenatal counseling is an aspect on which many units are currently engaged, especially if a prenatal diagnosis has been made. Members of the neonatal team meet with parents before the birth to discuss a likely admission and the approach that will be taken for the infant's problems. Parents are encouraged to visit the unit before their baby is born to familiarize themselves with the environment and the staff. After delivery, it is good practice to discuss medical and nursing issues in detail with parents to inform and, when possible, to involve them in decision making from an early stage. Parents should be informed as soon as possible about investigation results and any change in clinical condition. After overcoming their first moments of confusion and fear, parents can also help with the care of their preterm baby. This may extend beyond simple but important measures, including "skin-to-skin" contact, providing skilled care such as tube feeding, toileting practices, and joining intensive "developmental care" programs. Parents of other preterm babies can give support through "buddy" programs or informally [4]. Counseling through external organizations or formal support can be helpful even for families whose babies are not critically ill. This can involve various professionals, such as psychologists, social services, religious advisers, ethics committees. Written information about the neonatal unit, describing specific conditions or procedures may be useful. Routine contact between the neonatal unit and social services may allow financial support to be provided for the parents [5].

Despite intensive treatment and full medical support, patients in a neonatal unit may die. Although there are substantial differences between countries and cultures, a decision to limit active treatment may be considered because of the inevitability of death or a prognosis that indicates a very poor quality of life. Death, however it comes about, is a desperate time for affected families. In some cases, parents want to be involved in decision making at these times. They need full and frank information, given in a compassionate manner by experienced staff who know the family and their baby. In most cases, the decision to stop or limit treatment is made with senior medical and nursing staff. Family, friends, and external bodies (such as religious leaders and support groups) do not often have a substantial role in the decision to withdraw treatment but contribute to family support afterwards. Mothers and fathers may differ in the way they grieve and cope with their loss. Mementoes, formal contact with senior staff during the weeks after the death, and contact with a bereavement support worker or group may all help the process. Most families begin to come to terms with the death during the first year — not forgetting the child but adjusting to life without him or her. Bereaved parents often need factual information that may help explain why their baby has died. Without autopsy, important information can be missed, and in many neonatal units, postmortem examination is always considered and offered to the parents if appropriate. High profile cases where there have been procedural inadequacies and anxieties about organ retention have contributed to a decrease in the number of autopsies carried

out. Additionally, there has been a natural reluctance by parents to authorize further "suffering" for their infant and a lack of awareness of the questions that remain unanswered [6].

Discharge home, although an exciting time for families, can also be a time of extreme anxiety, and so a formal approach to "discharge planning" is often adopted. Mothers "room in" with their baby to promote bonding, establish feeding, and learn practical skills that might be needed. Support for the family in the community once the infant is discharged can also be arranged, including specialist neonatal nurses, primary care health staff (for example, health visitors, general practitioners), social workers, and national or local family support groups. Although managing the immediate stress of discharge home is important, it should be recognized that although practical issues may become easier with the passage of time, for some families considerable levels of stress and anxiety remain long after the discharge itself. Psychological support should be an integral part of neonatal follow-up programs.

Parents and families of babies who are admitted to a neonatal unit are exposed to a variety of stressors, and may face extremely difficult decisions in unique and unfamiliar situations. Many studies suggest that current VLBW follow-up programs might benefit from the addition of psychological and family services to traditional neurodevelopmental assessment programs, particularly during the neonatal period and up to infant age of 2 years. 10% of mothers of infants with VLBW reported severe symptoms of psychological distress during the neonatal period, five times the rate for term mothers, while almost one third of mothers of infants with VLBW had clinically significant levels of depression and anxiety. For mothers of high-risk infants with VLBW, significant symptoms recurred when the child was 2 years old. The neonatal period affords an opportunity to identify mothers who are most at risk using standardized, simple screening techniques [7]. Such identification and referral for treatment may prevent the development of more severe symptoms, which can interfere with effective parenting while the provision of social support may also effectively buffer distress [8]. By targeting this support appropriately, staff on neonatal units can provide a more complete package of care [9].

Neonatology and the Law

Vittorio Fineschi and Emanuela Turillazzi

30.1 Introduction

Neonatology is an area of medicine that has received much attention in recent years. This interest primarily concerns the constant progress in this field and the inherent ethical and medico legal problems. The extensive debate about some issues reflects both the technical and scientific progress that has been made in neonatology. Tightly argued issues such as medical malpractice litigation have reached crisis proportions in the neonatology and pediatrics. Moreover pediatric claims are very expensive because damages cover the life of the child and the juries tend to be very sympathetic toward children and their families [1]. Care of extremely preterm infants at the limits of viability and the "brain damaged newborn" are some of the more contentious areas of legal medicine in neonatology.

Neonatologists' concerns about a potential complaint, inquiry or lawsuit influence their practice of medicine in potentially positive ways such as developing audit procedures, maintaining better communication with parents and families, ensuring timely documentation of procedures, communication of complications, but also negatively such as increased prescribing of drugs, referrals and diagnostic testing, and avoiding treatment of certain conditions.

Since recognizing "red flags" can lessen the chances of malpractice claims against neonatologists [2], this chapter focuses on some issues that are highly vulnerable to claims of medical negligence and on high-risk situations. The principles are primarily the same for any doctor working in any country under any clinical circumstances. However, subtle differences in the law will apply to individual cases depending on circumstances and the jurisdiction that applies [3].

30.2 Neonatal Resuscitation Practices

30.2.1 Presuppositions

In recent years a lively debate has developed concerning the decision to interrupt or not to initiate resuscitation procedures on low gestational age newborns [4–6]. In many countries all over the world, rulings by multidisciplinary study groups is evidence of the importance of this debate, with neonatologists, pediatricians, obstetricians and bioethicists working together to develop a framework for making decisions about whether or not to initiate resuscitation of "at risk" newborns. At the same time there have been requests for juridical regulation of neonatal resuscitation practices as well as for clarification of the role of parents in decisions in this area.

The practical approach to the resuscitation of extremely low birth weight (ELBW) infants varies greatly between countries and, in the same country, between different centers, reflecting a paucity of evidence and consequent uncertainty among clinicians. Different possibilities for intervention in the care of ELBW infants reflect both the need to ensure that mother and newborn are offered adequate assistance and for them to be spared useless, painful and ineffective therapies.

The central issue regards the "of uncertain vitality" infants born between 22 and 25 weeks of gestational age whose treatment at birth is one of the most challenging for neonatologists [7].

When we are confronted with extremely low gestational age (22 weeks' gestational age (154–160 days' intrauterine life), there is general agreement that decisions regarding the treatment of the mother must be based on her health, that cesarean section must be performed only when indicated by the mother's clinical condition and that the newborn should be provided with care aimed at promoting comfort. On the other hand, with increasing gestational age if the newborn shows capacity to survive, the newborn's condition must be carefully assessed at birth and resuscitation performed if appropriate.

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

The presence of favorable objective clinical criteria (presence of attempts at respiration, valid cardiac frequency, recovery of skin color) suggest proceeding with extraordinary therapies, and intensive treatment of the newborn can becomes more appropriate.

It is widely believed that when gestational age is at 25 weeks, cesarean section may be performed for fetal reasons, the newborn must be resuscitated and subjected to intensive, extraordinary therapies, except those cases who present with severely compromised clinical conditions suggesting the impossibility of survival.

In this scenario, and after years of discussion across this troubled terrain, some crucial issues are intensely debate and remain to be solved.

30.2.2 Critical Assumptions

First, consider the assumption that all medical decisions about the non-institution or withdrawal of intensive care should be based on gestational age. There is actually a fair margin of error in the estimation of gestational age, so that in doubtful cases clinical evaluation of the newborn is of major importance. Neonatologists should take particular account of the newborn's conditions at birth, obstetric history and response to resuscitation. Recent studies [8] based on data from pregnancies induced with *in vitro* fertilization programs (the only case in which dating can be absolutely sure), show that the best echographic dating of pregnancy may show an error of between –10 and +7 days. The timing of the menstrual cycle is even more inaccurate with deviations of as much as 14 days [9]. There are obvious effects of such a range of error on decisions in a grey area where even a few days may lead to non-institution of neonatal resuscitation or its institution. Since neonatal prognosis is conditioned by many independent predictive factors (birth weight, use of steroids before birth, multiplicity of pregnancy) [10], it is evident that the chronological criterion of gestational age alone might lead to a dangerous simplification in evaluating decisional paths, giving excessive value to one single parameter. It is well known that the prognosis for very preterm children varies with the place of birth (level 3 perinatal center or not), the attitude of obstetricians and pediatricians about the interventions used, gestational age, postnatal age, and later co-morbidities [10]. Nevertheless, many authors still consider gestational age, although imperfect, the best indicator of the infant maturation (i.e. survival capacity) and guidelines refer to gestational age to guide behaviors and clinical choices [11, 12].

The second assumption is that one of the unique features of neonatal bioethics is its focus on guidelines that specify which extremely preterm babies should not receive resuscitation [13]. No other area of medicine has been as focused on such policies or as specific in delineating treatment limitations. In other areas, guidelines are broad and general, with much room for individual clinical judgment and professional discretion. Some authors have reported that policies for newborns appear very different from those for other patient populations [9]. In fact, even in critical situations burdened by high mortality or morbidity (for example adult patients with cardiac arrest after trauma, cardiac arrest in children following severe trauma, adult patients with a primary hemorrhagic stroke), a low chance of survival with possible long-term significant and disabling sequelae does not result in any recommendation not to resuscitate [14–16].

Finally, a point of fundamental importance is the central position of parents in the decision-making process relating to therapies administered to their premature newborns. Since resuscitation requires immediate decisions and prompt and timely actions, parents should be provided with understandable and detailed information about the complications of prematurity and associated life expectancy and its quality. Full psychological support should be provided. In the event of conflict between the parents' requests and the physician's decision, a joint solution should be sought, taking into consideration the best interests of the fetus and newborn.

30.2.3 The Crux of the Matter

The crux of the matter is whether strict guidelines, reference standards based on the gestational age parameter, and authority rules are necessary.

In a decisional area burdened by such limited prognostic certainties, an individual approach is infinitely more acceptable than a statistical approach: any decision ought to be based on the individual circumstances of each newborn rather than on reference to guidelines, especially if these are based on gestational age [17]. Physicians do not need rigid rules based on inflexible gestational age and birth weight guidelines but guidance to address the difficult and trying issues associated with infants born at the margins of viability and the ability to make a realistic assessment of the infant's clinical condition [18].

The principles regarding treatment of low or very low gestational age newborns should be the same of those followed for other patients, there is no need for specific policy statements. Generally, the purpose of guidelines is to improve knowledge regarding neonatal outcomes, to provide consistency in periviability counseling, and to promote informed, supportive, responsible choices. Flexible guidelines are well accepted and can be used by all neonatologists, obstetricians, and nurses who provide care to pregnant women and infants at extremely early gestational ages. However, resuscitation decisions for extremely preterm infants should be approached in the same way as for other patients. They should be individualized by objective and individual prognostication, which is as accurate as possible and which takes into account all relevant clinical characteristics.

30.3 The "Brain Damaged" Newborn

30.3.1 Presuppositions

New insights into the origins of cerebral palsy have recently transformed the old concept that most cases of cerebral palsy begin in labor. Many factors can damage the "developing" fetal brain including prepartum, intrapartum and postpartum ischemia/hypoxemia, developmental abnormalities, genetic factors, metabolic disease, infections, autoimmune and coagulation disorders, and maternal and fetal drug use [19]. Clinical signs of brain damage are often considered to result from intrapartum asphyxia and to be a consequence of perinatal obstetric and/or neonatologic mismanagement, leading to litigation. Contrary to previous beliefs and assumptions, clinical epidemiological studies indicate that in most cases the events leading to cerebral palsy occur in the fetus before the onset of labor, or in the newborn after delivery. It has been suggested that 70–80% of cases of cerebral palsy (CP) are due to prenatal factors and that birth asphyxia plays a relatively minor role. Intrapartum asphyxia is believed to account for around 10% of CP in term and near-term infants [20]. Notwithstanding advances in our understanding into the causation of cerebral palsy, defining a causal relation between acute intrapartum events and cerebral palsy remains very difficult.

Since the occurrence of a brain damaged newborn frequently leads to allegations of peripartum mismanagement, understanding the time of onset of the brain lesion is of paramount importance to medical and legal professionals. In Courts much of the debate focuses on whether or not there is evidence of acute intrapartum hypoxia and if so, whether the care provided was timely and of a satisfactory standard [21, 22].

30.3.2 The Timing of Perinatal Hypoxia

The timing of perinatal hypoxia is complex and incompletely understood. It is traditionally based on clinical, laboratory and physiological data, which are nonspecific markers of a difficult birth [23, 24]. These non-specific intra-partum markers provide poor information about the timing and duration of an asphyxiating insult [25]. A detailed clinical history, autopsy, placental and cord examination, laboratory tests and genetic studies may explain the cause of death and the time of onset of the neuropathology. Brain histological examination can provide useful information about the timing of an hypoxic-ischemic lesion: the patterns of perinatal brain injury depend on the etiology and the stage of development of the fetal nervous system, since the vulnerabilities of gray and white matter depend on post-conceptional age and on neuro-anatomic site [26, 27]. New insights into the mechanisms of neonatal hypoxic-ischemic brain injury have effectively challenged the old concept that most cases are the results of an acute hypoxia during labor and delivery.

In October 1999, the International Cerebral Palsy Task Force published a consensus statement for defining a causal relationship between acute intra-partum events and cerebral palsy with the aim of defining "an objective template of evidence to better identify cases of cerebral palsy where the neuropathology began or became established around labor and birth". It established three "essential criteria", which should be met before attributing cerebral palsy to an intra-partum hypoxic event and a number of "criteria that together suggest an intra-partum timing, but are non-specific" [21].

Laboratory studies may be useful for defining the timing of an hypoxic event, i.e., acid-base disturbance assessed by means of umbilical-artery pH measurement, serum concentration of brain-specific creatine kinase isoenzyme BB (CK-BB), other serum factors (blood lactate, hypoxanthine, aspartate-aminotransferase, erythropoietin beta-endorphin), factors meas- ured in the cerebrospinal fluid (lactate, neuron-specific enolase, lactate dehydrogenase, hydroxybutyrate dehydrogenase, fibrinogen degradation products, ascorbic acid). Imaging studies such as head ultrasonography may show typical injury patterns (periventricular leukomalacia, lesions of the basal ganglia, cerebral edema, ischemic infarcts). Cranial computed tomography (CT) may demonstrate ischemic or hemorrhagic lesions, generalized or focal edema, diffuse cerebral atrophy with ex vacuo ventricular dilatation due to severe hypoxemic insult. On CT, periventricular leukomalacia can be visualized as a region of decreased attenuation, occasionally intermixed with areas of increased attenuation due to secondary hemorrhage. However, magnetic resonance is the imaging modality of choice in the assessment of cerebral hypoxic lesion.

In cases of neonatal death it is essential that the contribution of post mortem examination is complemented by toxicological, microbiological and genetic investigations [28]. The histological study of the brain with traditional histochemical techniques can provide relevant data since it is well known that the distribution and the histological pattern of lesions in the brain changes dramatically depending on mechanism, severity and timing of the insult. There are numerous studies to define histological, histochemical and immunohistochemical markers to provide increasingly accurate information about the time of onset of hypoxic-ischemic brain damage. However, there are also fragmentary and contradictory data in the literature, citing experimental studies performed only on animals. Many reports are of experimental studies that have used markers with late expression (>24 hours) and which are therefore of limited use for the detection of cases of perinatal hypoxic-ischemic brain damage due to intra-partum asphyxia [27]. These neurobiological insights into cellular responses implicated in perinatal brain damages, and the characterization of the various mechanisms involved, might open new avenues for understanding the time of onset of cerebral hypoxic-ischemic lesions and for effective therapeutic strategies [29]. Immunohistochemical techniques in

studies on animals and humans have identified reliable and reproducible brain tissue markers of hypoxic-ischemic damage. The immunohistochemical picture obtained using a panel of selected antibodies (chaperonins HSPs, ORP-150, COX2) have identified a chronology of expression of the different markers of hypoxic-ischemic brain damage in newborns. This has been correlated with the duration of the insult and ascribed to the stimulation of the different cell types and to a different response by the same cells to the ischemic insult. Some immunohistochemical markers seem to be more reliable than others in the evaluation of the timing of the neonatal hypoxic-ischemic damage [30]. The results of histologic and immunohistochemical investigations suggest that the differential diagnosis of neonatal hypoxic –ischemia may be better defined in terms of the precise timing of the injury [29].

30.4 Informed Consent

Inadequate informed consent is a very frequent basis for alleged medical malpractice, particularly in neonatology where there are unique issues because consent is not obtained from the patient but from the family often during a very emotionally stressful period. Inadequate communication (between the obstetrician and pediatrician/neonatologist, the nurse and physician, or the healthcare team and the family) often leads to allegations of malpractice [1].

The relationship between the physician and patient's parents and families is critically determined by the quality and the amount of information and the use of language. There has to be differentiation between simply reporting a situation and imparting information. The two dimensions are not equivalent: the provision of news (i.e. reporting) and the provision of information are not the same thing. A fundamental issue is that of truth and of the amount of information to be provided to the newborns' family. How and how much is to be told about the newborn's disease, outcome and prognosis? Which are the risks of certain treatments? Which predictable sequelae should be revealed to the newborn's parents?

The purpose of information and communication is to enable parents to make informed choices about the health care of their baby. However, a crucial issue is the distinction of the rights of the newborn and the capacity to make autonomous choices. Great care is necessary when dealing with this issue; attention must be focused on what is to be done with a baby who has not the capacity to make autonomous choices. The issue of informed consent has become more difficult because of new technologies, which have increased the range of available interventions and the possibilities of diagnosis and cure. These have also meant that such issues are more likely to find themselves debated in a judicial setting.

When dealing with the issue of informed consent in the neonatology and pediatrics, there are some unique challenges that are different to those in adult medicine.

A crucial question that has major ethical importance is that of parents' rights in the decision making process. There are several aspects related to the newborn's parents, i.e. the recipients of information, that need to be taken into account by the physician: their desire for knowledge; their desire to participate in the therapeutic choices; their psychological state; their level of knowledge. There is a distinct risk that imparting information becomes only an episode of learned, specialist discourse which is unintelligible to parents. There is therefore a special burden on the neonatologist to ensure that the newborn or infant's parents understand the explanations and information given.

Since malpractice claims are filed by parents whose newborn babies have died or have suffered poor outcomes, the value of informed consent in reducing malpractice losses may be undermined by the tendency to approach informed consent as a means to "protect" the physician rather than to communicate with parents and to share with them clinical decisions, which are often very challenging.

Open communication with parents and families should represent the gold standard of the physician-parent-patient relationship. The physician and the parents have specific competences: those of the physician are technical and scientific; those of the parents are human, relating to pain, and perception of the quality of life. Thus cooperation is needed to achieve the aim of optimal health for the newborn baby. Parents should be active participants in a dialogue that is important to the shared decision-making process; the physician has a duty to ensure that comprehension is achieved and that the parents themselves are acting in the best interests of their child.

30.5 Conclusions

The unfortunate reality of the current practice of medicine is that physicians will likely be faced with a malpractice claim at some point in their career. Neonatologists and pediatricians are not immune. Recent publications addressing the malpractice situation as it relates to pediatrics [31] showed that pediatricians accounted for 2.97% of claims, making it 10th among the 28 specialties in terms of the number of closed claims. Pediatrics ranks 16th in terms of indemnity payments (28.13%) [32].

It is now believed that few of the medical malpractice claims filed actually involve negligence on the part of the physicians. A study performed as part of the Harvard Medical Practice Study concluded that less than 2% of the injuries in a hospital setting that are caused by negligence ever result in a malpractice complaint [33]. In neonatology and pediatrics failure to diagnose was the leading reason for child-related payments (18%), followed by sub-standard performance (9%), delay in diagnosis (9%), and poor management (6%) [34]. The most prevalent causes of malpractice suits against pediatricians involve errors in diagnosis. Part of the reason

for this lies in the nature of pediatrics: obtaining a history from a child is very different from that of an adult. Additionally, the pediatrician often tries to provide medical care and advice over the telephone, without the advantage of having the patient in front of them [35].

A patient's decision to sue his or her physician appears to have more to do with the physician' ability to communicate with the patient/ parents and demonstrate compassion and concern, than with the physician's clinical skills. In response, many physicians have resorted to defensive medicine in the hopes of averting a malpractice claim. Many doctors order additional tests, perform diagnostic procedures and refer patients for consultation when they do not believe that such action is clinically necessary.

Numerous studies have demonstrated that poor communication between physicians and parents/patients is the catalyst for most medical malpractice lawsuits. Communication and use of language is therefore critical. Good communication involves the use of lay terms and the avoidance of medical jargon [31].

Environment and Early Developmental Care

Dominique Haumont

31.1 Introduction

The spectacular development of neonatal intensive care since the 1960s has allowed a drop in neonatal mortality of very-low-birth-weight (VLBW) infants from 50% to less than 15% in the last decade [1]. However 15 to 25% of the VLBW infants will present neurodevelopment impairment in the following fields: motor function, vision, auditory function, cognition, behavior, attention deficit and hyperactivity disorders, visual-motor integration and language [2, 3]. Compared to their term pairs there is substantial scientific evidence of altered early brain development [4]. These infants spend weeks and sometimes months in the neonatal intensive care unit (NICU), which is a quite different environment compared to what they would experience in utero. At this young age brain growth and development is particularly critical. The configuration of neurons is genetically predetermined, but the further organization and wiring of the neural circuits will depend on endogenous and exogenous stimulation. The existing evidence of interaction between environment and brain development has been extensively reviewed and better practices encouraged [5]. It is against the background of the potential harmful effects of the traditional NICU that developmental care and environmental strategies have gained more and more attention.

31.2 Early Developmental Care and Neonatal Individualized Developmental Care and Assessment Program

The term early developmental care (EDC) is confusing because it ranges from very simple interventions like light and noise control, positioning or non-nutritive sucking to the very complex Neonatal Individualized Developmental Care and Assessment Program (NIDCAP) [6]. The complex NIDCAP model is an early intervention program based on the observation of the preterm infant's behavior [7]. The theory behind NIDCAP is designated as "synactive theory". The concept derives from the interdependency, differentiation, modulation and regulation of five behavioral subsystems: autonomic, motor, state organizational (maturation of well-defined sleep and wake states), attentional/ interactional and self-regulatory. The assessment tool in NIDCAP is a formal and repeated observation of the infant behavior before, during and after a care. These observations describe the reactions of the baby towards the sensory inputs and his capacity of self-regulation. The developmental goals for each infant will be defined according to his individual skills and weaknesses. Individual care-giving plans and environmental adaptations will be recommended. As the NIDCAP implementation evolves in the unit the caregivers become more and more aware of the signs shown by the baby and handling is adjusted accordingly. The families are empowered in the caregiving and put in a central position. The competence of the NIDCAP observer has to be validated by certified NIDCAP trainers. The program requires a philosophy of care by the whole department and has to be strongly supported by medical and nursing directions.

Babies in the NICU are overwhelmed by sensory inputs. They perceive pain, thermal changes, movements, olfactory, vestibular, visual stimuli and social interactions with parents and caregivers. The effects of these sensory stimulations and the EDC recommendations are described below.

31.3 Sensory Stimulation and EDC Recommendations

31.3.1 Light

The development of the visual system has been fairly extensively investigated. The endogenous stimulation originating

Saint-Pierre University Hospital, Brussels, Belgium

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

from the spontaneous firing of neurons is important at different critical periods. The synchronous ganglion cell waves are targeting the different neurons to allow appropriate transmission towards the visual cortex. The protection of REM sleep is in this regard essential for normal development of ocular dominance columns. Light stimulation diminishes the action of the formative retinal waves [8, 9].

The preterm neonatal eye shows specific characteristics. Eyelid opening is related to the illumination of the NICU and the infant's developmental stage. The pupillary light reflex appears only after 30 weeks of gestation and mydriasis is physiological until 32 weeks. Light also acts as a stimulus for the production of free radicals in retinal membrane lipids. It has been suggested that the immature antioxidant status of the preterm infant might play a role on their susceptibility to retinal damage. Phototherapy and light are potential inducers of lipid hydroperoxides in babies receiving intravenous lipids [10].

31.3.2 Cycled Light

The endogenous biological clock of the circadian rhythmicity is located in the hypothalamic suprachiasmatic nuclei (SCN) at the base of the third ventricle. Input pathways entrained by light are relayed to the SCN, which will express output signals. These include temperature, cortisol, melatonin, sleep-wake-cycle, behavior and cardiovascular function. In utero, the fetus has a biological clock responding to maternal entraining signals. If the baby is born preterm he will be deprived of this circadian rhythm and submitted to an often chaotic NICU environment. Preterm infants have ultradian rhythms (period lengths much less than 24 hours), which parallels the maturation of the sleep pattern [11]. There is some clinical evidence that babies in cycled lighting grow and sleep better [5].

EDC recommendations include ambient lighting levels adjustable through a range of at least 10 to no more than 600 lux. No direct view of the electric light source or sun in the infant space. Separate adjustable procedure lighting up to 2000 lux shall be available to evaluate a baby or to perform procedures. Lipid infusion lines have to be protected from phototherapy light sources. The staff areas for preparation of medication or charting should be illuminated adequately. Windows provide an important psychological benefit for caregiving and tasks. Daylight should be controlled by shading devices to allow flexibility [12].

31.3.3 Noise

The acoustic stimuli of the fetus are fluid conducted, with predominance of the low frequencies of the mother's voice imbedded in circadian rhythms and less background noise. The preterm infant in the NICU receives air conducted sounds in all frequencies, sometimes very loud, unpatterned staff language signals with important background sounds and with no circadian rhythms [13]. It has been hypothesized that elevated noise levels and unpredictable background sounds are dangerous for the hearing development but also for the global brain development integrating all sensory channels. Clinical studies have shown the occurrence of hypoxic episodes and behavioral changes due to noise [14]. Nasal CPAP generates a high level of noise, which might be worrying [15]. Chaotic noise has also been shown to impact negatively on staff behavior.

EDC recommendations limit noise levels to 60 dB around the infants' space. Diurnal exposure to mother's voice should be encouraged. The acoustic environment should favor the baby's physiological stability and the needs of staff and parents [5, 12, 16].

31.3.4 Protection of Sleep

The term newborn sleeps around 70% of the time with about half of the time in well recognizable active sleep (AS or REM sleep) and quiet sleep (QS) patterns. Before 27 weeks it is not possible to identify a sleep pattern comprising AS and QS in the same cycle [17]. In the ontogeny theory, REM sleep is considered as a very intense cerebral activity playing an important role in brain maturation. The ultradian cycles of the preterm infant will progressively mature towards a circadian model of sleep/wake cycles. Maturation of sleep will be characterized by progressive change in the proportion of REM sleep towards a predominance of quiet sleep after term. The endogenous synaptic proliferation during REM sleep will prepare the brain for further refinement with exogenous stimulation.

There is growing evidence in animal and human research that supports the importance of sleep during early brain development. Animal studies on sleep deprivation showed structural and functional deterioration in several models. The need of endogenous synchronous waves during REM sleep has been well established for the development of synaptogenesis in the visual system [18].

EDC recommendation is to protect newborn sleep in the NICU [5].

31.3.5 Positioning and Handling

The flexed position and containment experienced by the baby in utero is a theoretical approach for subsequent positioning of the infant. Swaddling has been practiced for a long time and is associated with better sleep and diminished pain and stress response [19]. Babies with respiratory problems do often better in the prone position [20]. The strong neck extensor muscles have to be counterbalanced to support later motor development [21]. Healthy preterm infants have been shown to benefit from positioning in nests with flexed posture favoring more elegant movements and reducing frozen postures [22]. Routine cares like simple diaper changes can alter heart rate stability and oxygen saturation [23].

EDC recommendations are positioning of the baby in flexed position, with alignment of the head and minimal handling.

31.3.6 Kangaroo Mother Care (KMC)

KMC was started in 1978 in Columbia to support low birth weight infants in a low cost way [24]. The proven effectiveness and safety have since enlarged this practice in countries with no limited resources. The benefits attributed to KMC are decreased morbidity, improved weight gain, breastfeeding, neurobehavioral assessment and more mature sleep patterns. KMC is beneficial for the mother because it favors attachment and diminishes stress. Although less research about KMC in industrialized countries has been undertaken it is now current practice in the "Scandinavian model" [25].

EDC recommendations encourage KMC according to the baby's tolerance.

31.3.7 Pain and Stress

It is well known that newborn infants in the NICU undergo many painful procedures [26]. The fear of side effects of long-term exposure to narcotics on brain development and not recognizing pain and stress symptoms results in inappropriate pain relief in newborns. It has been shown that NIDCAP trained nurses, familiar with subtle clinical assessment were more likely to see clinical manifestations of pain [27]. On the other hand non-pharmacological interventions like oral sucrose, non-nutritive sucking, swaddling and facilitated tucking have been proven efficient [28]. Some units will claim an aggressive pain management with very liberal use of medication for medical procedures. However the first step in medical care is "do no harm" and therefore each procedure should be questioned. It is very likely that many routine interventions are historical and suppressible.

EDC recommendations consist of questioning the rationale of the procedure, carefully assessing the baby's behavior by skilled staff and adapting positioning, manipulation and medication.

31.3.8 Parental Presence

In the early days of neonatal intensive care universal nursing barrier was recommended and the babies were not supposed to need social interaction. It took many years before parental friendly attitudes were applied, although the importance of early relationships between the newborn infant and his parents has been shown a very long time ago [29]. Despite the general acceptance of unrestricted parental presence, standards of care are probably not applied everywhere due to local resistances.

EDC recommends intensive and if possible permanent parental presence and cooperation in the care giving of the infant. The impact of parents staying in the Nicu from admission to discharge is described in the Stockholm neonatal family centered care study. Length of stay was diminished and there was a reduced risk of moderate-to-severe bronchopulmonary dysplasia [30].

31.3.9 Oxidative Stress (OS)

Periventricular leukomalacia is the most important brain injury underlying the neurodevelopmental complications of preterm infants in later life. New insights into this disease relate the pathogenesis to incomplete vascular supply, deficient regulation of blood flow and the susceptibility of oligodendroglial precursor cells towards OS [31]. Many clinical situations in preterm infants will produce excessive free radical production: ischemia reperfusion injury, hypoxia and hyperoxia, inflammatory diseases, phototherapy and intravenous nutrition with long chain poly-unsaturated fatty acids [32, 33]. Their immature antioxidant defenses will put them at increased risk for OS. Any intervention in the NICU, which causes hypoxia, is potentially a source of OS. Intensive care procedures like intubation, chest drainage or intratracheal suctioning are well known to destabilize the baby. But even routine procedures like chest X-ray, changing electrodes, physiotherapy, excessive noise, weighing or even diaper change are accompanied by an acute decrease in transcutaneous oxygen tension [20].

EDC recommendations are to avoid any hypoxic event or unnecessary care.

31.4 Conclusions

We have summarized the neonatal practices where EDC might have an impact. We know that these recommendations are only partly applied in most of NICUs. Neonatal intensive care were framed like adult and pediatric intensive care units. But, in contrast to older patients, babies stay for a prolonged period and the caregivers have very few benchmarks for preterm infant normal behavior. These small patients have limited physical and undefined mental capabilities to express their suffering in ways that are understandable to their caregivers. Therefore they are totally dependent on the healthcare team to interpret, understand and intervene to alleviate their distress. The NIDCAP model addresses all these issues in a complex and holistic program. The literature overview demonstrating the effects of NIDCAP on neurodevelopmental outcomes is conflicting [6]. However, one can consider that caring for babies and paying attention to pain, stress and parental involvement is just a normal and humane behavior [34]. Sweden, which was a pioneer in NIDCAP training, has

Table 31.1 NIDCAP: 10 answers to early developmental goals

1.	Understand physiological organization of the preterm infant
2.	Diminish pain and stress
3.	Help parents in their difficulties: family centered
4.	Promote Kangaroo mother care
5.	Promote breastfeeding
6.	Stimulate parental presence
7.	Help the baby in his sleep organization
8.	Achieve a supportive patient-caregiver relationship
9.	Spread the spirit of humanization in the hospital
10.	Have a structured tool for change in the NICU

now been followed by several training centers in Europe, which support the diffusion of EDC [35, 36]. The advantage of the NIDCAP model is the consistency of the program and the global answers to our goals in EDC (Table 31.1).

Implementing EDC has also some side effects. One important aspect is the NICU architecture and design [12]. Many newly built NICUs have planned single rooms combining the requirements of intensive and special care in an EDC perspective. Putting respect, security, protection and privacy of the families in a central position will also impact attitudes in difficult situations like end-of-life decision making [37].

Introducing EDC in the NICU is moving away from traditional care towards a new culture characterized by respect of the preterm infant's physiology, diminishing pain and stress, with the parents as primary caregivers. It is likely that the construction of family wards and "couplet care" will allow optimal developmental care restoring the disrupted maternal continuity and her human monitoring capacities.

Neonatal Pain: Neurophysiology, Recognition and Prevention

Carlo Bellieni

To address the question of pain in newborns, one must use indirect evidence from a variety of sources, and then make an informed guess. These sources include studies of behavior, anatomy and physiology. Evidence indicates that the experience of pain begins in the second trimester, well before the third and last trimester of human gestation [1] and that fetuses of that age can perceive pain [2].

32.1 Anatomy

First, we will take into account anatomical considerations. To feel pain, it is necessary for stimuli to involve neural connections between peripheral receptors and the spinal cord, upward transmission via the spinal cord to the thalamus, and from there to the outer cerebral layers. The development of the human nervous system is a progressive and ascending process, with the cerebral cortex the last region to develop. Thus, to experience pain, an intact system of pain transmission must be available.

32.1.1 Development of Connections

Peripheral receptors develop from the seventh gestational week [3]. Connections from the periphery to the spinal cord are formed early, at about 8 weeks [4]. C fibers begin to grow into the spinal cord at about 10 weeks. Early in gestation, after the tenth week of gestation, substance P and enkephalin-positive fibers appear [5]. From 13 weeks' gestation, the afferent system located in the substantia gelatinosa of the dorsal horn of the spinal cord develops [4, 6]. Spinothalamic connections start to develop from 14 weeks and are complete at 20 weeks' gestation, and thalamocortical connections are present from 17 weeks and completely developed at 26–30 weeks' gestation [7]. From 15 weeks, there is a subplate zone which lies beneath the cortex. This is a layer of neurons below the cortex that is specific to the fetus (see later). The thalamus plays a pivotal role in regulating the spinal-brainstem-spinal loops that mediate context-dependent descending facilitation or inhibition, coordinated through the key mechanisms underlying conscious- ness. In contrast to direct thalamocortical fibers, which are not visible until almost the third trimester, thalamic afferents begin to reach the somatosensory subplate at 20 weeks' gestation [8] and the visual subplate at 20–22 weeks' gestation [9]. Thalamic fibres penetrate the cortical plate from 24–28 weeks' gestation. From 20 weeks' gestation, peripheral receptors are present on the whole body [6, 10]. Recent studies have noted robust activation of the somatosensory cortex in preterm neonates exposed to tactile or painful stimuli, modulated by gestational maturity, postnatal age, sex, laterality, and sleep/ wake states [11, 12]. Cortical development starts only at about 17 weeks' gestation, but continues until long after birth. Synapses appear within the cortical plate from mid-gestation.

32.1.2 Subplate Zone and Cortex

The role of the cerebral cortex is crucial for pain sensitivity, but we should not ignore the role of the subplate in the development of sentience and consciousness. The subplate zone is a prominent, transient laminar compartment of the cerebral wall of the human fetus. The importance of the subplate as the main synaptic zone of the human fetal cortex is based on the rich input of "waiting" afferents from thalamus and cortex during the crucial phase of cortical target area selection. Recent neurobiological evidence shows that the subplate is an important site of spontaneous endogeneous activity, building a framework for development of cortical columnar

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

organization [13]. The conscious perception of pain requires peripheral pain receptors, connections to the spinal cord through an afferent system, fibers that connect the spine and the thalami, and most importantly, connections between the thalamus and the subplate zone or cerebral cortex. It is also important to know that pain impulses may be processed in other subcortical structures, including the hypothalamic pituitary system and amygdala (important for the emotional modulation of pain) [14]. The subplate zone expands considerably between 17 and 20 weeks and recedes after 30 weeks' developmental age [15]; from about 17 weeks, there is a shifting population of connections from the thalamus to this region. Neurons in the subplate zone initiate excitatory amino acid or peptide neurotransmission in the cortex, influencing the development of fetal cortical circuits [16, 17], while the cortical plate matures into the six layers of the cerebral cortex [18]. Differentiation of subplate neurons at 17–25 weeks' gestation produces five cellular subtypes whose distinct dendritic and axonal patterns correspond to different functional roles in development [19, 20]. From 16 weeks' gestation, pain transmission from a peripheral receptor to the cortex is possible and is certainly completely developed from 26 weeks' gestation. Assuming that activity in the cerebral cortex or subplate zone is necessary for consciousness, then for the fetus to be conscious of an external experience these regions need to be connected with incoming nervous activity. This starts to happen at about 16 weeks and puts an early limit on the timepoint at which it is likely the fetus might feel what is going on in its body or elsewhere [2]. Serotonin-releasing inhibitory descending pain fibers only develop after birth and it is therefore possible that preterm babies and fetuses feel more pain than small infants.

32.2 Stress Responses

32.2.1 Hemodynamic and Neuroendocrine Responses

Neonatal responses to painful stimuli have been evaluated using a variety of measures within three classes of responses (biochemical, physiological, and behavioral). Plasma catecholamine assays may provide the most valid and reliable measures of the biochemical responses of neonates to painful stimuli [21]. As early as 16 weeks' gestational age, the human fetus mounts a cerebral hemodynamic response to invasive procedures involving transgression of the fetal body, which is consistent with the "brain-sparing" effect [22]. Increased cerebral blood flow is not necessarily indicative of pain, as this response is thought to constitute a "brain-sparing" mechanism associated with hypoxia [23] and intrauterine growth restriction [24]. Nevertheless, fetal plasma concentrations of cortisol, -endorphin, and noradrenaline increase after intrauterine needling of the hepatic vein to a greater degree than of the umbilical cord [25, 26].

32.3 Long-Term Consequences

The evidence for adverse consequences on future neural development due to early exposure to noxious stimuli is increasing. Ruda et al studied an animal neonatal model of persistent hind paw peripheral inflammation. They found that, as adults, these animals exhibited spinal neuronal circuits with increased input and segmental changes in nociceptive primary afferent axons and altered responses to sensory stimulation [27]. Preterm infants who spend post-conceptional weeks 28 through 32 in a NICU are less mature in their pain response to heel prick than newborn premature infants of 32 weeks' post-conceptional age (PCA) [28]. Differences in these response patterns were strongly correlated with the number of invasive procedures experienced since birth, rather than other clinical factors (e.g. age, severity of illness, Apgar score, birth weight). These data suggest that repetitive pain and stress might alter the neurological response to pain, leading to altered neurobehavioral reactions to subsequent painful events [2]. According to Anand et al, repetitive pain in neonatal rat pups may lead to an altered development of the pain system associated with decreased pain thresholds during development [29]. Increased plasticity of the neonatal brain may allow these and other changes in brain development to increase the vulnerability of these animals to stress disorders and anxiety-mediated adult behaviour. Similar behavioral changes have been observed during the later childhood of ex-preterm neonates who were exposed to prolonged periods of neonatal intensive care: infants who are born prematurely or seriously ill are commonly exposed to multiple painful and stressful events as part of their prolonged hospitalizations and required medical procedures.

There is now evidence that early events not only induce acute changes, but that permanent structural and functional changes may also result [30]. Recent studies suggest that although early painful memories are not accessible to conscious recall, they might be encoded in "procedural memory" and lead to abnormal behavioral patterns or altered sensory processing in later life. Taddio et al demonstrated that infants circumcised at birth without analgesia showed a stronger pain response to subsequent routine vaccination than uncircumcised infants, or than those who underwent the procedure with analgesia [31]. It is becoming increasingly clear that neonatal painful experiences may leave a legacy of altered sensitivity to subsequent pain, perhaps for the entire life of the individual [32]. These findings should focus the attention of clinicians on the long-term impact of early painful experiences, and highlight the urgent need for developing therapeutic strategies for the management of neonatal and fetal pain.

32.4 Overcoming Procedural Pain

It is only since the end of the 1980s that neonatal pain has been widely recognized and treated. However, many different reasons for resistance still exist, as follows:

1. difficulty in defining pain [33];
2. lack of legal consequences for provoking pain;
3. confusion between understanding suffering and pain, leading to the false belief that drugs are the only answer to stress;
4. incorrect idea that newborns' fragile lives mean "fragile humanity", and they have a different moral status than older people;
5. self-censure on pain that is being provoked, to avoid being overwhelmed by it.

It is important to prevent, recognize and cure pain. Now we have the wherewithal to do so.

32.4.1 Prevention

Awareness of the full humanity of neonates In some cases neonates are still considered as having a different moral state than adults or older children [34]: for instance, end-of-life decisions may sometimes be taken considering not only the best interest of the neonate, but also parents' burdens and desires. Moreover, it has sometimes been argued that the apparent lack of consciousness in a neonate means a lack of personhood and of a full sensation of pain. Recognizing babies' full personhood means recognizing their right to a full well-being, including analgesia.

Manipulations and painful procedures must be reduced in number Babies have a lower pain threshold than older babies "because of the immaturity of their pain inhibition system" [35] and they undergo a mean number of 14 painful procedures/ day when in the NICU [36]. Any manipulation is potentially stressful if not painful: changes in temperature, light and noise can disrupt their behavioral states with harmful consequences.

Reduction of stress induced by clinical trials Clinical trials often provoke manipulations unnecessary to a baby's health. Moreover, studies of painkillers should never have placebo-treated babies as a reference group, because we cannot impose pain on anyone without his/her consent: parents should not be given the burden of deciding whether to enter their baby in a painful experiment, since pain must never be part of neonatal research (for a control group, a commonly recognized painkiller should be used). Unfortunately, preventing pain is not among the pre-eminent concerns of researchers: 75% of the studies considered in a recent review [37] showed that infants suffered pain during the research because placebo, no treatment or otherwise inadequate pain management was applied.

Provide newborns with an environment tailored to their needs Babies in incubators are exposed to very high electromagnetic fields [38], loud noises, disturbing lights, stressful manipulations and sometimes they are isolated from their family. We performed studies [39–41] to overcome some of these forms of environmental pollution, and effective developmental care, centered on the single baby and his/her family, is now recommended (Table 32.1) [42].

Table 32.1 Simple rules to approach neonatal pain

1. Address simultaneously the three sources of newborns' pain: procedural pain, parents' pain and doctors' and nurses' pain
2. Newborns' stress is often not only pain but also suffering: drugs cannot be the only answer
3. Newborns are full people: they need not only cures but full well-being
4. Reduce the number of stressful events and always apply good analgesia
5. Clinical research should not provoke pain and discomfort: alternative methods should be used and placebo use in studies on pain should be proscribed
6. Approaches like NIDCAP or sensorial saturation are an initial but good response
7. The perception caregivers have of a baby's pain may differ from the actual baby's experience: the use of validated pain scales is mandatory to be objective
8. Put pain treatment and developmental care in your basic medical know-how

32.4.2 Recognition

Carers should be able to recognize the main physical signs associated with pain. Most are non-specific: babies can cry for reasons other than pain, and pain is expressed through complex behavior. This does not mean that a crying baby should be ignored "because we are not sure" that he/she is crying for pain. On the contrary, this should alarm us as if it were pain: our duty is to exclude it and/or to treat it. Newborns show a distinct pattern of behavior to painful stimuli. This includes a wide range of expressions including screwing up the eyes, frowning, opening the mouth, extending the fingers, kicking, as well as clenching. For a thorough assessment, pain scales exist.

Chronic pain scales It is mandatory to monitor pain in order to prevent its occurrence, mainly after surgery or in ventilated babies. For this purpose, scales exist to evaluate the level of pain and stress in the previous period.

Acute pain scales Many scales exist in this field and are scarcely used. There are two reasons for this. First, the difficulty of applying scales where many items have to be assessed simultaneously [43]. Second, the lack of any point in assessing pain after it has occurred. Acute pain scales are useful for research purposes since they provide an objective way

Table 32.2 ABC acute pain scale

	Yes	Intermediate	No
Acuteness of the first cry	2	–	0
Crying constancy in time	2	1	0
Rhythmicity	2	–	0

of measuring the effectiveness of an analgesic drug. We recently described that the first cry after a heel prick is high-pitched if it is very painful. We also described that babies cry in 1 second bursts separated by short and regular pauses when pain is high [44]. We developed the ABC scale on this basis [45], which, unlike most other scales, can be used by the caregiver who is performing the procedure, without interrupting it to score pain, as it is uniquely based on recognizing the acoustic features of crying (Table 32.2).

32.5 Overcoming Parents' Pain/Anxiety

In the treatment of neonatal pain it is important to consider additional but often concealed parental pain, also because parents play an important role in the improvement of the baby. Caregivers should give adequate relationship-based care, and help couples to become true parents. In the NICUs this often happens through the foresight of the caregivers. Parents should be accompanied to meet their baby, gently encouraged to call him/her by name, and dedicate all the time needed to them; in some cases, they may require the help of a psychologist [46]. Parents' pain and stress will have two negative consequences: they may increase the difficulty of communication with physicians, leading to bad compliance and discussion; and will be transferred to the baby who may change his/her behavior accordingly.

32.6 Overcoming Healthcare Professionals' Pain/Anxiety

Healthcare professionals' pain/anxiety pain is often underestimated [47], but it is useful to consider that people work in a NICU side by side with death and pain on a daily basis, sometimes in difficult conditions. These people bear all this along with their own fears and anxieties. Much should be done to help them to find ways to cope with all this pain, to avoid their beautiful and important work becoming a routine, losing much of its usefulness, and sometimes reflecting upon the type of treatment they give babies [48]. Caregivers should be trained to have a positive vision of the baby, and encouraged to exploit any effort of the parents and any progress of the baby. Caregivers' anxieties can lead to unnecessary overtreatment or undertreatment [49].

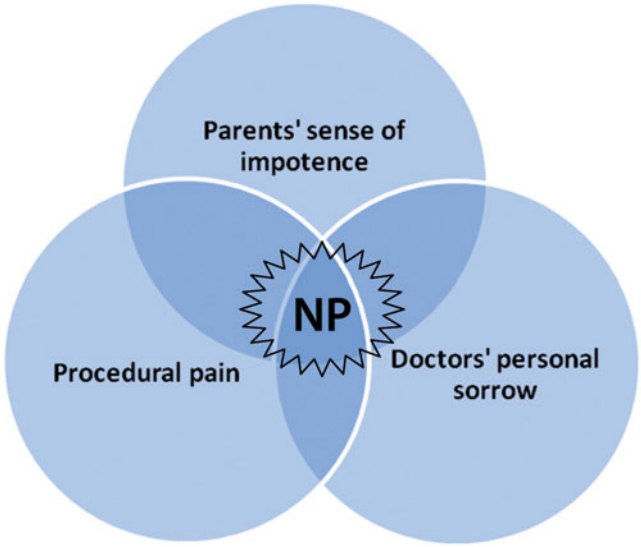

Fig. 32.1 Representation of neonatal pain (NP). Treating only one of the three legs of this tripod will be utterly insufficient

32.6.1 A Therapeutic Tripod

The therapeutic tripod represents an approach to pain relief. Neonatal pain can be relieved only by taking care of all of the legs (Fig. 32.1), considering non only procedural pain, but also caregivers' suffering [50–53]. Medical intervention should not be limited to drugs and technical procedures. What is required is "advocacy". Nurses and neonatologists should be advocates. They should also support parents to become active advocates, not to be frightened by their baby's apparent fragility, immaturity and lack of reactivity and to be able to interpret their baby's discomfort.

Procedural Pain Management with Non-Pharmacological Interventions

Celeste Johnston, Ananda M. Fernandes and Marsha Campbell-Yeo

Neonates who are born preterm spend weeks in the neonatal intensive care unit (NICU) and undergo numerous painful procedures as part of their routine care [1]. In spite of evidence of negative effects and published guidelines on pain control, about one third of procedures remain unmanaged [2].

There are several difficulties with pharmacological interventions for procedural pain. Topical anesthetics have been shown not to be effective with heel lance or venepuncture, the most common painful procedures in neonates [3]. Systemic drugs, specifically opiates, have significantly slower clearance in neonates [4], and are also not necessarily effective for acute procedural pain [5]. Given the frequency of painful procedures in NICUs and the difficulties with pharmacological management, new approaches are required, and ones that have been tested will be reviewed.

33.1 Oral Sweet Solutions

Studies using sucrose started in the late 1980s and have included term infants as well as preterm and very preterm infants. Sucrose is the oral solution used most frequently and studies of it have been examined in two systematic reviews by Gaspardo et al and Tsao et al [6, 7] and one meta-analysis by Stevens et al [8]. These reviews concluded the positive efficacy of sucrose in reducing procedural pain in preterm neonates.

Concentrations of sucrose and have varied from 12–50%. Although one study reports a flat dose-response function [9], there seems to be a dose-response effect in the reduction of crying with increasing concentration of sucrose [10]. Volumes of sucrose administered in a single dose were 0.05 mL [11], 0.5 mL [12], 1 mL [13, 14] and 2 mL in all other studies. Sucrose has also been used in three repeated doses of 0.05 mL [11] and 0.1 mL [15] 2 minutes before heel lance. In the Cochrane review the recommended dose is 0.012–0.12 g (0.05–0.5 mL of 24% solution) and no statistically significant benefit in concentrations higher than 0.5 g (2 mL of 25% solution) was found [8].

Since sucrose was found to reduce composite measures of pain by approximately 20%, additional pain relief measures are recommended [8]. As will be described below, adding a pacifier improves the effect of sweet solutions.

Only a few studies have evaluated the occurrence of immediate adverse effects. Blood levels of glucose were monitored in infants who had 2 mL of 24% sucrose for three consecutive heel lances and no difference was found when compared to infants given a placebo [16]. The youngest infants in one report did have a higher incidence of immediate negative effects to sucrose, such as wretching, gagging, sustained tachycardia, and oxygen desaturation [17].

The effects of using sucrose routinely on consecutive days have been addressed but need further investigation. While one study of sucrose for all painful procedures in the first week of life in the NICU reported poorer neurodevelopmental scores with higher doses of sucrose [15], a secondary analysis found that this was the case in infants who had received more than ten doses over 24 hours [18]. Another study evaluating the routine use of sucrose over 4 weeks in the NICU did not find a higher incidence of intraventricular hemorrhage, nor neurobiological risk [19].

33.2 Non-Nutritive Sucking

Among non-pharmacological interventions, non-nutritive sucking (NNS), or pacifier use, was the first to be studied in the mid 1980s. Its use in term and preterm infants treated in neonatal intensive care and in minimal care shows that behavioral distress, namely percent time spent in the fussing and crying state, is reduced during and after heel stick [20]. Pacifier with sucrose was found to be more effective than no

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

intervention (mean PIPP [Premature Infant Pain Profile] score difference 1.92, $p < 0.0001$) and so was pacifier with distilled water (mean PIPP score difference 1.37, $p < 0.0006$) [21]. A meta-analysis of the effects of NNS on heart rate and transcutaneous oxygen tension ($TcPaO_2$) in studies from the past 30 years [22] found that NNS significantly reduced heart rate both in the presence and absence of painful stimulation and significantly increased $TcPaO_2$.

33.3 Breastfeeding

Several studies have also examined the possible benefits of supplemental breastmilk and or breastfeeding in full-term and older newborns. In a recent systematic review of 11 clinical trials, breastmilk and breastfeeding were shown to provide analgesia during routine procedural pain from heel stick and venepuncture [23].

Breastmilk alone does not appear to be as analgesic as sweet taste [24]. Only one study has examined breastmilk analgesia in infants younger than term gestation and found that it was not efficacious [24].

On the other hand, breastfeeding has been shown to be as effective as sucrose for the relief of procedural pain [25]. There is some evidence that breastfeeding may be superior to sucrose [26]. The benefits of glucose and breastfeeding may be cumulative when provided simultaneously [27].

Maternal presence appears to play a valuable role. Healthy full-term infants cried and grimaced less by 91% and 84% respectively when held during breastfeeding rather than swaddled during heel stick [28]. Breastfeeding and maternal holding with pacifier significantly reduced full-term infants crying behavior during heel stick when compared to the group being held by an assistant with pacifier [29]. During heel lance, being held by mother and breastfed was compared to being held by mother with pacifier and to being held by non-mother with pacifier [30]. In the first two conditions infants cried significantly less (33% and 45%) compared to being held by non-mother (66%, $p<0.01$ and $p = 0.03$, respectively).

33.4 Skin-to-skin Care or Kangaroo Care

Interest in kangaroo care (KC), described as the mother holding the baby naked with only a diaper in a prone up-right position against her bare breasts, for pain is recent. The effects of KC on infants' pain response were first studied in full-term infants [31] and were shown to reduce crying by 82% and grimacing by 65%, compared to infants who stayed in the crib during heel lance. Similar results have reported in fullterms [32].

The first study in preterm infants of 32–36 weeks gestational age was in 2003 [33] and other studies followed. These studies consistently show that KC significantly reduced PIPP scores during and after the painful procedure [34, 35]. In a trial comparing placebo, oral glucose and KC for heel lance [36], there were significantly lower pain scores in the KC group. The addition of rocking, singing and sucking in infants 32–36 weeks of gestational age, did not prove better than KC alone [37].

33.5 Containment/Facilitated Tucking and Swaddling

Containment refers to restricting the premature infants' motions by holding or using an arm to place the neonate's arms and legs near the trunk to maintain a flexed in utero posture with limbs placed in body midline [38]. It is also referred to as facilitated tucking [39]. The effects of facilitated tucking have been examined in preterm infants undergoing commonly performed tissue breaking procedures in the NICU and have been shown to diminish the magnitude of physiological and behavioural pain response [39, 40].

Similar to facilitated tucking in respect to containment and midline positioning, swaddling consists of wrapping the infant in a sheet or blanket [41]. The first study was published 20 years ago [42] where it was less efficacious in reducing pain than the pacifier. In preterm infants with a postconceptional age greater than 31 weeks, swaddling improved recovery from heel lance [43], but less so in infants with a postconceptional age of less than 31 weeks. A meta-analysis of four studies in Thailand reports that the effect size of swaddling compared to no intervention on pain scores during heel stick in term infants was 0.79 (95% CI = 0.53; 1.05) and in preterm infants was 0.53 (95% CI = 0.27; 0.80) [44]. Comparing containment to swaddling, there is little difference between their effects and therefore these interventions can be used interchangeably [38].

33.6 Rocking

Rocking, compared to pacifiers and routine care after heel lance, promoted arousal levels, while pacifiers promoted sleep and reduced heart rate [45]. Based on studies of rocking being effective in full-term neonates and on studies of simulated rocking promoting quiet sleep [45], simulated rocking was tested for pain in 85 preterm neonates, and rocking alone was no better than control unless coupled with sucrose.

33.7 Auditory Recognition/Music

The human fetus is thought to be capable of auditory perception by 29 weeks gestational age [46] and have the ability to remember auditory stimuli from their intrauterine environment [47]. In a crossover design study with infants 30–41 weeks

gestational age, music therapy alone consisting of intrauterine maternal pulse sounds with soothing music, music therapy combined with non-nutritive sucking, non-nutritive sucking alone and no intervention, were compared when used for 5 minutes after heel lance [48]. Music therapy alone had the strongest effect on neonates' heart rate. Butt and Kisilevsky [49], in a randomized cross-over design, exposed 16 preterm neonates to vocal or instrumental music for 10 minutes after the end of a heel lance. Infants above 31 weeks in the music group had a significantly more rapid recovery.

Similar findings were not observed in a recent study examining a recorded and filtered maternal "singsong" voice versus no voice during heel stick procedure [50]. These results may have been affected by the high volume of the recorded sound (70 db) or may indicate that familiar sound alone may not be sufficient to ameliorate the effects of a tissue breaking procedure in younger more immature infants.

33.8 Olfactory/Aromatherapy Recognition

There is now compelling evidence that both term and preterm infants remember, recognize and prefer smell that is associated with their intrauterine environment and their mothers, and that olfactory stimuli can provide infants with comfort and modulate pain response [51, 52]. These results were seen in both full-term [52, 53] and preterm (average 32.3 weeks gestational age) [51]. In a study that combined several sensory modalities, referred to as sensorial saturation, Bellieni [54] studied its effect on decreasing pain scores in preterm neonates in comparison to no treatment control, 10% glucose by mouth, sucking and combination of sucking and glucose. According to their definition of sensorial saturation, by simultaneously placing the baby in a flexed position with limbs brought to midline, talking to the baby while face-to-face, massaging the baby's face and back with baby oil scented hands, as well as orally administering 10% glucose, there was almost no pain (3/21). In a subsequent study with full-term neonates, Bellieni and colleagues [55] used 33% glucose in combination with sensorial saturation and essentially obliterated the pain response. Finally, this group tested the feasibility of training mothers to use sensorial saturation with the removal of baby oil to scent the hands, and found that they were as effective as highly trained staff and more effective than glucose and pacifier by two points on their pain score based on crying [56, 57].

33.9 Conclusions

Given the efficacy of numerous non-pharmacological interventions [58] for procedural pain in neonates and the difficulties with pharmacological agents in this population, for common painful procedures such as heel lance and venepuncture, non-pharmacological interventions should be the first choice in uncompromised infants [59]. They are cost-effective and easy to administer. Mothers are clearly implicated in breastfeeding and kangaroo care, but can also be included in other interventions [40, 57]. Initially, there is a requirement to train staff and parents in these methods, and it may seem easier to give a solution in an intravenous line than to coordinate care to coincide with parental visiting. Nevertheless, parents find pain the most distressing aspect of the NICU and also wish to actively participate in comforting their infant. These approaches are consistent with modern family centered care in neonatal units in which the best interests of the infant and family are put ahead of staff convenience.

Neonatal Anesthesia

Nicola Disma, Maria L. Massone, Leila Mameli, Giovanni Montobbio and Pietro Tuo

34.1 Anesthesia

About 1.5 million fetuses or newborns are exposed to anesthetic agents each year.

Administration of anesthetic drugs, both with surgery and concomitant disease, can interfere with the developmental changes of neonatal life. It is mandatory for the pediatric anesthetist to know the pathophysiology of neonatal diseases in order to correctly apply the principles of neonatal anesthesia and surgery.

34.1.1 Preanesthetic Assessment

It is important to note details of the perinatal period and delivery and preoperative anesthetic evaluation should focus on the infant's transition from fetal to extrauterine life.

The intrauterine environment can interfere with growth and the ability of the neonate to adapt to extrauterine life. Maternal exposure to some drugs (e.g., phenytoin, alcohol, steroids) or abnormalities of placental blood flow may result in poor fetal growth or premature labour.

A complicated labor and delivery may result in respiratory, cardiovascular and metabolic instability for a variable length of time. Gestation and the infants' size also need to be taken into account.

The physical examination starts with the gestational age and the weight of the baby. A complete examination must be performed before withholding anesthesia from an infant, with particular attention for some parts of the body and systems, as summarized in Table 34.1.

N. Disma (✉)
Department of Anesthesia, Pediatric and Neonatal Intensive Care
Giannina Gaslini Children's Hospital, Genoa, Italy

34.1.2 Intraoperative Management

Safe and effective intra-operative management of the newborn depends on an understanding of physiology and pharmacology. Technical aspects of monitoring and anesthesic equipment require consideration.

34.1.3 Induction of Anesthesia and Tracheal Intubation

The techniques for induction of anesthesia vary with the infant's size, gestation, medical status and surgical procedure.

A specific case is the infant with a full stomach. An "awake" or a rapid sequence intubation should be undertaken. However, the former approach is associated with significant morbidity (increased intracranial pressure, bradycardia, desaturation, etc.), and the latter is a real challenge, especially for small preterm infants.

Neonates with an expected difficulty in airway management (micrognathia, macroglossia, protruding maxilla, cleft palate, masses obstructing the airway) must not be paralyzed. Tracheal intubation can be performed with pharmacological sedation and with the infant breathing spontaneously. Topical anesthesia with lidocaine on the vocal cords can facilitate tracheal intubation.

The anatomical peculiarities of the neonate and subsequent anesthetic implications are summarized in Table 34.2.

The Miller-0 straight laryngoscope blade is the recommended device for visualizing the airway for tiny neonate, preterm or of low birth weight, and the Miller-1 is used for term neonates. Uncuffed 3.0–3.5 mm endotracheal tubes are usually appropriate for tracheal intubation of term newborns. A tube that fits too tightly can damage the subglottic mucosa, causing edema and postoperative stridor or possibly subglottic stenosis. A leak around the tube during manual positive breaths (about 20 cmH_2O pressure) ensures that the

Table 34.1 Pathophysiology and anesthetic implications in the newborn

Organs / Systems	Pathophysiology	Anesthetic implication
Head and Neck	Micrognathia CHARGE syndrome	Possible difficulties in airway management Peculiar embryology and anatomy in preterm and term infants
Respiratory	Immaturity of control mechanism More compliant chest wall 10–25% type I fibers Surfactant deficiency Oxygen toxicity	Respiratory depression in case of hypoxia Airway collapse Predisposition to respiratory fatigue Respiratory distress syndrome (RDS) Bronchopulmonary dysplasia (BPD) development
Cardiovascular	Hypoxemia or acidosis	Return to fetal circulation, persistent fetal circulation (PFC), persistent pulmonary hypertension of the newborn (PPHN)
CNS	Fragile vessels Immaturity of cerebral blood flow	Increased risk of hemorrhage Hypoxia, acidosis, seizures may disrupt autoregulation
Renal	Immaturity	Lost of electrolytes
Metabolic	Active transplacentar delivery of calcium and transient hypoparathyroidism Delay in normal feeding	Hypocalcemia Hypoglycemia

Table 34.2 Airway management in the newborn

Anatomy of the newborn	Action during tracheal intubation
Prominent occiput and large head	"Sniffing position" without the additional support of a pillow under the head neck
Larynx is cephalad (C4) and anterior	Extension of the neck may impede visualizing of the vocal cords, gentle pressure with finger can facilitate larynx view
Epiglottis	Large and with "ʊ form", difficult visualization of the vocal cords
Narrow nostril and large tongue	Obligate nasal breathing, airway obstruction, possible bleeding
Cricoid cartilage	Is the narrowest airway of the newborn, small and uncuffed tubes

endotracheal tube is not too large. Ensuring that the appropriate depth in the trachea of the newborn is reached also requires care. The distance from the vocal cords to the carina in the term infant is about 4 cm.

34.1.4 Intraoperative Fluid Therapy

Intraoperative fluid therapy has four components:

1. *Maintenance of fluid* Normal fluid losses consist mainly of insensible water loss from the respiratory system, evaporation from the skin, urinary and fecal loss. The normal requirement is 100 mL/kg/day.
2. *Fluid deficits* These are caused mainly by preoperative fasting or excessive gastrointestinal losses without parenteral replacement. The deficit is calculated by multiplying the hourly maintenance requirement by the number of hours since the last fluid intake.
3. *Third space fluid loss* Surgical trauma can result in translocation of extracellular fluid from the intravascular space into the interstitial space (edema in the bowel wall and mesentery during intra-abdominal surgery). Guidelines for the replacement of third space losses include:
   a. superficial surgery: 1–2 mL/kg/hour
   b. abdominal, chest or hip surgery: 3–4 mL/kg/hour
   c. extensive abdominal surgery: 6–10 mL/kg/hour or more.

   Third space losses must be replaced with an isotonic or iso-osmotic solution such as normal saline solution, lactate Ringer's solution, or other balanced salt solutions.
4. *Other fluid losses* These include those due to gastric or endotracheal suction or removal of gastric intestinal fluid or drainage of an ileostomy, diarrhea or excessive sweat losses. In these cases the electrolyte content of the fluid losses should be measured to determine replacement fluids.

A normal urine output (0.5–2 mL/kg/hour) indicates normal hydration. Serum osmolarity is also a useful monitor of electrolyte and fluid therapy.

Standard hemodynamic intraoperative monitoring contributes to assessing the adequacy of fluid therapy.

As with older infants, the decision to deliver blood during surgery depends on the underlying and current cardiorespiratory status, ongoing blood loss, anticipated further blood loss, and baseline hemoglobin. Transfusion of other blood components should be guided by a combination of laboratory studies and clinical status.

34.1.5 Anesthetic Drugs: Inhaled and Intravenous Agents

The aim of anesthesia is to provide insensibility to pain during surgery. Anesthesia may be provided by regional or general anesthesia or the combination of both. General anesthesia can be delivered using both inhaled and intravenous drugs for a variety of surgical procedures.

Minimum alveolar concentration (MAC) defines the anesthetic depth for inhaled agents at which 50% of patients respond to painful stimulus with movement. It has been found that MAC is considerably less in preterm than in full-term infants and that 1 MAC of inhaled drugs results in 20-30% reduction in arterial pressure. Sevoflurane, newer inhaled agent, afford a rapid induction and emergence from general anesthesia and is now widely used for anesthesia in infants. Moreover, sevoflurane possesses less airway irritability than isoflurane and desfurane, and it can be used for inhalational induction and in infants with bronco pulmonary dysplasia. The traditional mask induction of anesthesia is accomplished with incremental increases in sevoflurane up to 8%, in a mixture of oxygen and air. Maintenance of anesthesia is performed with 1 MAC of sevoflurane, and it can be reduced in case of opioid administration or combination with regional anesthesia.

Intravenous drugs for anesthesia may include opioids, benzodiazepines, propofol, ketamine, barbiturates, and dexmedetomidine which is recently introduced in clinical practice. Opioids possess analgesic and sedative properties and they are usually combined with hypnotic drugs as propofol or benzodiazepines. Pharmacokinetic of fentanyl has been studied in infants and the elimination half time has been found to be from 6 to 32 hours, which is significantly longer than in adults. Remifentanil, a new synthetic short acting opioid, is rapidly inactivated by esterases in blood and tissues and because of its short half-life is administered by continuous infusion. For this reason is now largely used in all ages and is a suitable opioid even in small infants [1]. Doses of some anesthetic drugs are summarized in Table 34.3.

34.1.6 Anesthesia for Preterm and Ex-Premature Infants

Preterm and ex-premature infants undergoing elective surgery are more likely to encounter perioperative apnea than term infants. Factors predisposing premature infants to apnea include hypoglycaemia, hypoxia, hyperoxia, sepsis, anemia, hypocalcemia and pharmacologic effects of general anesthesia on the immature respiratory centres. As a consequence, postoperative monitoring is mandatory for the 24 hours following anesthesia.

Preterm and ex-premature infants may have dramatic responses to narcotics and potent inhaled anesthetics. The benefit of providing adequate anesthesia and analgesia must be carefully balanced against the significant risk of cardiorespiratory depression in these vulnerable patients.

Table 34.3 Principal drugs and doses used for neonatal anesthesia

	Induction	Maintenance
Sevoflurane	Incremental, up to 8%	0.5–2 MAC
Ketamine	1–2 mg/kg	Not recommended
Propofol	2–5 mg/kg	50–200 μg/kg/min
Thiopental	4–6 mg/kg	Not recommended
Midazolam	0.05–0.2 mg/kg	100–200 μg/kg/h
Fentanil	0.5–3 μg/kg	Up to 100 μg/kg for cardiac or major surgery
Remifentanil	0.1–1 μg/kg/min	0.1–1 μg/kg/min

34.1.7 Regional Anesthesia

Epidural analgesia in combination with light general anesthesia is a useful alternative for infants and neonates undergoing major surgery, avoiding the adverse effects related to systemic administration of opioids and other agents. Apart from providing good intraoperative and postoperative analgesia, epidural blockade has beneficial effects on the humoral, metabolic and hemodynamic responses to surgery and may improve postoperative respiratory performance.

The complication rate of epidural analgesia performed by an experienced operator is low. Caudal epidural anesthesia remains the most frequently performed regional anesthesia technique for infants and children. It is a popular "single shot" technique characterized by a high level of efficacy and safety.

Because of the lower levels of plasma protein α1-acid glycoprotein, albumin, and lower bicarbonate reserves, neonates are risk of local anesthetic toxicity, e.g. cardiac dysrhythmia or respiratory arrest, which are more likely than convulsions in neonates and infants. This can be avoided using bolus doses and infusion rates that are within recommended guidelines and by taking into account pharmacokinetics of local anesthetics in neonates. The low intrinsic toxicity of new local anesthetics like ropivacaine and levobupivacaine makes them ideal as local anesthetic for pediatric use.

The use of spinal anesthesia for hernia repair in premature infants with or without respiratory distress syndrome (RDS) is a safe and satisfactory alternative to general anesthesia. Although a review by Craven in The Cochrane Database of Systematic Reviews [2] reported no reliable evidence on the incidence of apnea, bradycardia, or oxygen desaturation in ex-preterm infants for spinal anesthesia compared to general anesthesia, spinal anesthesia may be considered a safe alternative for the avoidance of general anesthesia related risks. Further studies are needed to confirm whether there are real additional benefits for spinal anesthesia for small infants.

34.1.8 Anesthesia Outside the Operating Room

Sedation outside the operating room or in remote locations is increasingly called, particularly for radiologic procedures and medical interventions. Providing anesthesia in locations far from the operating room requires familiarity with the procedures as well as careful and extensive planning and resources in order to manage life-threatening situations. Some of remotes locations that may require sedation include dental clinics, gastroenterology suites, cardiology sites, plastic surgery centres, radiology suites, oncology areas. It is advisable to delegate a team of anesthetists that is committed to providing off-site anesthesia care. Each member of the anesthesia team should rotate regularly through the different off-site areas to maintain a familiarity not only with the procedures and personnel but also with the particular anesthesia demands unique to each area. A standard anesthesia cart should be at each anesthesia site, fully stocked with essential medications, necessary adjuvant equipment, a variety of oral/nasopharyngeal airways, spare Ambu bag, laryngoscope handles and blades, endotracheal tubes, alternate airway devices including laryngeal mask airways (LMAs), suction catheters, and intravenous supplies.

The most important topic to be considered before performing a sedation outside the operating, especially in infants younger than 1 months of age, are:

- History of ongoing apnea or prematurity with post-conceptional age less than 60 weeks
- Respiratory compromise and abnormal airway
- Congenital cardiac disease or unstable cardiac status
- High-risk procedure
- Inadequate qualified personnel or inadequate anesthesia and resuscitation equipment.

A clear understanding of the definition of sedation is mandatory to recognize when the child has progressed to a deeper level of sedation than anticipated and is at increased risk (i.e., from moderate sedation to deep sedation or from deep sedation to general anesthesia). Recognition of this transition allows escalation of monitoring and care to avoid complications.

The following are the definitions of the American Academy of Pediatrics (AAP) and the American Society of Anesthesiologists (ASA) [3], strong considering that infants may quickly move from one level of sedation to another.

Minimal sedation A drug-induced state during which patients respond normally to verbal commands.

Moderate sedation A drug-induced depression of consciousness during which patients respond to light tactile stimulation. No interventions are required to maintain a patent airway, and spontaneous ventilation is adequate.

Deep sedation A drug-induced depression of consciousness during which patients cannot be easily aroused but respond after painful stimulation. The ability to independently maintain ventilatory function may be impaired. Patients may require assistance in maintaining a patent airway and spontaneous ventilation may be inadequate.

General anesthesia A drug-induced loss of consciousness during which patients are not arousable, even to painful stimulation. The ability to independently maintain ventilatory function is often impaired. Patients often require assistance in maintaining a patent airway, and positivepressure ventilation may be required because of depressed spontaneous ventilation or drug-induced depression of neuromuscular function. Cardiovascular function may be impaired.

Several anesthetics drugs [4, 5] for sedation in infants are summarized in Table 34.4.

Table 34.4 Sedative drugs for infants

Drug	Doses	Comments
Midazolam	0.5–0.75 mg/kg PO or ER 0.025-0.05 mg/kg IV 0.02-0.03 mg/kg intranasal	Possible paradoxical effects. Doses must be reduced in case of concomitant opioid administration
Ketamine	1–2 mg/kg IV 3–4 mg/kg IM 4–6 mg/kg PO or ER	Possible laryngospasm, apnea, agitation, hallucinations. Anticholinergic to control secretions. Frequent associated tachycardia, hypertension, and bronchodilatation. No antagonist available
Nitrous oxide	50% in 50% oxygen for "minimal sedation"; up to 70% for moderate sedation	Requires specialized equipment for delivery, monitoring, and scavenging. When used alone or with local anesthesia is considered "minimal sedation." Contraindications include respiratory failure, altered mental status, otitis media, bowel obstruction, and pneumothorax
Sevoflurane	1–2 MAC inhalational	Safely used for MRI and TC. It has little toxicity and its hemodynamic and respiratory depressive effects are moderate and well tolerated
Naloxone	0.01–0.1 IV or IM, may be repeated every two minutes	Specifically antagonizes opioid effects. Adverse reactions: nausea, vomiting, tachycardia, hypertension. Reversal after long-term opioid use may lead to acute withdrawal
Flumazenil	0.01–0.02 IV, may be repeated every one minute	Specific benzodiazepine antagonist. Does not antagonize opioids or other sedatives. Re-sedation may occur in 1 hr. Prolonged observation (2 hr) required. Not for routine sedation reversal

PO per os, *ER* endo-rectal, *IV* intravenously, *IM* intramuscularly, *MAC* minimum alveolar concentration.

34.1.9 Neonatal Anesthesia and the Risk of Neurotoxicity

A great deal of concern has recently arisen regarding the safety of anesthesia in infants. There is a convincing preclinical evidence that commonly used anesthetics are neurotoxic to the developing brain and may cause neurobehavioral abnormalities [6-8]. The clinical relevance of anesthetic neurotoxicity is an urgent matter of public health and two large-scale clinical study are currently underway to further address this issue. The GAS Study is an international randomized study comparing two anesthetic techniques, general sevoflurane anesthesia and regional anesthesia, in 660 infants undergoing inguinal hernia repair. The neurodevelopmental outcome will be at age 2 and 5 year. The results from this study should contribute significant information related to anesthetic neurotoxicity in neonates.

34.2 Analgesia

Interest in newborn and preterm pain has greatly increased during the last three decades, including management of pain associated with intensive care and surgery. In the past, pain relief in these very vulnerable subjects has been neglected, reflecting the current beliefs and a resistance to change practice.

34.2.1 Effects of Pain

The fetus is able to respond to noxious stimuli by increasing stress hormone levels and cerebral blood flow, whereas fentanyl dampens the stress response by preterms undergoing surgery [9]. These observations support the notion that autonomic and metabolic reactions are triggered before pain pathways are mature.

Between 17 and 25 weeks of gestational age, several neuronal cells types and dendritic and axonal networks differentiate from subplate neurons, assigned to guide the development of cortical and thalamic structures. Because of nervous system plasticity, repetitive noxious stimuli reaching the subplate neurons may result in the formation of permanent abnormal synapses and hyperactivity of pain responses, resulting in possible future behaviour disorders.

34.2.2 Pain in the Neonatal Intensive Care Unit

Though guidelines to manage pain in the neonatal intensive care unit (NICU) have been issued [10], many newborns undergo repetitive noxious procedures without adequate pain relief. Acute pain assessment can be difficult, because of difficulties in (a) the discrimination of pain from other causes of distress and (b) recognizing pain cues in the sickest babies. Furthermore, signs of pain may not be apparent because of limited energy reserves and exhaustion in the sickest infants. Other obstacles to pain management can be fear of respiratory depression, routine practice, old beliefs and lack of validated prolonged pain assessment scales [11].

Beyond procedural, perioperative and disease-related pain relief, sedation in mechanically ventilated neonates has been advocated, aiming at promoting stress reduction, blood pressure stability and ventilator synchrony, leading to decreased cerebral injury and death. In 2004, the NEOPAIN multicenter trial evaluated 898 ventilated preterm newborns randomized to receive morphine or placebo. The study did not demonstrate any difference in the incidence of intraventricular hemorrhage, periventricular leukomalacia and death between the groups, while the morphine group had more hypotension, prolonged ventilation and feeding intolerance [12].

Although opioids cannot be currently recommended for routine sedation in ventilated neonates, they should be routinely administrated during surgery, invasive procedures and inflammatory diseases, on the basis of pain evaluation and clinical judgement [13].

34.2.2.1 Opioids

The most commonly used opioids in NICU are morphine and fentanyl. Morphine shows an onset time of 5 minutes and a peak effect at 10–30 minutes. The effect lasts 3–8 hours in neonates. Clearance reaches adult values at 6 months. The relative permeability of the newborn blood-brain barrier facilitates the penetration of morphine into the central nervous system compared to older subjects. Morphine is administered for perioperative analgesia, but has not proved to be so effective for procedural acute pain. Usual intravenous dosage in infants receiving ventilatory support is 50–100 μg/kg as a single dose, followed by an infusion of 10–30 μg/kg/h. Lower dosages are adequate for lower gestational ages and small incremental doses (25–50% of the usual) are advised for non-ventilated infants.

Fentanyl is more lipid soluble and has a potency 100-fold that of morphine. The peak effect is reached by 5–15 minutes and its duration is 1–2 hours. Fentanyl is less sedating and has minimal cardiovascular effects. It is suitable for hemodynamically unstable patients. Nevertheless, disadvantages of fentanyl are the rapid development of tolerance and chest wall rigidity, which is particularly problematic for non-intubated infants. Fentanyl is usually administered intravenously at a dosage of 1–3 μg/kg as a single dose, followed by an infusion of 0.5–2 μg/kg/h.

Tolerance develops more rapidly with fentanyl (3–9 days) than with morphine and with a continuous infusion than with intermittent doses. Non-pharmacological measures and switching from opioids to sedatives (when appropriate) can

reduce the risk of developing tolerance. Opioid tapering protocols should be implemented in every NICU.

Codeine is administered only by the enteral route, needing the enzyme CYP2D6 to be metabolized to morphine. Poor and intermediate metabolizers can undergo dose-related toxicity or therapeutic failure. Ultrarapid metabolizer breastfeeding mothers expose their babies to the risk of life-threatening respiratory depression [14].

Tramadol is an analogue of codeine, acting both as μ-receptor agonist and monoamine reuptake inhibitor. CYP2D6 metabolizes tramadol to O-demethyl tramadol, which shows a much higher affinity for μ-receptors than the parent compound. In term neonates, CYP2D6 activity seems to be equal to adult slow metabolizers and reaches adult activity level at 44 weeks. Tramadol is administered at the dose of 2–3 mg/kg as a bolus and 5–8 mg/kg/day as a continuous infusion [15].

34.2.2.2 Paracetamol

Paracetamol is a very common analgesic in infancy, but in neonates poor pain relief is reported after its administration for painful procedures, probably indicating its inadequacy for this type of pain. Newborns are relatively protected from paracetamol hepatotoxicity, because of a lower CYP450 level and lower glucuronide/sulphate metabolism ratios [16]. Increased unconjugated hyperbilirubinemia reflects the hepatic conjugating ability and can be a marker of reduced paracetamol clearance. The relative bioavailability of rectal versus oral formulations is higher in neonates and approaches unity, while the rate of duodenal absorption is slower and the rate of rectal absorption is slower and more erratic in neonates compared with older infants. To reach a target plasma concentration of 10–20 μg/mL, a loading dose is recommended. Doses should be adjusted in relation to weight, gestation, postnatal age and route of administration. Term newborns should not receive more than 60 mg/kg/day of paracetamol at 6 hourly intervals, whereas preterms should receive lower doses (30–40 mg/kg/day) at longer intervals (12–8 hours) [17]. Intravenous paracetamol can be given as opioid sparing drugs either alone or in association with an opioid. The full dosage ranges from 30 to 60 mg/kg/day and should not be continued for more than 4 days.

34.2.2.3 Ketamine

Ketamine is a "dissociative" drug, providing anesthesia, analgesia and amnesia, while displaying a safe respiratory and hemodynamic profile. The new S(+) ketamine seems to be better than the older racemic compound. Drug action is mediated mainly by N-methyl-D-aspartate (NMDA) receptor antagonism. An intravenous dose of 1–2 mg/kg exhibits an onset time of 1 minute, a peak effect by 5–10 minutes and a duration of 30–60 minutes. In NICU procedural pain, ketamine reduces the discomfort associated with tracheal suctioning [18]. Recently, the Food and Drug Administration have invited the anesthesia community to address the issue of the potential neurotoxicity of anesthetic agents in neonates on the basis of their neurodegenerative effects on the developing brain in experimental trials [19]. NMDA receptor antagonists and γ-aminobutyric acid (GABA) agonists in doses and durations of exposure exceeding those clinically used, induce neuronal injury and death in the brains of juvenile rodents. Most of these studies relate to ketamine, as initial observations had suggested a possible role for NMDA antagonists as neuroprotective agents. However, subsequent studies have shown neurotoxic effects. The applicability of these reports to clinical situations needs further confirmation.

34.2.2.4 Midazolam

Benzodiazepines are the most popular sedative drugs used in children, often combined with opioids. They share the same GABA-ergic mechanism of action with propofol and barbiturates, resulting in hyperpolarization of the neuronal membrane and producing anxiolysis, amnesia, sedation, muscle relaxation and anticonvulsant effects. Potential adverse effects are hypoventilation/apnea and hypotension. Midazolam is characterized by a faster onset and shorter duration than other drugs such as diazepam and lorazepam. The immaturity of enzyme systems involved in the metabolism of the drug (CYP450 and glucuronyltransferase) are linked to gestational and postnatal age, organ dysfunction and drug interactions, and explain the marked interpatient variability in dosage requirements to produce sedation in critically ill pediatric patients [20]. The use of midazolam in NICU has been recently reassessed on the grounds of both clinical and experimental observations. In 1999 the NOPAIN trial showed a higher incidence of adverse neurologic events and death in a midazolam group compared with morphine or placebo groups [21]. The potential of midazolam to induce apoptotic neurodegeneration in the brain, while failing to sedate and sensitize cutaneous reflexes in neonatal rats, has raised concerns about the safety of midazolam during the first days of life. Midazolam infusions for sedation in NICU are, however, used.

34.3 Conclusions

Physiology and pathophysiology of the neonatal age and the pharmacology of anesthetic and analgesic drugs form the basis for anesthesia management of the newborn. Small infants, preterms and neonates with complex syndromes can be safely managed but only by experienced pediatric anesthetists.

Neonatal Care in the Delivery Room: Initial Management

Tara M. Randis

35.1 Introduction

Ancient accounts of neonatal resuscitation strategies may be found in the Old Testament, the Talmud, and early writings of Hippocrates [1]. Mouth-to-mouth resuscitation of newborns was described as early as 1472 in a textbook on childhood diseases written by Bagellardeus [2]. While, some of these early resuscitation practices were truly revolutionary, the vast majority reflected a limited understanding of the dramatic physiologic changes that take place during birth. Techniques including swinging the infant upside down, immersion in cold water, electric shock, shaking, yelling, slapping and even insufflation of tobacco smoke into the rectum were widely practiced as recently as the early 20th century [1–3]. In 1953, Virginia Apgar wrote the following regarding the resuscitation of newborn infants:

> Seldom have there been such imaginative ideas, such enthusiasm, and dislikes, and such unscientific observations and study about one clinical picture. There are outstanding exceptions to these statements, but the poor quality and lack of precise data of the majority of papers concerned with infant resuscitation are interesting. [4]

Over the past several decades, an improved understanding of neonatal transition to extrauterine life accompanied by major advancements in medical technology have led to dramatic improvement in the care of the compromised newborn.

Recognition of the growing need for standardization of delivery room practices has led to the development of national committees dedicated to the establishment of consensus guidelines for newborn resuscitation. A global movement towards the practice of evidence-based care in the delivery room emerged and in 1992 the International Liaison Committee on Resuscitation (ILCOR) was established to provide a forum for liaison between resuscitation organizations in the developed world [5]. Importantly, this committee not only provides recommendations regarding the care of the newborn, but also has acknowledged ongoing controversies and identified areas in which additional research is needed. In addition, the training of caregivers in the delivery room has become the focus of recent clinical investigations, as innovative educational strategies such as video recording of resuscitations and simulator-based teaching become an integral part of many pediatric training programs [6, 7].

35.2 Delivery Room Preparation

Successful resuscitation hinges upon preparedness. Nearly 10% of newborns require some assistance to begin breathing at birth and approximately 1% will require extensive resuscitation. Personnel trained in basic resuscitation skills (including initiation of positive pressure ventilation and chest compressions) should be present at every delivery. A person trained in Advanced Life Support techniques should be readily available for low-risk deliveries and present in the delivery room for those considered high-risk. Published recommendations regarding the necessary equipment and drugs for resuscitation of the newly born infant exist and delivery rooms should be stocked accordingly (Table 35.1)[8]. Communication with maternal care providers is critical, as a thorough maternal history will often identify those neonates most likely to require resuscitation. In 2008, Aziz et al [9] published a prospective, clinical trail identifying both ante-partum and intra-partum factors that were strongly associated with the need for positive pressure ventilation in the delivery room. These included multiple pregnancy, maternal infection, maternal hypertension, oligohydramnios, preterm delivery, breech presentation, meconium stained amniotic fluid, non-reassuring heart rate patterns, and emergency C-section.

Table 35.1 Neonatal resuscitation supplies and equipment

Suction equipment	Bulb syringe Mechanical suctioning and tubing Suction catheters (5F or 6F, 8F, 10F, 12F or 14F) 8F feeding tube and 20 mL syringe Meconium aspirator
Bag and mask equipment	Device for delivering positive-pressure ventilation (capable of delivering 90–100% O_2) Face masks, newborn and premature sizes (cushion-rim masks preferred) Oxygen source with flowmeter (flow rate up to 10 L/min) and tubing Compressed air Oxygen blender with flowmeter Pulse oximeter and probe
Intubation equipment	Laryngoscope with straight blade, No. 0 (preterm) and No. 1 (term) Extra bulbs and batteries for laryngoscope Endotracheal tubes (sizes 2.5, 3, 3.5, and 4 mm ID) Stylet (optional) Scissors Tape or securing device for endotracheal tube Alcohol sponges CO_2 detector or capnograph Laryngeal mask airway (optional)
Medications	Epinephrine: 1:10,000 concentration (0.1 mg/mL) [3 mL or 10 mL ampules] Isotonic crystalloid (normal saline or Ringer's lactate) for volume expansion Sodium bicarbonate: 4.2% (5 mEq/10 mL) [10 mL ampules] Naloxone hydrochloride: 0.4 mg/mL [1 mL ampules], or 1.0 mg/mL [2 mL ampules] Dextrose 10%, 250 mL Normal saline for flushes Umbilical vessel catheterization supplies (sterile gloves, scalpel or scissors, antiseptic prep solution, umbilical tape, umbilical catheters, 3.5F, 5F, three-way stopcock) Syringes 1, 3, 5, 10, 20, 50 mL Needles, 25, 21, 18 gauge, or puncture device for needless system
Miscellaneous	Gloves and appropriate personal protection Radiant warmer or other heat source Firm, padded resuscitation surface Clock with second hand (timer optional) Warmed linens Stethoscope Tape, ½ or ¾ inch Cardiac moniter and electrodes or pulse oximeter an probe (optional for delivery room) Oropharyngeal airways (0, 00, 000 sizes or 30, 40, and 50 mm lengths)
For very preterm babies (optional)	Compressed air source Oxygen blender to mix oxygen and compressed air Pulse oximeter and oximeter probe Reclosable, food-grade plastic bag (1 gallon size) or plastic wrap Chemically activated warming pad Transport incubator to maintain baby's temperature during move to the nursery

From [8], with permission of AAP.

Those infants born after a full-term gestation, with no evidence of meconium or infection, with spontaneous breathing and good muscle tone are unlikely to require resuscitation and therefore may be dried and immediately placed upon the mother's chest [8]. If an infant does not meet these criteria, then the health care practitioner should proceed with the initial steps of resuscitation including:

1. Placing the infant under a radiant heat source
2. Proper positioning/clearing of the airway
3. Drying and, if necessary
4. Stimulating the infant to elicit effective respirations.

35.3 Positioning and Clearing the Airway

Placement of the newborn on his or her back under a radiant warmer with the head in a slightly extended position will open the airway. If respiratory efforts are present but ineffective (retractions, inadequate chest wall movement or poor air entry), the airway may be obstructed.

Secretions should be cleared first from the oropharynx and then the nasopharynx with either a bulb syringe or suction catheter. Care must be taken to avoid deep or vigorous suctioning as this may result on laryngeal spasm and/or vagal bradycardia.

35.4 Stimulation

Most infants cry spontaneously upon delivery and establish regular respiration by 1 minute of age. If this does not occur, the majority of infants will respond to tactile stimulation such as gentle rubbing of the back, as occurs with drying of the infant, or gently flicking the bottom of the feet. Failure of the infant to respond to these measures indicates the infant may be experiencing secondary apnea, and will require positive pressure ventilation. Resuscitative measures beyond these initial few steps are discussed in detail in subsequent chapters.

35.5 Thermal Stability in the Delivery Room

Fetal temperature in utero is tightly regulated. Fetal metabolism results in a net production of heat that is removed by placental blood flow and is ultimately dispersed through the mother. As a result, there is a slight temperature gradient, with fetal temperature approximately 0.5°C greater than the maternal core temperature [10]. Upon parturition, the neonate rapidly loses heat through a variety of mechanisms as the ambient temperature falls dramatically from 37ºC *in utero* to

approximately 25ºC in the delivery room. Because the newborn is coated with amniotic fluid, there is substantial evaporative heat loss. Circulating air currents in the delivery room contribute to convective heat loss. Conductive heat loss occurs when the infant is placed upon cooler surfaces such as unwarmed mattresses and blankets. Finally, heat is lost through radiation to cooler surfaces surrounding the infant but not in direct contact with the infant.

The newborn is capable of sensing this cold stress and immediately triggers homeothermic mechanisms to minimize further heat loss. Vasoconstriction of the dermal arterioles minimizes the flow of warm blood to the cooler surface of the skin. Non-shivering thermogenesis, in which brown fat stores undergo exothermic reactions thereby generating heat, is initiated. Despite these adaptive measures, the core temperature of the newborn will continue to fall unless intervention by caretakers occur in a timely manner.

The low birth weight infant is exquisitely susceptible to heat loss in the immediate postnatal period as they have a larger surface area to weight ratio and limited subcutaneous fat. The preterm infant, in particular, is less able to adapt to these environmental changes secondary to an immature epidermal barrier and a paucity of brown fat stores. For these reasons, the preterm infant has often been referred to as a functional poikilotherm.

It is generally accepted that the newborn should have a core body temperature at or near 37ºC. However, it is important to recognize that even a newborn with a normal core body temperature may be exerting a tremendous amount of energy to maintain this temperature and therefore, is cold stressed. While it has been recognized for decades that cold stress at birth has a negative impact upon infant survival, particularly in low birth weight infants [11], it is surprising to learn that despite dramatic advances in neonatal care, temperature management in the delivery room remains an ongoing challenge.

A large, multicenter, observational study published by Laptook et al [12] examined the distribution of body temperatures in low birth weight infants admitted to the neonatal intensive care unit. The study included more than 5,000 very low birth weight infants and found that nearly 47% had low admission temperatures defined as less than 36ºC. Futhermore, there was a significant association between the extent of reduced temperature upon admission and late-onset sepsis and in-hospital mortality. These findings were similar to those published earlier in the EPIcure study, where approximately 40% of infants less than 26 weeks gestation had admission temperatures below 35ºC and this was correlated with decreased survival [13].

Interventions to limit heat loss in the delivery room include the pre-warming of blankets and mattresses, rapidly drying the newborn and removing wet blankets from infant contact. Swaddling infants in a warmed blanket is generally sufficient for stable, term infants. Early initiation of kangaroo care, allowing for direct skin-to-skin contact with the parent, is another effective means of maintaining the newborn's temperature [14].

Overhead heaters are necessary for those infants requiring further resuscitative efforts. Occlusive wraps (polyurethane, polyethlylene, or polyvinyl) may be beneficial in minimizing heat loss in extremely preterm infants, as their use has been associated with higher admission temperatures to the intensive care unit [15].

While it has long been recognized that neonatal hypothermia is associated with decreased survival, potential morbidities related to neonatal hyperthermia have more recently been described [16].

Neonatal hyperthermia may occasionally be iatrogenic in nature (inappropriate use of radiant warmers, occlusive wraps). However, it most often results from an elevated maternal temperature secondary to epidural anesthesia, prolonged labor or chorioamnionitis. Shalak et al [17] examined a cohort of term infants with clinical chorioamnionitis and found that elevated temperature at 30 minutes of life was correlated with neonatal depression at birth (requiring positive pressure ventilation or Apgar score less than 5 at 5 minutes) and admission to the neonatal ICU [17]. Other investigators have demonstrated an association between maternal fever and neonatal encephalopathy [18]. Because these studies utilize maternal fever as a surrogate for neonatal hyperthermia, it remains unclear if maternal fever alone is sufficient to cause neurologic insult or if it is simply a marker for other intrapartum risk factors.

35.6 Assessment of Resuscitation Efforts: the Apgar Score

In 1952, Virginia Apgar created a scoring system to rapidly assess the physical condition of infants shortly after birth in order to recognize those infants in need of further interventions to establish breathing [4]. The Apgar score, which includes evaluation of heart rate, respiratory effort, muscle tone, reflex irritability and color, remains widely used today as a measure of the infants response to resuscitative efforts.

Several investigators have attempted to expand the utility of the Apgar score beyond the scope of the delivery room, using it as a measurement of risk for later impairment. While there is some evidence to suggest that a low 5 minute Apgar score may be associated with future neurologic disability, the American Academy of Pediatrics cautions against its use as a predictor of long-term outcome or as a specific marker of intrapartum asphyxia, as this was not the original intent [19]. Interestingly, a low 5 minute Apgar score (0–3) has been shown to be a valid predictor of neonatal mortality [20]. The Apgar score is affected by gestational age and therefore its significance in preterm infants remains unclear.

Approach to Low Risk Newborns

Jennifer M. Duchon

36.1 Introduction

Of the approximately 4 million live births occurring annually in the United States [1] over 90% require nothing but routine care of the infant in the delivery room. The majority of these births are considered low risk, but the percentage of deliveries that are categorized as low risk has decreased in recent years. This is in part due to increasing numbers of births at the extremes of childbearing age, an increase in complications due to maternal morbidities such as obesity, and an increasing preterm birth rate.

In many cases, the need for newborn resuscitation can be anticipated. However, at every birth, the appropriate equipment should be available. Neonatal Resuscitation Program (NRP) guidelines and common sense recommend that at least one person skilled in neonatal resuscitation whose only responsibility is the management of the newborn is present at every delivery. This person does not need to be a physician, but should possess the ability to perform the initial steps in resuscitation until additional help arrives [2].

The initial steps in the management of the newborn will be discussed elsewhere in this text. Several key aspects of continuing care of the well newborn in the delivery room and during the recovery period will be discussed.

In the healthy term newborn the goal of delivery room care should be to assess the newborn for any features that may confer the need for closer monitoring and follow-up, and to promote the natural bonding between mother and infant. In this regard, much of the continuing care of the newborn can be done in such as way as to be minimally invasive to the infant and not disruptive to the mother-infant dyad.

36.2 Routine Assessment

36.2.1 Physical Exam

Every newborn should be assessed with a brief physical examination in the delivery room. The complete physical exam of the newborn will be discussed in detail in later chapters, and has a different goal. As previously stated, the purpose of the physical exam in the delivery room should be to assess the newborn for any features that may indicate the need for immediate intervention or for further investigations and follow-up during the nursery stay. Important findings to identify are:

- visually patent and normally placed anus
- normal external genitalia
- presence of cleft lip or palate
- intact spine and sacral area.

Most major congenital malformations are discovered during routine prenatal care, and second trimester ultrasound at 18–22 weeks gestational age remains the most common imaging modality. When performed at tertiary care or University affiliated institutions, second trimester ultrasound has been shown to have good specificity and fair sensitivity for the detection of fetal anomalies [3]. However, defects such as those listed above, especially small facial anomalies, are frequently difficult to detect with traditional 2-dimensional ultrasound techniques. As more sophisticated techniques such as 3-dimenstional ultrasound or fetal magnetic resonance imaging (MRI) come into wider use, the detection rate for these anomalies, especially spinal and facial defects, may improve [4].

It is not recommended to perform a rectal probe exam, such as a rectal temperature, to document patency of the anus. Deep suctioning of the nasally or orally is also neither necessary nor recommended to determine patency of the nares or esophagus, as this may lead to trauma or perforation of the mucosal tissues. This is supported by recommendations from The American Academy of Pediatrics (AAP) section on breastfeeding, which states that unnecessary, excessive, and overvigorous suctioning of the oral cavity, esophagus, and

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

airways may traumatize the infant and lead to aversive feeding behavior [5]. An early physical examination of the infant can also document normal variants such as molding or caput of the scalp, Mongolian spots or sucking blisters, and reassure parents of the benign nature of such findings. The initial physical assessment of the baby can be performed while skin-to-skin contact with the mother is taking place.

36.2.2 Thermal Regulation

Thermal regulation of the neonate, both preterm and full-term, is one of the major challenges faced in the delivery room. Heat loss in newborns occurs through four basic mechanisms: radiation, conduction, convection and evaporation.

Heat loss through radiation is related to the temperature of the surfaces surrounding the infant but not in direct contact with the infant, and is an important mechanism in heat loss in term infants. This is the rationale behind placing the infant on a radiant warmer immediately after delivery. However, the infant may emit radiant heat to a colder source, such as walls or windows. Conduction is the transfer of heat through direct contact with a surface that is colder or warmer, such as the bedding or swaddling that the infant is initially placed in. In convection, heat transfer occurs when air currents carry heat away from the body surface. The fetus generates heat, and the temperature of the newborn is approximately 0.5°C higher than the maternal temperature. Most delivery rooms are obviously colder than the newborn, and heat is first conducted into the air and then carried away by the convective air currents. This is an especially prominent phenomenon in the operating room, where the ambient air temperature is often kept cooler for the comfort of the garbed medical staff. Evaporation occurs when water is lost from the skin. During evaporation, approximately 0.6 kcal of heat is lost for every 1 g of water lost from the body [6–8]. Reducing heat loss though evaporation is a target of intervention that is especially important in the very preterm infant. In the full-term infant, the initial step of drying the infant with warm blankets ameliorates both evaporative and conductive heat loss.

Heat is generated by the newborn primarily though non-shivering thermogenesis. Non-shivering thermogenesis is the production of heat that does not occur through muscle activity. In neonates, this occurs primarily though the metabolism of brown fat. Brown fat, found in infants greater than 30 weeks, contains a high concentration blood vessels and sympathetic nerve fibers, and its metabolism causes an increase in sympathetic activity leading to an increase in norepinephrine, thyroid-stimulating hormone, T4 and T3. These mediators cause increased fat oxidation and heat production [6–9].

There are several ways to reduce heat loss and prevent resultant cold stress. The simplest method is that of skin-to-skin contact. The mother is an optimal heat source for the infant. Skin-to-skin contact has been well studied in many different cultures and resources settings, and has been shown to successfully maintain normal temperature of healthy term neonates. This type of contact can also alleviate mind hypothermia. It has been shown to promote bonding and facilitate both the initiation and continuation of breastfeeding [5, 6]. Other methods of preventing hypothermia in the newborn include placing a cap on the infant, and keeping the temperature of the delivery room such that heat loss due to evaporation and conduction, respectively, are minimized.

36.2.3 Initiation of Breastfeeding

The full physiology and nutrition of breastfeeding and breast milk will be discussed in Section III. For the purpose of the care of the infant in the delivery room, the initiation of breastfeeding may be considered one of the most important contributions to the health and well-being of a newborn. Briefly, the AAP recommendations for breastfeeding and breast milk include:

- breast milk for all infants for whom it is not medically contraindicated
- exclusive breastfeeding for the first 6 months of life
- continuation of breastfeeding for at least one year
- peripartum practices that facilitate breastfeeding.

The alert, healthy newborn infant is capable of latching on to a breast without specific assistance within the first hour after birth [5, 10]. In keeping with the previous discussion on temperature regulation, the AAP recommendations to promote breastfeeding in the delivery room encourage that well, full-term infants be placed and remain in direct skin-to-skin contact with their mothers immediately after delivery until the first feeding is accomplished [5, 10]. Weighing, measuring, bathing, and other non urgent interventions should be delayed until after the first feed is completed. For both bonding and breast feeding purposes, the newborn infant should remain with the mother throughout the recovery period. A Cochrane review confirms that institutional changes in maternity care practices effectively increased rates of breastfeeding initiation and duration [11]. Institutional policies surrounding routine care of healthy newborn should be developed with the goal of safety and the promotion of the mother infant bond, as opposed to convenience of the medical and ancillary staff.

36.3 Vital Signs and Measures

36.3.1 Vital Signs

Non-invasive vital signs, such as heart rate, respiratory rate and temperature, as well as the procedure of weighing and measuring the infant, are often performed in the delivery room. Some institutions also have protocols involving more

invasive measures, such as screening for oxygen saturation, hypoglycemia, anemia or polycythemia.

A vigorous term infant who has been ascribed good APGARS is unlikely to have major derangements in pulse or respiratory rate. Mild tachypnea may be a physiologic part of the transition from fetal to extrauterine life. The increased pulmonary vascular resistance of the newborn as manifest by oxygen saturation takes time to normalize. Studies have demonstrated that healthy full-term neonates rarely reach oxygen saturations of greater than 90% until after the first 10 minutes of life, and may have lower post-ductal saturations for an even longer period [12, 13].

36.3.2 Hemoglobin and Hematocrit

Healthy full-term infants have, in past years, been targeted for treatment of anemia or polycythemia based on values obtained from routine screening at birth. This can be troublesome from several perspectives. The definition of both anemia and polycythemia can vary. Most practitioners define anemia as a greater than 2 standard deviations below the mean hemoglobin, or less than the fifth percentile. For full-term neonates, this is approximately 13 g/dL from a sample of blood drawn centrally, or 14.5 g/dL drawn from capillary sampling. Symptoms of anemia in the immediate newborn period may range from pallor to tachypnea to severe respiratory distress and circulatory collapse. Polycythemia can be defined in a similar manner, but has traditionally been diagnosed as a hematocrit greater than 65% drawn centrally or 70% drawn from a capillary specimen. Risk factors include macrosomic infants, or infants who are born to mothers who have conditions that affect placental blood flow, as a compensatory mechanism from the fetus.

Symptoms of polycythemia include central nervous system (CNS) manifestations such as lethargy and tremulousness, hypoglycemia, as well as evidence of organ failure such as respiratory distress, renal failure, congestive heart failure, or intestinal symptoms. Both obstetric practices, such as method of delivery, timing of cord clamping and positioning of the infant relative to cord clamping, can affect these values, as do the timing of blood draw relative to delivery [14, 15]. The degree to which an individual infant is symptomatic at a particular hemoglobin or hematocrit is extremely variable. It is also very difficult to differentiate the clinical effects, both short and long-term, of polycythemia and anemia in an asymptomatic infant, from the effects of the cause of the abnormal indices. Especially for polycythemia, there is no evidence to suggest that the treatment modality, partial exchange transfusion, of an asymptomatic infant improves outcome. The most sensible approach would be to consider screening infants who are at risk for anemia from fetal or intrapartum complications, and may warrant closer follow-up, or for any infant who displays symptoms of abnormal hemoglobin or hematocrit [15].

36.3.3 Monitoring of Glucose

There has been much discussion in recent years as to the measurement and management of glucose levels in the low risk infant.

The fetus has a complete and continuous supply of glucose from the mother from placental transfer, via carrier mediated facilitated diffusion. After birth, when this supply is abruptly cut off, there are several mechanisms to maintain adequate energy to the infant:

- glycogenolysis
- gluconeogenesis
- lipolysis
- fatty acid oxidation and ketogenesis
- hormonal/endocrine regulation of these systems.

Serum glucagon, catecholamines and growth hormone rise after cord clamping and insulin levels fall, favoring glycogenolysis, lipolysis and gluconeogenesis. Full-term infants are born with adequate glycogen stores, but these are depleted within the first several hours after birth unless feeding is established. Lipolysis can occur shortly after birth, and releases free fatty acids that can be used as an energy source by many tissues, although not by the brain. Fatty acid oxidation and ketogenesis take place in the liver, and produces ß-hydroxybutyrate, acetoacetate and ketones which can be used by as an energy source for the brain. Several of the major hormones required for control of these systems rise in the first few hours of life, leaving the production of usable energy from both gluconeogenesis and hepatic ketogenesis delayed. This leaves free fatty acids from lipolysis and glucose from breakdown of glycogen stores as the major energy sources immediately after birth [8, 16]. In infants with poor stores of adipose tissue or glycogen, such as preterm or growth restricted infants, maintaining an adequate supply of fuel for the metabolic needs of the brain becomes of great concern. Infants who are well may also be at risk. Non-shivering thermogenesis is the major mechanism of heat production in the neonate, and cold stress in the delivery room can occur. A newborn infant left unattended in an environment at typical "room temperature" experiences energy losses of approximately 150 kcal per minute, rapidly using up energy stores [6]. Delay in enteral feeding for routine newborn care can also exacerbate hypoglycemia. This provides further evidence for care to be performed skin–to-skin with the mother with early initiation of breastfeeding.

Many nurseries still monitor serum glucose levels in low risk, healthy infants as part of routine care. A problem can then arise, as debate occurs about what level of serum glucose should be considered abnormal and require intervention in an asymptomatic, otherwise well newborn. When it was first recognized as a pathologic state, hypoglycemia was defined as less than 20 mg/dL (1.1 mmol/L) in preterm infants and less than 30 mg/dL (1.7 mmol/L) in full-term infant. Cohort studies later showed that infants with symptomatic hypoglycemia had poorer neurodevelopmental outcomes [17]. Since that time,

there has been little agreement about minimum acceptable level of glucose in healthy term infants. Some authors contend that 45 mg/dL (2.5 mmol/L) is the lower limit for all infants [18, 19]. Other maintain that due to the key time in development, and lack of evidence for compensatory mechanisms that protect the neonatal brain from hypoglycemic injury, glucose values should be the similar in newborns as in older children, greater than 60 mg/dL or 3.3 mmol/L [16]. Symptoms from hypoglycemia include tremulousness, lethargy, seizures, hypothermia, or can mimic respiratory distress. Infants who are considered at risk for hypoglycemia are those who are small or large for gestational age, or who have maternal risk factors for abnormal glucose such as gestational diabetes or medications affecting glucose metabolism. Also at high risk for sequelae from hypoglycemia are those infants who have evidence of infection, hypothermia, polycythemia or hypoxia-ischemia [18, 19]. It is generally accepted that healthy term infants, either breast-fed or formula-fed, who do not have risk factors for compromised metabolic adaptation and who are asymptomatic need not have routine glucose monitoring [15]. Any infant who appears symptomatic from hypoglycemia, or in whom risk factors for increased altered glucose metabolism exist should be evaluated and treated as necessary.

36.4 Common Routine Treatments

36.4.1 Eye Care

Neonatal ophthalmia is defined as conjunctivitis that occurs within the first 28 days of life. It is a relatively common illness, occurring in 1–12% of newborn infants. Originally, neonatal ophthalmia referred to conjunctivitis in the newborn caused by infection with *Neisseria gonorrhoeae*, but now the term refers to any conjunctivitis in this age group, regardless of the cause [20]. Gonococcal ophthalmia was, in the past, a leading cause of blindness, but is now rare in most developed populations with access to treatment and screening during pregnancy. It is for this historical reason that delivery room prophylaxis was geared towards prevention of blindness from this pathogen. Since the diminishment of gonococcal ophthalmia, there has been debate about which agent, if any, to use as prophylaxis against conjunctivitis in the delivery room. Most cases of conjunctivitis in the neonatal period are due either to chemical conjunctivitis or non sexually transmitted colonizing bacteria. *Chlamydia trachomatis* also causes a portion of ophthalmia, depending on local incidence. With the exception of gonococcal and chlamydial conjunctivitis, the condition is mild, and usually responds well to local treatment with no long-term sequelae with appropriate therapy. It is the consensus from the AAP, as well as the Canadian Paediatric Society (CPS) that eye prophylaxis, in the form of 1% silver nitrate, 0.5% erythromycin, or 1% tetracycline drops or ointment be given. The medication should be instilled as soon as possible in the delivery room, and should not be wiped off. There is no data suggesting that delaying administration until after the first breastfeed in any way affects efficacy. Erythromycin ointment has replaced other forms of prophylaxis in the US, as some initial data suggested that there may be protection against chlamydial species. Later studies disproved this [21] probably due to the fact that local treatment will not eradicate nasophargyngeal colonization of the organism. Many US physicians feel that erythromycin causes less chemical conjunctivitis than silver nitrate and the drug remains in wide usage. This is not the case in other countries, where aminoglycoside, chloramphenicol, or no prophylaxis is used. As demonstrated by Guala et al [22], agents used as prophylaxis against neonatal ophthalmia vary widely between centers and are functions of local practice and tradition, as opposed strictly to evidence based medicine.

36.4.2 Vitamin K

Due to limited stores at birth, neonates are prone to vitamin K deficiency if no sufficient intake is provided. The clinical syndrome associated with vitamin K deficiency has been termed hemorrhagic disease of the newborn, and comprises three distinct presentations. The very early form presents within 24 h of birth and is almost exclusively seen in infants of mothers taking drugs which inhibit vitamin K. These drugs include certain anticonvulsants, some antibiotics and vitamin K antagonists, many of which are now avoided in pregnancy. Clinical presentation can be severe, with cephalohematomas, intracranial and intra-abdominal hemorrhage. Classical vitamin K deficiency occurs between 24 h and 7 days of life and is associated with delayed or insufficient feeding. Clinical presentation is often mild, with bruises, gastrointestinal bleeding, or bleeding from the umbilicus and puncture sites. The late presentation of vitamin K deficiency is associated with exclusive breast-feeding. It occurs between the ages of 2 and 12 weeks and infants can be gravely ill, with a mortality rate of 20%. Intracranial hemorrhage occurs in up to 50% of those affected [23]. After the discovery of vitamin K in the mid 20th century, it was shown that treatment with vitamin K could abolish hemorrhagic disease of the newborn. It then became standard practice to administer the drug soon after birth to all infants. Controversy has arisen about this practice for several reasons. Both classic and late vitamin K deficiency are relatively rare: recent reviews cite estimates of 0.01–0.44% in the general population for the classic form, and between 4.4/100,000 and 7.2/100,000 births for the late form in fully breast-fed infants who did not receive vitamin K at birth [23]. The present dose of 1 mg represents a very large amount when compared to the daily requirement of 5–10 μg in infants. The dose of 1 mg appears to have been chosen fairly arbitrarily, with no formal studies being performed to establish what dose

might be appropriate. Intramuscular form became the route of choice based primary on the available formulation at the time [24]. In the 1990s, a study from Britain linked the administration of intramuscular vitamin K at birth to childhood cancers and leukemia [25]. Later studies failed to confirm this association, but the guidelines for universal prophylactic vitamin K were revised in many countries to include enteral dosage. It is universally accepted that vitamin K is necessary to prevent all forms of clinical disease in newborns. However, the method of administration and timing remain non-uniform across guidelines. For infants at risk from maternal medications, traumatic delivery or prematurity, the intramuscular route is preferred. For healthy term newborns at low risk, the CPS recommends that vitamin K should be given as a single intramuscular dose of 1.0 mg to all newborns within the first 6 hours after birth. For infants whose parents refuse an intramuscular injection, an oral dose of 2.0 mg of vitamin K at the time of the first feeding with dosages repeated at 2–4 weeks and 6–8 weeks of age may be used [26]. Some countries have investigated the use of a small daily dose of enteral vitamin K in lieu of large doses less frequently in breastfeeding infants who did not receive the injection at birth, with apparent success [23]. Parents choosing oral dosing should be advised of the necessity of follow-up doses and be cautioned that their infants remain at an increased risk of late vitamin K deficiency (including the potential for intracranial hemorrhage) using the oral as opposed to parenteral route [26].

36.5 Conclusions

A 1995 study performed across several Italian nurseries showed that despite the availability of evidence based national and international guidelines pertaining to routine newborn care, practices were guided by long standing habit and previously developed experiences [22]. This can be extrapolated to many aspects of neonatal care. However, in the low risk, well newborn, the guiding principle should be to ensure the health and well-being of the baby, and facilitate practices that will encourage continued health through maternal child interaction.

Early Detection of Neonatal Depression and Asphyxia

Paolo Biban and Davide Silvagni

37.1 Introduction

Perinatal asphyxia is an insult to the fetus or newborn due to hypoxia and/or ischemia, persisting long enough to cause pathological biochemical changes and a variable degree of injury to various organs, including the brain. The effects of hypoxia and ischemia are often difficult to separate clinically. Hypoxia refers to an arterial concentration of oxygen that is less than normal, while ischemia occurs when the blood flow to the cells or organs is insufficient to maintain normal function. In its more severe forms, the impaired gas exchange secondary to asphyxia is also associated with tissue lactic acidosis and hypercapnia [1].

Neonatal depression is a general term to describe the condition of any newborn in the immediate postnatal period (approximately the first hour after birth) showing a prolonged transition from intrauterine to extrauterine life. The degree of depression is described by the Apgar score: a 1 minute score of 4–6 is considered as moderate depression, and a score of 0–3 indicates severe neonatal depression, requiring the institution of immediate resuscitation.

37.2 Incidence and Definition of Neonatal Asphyxia

Despite major advances in monitoring technology, obstetric care and knowledge of fetal and neonatal pathologies, asphyxia remains a serious condition causing significant mortality and long-term morbidity. According to the World Health Organisation (WHO), 4–9 million cases of newborn asphyxia occur each year [2]. More than a million newborns that survive asphyxia at birth develop long-term problems such as cerebral palsy, mental retardation, speaking, hearing, visual and learning disabilities [2]. Globally, it is estimated that out of 4 million neonatal deaths annually, nearly one fourth are attributable to asphyxia [3]. In the developing world the incidence of asphyxia is believed to be considerably higher due to the increased prevalence of risk factors. However, the incidence of birth asphyxia may vary markedly, depending on the definition used, as well as the gestational age of the infant.

Many definitions of perinatal asphyxia can be found throughout the available literature, but a universal definition is still lacking [4–6]. One of the most utilized is that promulgated in 2003 by the American Academy of Pediatrics and the American College of Obstetrician and Gynecologists, which includes the following criteria [7]:

1. metabolic or mixed acidosis (pH < 7.00) in an arterial cord blood sample;
2. Apgar score 0-3 for more than 5 minutes after birth;
3. evidence of neurologic signs in the immediate neonatal period;
4. evidence of multiorgan failure in the immediate neonatal period.

Newborn infants suffering episodes of perinatal asphyxia are at high risk of dying or developing brain damage. Postasphyxial hypoxic-ischemic encephalopathy (HIE) is viewed as the hallmark and most important consequence of asphyxia, being a major cause of death and of disability in term and near-term newborn infants in developed countries [8].

Approximately 1–2 infants per 1000 live term births are affected by hypoxic-ischemic encephalopathy, with outcomes ranging from complete recovery to death [9]. HIE is a well-recognized clinical syndrome, with a large spectrum of clinical manifestations ranging from mild to severe. The clinical staging of Sarnat and Sarnat has been widely used since the 1970s to estimate the severity of the hypoxic-ischemic insult in infants of 36 or more weeks of gestation [10]. In most cases, the severity of the encephalopathy predicts the risk of death and long-term neurodisability [10, 11]. However, an hypoxic ischemic encephalopathy secondary to intrapartum asphyxia cannot reliably predict the consequent neurodevelopmental

outcome [8, 12]. Most term newborns with perinatal asphyxia have uneventful courses and a low likelihood of subsequent neurological sequelae [8, 13]. Perinatal depression, when defined as low Apgar scores in the first minutes of life, may be not only related to birth asphyxia but also to other factors carrying a much lower risk of unfavorable short and long-term outcome, including a vagal response due to nasopharyngeal stimulation, low gestational age, depression because of maternal anesthesia [8]. The prognosis for any given baby remains uncertain and reliable diagnostic and prognostic indicators related to perinatal asphyxia are still needed. Accurate markers of severe asphyxia and predictors of outcome would facilitate parental counselling as well as the choice of appropriate levels of care, which may include withdrawal of intensive care or the initiation of neuroprotective strategies.

Perinatal asphyxia may be categorized as occurring in three phases: 1) intrapartum; 2) immediate postpartum and 3) early neonatal period.

37.3 Intrapartum Asphyxial Markers

Assessment of the intrapartum condition of the fetus includes electronic fetal heart rate monitoring (EFM), the observation of meconium in the amniotic fluid, fetal scalp blood sampling for acid-base and lactate measurements.

Electronic fetal monitoring Electronic fetal monitoring (EFM) has been used to predict fetal distress or well-being. Heart rate abnormalities have been identified as a marker of asphyxia during labor, fetal bradycardia being one of the most serious [14]. However, EFM has been shown to be imprecise in detecting fetuses with metabolic acidosis and predicting those likely to develop an hypoxic-ischemic encephalopathy [15, 16]. Furthermore, in low-risk pregnancies intrapartum EFM has led to an increase in cesarean and operative vaginal delivery rates, but not to a documented improvement in neonatal outcome. Newer technolo- gies, such as fetal pulse oximetry and fetal electrocardiography may more accurately identify fetuses at risk. Other techniques, such as Doppler measurement of blood flow velocity, near infrared spectroscopy and fetal electroencephalogram, although useful are less suitable for a routine clinical application [8].

Meconium passage in utero Meconium passage in utero is frequently cited as a sign of fetal stress, but several studies have failed to demonstrate a correlation between meconium stained amniotic fluid and permanent neurological sequelae [17]. Currently, meconium passage in utero is considered neither a significant nor a specific marker of fetal distress unless associated with other abnormalities [8, 18].

Fetal scalp blood sampling Fetal scalp blood sampling (FBS) was introduced by Bretscher and Saling in 1962 and was primarily based on pH analysis [19]. They defined pH cut-off values as normal (>7.25), pre-acidotic (7.20–7.25) and acidotic (<7.20), recommending prompt delivery for cases with acidosis. These guidelines are still regarded as the "gold standard" for diagnosing intra-partum fetal distress. Fetal acidemia due to an hypoxic-ischemic insult is usually metabolic and a consequence of anaerobic glycolysis due to prolonged intrauterine hypoxia. In a large retrospective study, Kruger et al [20] performed 814 lactate and/or 1221 pH scalp blood measurements when fetal distress was suspected. In terms of sensitivity and specificity, lactate performed better than pH in the prediction of severe neonatal morbidity [20]. In addition, Kruger et al [21] demonstrated a good correlation between lactate obtained by FBS close to delivery and from cord arterial blood immediately after delivery. The potential usefulness of fetal scalp and cord blood lactate measurements to monitor the peripartum conditions of the fetus has been recently reviewed by Nordstrom [22].

Fetal scalp blood acid-base and lactate measurements, especially when combined with fetal heart rate monitoring, seem to be of value in predicting the condition of newborns at birth. However, this invasive approach can be performed only after rupture of membranes and is not widely used. Associated complications, although rarely observed, are soft tissue damage and scalp infections [23].

37.4 Immediate Postpartum Asphyxial Markers

Common markers of asphyxia used immediately after birth include low Apgar scores, umbilical artery acidemia and high blood lactate concentrations.

Apgar score The Apgar score was originally used as a rapid method of assessing the need for newborn resuscitation and to define newborn asphyxia [24]. However, the Apgar score has a number of limitations, mainly due to a considerable inter-observer variability and the different physiological implications of the five factors which make up the final score. Furthermore, causes other than asphyxia may result in low Apgar scores but without a high risk of brain injury, such as resuscitation procedures, infections, congenital malformations, maternal anesthesia [7]. Moreover, Apgar scores assigned during mechanical ventilation are not equivalent to scores assigned to spontaneously breathing infants, and the significance of low Apgar scores calculated in extremely premature babies are likely to differ from those awarded to term or near-term infants.

Finally, although the Apgar score has been used to predict specific neurological outcome in the term infant, several studies have demonstrated a weak correlation between low Apgar scores and severe birth asphyxia and subsequent adverse neurological development [13]. Nevertheless, the Apgar score is widely used and is useful for describing the condition of newly born infants and their response to resuscitation. It is

not appropriate to use it alone to establish the diagnosis of asphyxia, but, when combined with other conventional markers, such as arterial umbilical cord pH and base deficits, it has some predictive value for the development of hypoxic-ischemic encephalopathy [20, 25].

Acid-base measurements in umbilical cord blood Because Apgar scores are poor markers of severe birth asphyxia, some investigators have suggested the use of early acid-base status as a more objective indicator and the finding of a severe metabolic acidosis in the umbilical cord arterial blood at birth is probably the most objective assessment of intrapartum hypoxic ischemia [7]. Metabolic acidosis occurs because of a prolonged tissue oxygen deficit, reflecting hypoxia or impaired blood gas exchange of significant duration to allow the accumulation of fixed acids, mainly lactic acid. Most studies assess acid-base status on the arterial cord blood as soon as possible after birth [7]. The acid–base criteria commonly used to diagnose intrapartum asphyxia are a pH <7.00 and a base deficit (BD) value >16 mmol/L in umbilical arterial blood at birth or during the first postnatal hour [5, 7, 26].

In a cohort of term infants with an umbilical arterial pH <7.00, nearly two-thirds did not require admission in NICU and had no apparent neurological sequelae [27]. The need for cardiopulmonary resuscitation and adrenaline administration in the delivery room identified those neonates with pH <7.00 at greatest risk for a short-term adverse outcome [27]. In a comprehensive review, Graham et al [16] searched for studies reporting the incidence of umbilical arterial pH <7.00. Combining data from seven different studies, they found the mean incidence of umbilical arterial pH <7.00 at term in 3.7/1000 infants. Of 386 infants, about 17% survived with neurological morbidity, 16% developed seizures, and 6% died during the neonatal period. The combined incidence of neonatal neurological morbidity and mortality for term infants with an umbilical arterial pH <7.00 at birth was 23%, with the remaining 77% being neurologically normal at the time of neonatal discharge [16]. In another study, the incidence of encephalopathy in 109 term infants with umbilical artery pH <7.00 was 31%: seizures occurred in 9% of infants with pH between 6.90 and 6.99, and in 80% of those with pH between 6.61 and 6.70 [28]. In a smaller study, Nagel et al [29] reviewed 21 infants born with a pH <7.00 over a 19-month period. Two out of 21 infants died in the neonatal period, but when the survivors were evaluated at 1–3 years, they showed normal developmental scores. Therefore, even though a pH value <7.00 at delivery seems to be a good marker of severity of acidosis, it appears less well related to short- and long-term neurological outcomes.

Conventionally, in the newborn the degree of metabolic acidosis is measured also by the umbilical artery base deficit. Studies have shown that a base deficit excess greater than 16 mmol/L is predictive of neonatal encephalopathy. Low et al [30] observed a significant increase in moderate and severe encephalopathy with an umbilical artery base deficit >16 mmol/L, suggesting that a base deficit excess measured in arterial cord blood is a good index of prolonged asphyxia, reflecting the severity and duration of intra-partum asphyxia.

Recently, Shah et al [31] evaluated the rate of recovery of base deficit in 244 term infants with HIE due to intra-partum asphyxia. In their series, BD values normalized by the first 4 hours in the 96% of infants. Notably, the BD recovery rate of infants with severe adverse outcome at 12 months was similar to those with a relatively good outcome. Thus, although the rate of recovery of base deficit may reflect the ability of the infant to recuperate from the oxygen debt, it is not predictive of long-term outcome [31].

Blood lactate at birth Lactate is produced as a consequence of hypoxia and poor tissue perfusion [32]. When a critical reduction in oxygen and substrate delivery occurs, aerobic metabolism through Kreb's cycle cannot be sustained and tissues use anaerobic metabolism to meet their energy requirements. This in turn leads to an increase in the production and accumulation of blood lactate [33]. A significant association has been found between blood lactate concentrations and neurological evolution. da Silva et al [32] measured blood lactate at 30 minutes of life in 115 term infants with suspected asphyxia. Significantly higher blood lactate concentrations were observed in neonates with moderate to severe HIE [32]. In a group of 61 full-term infants with suspected asphyxia, Shah et al [34] observed that blood lactate concentrations were significantly higher and took longer to normalize in neonates with moderate to severe HIE, compared to those with mild or no HIE. Furthermore, they reported a higher risk of neurological and systemic complications when the blood blood lactate concentrations were more than 7.5 mmol/L at 1 hour of age with a sensitivity of 94% and a specificity of 67%. In their study the sensitivity and negative predictive value of lactate in the first hour of life were greater than either pH or base deficit [34]. A recent study by Murray et al [35] found that a normalization time of blood lactate concentrations greater than 10 hours was associated with a high risk of encephalopathy.

37.5 Asphyxial Markers in the Early Neonatal Period

Suspected intrapartum asphyxia causing brain injury can be confirmed in the first hours after birth by various clinical, biochemical and other measures. Some authors have attempted to develop models able to predict early and reliably the development of HIE and/or subsequent neurological sequelae in asphyxiated newborns. In a large retrospective cohort study, Shah et al [36] tried to validate a prognostic model for term infants with moderate to severe postasphyxial HIE. They used relatively simple clinical and laboratory observations available within the first 4 hours of life, and identified three significant

predictors: chest compressions >1 minute, onset of spontaneous breathing >30 minutes and a base deficit value >16 mmol/L in any blood gas analysis within the first 4 hours. In this cohort of term infants with HIE, a severe adverse outcome was found in 93% of subjects in whom all three predictors were present. However, infants with none of the three predictors also had a high possibility of adverse outcome (46%) [36]. More accurate prediction models are therefore still needed for the early identification of those infants most likely to benefit from interventions. At present, the occurrence of abnormal neurological features after signs of intrauterine asphyxia, namely postasphyxial hypoxic-ischemic encephalopathy, remains the best indicator of a newborn infant at risk of subsequent neurological impairment [8]. Other early markers include multiorgan dysfunction, urinary lactate/creatinine ratio and nucleated red blood cells counts. Other useful techniques include early electrophysiological and neuroimaging studies, such as amplitude integrated electroencephalogram (aEEG), cranial ultrasound, magnetic resonance imaging (MRI) and computed tomography (CT) (see also Chapter 132).

Postasphyxial neonatal encephalopathy Neonatal encephalopathy is characterized by abnormal consciousness, tone and reflexes, and seizure activity. The main cause of neonatal encephalopathy is intrapartum hypoxic ischemia, followed by trauma, infections, metabolic diseases and developmental abnormalities. Prognosis is related to the severity of the HIE syndrome, the onset of seizures and the duration of the neurological abnormalities.

Although several classifications are available, the most popular remains that proposed by Sarnat et Sarnat in 1976 to indicate the severity of the hypoxic ischemic insult in infants of 36 or more weeks of gestation [10]. The sequential appearance and resolution of the various transient clinical signs in the first 2 weeks suggest the extent of neurologic impairment and define different clinical categories in the early assessment of infants with HIE [1]. The Sarnat and Sarnat staging of HIE ranges from mild (grade I) to severe (grade III). Grade I comprises a mild encephalopathy with the infant being hyper alert, irritable and oversensitive to stimuli, but with a normal EEG. Virtually all these patients have a normal neurological outcome. In grade II there is a moderate encephalopathy, with the infant displaying lethargy, hypotonia and proximal weakness, low resting heart rate, small pupils. The EEG is abnormal and 70% of the infants will have seizures. About 20% of these patients may manifest abnormal neurological outcome. In grade III, there is a severe encephalopathy with the infant stuporous, flaccid and no reflexes. EEG is abnormal with decreased background activity and/or voltage suppression. About half of these patients die, whereas the surviving 50% suffer major neurological injury, with epilepsy and mental retardation [1, 10].

Multiorgan failure The American College of Obstetrician and Gynaecologists considered multiorgan failure (MOF) as a constant feature of the neonatal post-asphyxial syndrome [37]. However, this assumption has been questioned by several authors and the incidence of MOF in asphyxiated infants is variable. Such variability may partly depend on differences of selection criteria, definitions of MOF, or timing of the diagnosis of MOF.

In term newborns with arterial cord pH <7.00, Goodwin et al [28] observed an incidence of MOF of 30%. In a retrospective cohort study, all infants with severe HIE had evidence of MOF. However, the presence of MOF, regardless of the combination of different organs involved, did not correlate with long-term neurological outcome [38].

Thus, MOF may reinforce the suspicion of intrapartum hypoxic ischemia in newborns with HIE, but it is not a useful criterion for the early identification of infants at risk for an adverse neurological outcome.

Urinary lactate/creatinine Huang and coworkers investigated the role of urinary lactate/ creatinine ratio to differentiate normal infants (58 subjects) from infants with asphyxia (40 subjects) [39]. The measurements of urinary lactate and creatinine were obtained by proton nuclear magnetic resonance spectroscopy (1H NMR) within 6 hours of birth and at 48 and 72 hours. Sixteen of the infants with asphyxia went on to develop an encephalopathy. Within 6 hours after birth, the mean lactate/creatinine ratio in infants who subsequently developed encephalopathy was 186 times as high as the ratio in normal controls, and 88 times as high as that in infants with asphyxia not progressing to HIE. A urinary lactate/creatinine ratio of 0.64 or higher showed 94 percent sensitivity and 100% specificity for predicting the development of HIE. Thus, even if measurement technique by 1H NMR is expensive and not readily available, urinary lactate/ creatinine ratio could be a potentially useful marker for the early identification and treatment of infants at high risk for HIE [39]. Confirmation of these preliminary results is still needed.

Nucleated red blood cells The nucleated red blood cell (NRBC) count is a marker of fetal hypoxia in term and preterm infants. In 1996, Korst et al [40] reported a raised NRBC in cord blood from a group of neurologically impaired term infants compared with controls. In a prospective study, Buonocore et al [41] observed that the NRBC count in umbilical cord blood was significantly higher in infants showing abnormal neurodevelopment at age 3 when compared to normal controls.

Amplitude integrated EEG Continuous monitoring by amplitude integrated EEG (aEEG) can be done soon after admission to a NICU. It is helpful in the early assessment of the asphyxiated term newborn [42]. Changes in background activity and seizure activity are relatively easy to identify, allowing for prompt intervention. aEEG may provide useful information about the functional integrity of the brain, presence or onset of subclinical seizure activity and the effect of anticonvulsant drugs. It may also aid the selection of patients

suitable for neuroprotective interventions and in the early prediction of neurodevelopmental outcome [43–45]. Some authors have shown that aEEG can predict outcome accurately at 6 hours of age following intrapartum hypoxic ischemia with a positive predictive value of 84–86% and a negative predictive value of 92–96% [44, 45].

Early neuroimaging investigations Advanced neuroimaging techniques such as cranial ultrasonography (CUS), MRI and CT can be used in the early post-partum phase. CUS is a non invasive and widely available technique. Up to 50% of newborns with HIE may initially show a normal CUS. Furthermore, it is not difficult to visualize parasagittal cerebral lesions, cortical or brain stem injuries.

CUS is of value in the identification of focal areas of necrosis (especially if hemorrhagic) in the thalamus and basal ganglia as well as for the detection of necrotic and cystic components of periventricular white matter injury (PVL) and, although not optimal, in the evaluation of focal ischemic injuries. CUS may also be used to study the evolution of brain lesions [8].

MRI is considered the gold standard for the early evaluation of the infant with hypoxic-ischemic injury. Particularly with the development of diffusion weighted imaging, MRI is considered by some to be the method of choice to assess the newborn brain even in the first few days of life, providing valuable information on the location and extent of the neurological damage in moderately to severely asphyxiated infants [46, 47].

Because of radiation exposure and its poorer imaging definition compared to MRI, CT is less frequently used for infants with hypoxic-ischemic injury. CT is, however, still occasionally useful for the identification of focal ischemic or hemorrhagic brain injuries and when MRI is not readily available [8].

New biochemical markers in early detection of neonatal asphyxia Newer early markers of perinatal asphyxia such as S-100 Protein and activin A have been recently investigated [48, 49]. Activin A, a glycoprotein expressed in the central nervous system, has been found in higher concentrations in newborns with perinatal hypoxia and in infants developing HIE. In a recent study, Florio et al [49] measured activin A in urine collected immediately after birth in 30 severely asphyxiated term newborns and 30 healthy controls. Urine activin A was significantly higher in patients with moderate or severe HIE compared to controls. Activin A > 0.08 μg/L had a sensitivity of 83% and a specificity of 100% for predicting the development of moderate or severe HIE. The sensitivity and specificity increased to 100% and 98% between 12 and 72 h, respectively [49].

37.6 Conclusions

Early detection of perinatal asphyxia still constitutes a challenging target in neonatology. In addition, birth asphyxia can be associated either with an uneventful course or with significant mortality and long-term morbidity. Therefore, reliable diagnostic and prognostic indicators are essential for a prompt recognition and treatment of newborns at risk for subsequent negative outcome.

In the last decades many biochemical markers of asphyxia have been identified, both in cord blood and in blood samples after birth, including arterial pH, base excess and lactate. However, such indicators have shown a limited value in predicting long-term neurological outcome.

Other promising biochemical markers, e.g. S100 B protein, Activin A, urinary lactate/creatinine ratio or nucleated red blood cells, still need further evaluation before their inclusion in the routine assessment of asphyxia.

Some recent electrophysiological and neuroimaging investigations, such as amplitude integrated EEG and diffusion weighted MRI, may also provide early valuable information on brain damage and outcome of asphyxiated babies. However, these techniques are not always available and could be difficult to perform in critically ill neonates.

Further research is still required to overcome the limitations due to the assessment of perinatal asphyxia by single parameters. The combination of clinical and biochemical indicators should aim to validate prediction models capable to identify neonates at risk of dismal outcome due to asphyxia, allowing an adequate and timely diagnosis, treatment and counselling.

Resuscitation of the Newborn

Ola D. Saugstad

38.1 Introduction

Each year 6–10 million of the approximately 130 million newborn infants born in the world need some kind of resuscitation at birth. In the USA 5–10% of all newborn infants require basic life support in the delivery room, or nursery, constituting at least 200,000 newborn infants in the USA alone. In Western Europe there are similar figures. Approximately 1% of newborns require more extensive resuscitation procedures [1–3]. Recent estimates indicate that worldwide 814,000 die and an equal number develop sequels after birth asphyxia [4].

However, data from for instance California indicate that birth asphyxia is decreasing from 14.8 to 1.3 per 1000 in the period of 1991-2000 and data from England show that there is a reduced need of ventilation at birth [5, 6]. In spite of that there is no doubt that, both in industrialised and low income countries a large number of newborn infants are in need of resuscitation at birth. Therefore and because a vast number of deliveries throughout the world still occur at home without authorized health personnel present, it is also important to develop simple resuscitation routines.

38.2 Preparation for Resuscitation and Selection of Risk Cases

Approximately 95% of deliveries are uneventful and the adaptation to extrauterine life occurs smoothly. Only in some infants should more vigorous resuscitation procedures be carried out. As mentioned above, as many as 5% or more need basic resuscitation including ventilation using a bag and mask. However, only a few newborn infants need advanced resuscitation. In 1:100 to 1:700 endotracheal intubation is needed, 1:1000 needs chest compression, 6:10,000 need epinephrine (adrenaline) and as few as 1:12,000 of near-term and term infants need volume therapy [6–8]. For preterm infants these numbers are higher.

It is important to anticipate which infants are at risk and the antepartum and intrapartum history often can be a help in predicting which infants will need resuscitation. Fetal-movement counting, non-stress testing, fetal biophysical profile, electronic fetal monitoring, and scalp pH measurement all contribute to an identification of infants at risk for low Apgar scores and need of resuscitation. Electronic fetal-heart monitoring combined with scalp pH determinations improves the specificity; however, sensitivity is low. In spite of these measures, the need for resuscitation can often not be foreseen and 20-50% of the infants requiring resuscitation have no identifiable risk factors. This implies that at every delivery the health provider should be prepared to perform resuscitation. Equipment and facilities should be ready. Further, every health personnel attending deliveries need to be trained in resuscitation skills.

38.3 Indication for Resuscitation

The decision to resuscitate is based on clinical judgement. By observing breathing movements, tone, colour, and not least heart rate, it is decided whether the infant is in need of resuscitation or not. Every time a child is delivered the following three questions should according to the International Liaison Committee on Resuscitation (ILCOR) guidelines [1] be answered: 1) Is the baby breathing or crying? 2) Is there a good muscle tone? 3) Is the baby born at term? If the answer is "no" to any of these questions resuscitation should be considered. In former guidelines [9, 10] a fourth and a fifth question were included: 4) Is the colour pink? 5) Is amniotic fluid clear of meconium? Recent data, however, indicate that a

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

newborn baby not necessarily needs to be pink the first few minutes of life, in fact there are strong indications this may be harmful. This question therefore was removed from the 2005/6 ILCOR guidelines [10]. In the 2010 ILCOR guidelines no firm recommendations for suctioning of babies with meconium stained amniotic fluid was given and consequently this fifth question was removed [1].

38.4 Guidelines for Resuscitation of the Newly Born

There are several sets of international guidelines for newborn resuscitation. The World Health Organisation (WHO) published their guidelines for basic newborn resuscitation in 1998 [11], which presently are under revision. These are applicable for most children around the world. The ILCOR guidelines are widely used internationally; these were first published in 1992 [12] and revised in 1999 [9], 2005 [10] and 2010 [1]. American Heart Association (AHA) and American Academy of Pediatrics (AAP) and European Resuscitation Council (ERC) in close collaboration with ILCOR produced their own guidelines [2, 3]. A number of countries have their own national guidelines modifying the ILCOR guidelines.

38.5 Physiological and Biochemical Changes

The physiological changes during asphyxia are well described in animal experiments.

Traditionally the asphyxial process has been divided into primary and secondary apnea. During primary apnea heart rate is still present even as high as 100 beats per minute (bpm) and there is cyanosis in mucus membranes and the skin. In secondary apnea the baby is pale and the heart rate is low or not present. In some guidelines different approaches are recommended for a primary and a secondary apneic situation. However, it is probably not wise to spend time to figure out in which of these stages the infant is. Preterm infants have a more rapid drop in heart rate than term infants and the distinction between primary and secondary apnea in the smallest infants probably is not very useful.

A metabolic and respiratory acidosis exists in newborns with birth asphyxia. Both animal and clinical studies have shown that base deficit is eliminated at a constant rate of 6-7 mmol/L/hour [13]. This elimination seems to be constant independently of the severity of birth asphyxia. Therefore, if the acid base status at birth is not known, this figure can be used to extrapolate back to the situation at birth. For instance if base deficit is 10 mmol/L at one hour of age it probably was approximately 16-17 mmol/L at birth. Such calculations can be useful for assessing prognosis and for court cases.

38.6 Initial Evaluation and Stabilisation

ABCD for resuscitation is the same whatever size of the patient.

- A: Airways should be cleared and the infant positioned correctly
- B: Breathing should be stimulated or performed
- C: Circulation should be assessed by heart rate and skin colour
- D: drugs, are rarely needed in the newborn.

38.6.1 Response to Birth

Resuscitation is a team work: optimally, two trained persons should actually perform the resuscitation and one should assist. Each team member should identify themselves and it should be clear who the team leader is. Each order should be stated clearly and repeated by the recipient.

As soon as the infant is delivered, a clock is started and, during the transport to the resuscitation table, the personnel should make a preliminary opinion regarding the seriousness of the situation. First and foremost the respiratory efforts are assessed and the heart rate is recorded. Heart rate should, after the short initial stabilization, be monitored more precisely. Bradycardia combined with no respiratory efforts or gasping are warnings of immediate intervention. Central cyanosis indicates insufficient oxygenation. Pallor may be a sign of reduced cardiac output, anemia, hypovolemia, hypothermia, or acidosis. Apgar scoring is not performed before 1 minute of life and in addition it takes some time. Apgar score therefore in itself should never be used as a criterion for resuscitation.

38.6.2 Initial Stabilisation

Start out by assessing the baby's response to birth and keep the baby warm and position it correctly; supine with the head close to the examiner, and keep airways clear.

Most infants require only to be delivered into a warm room where they can be dried immediately. The umbilical cord should be cut with sterile equipment and the breathing pattern should be observed. The mother herself is most often the best caregiver and provider of warmth, food and protection from infections.

Heat loss should be prevented and this is one important reason why deliveries should be performed in a warm room. For preterm infants a temperature in the room of 26°C is recommended. The newborn should be quickly dried with towels, giving particular attention to the drying of the head, and swept into preferably pre-warmed towels or other linens. It is recommended that the infant be placed supine under a radiant heater on a table designed for resuscitation with the head

toward the person performing resuscitation. Extremely low birth weight infants are put into plastic bags before dried. This secures a more stable temperature until the child is put into an incubator.

38.6.2.1 A - Airways

Stimulate the infant to breathe by drying. Airways are secured both by suctioning and by positioning the infant correctly in the supine position. There is however, no justification for the practice of routine suctioning in the mouth and pharynx or gastric emptying not even after C-section, because such suctioning might even be harmful. A child who starts to breath spontaneously within 10-15 seconds most probably does not need to be suctioned. In addition, it seems that the esophagus functions as a seal and a closed esophagus therefore helps blowing air into the lungs instead of the stomach during bag and mask ventilation. Opening the esophagus with a suctioning catheter will result in more air into the stomach in case of bag and mask ventilation. However, occasionally the mouth, nose, and pharynx should be suctioned to clear airways. Remember that the mouth should be suctioned before the nose to prevent aspiration if the newborn should gasp when his or her nose is suctioned. Suctioning deep in the pharynx or the larynx, especially the first 5 minutes of life, may elicit bradycardia and bronchospasm. Airways are best opened with the head in the "sniffing position", overextension should be avoided. Tactile stimulation as gentle rubbing of the back may be useful but do not shake the baby and do not waste time by tactile stimulating an apneic child.

38.6.2.2 B - Breathing

According to a recent study from United Kingdom in 2000 bag and mask ventilation was performed in 2.6% of all deliveries. This was a decrease from 3.9% in 1988 [6]. These figures are lower than given above from the USA and indicates that the need for bag and mask ventilation may vary throughout the world and is less than 5% in Western Europe. Still the number who would need bag and mask ventilation is high.

Clinical judgement for when to initiate ventilation should be based on heart rate, breathing efficiency, colour, and tone. However, the formal indications are very simple:

Start ventilation

- If the newborn is apneic or there is insufficient breathing movements and/or heart rate < 100 bpm
- If the newborn is breathing with heart rate > 100 bpm but is persistently cyanotic.

Apneic infants with heart rate > 100 bpm probably represent those with primary apnea, and they often require tactile stimulation and a few inflations with a bag and mask only. Apnea and heart rate <100 bpm may represent secondary apnea, and ventilation should be initiated. In most of these cases, the heart rate improves and spontaneous ventilation quickly develops. Ventilation, when needed, should start as soon as possible, preferably not later than 30 seconds after birth.

The recommended rate of ventilation according to the AHA/AAP is 40–60 breaths per minute. Inflation pressure of 30 cmH_2O or even greater may occasionally be needed for term babies in order to open the lungs. For preterm infants peak inspiratory pressure should be lower for instance 20 cmH_2O, however, depending on the size of the baby. The best way to monitor successful ventilation is to follow the heart rate which should be rapidly increasing. In addition, observe improvement in colour and muscle tone and movements. Recently it has been shown that it is difficult to make an assessment of colour [14], and in the most recent guidelines there is therefore less emphasise on colour assessment. Observation of the chest wall movements is difficult. Recent data indicate that tidal volumes may be too high when there is a clear rise and fall of the chest during the respiratory cycle. It has also been shown that assessment of tidal volume by observing chest rise is extremely difficult [15, 16].

Heart Rate

Traditionally a cut off for heart rate < or > 100 bpm has been used. This has been based on the assumption that a heart rate < 100 bpm in a newborn indicates bradycardia which in most cases is caused by asphyxia. It was demonstrated 2 decades ago that it takes 1 to 2 minutes to establish an efficient gas exchange in vaginally delivered babies and a few more minutes are needed after C- section [17, 18]. Because there is a relation between gas exchange and heart rate it may be normal not to achieve a heart rate of 100 bpm or more even at an older age than one minute. Supporting this are the recently published values for heart rate the first ten minutes of life in normal non-asphyxiated newborns with no medical intervention [19]. At one minute of age term infants have in mean a heart rate of 99 bpm with interquartile range of 66–132 bpm. For preterm infants the values are 96 (72–122) bpm. Recent studies indicate that the heart rate is underestimated by auscultation [20].

In term or near-term infants the pulse very quickly picks up during a successful resuscitation procedure for instance increasing from typically 90 beats per minute (bpm) at one minute of age to 110 bpm at 90 seconds of life. In babies with the lowest Apgar score heart rate is initially lower but typically increases with 20 bpm during the first 30 seconds of resuscitation [13, 21]. In infants < 30 weeks of gestation the heart rate increase is slower. It takes in median 73 seconds (inter quartile range 24–165 seconds) to reach a heart rate of 100 bpm and 243 (191–351) seconds to reach 120 bpm. The heart rate in such small babies is not stable until it reaches 120 bpm [22]. An adequate response to adequate ventilation therefore should for most term and near-term infants be ap-

proximately 20 bpm increase the first 30 seconds of bag and mask ventilation, however slower in preterm infants. After adequate ventilation has been established for 30 seconds, the heart rate should be recorded for not longer than 10 seconds. If the heart rate is at least 100 bpm and spontaneous respirations are established, positive pressure ventilation may be discontinued. If the heart rate is > 60 bpm and improving, ventilation should continue. If the heart rate is less than 60 bpm and not improving, assisted ventilation is continued and external heart massage is started.

Ventilation

A self-inflating bag, a flow-inflating bag, or a T piece resuscitator can be used. The use of a bag and mask requires experience and it is possible to practice on mannequins. By inserting a resuscitation monitor which is a hot-wire anemometer placed between a ventilation device and the face mask or endotracheal tube, the operator can minimize leaks by adjusting the face mask position to minimize leaks [23, 24]. In an Australian study an average of 60% leaks were found around the face mask, however after the operators adjusted the mask position the leak was reduced to 10% [24].

It is not easy to deliver an adequate tidal volume by bag and mask ventilation. However, it seems that starting ventilation in many instances stimulates the baby to breath because the inflation pressure induces the baby to make inspiratory efforts (head's paradoxical reflex) securing an adequate tidal exchange [25]. The optimal tidal volume for newborn resuscitation is not known. However, a range between 4–8 mL/kg is often recommended. Excessive tidal volume may lead to volutrauma [26], and a too low tidal volume leads to atelectasis and inadequate gas exchange. Both conditions may trigger cytokine release and inflammatory changes in the lung [27, 28].

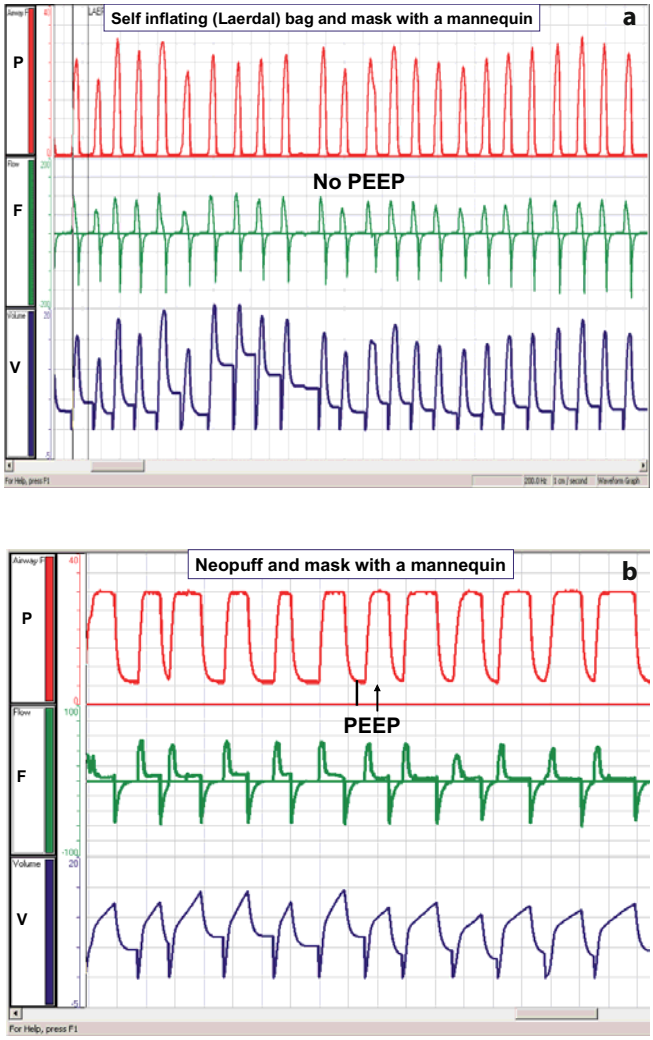

Fig. 38.1 **a** Ventilation of a mannequin with a self inflating bag. Notice the variable peak inspiratory pressure (*P*), flow (*F*), and volume (*V*), and the lack of positive end expiratory pressure (*PEEP*). **b** Ventilating a mannequin with a T-piece device. Notice the identical and exact peak inspiratory pressures (*P*), the presence of PEEP and the uniform flow and volume delivered

PEEP or CPAP?

In order to oxygenate the lungs must be ventilated to develop a functional residual capacity. Infants who do not breathe will need respiratory support. Positive end expiratory pressure (PEEP) has been tested out in animal models [28–30]. There is however, not much evidence regarding the use of PEEP or not in the delivery room. However, one randomised controlled trial in preterm infants showed that more infants were subsequently intubated and ventilated in a group without continuous positive airway pressure (CPAP)/PEEP compared with a group ventilated with a 10 second prolonged inflation followed immediately by CPAP/PEEP [31]. It is becoming more and more common to apply PEEP during ventilation in the delivery room. CPAP in many centres is applied immediately for low birth or extremely low birth weight infants (ELBWI). More and more centres are using a T-piece device when ventilating the newborn in the delivery room. This delivers a PEEP that can be adjusted to the wanted level. Fig. 38.1 shows recording when a mannequin is ventilated by the author with a self inflating bag (Fig. 38.1a) and a T-piece device (Fig. 38.1b). By using a T-piece device peak inspiratory pressure and volume are similar from breath to breath.

Studies have shown that a T-piece device delivers more exact peak inspiratory pressures than a self inflating or a flow inflating bag, in addition to delivering an exact PEEP.

In premature infants, especially in ELBWI, ventilation may be difficult because of airway obstruction. In such cases airways and the mask must be repositioned [23]. Fig. 38.2 illustrates leak during bag and mask ventilation of a 27 weeks gestation newborn [16].

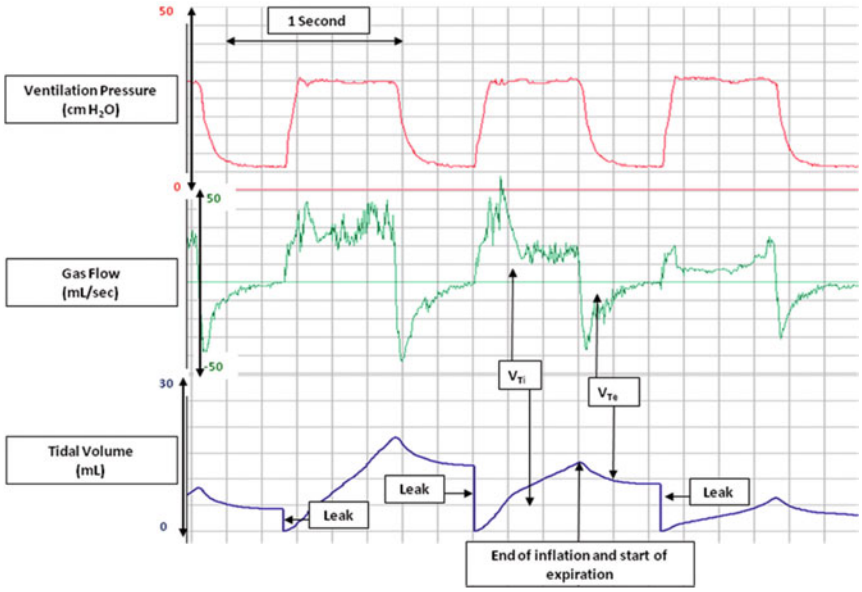

Fig. 38.2 Airway leak in a 27 week infant ventilated with face mask. The area underneath the inflation flow curve is greater than that under the expiratory flow curves. Leak is displayed as a straight line in the tidal volume curve. Notice the variable leaks. From [16], with permission

Endotracheal Intubation

Endotracheal intubation is necessary when bag-mask ventilation is not efficient to normalize the heart rate and establish spontaneous respiration. If chest compressions do not quickly improve heart rate or prolonged assisted ventilation is anticipated, endotracheal intubation should also be carried out. A newborn infant without any heart beat or respiratory movement should also promptly be intubated, as bag and mask ventilation probably is not very efficient. Some infants in secondary apnea also need intubation and the most immature infants who often do not have sufficient muscle strength for their respiratory drive. The ILCOR guidelines recommend that exhaled CO_2 is monitored for confirmation of tracheal tube placement by for instance a colorimetric detector. Their use and limitations have been described in the literature and is reliable in most cases (32–34). By using a resuscitation monitor a correct placement of the endotracheal tube can in most cases be established after the first breath by observing the gas flow in and out of the trachea [35, 36]. By observing

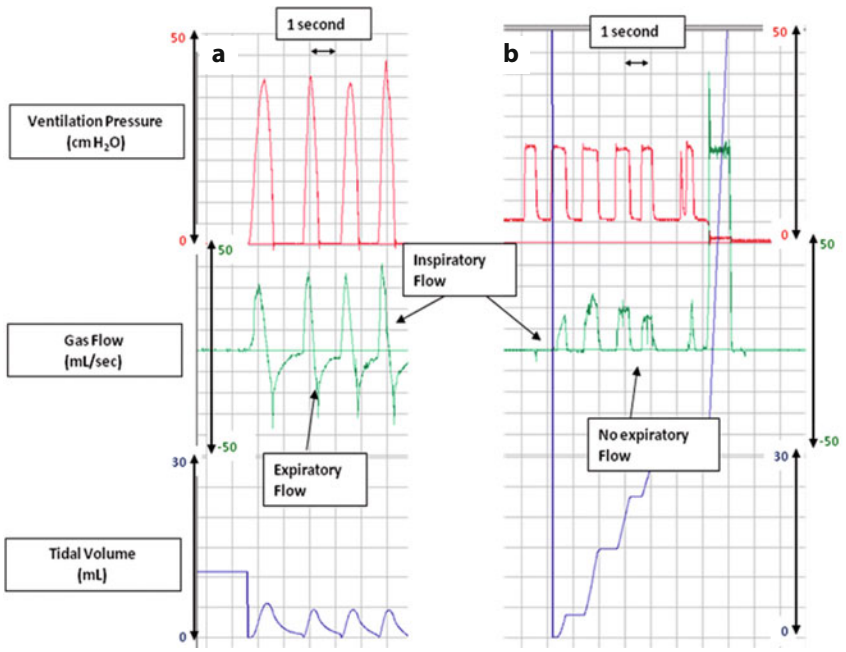

Fig. 38.3 **a** Correct endotracheal tube placement in a 26 week infant. Both inflation and expiratory flow curves return to baseline, indicating a correct placement of the endotracheal tube. **b** Esophageal tube placement in a piglet. The inspiratory flow curve returns to baseline indicating gas flow towards the endotracheal tube. In contrast there is no expiratory flow curve indicating endotracheal tube placement in esophagus. From [16], with permission

the leak it is also possible to make an assessment whether the size of the tube is correct or not. See Fig. 38.3.

Endotracheal intubation is rarely needed in term infants. In one study from USA it was carried out in approximately 1 per 1000 deliveries [5]. A study from UK has shown a decrease in the need of intubation between 1993-7 from 2.4% but still as high as 1.2%, of all live born [37]. This indicates a wide variation in intubation practise from approximately 1 per 100 to less than 1 per 1000 babies.

In another UK study the need of endotracheal intubation for all weight groups decreased in the period 1988 to 2000 from 0.51% to 0.07% [6]. However, for infants with birth weight < 1500 g this decrease was not very evident and their intubation need was 50 fold increased compared with babies with birth weight 3000–3500 g. If Apgar score at 5 minutes was 0–3 intubation rate was increased 234 folds. Even an Apgar score at 5 minutes of 4–5 increased the intubation rate 100 fold. Emergency C-section and breech delivery increased the need of intubation 2–3 fold [6]. This dramatic reduction in intubation rates indicates both a reduction in birth asphyxia and an increase in C-section, and also a more restrictive attitude regarding need of newborn intubation.

Oxygen Supplementation

High concentration of supplemental oxygen (80–100%) has usually been recommended by most textbooks and guidelines dealing with newborn resuscitation. There was, however, no scientific basis for such recommendations. New studies have shown that even the most depressed term or near-term newborn infants are adequately resuscitated with room air. Several meta-analyses [38, 39], now including ten studies enrolled more than 2000 newly born infants in need of resuscitation [39], have shown that early recovery is faster if resuscitation is carried out with ambient air instead of 100% O_2; time to first breath was registered 30 seconds earlier, heart rate at 90 seconds and 5 minutes Apgar score were higher [21]. More importantly is that neonatal mortality is significantly reduced with 30–40% in room air resuscitated babies [38, 39]. In a meta-analysis from European countries relative risk for neonatal death was in fact reduced 69% from 3.2% to 1.1% in those resuscitated with 21% compared with 100% oxygen [39]. For this reason 100% oxygen should be avoided as a routine for newborn resuscitation. The 2010 ILCOR guidelines state it is for term babies "best to start resuscitation with air". For babies < 32 weeks a blender is often needed and for babies with gestational age between 32–37 weeks the optimal initial FiO_2 is not known [1].

Recent animal data also show that the pulmonary resistance by and large is reduced as efficiently with 21% as with 100% oxygen [40]. In addition, it seems that the exposure of hyperoxia increases the reactivity of the pulmonary vessels subsequently increasing the risk of pulmonary hypertension [41].

As mentioned, above extremely low birth weight infants may need some oxygen to get started. However, some smaller studies have so far shown that 30% oxygen is at least as efficient as 90% oxygen. ELBWIs who need resuscitation therefore safely can be initiated with FiO_2 of 0.21–0.30 [42–44].

If room-air resuscitation is not successful within 90 seconds we still supplement with oxygen. In such case, it probably is optimal to monitor the arterial oxygen saturation by pulse oximetry. The arterial oxygen saturation at one minute of life in non-asphyxic term or near-term babies is typically 60–70% and may be as low as 40% the first 3–4 minutes of life. Within 5–7 minutes approximately 50% of these babies have reached a SaO_2 of 90%. After C-section the saturation is in general 2 minutes behind the values found in babies born after vaginal delivery [45]. In high altitude the SaO_2 is lower than at sea level, still it is recommended to start resuscitation with air also in such areas of the world.

The oxygen supply in all delivery units should have a blender, so that the oxygen concentration can be adjusted to the requirement. If justified to give supplemental oxygen it is recommended to start with not more than 30–40% oxygen and adjust according to the clinical response, preferably following oxygen saturation measured by pulse oximetry. It is in case recommended that oxygen saturation follow the 10th to 25th percentile of recently published nomograms for normal SpO_2 values the first minutes of life of non-asphyxiated newborn babies [46]. The aim is to reach a SpO_2 of 90% after 5–10 minutes in term and near-term infants and 85% in premature infants less than 32 weeks.

38.6.2.3 C - Circulation

Chest compressions are rarely needed and not included for basic newborn resuscitation. If bradycardia persists with a heart rate of less than 60 per minute and no signs of improvement after adequate ventilation, chest compressions should be started. This is needed in 0.5 to 1 per 1000 births [7].

Chest compression should always be carried out simultaneously with adequate ventilation [47]. Chest compressions and ventilatory rate of 3:1 should be synchronized giving 90 compressions and 30 breaths per minute. The two thumb technique is recommended [48]. An adequately performed resuscitation with chest compressions obviously requires at least two trained persons. Heart rate should be assessed after 30 seconds of well- coordinated chest compressions and ventilation. When the spontaneous pulse rate has reached 60 per minute, chest compressions should be discontinued and positive pressure ventilation is continued at a rate of 40–60 breaths per minute. There are not much data, if any, supporting why a ratio of 3:1 between compressions and ventilation is chosen for newborns.

If the cardiac arrest is not of asphyxial genesis, a ratio of 15:2 may be considered [1].

38.6.2.4 D - Drugs

When oxygenation is established through an adequate ventilation of the asphyxiated infant, it is extremely rare that drugs are needed. Epinephrine (Adrenaline) was in one study indicated in 1:1200 deliveries [8] and is indicated in asystole or in sustained bradycardia (Hr < 60 bpm) in spite of adequate ventilation and oxygenation and at least 30 seconds of coordinated chest compressions and ventilations. One study showed that even trained resuscitators are not able to give epinephrine earlier than 4–5 minutes of age [8]. Epinephrine (1:10,000 solution) is given as a bolus as rapid as possible preferably intravenously in a dose of 0.01–0.03 mg/kg (0.1–0.3 mL/kg) which may be repeated every 3–5 minutes if needed. If the endotracheal route is chosen [49] a higher dose can be used (0.05–0.01 mg/kg). Bradycardia due to insufficient ventilation technique should be corrected by adequate ventilation before administration of epinephrine. The optimal epinephrine dose for newborn resuscitation has not been studied systematically.

Volume Therapy

Hypovolemia is rare and volume infusion was in one study administered in 1:3000 deliveries, however hypovolemia was found in only 25% of these. Thus hypovolemia is an extremely rare event occurring in only 1:12,000 near-term or term infants [8]. Hypovolemic shock should be suspected if there is pallor; delayed capillary refill, weak pulses, persistently low heart rate, or the circulatory status does not improve in response to the treatment steps described above. Shock may be treated with repeated transfusions of volume expanders, usually 10 mL/kg. As volume expanders, normal saline or Ringer's lactate are recommended. The volume expander may be given over 5–10 minutes and repeated. Albumin or other plasma substitutes are not so much recommended any more. Blood volume expanders during acute resuscitation are only indicated when there are unmistakable signs of shock with evidence of acute blood loss, including feto-maternal hemorrhage. If there has been blood loss O-negative blood cross-matched with the mother's blood is given. Avoid rapid boluses of volume expanders or hyperosmolar solutions to premature newborn infants. In one experimental study in hypovolemic and asphyxiated newborn piglets the use of volume therapy seemed to be counterproductive [50]. Volume therapy therefore should be given on strict indications only.

Sodium bicarbonate, THAM or naloxone have no routine place in newborn resuscitation [1, 51].

38.7 Meconium Aspiration

If the amniotic fluid is meconium-stained, there is no evidence that suctioning the oropharynx before the thorax is delivered has any beneficial effects. There are today no indications that an infant with thick meconium-stained amniotic fluid benefits from routine intubation and suctioning.

The previous practise of tracheal suctioning does not seem to have reduced the incidence of meconium aspiration syndrome or mortality [52]. It is therefore not anymore recommended that suctioning of the nose, mouth and posterior pharynx be carried out thoroughly before delivery of the shoulder and thorax. According to previous guidelines the trachea should be suctioned in "non-vigorous" child. If the child is vigorous, the mouth and nose should be suctioned only and resuscitation proceeded as required. "Vigorous" is defined as a newborn having strong respiratory efforts, good muscle tone, and a heart rate greater than 100 bpm. In the 2010 ILCOR guidelines it is written that "the available evidence does not support or refute the routine endotracheal suctioning of depressed infants born through meconium-stained amniotic fluid" [1]. Thus, there has been a shift in recent years from a very active to a less active approach in these children.

38.8 Preterm Infants

There are no or very few studies on optimal resuscitation of premature infants. This means that even the extremely low gestational age newborn infants are often resuscitated according to the guidelines and principles established for term and near-term infants. Recent studies have shown that cardio-respiratory resuscitation of these in the delivery room is not futile and a more active approach seems therefore to be established [53] and this has lead to a more active approach [54–58]. It is also clear that preterm infants need intervention more often than near-term or term newborn infants. In one study from the USA 5% of babies with birth weight between 500 and 1500 g needed chest compressions and 4% received epinephrine [53].

Babies with gestational age < 28 weeks should be put into polyethylene wraps or a plastic bag up to their neck, before drying, in order to maintain the temperature [1]. They often need to be intubated given surfactant and in some centres they are immediately extubated, the so-called INSURE (INtubation SURfactant Extubation) approach [59]. Ventilation should be carried out using a PEEP of 5–6 cm H_2O and many authors recommend putting these babies directly on CPAP [60]. These infants should be handled as gently as possible. Avoid rapid boluses of fluid and quick changes in body positions.

Preliminary data indicate that the extremely low birth weight infant in need of resuscitation often would need a brief exposure of oxygen- for instance start out with 30% O_2 in order to get an adequate heart rate response [43–45]. More data are needed before firmer recommendation for these tiny infants are given.

38.9 Withholding and Withdrawing Resuscitation

In some cases, resuscitation should be withheld or withdrawn [61]. The present ILCOR guidelines state that resuscitation could be withheld for neonates at the margins of viability or those with conditions which predict a high risk of mortality or morbidity. Many centres do not resuscitate newborn infants with gestational age of less than 23 weeks. In earlier recommendations resuscitation was not recommended if there was anencephaly, bilateral renal agenesis, spinal muscular atrophy type I (Werdnig-Hoffmann disease) with neonatal onset, trisomy 13, or trisomy 18. However, according to the newest guidelines [1] and I agree in that, strict indications are not given for which newborns who should not be resuscitated. This author resuscitates and tries to stabilize infants with a gestational age of 23 weeks or more.

Often, neither the exact diagnosis nor the gestational age is known at birth. A liberal policy of resuscitation is recommended whenever doubt about the care of the individual infant exists. This allows the doctor to collect more information about the clinical status and prognosis of the child. This also allows one to inform the parents so that they can become prepared and participate in the discussion and decisions about subsequent therapy. In the new ILCOR guidelines [1] resuscitation of babies without any pulse and not giving response with heart rate increase within 10 minutes can be considered to be stopped because of very poor prognosis in these children. However in babies with Apgar score > 0 the prognosis is not so well known and resuscitation could continue longer for instance 20 minutes.

38.10 Post Resuscitation Care

After a successful resuscitation, heat loss should be prevented. The child should be labelled and frequently checked with regard to breathing efforts, respiratory rate, colour, and heart rate, signs of birth injury or malformations. If the resuscitation was brief and the situation was not too dramatic, the newborn could be monitored in the nursery provided an adequate respiration is established. The child could be placed so that skin-to-skin contact with the mother is obtained. However, this depends on the local conditions and the possibilities for adequate observation by a trained observer.

Even if the infant is not in need of artificial ventilation following resuscitation, the child is often brought to the intensive care unit for further close follow-up which includes monitoring of the heart rate, ventilation, determination of arterial pH and blood gases, treatment of any hypotension with volume expanders or pressors, appropriate fluid therapy, and treatment of any seizures. Any hypoglycaemia or electrolyte disturbances should be corrected. Breast-feeding should be encouraged, if possible, as soon as 1 h after birth. If the resuscitation was unsuccessful and the child died, the parents need a close follow-up.

Every baby who has been resuscitated, even briefly, is at risk and should be followed-up carefully both at short and long term. Blood glucose should be kept within normal ranges [62].

38.10.1 Hypothermia Therapy

The 2010 ILCOR guidelines recommend moderate hypothermia as a protective treatment to term infants with hypoxic ischemic encephalopathy. Hypothermia should in case be induced in a controlled way following written protocols [63]. In the delivery room it is important to avoid hyperthermia because this may augment any brain injury in severe asphyxia [64].

38.11 Documentation

It is useful if one attending person observes and immediately writes down the procedures performed. A thorough documentation in the medical record of all observations and actions and names of the participants is required before the resuscitation is complete. Each institution should keep records documenting the condition and procedures carried out at birth. Every institution that provides deliveries must develop its own standards for newborn resuscitation and a plan of action should exist. The personnel should gain and maintain skills in newborn resuscitation by training using manikins, and an evaluation of the training is necessary.

38.12 Conclusions

Newborn resuscitation is not yet fully evidence based. However, recent years a rapid development has occurred and a more evidence based practice has been established. Still there are numerous unanswered questions.

The optimal PEEP has not been determined. Today a low oxygen approach should be chosen for newborn resuscitation starting with air in near-term and term babies. However, there are still uncertainties regarding the use of oxygen supplementation for premature infants and which oxygen saturation one should aim at in term babies not responding adequately to the initial resuscitation. How to use supplemental oxygen during chest compressions is not known. The optimal adrenaline concentration and the effect of volume therapy are uncertain. Further, the optimal procedure for chest compressions is not defined. None of the guidelines discuss the importance

of pCO_2 and a moderate hypercapnia in order to restore cerebral blood flow. This should be an area of research for the coming years.

In spite of that there is general agreement that the most important is to start ventilation as soon as this is indicated. In most cases a few blows of air is sufficient to restore the heart rate and help the baby start breathing on its own. By avoiding non-evidence based detrimental procedures such as hyperoxygenation of the child the results will be much improved. "Give a breath – save a life" was the name of a large Indian campaign for newborn resuscitation launched in the 1990's. This is what it is all about. To give breaths and to save lives.

Oxygen Toxicity

Giuseppe Buonocore, Rodolfo Bracci, Serafina Perrone and Maximo Vento

39.1 Introduction

Although the use of oxygen in the care of newborns dates since the eighteenth century [1] and the toxic effects of oxygen had been mentioned already at the end of the 19th century [2], the first evidence of a relationship between oxygen toxicity and neonatal diseases emerged in the early 1950s when retinopathy was observed in premature infants breathing high concentrations of oxygen [3]. At about the same time, the red cells of newborns were demonstrated to have increased susceptibility to oxygen damage [4]. Great advances in our understanding of toxic effects of oxygen were made in the years that followed, when oxygen toxicity was recognized to be due to the development of reactive oxygen species (ROS). The main ROS are the superoxide anion (O_2^-), hydrogen peroxide (H_2O_2), lipid peroxide (LOOH), peroxyl radicals $RO_2^{\bullet}$ and the hydroxyl radical ($OH^{\bullet}$). Other important radicals are the highly reactive electron delocalized phenoxyl radical (C_6H_5O) and nitric oxide (NO) [4]. The term ROS includes free radicals, which are atoms or molecules with one or more unpaired electrons. A free radical can be defined as any molecule capable of independent existence with one or more unpaired electrons. In addition, ROS encompasses molecules that can be defined as free radicals (e.g., anion superoxide) and others that are oxidizing species, relative to molecular O_2 but do not possess an unpaired electron (e.g., hydrogen peroxide) [5]. Free radicals may react with other radicals, the unpaired electrons forming a covalent bond. The resulting molecule may decompose other molecules into toxic products. Free radicals may react with non-radical molecules in free radical chain reactions, which are stopped by antioxidant molecules, enzymes or protein reactions. Superoxide anion [O_2^-] is the precursor of most ROS and a mediator in oxidative chain reactions. Dismutation of O_2^- by superoxide dismutase (SOD) produces H_2O_2 which in turn may be fully reduced to water by glutathione peroxidase (GSH-Px) and catalase (Cat) or partially reduced to hydroxyl radical [$OH^{\bullet}$]. The latter reaction is called the Fenton-Haber Weiss reaction and is catalyzed by reduced transition metals, particularly iron, but also copper and zinc [6]. There is no specific scavenger for this radical and, once released, $OH^{\bullet}$ reacts with lipoproteins, cell membranes, lipids, proteins, DNA, amino acids and other molecules causing structural and functional damage to theses structures. Since the $OH^{\bullet}$ is formed by the so called Fenton reaction which is dependent on non protein bound iron (NPBI), the conditions of intracellular or extracellular availability of NPBI is one of the most important source of ROS dependent tissue damage. Oxidative tissue damage may also be mediated by reactive nitroxide species [6]. The reaction product of NO and O_2^- is the unstable molecule peroxynitrite ($ONOO^-$) which is regarded as highly reactive [6].

Free radical reactions are a normal occurrence in living organisms and ROS are involved in a myriad of physiological reactions. The possible toxicity depends upon various conditions. For example, production of O_2^- by phagocytes is an important defense mechanism, but extracellular release of free radicals by activated phagocytes may be a mechanism of tissue damage during inflammation and, in turn, this event may be favorable or unfavorable depending on different conditions [7, 8]. Oxidative balance, therefore, is an intriguing question, and much recent research has increased our knowledge of the relations between ROS and human diseases.

39.2 The Oxidative Stress in Fetus and Newborn

An excess of ROS, in relation to detoxification capacity, is called oxidative stress, a term coined for the first time by H. Sies [9] and used to describe the imbalance between oxidants and antioxidants that is a potential cause of damage. If oxidative stress is mild, cell defenses may increase by a mechanism

G. Buonocore (✉)
Department of Pediatrics, Obstetrics and Reproductive Medicine
Division of Neonatology, University of Siena, Siena, Italy

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

which generally involves enhanced gene expression of ROS scavenging activities [10]. Severe oxidative stress is generally followed by cell injury which may proceed to necrosis or apoptosis [10].

Oxidative stress in the fetus and newborn may result from decreased antioxidants, increased ROS or both.

The main sources of ROS are NADPH oxidase reactions, hypoxia-reoxygenation (hypoxanthine-xanthine oxidase reaction: Fig. 39.1), hyperoxia and paradoxically hypoxia [6, 11]. Intracellular and extracellular presence of ROS is provided by activated phagocytes. ROS released inside phagocytes during infection and cytokine production is an essential defense mechanism. It also alters the extracellular oxidative balance and harms tissues since the cells undergo an efflux of O_2^- [12]. Opsonization and activation of phagocytes is also known to occur not only following infection but even as a consequence of asphyxia and particularly hypoxanthine-xanthine oxidase reaction and, therefore during hypoxia-reoxygenation [13, 14] (see Fig. 39.1).

Intracellular physiological generation of ROS can occur as a byproduct with mitochondria, peroxisomes, cytochrome P 450, and other cellular elements [11]. The discovery of the homologs of the cytochrome subunit of the NADPH oxidase, the NOX family, demonstrated the importance of ROS generation via NOX since these enzymes have been found in virtually every tissue [15] (see Fig. 39.2). The complex mechanism of ROS production has been extensively investigated in mitochondria where ROS generation contributes to mitochondrial damage in a range of pathologies [11]. An important factor involved in ROS production is the concentration of the enzyme or protein containing electron carriers that can exist in a redox form able to react with O_2 to form O_2^-. The concentration of these enzymes will vary with organism, tissue state, age and hormonal status [11]. It has been recently pointed out that many of non-mitochondrial enzymes are ubiquitously expressed and may contribute to ROS production in parallel with mitochondria. The enzyme activity of NOX family in which each of the NADPH homologs produces ROS may be responsible of oxidative stress in different cells under different stimulation [15]. In the CNS, hypoxia induced ROS generation has been demonstrated [16].

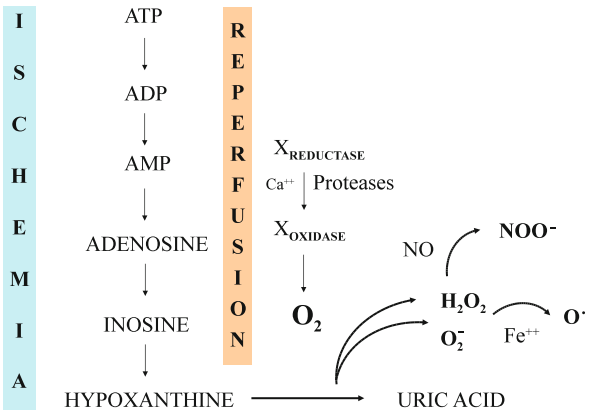

Fig. 39.1 Xanthine oxido-reductase system

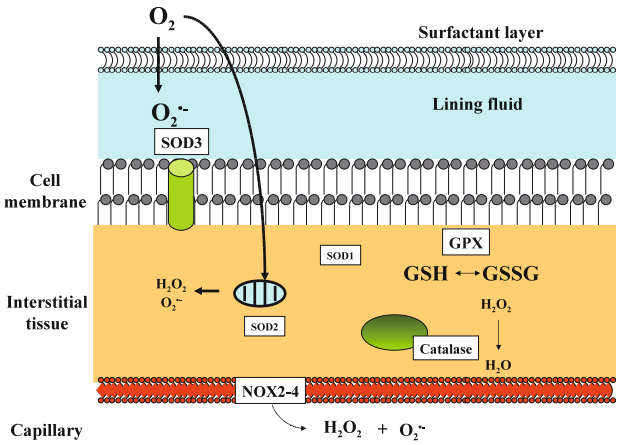

Fig. 39.2 Oxidative stress following hyperoxia

Oxidative stress following hyperoxia has been extensively investigated and has been recognized to be responsible for lung injury and possibly generalized tissue damage [17] (see Fig. 39.2). The sequence high inhaled oxygen (even for a short time), membrane bound NADPH oxidase activation, ROS production and DNA damage with cell apoptosis have been suggested as a consequence of exposure to high oxygen concentration [18]. Modification of neuronal nuclear membrane function leading to increased nuclear Ca^{++} influx, activation of Ca^{++}/Calmodulin dependent protein kinase, and protein mediated apoptotic protein expression has been reported in animals exposed to high oxygen concentration [19]. An important example of the various conditions capable of modifying ROS production and creating serious oxidative stress occurs in the endothelium. It is well known that endothelium dysfunction is mainly due to oxidative stress enhanced by various factors such as cytokines, ischemia re-oxygenation, glucose, LDL cholesterol, angiotensin II, shear stress, and vascular endothelial growth factor (VEGF) [20]. The occurrence of endothelium oxidative stress is important in neonatology, taking into account that endothelium is deeply involved in the infection mediated alteration of the coagulation system, and vascular troubles of neonate.

The risk of oxidative stress is enhanced in the neonate by the lower antioxidant capacity of the newborn and particularly the premature, in comparison with the adults. Free radical scavenger enzyme activities and many other components of the antioxidant system increase during intrauterine life and are low in the neonate [21, 22].

Of note is that the level and activity of the most-relevant antioxidant enzymes such as superoxide dismutases (SOD; EC 1.15.1.1), catalase (CAT; EC 1.11.1.6), and glutathione peroxidase (GPX; EC 1.11.1.9) change dynamically during development and mature in the last weeks of gestation, preparing the fetus for lung respiration [23–25].

In the fetal-to-neonatal transition, both blood oxygen content and oxygen availability abruptly increase in the first few minutes after birth to adult values, eliciting the generation of a burst of oxygen free radicals [26–28].

Free radicals in the fetal-to-neonatal transition may act as signaling molecules modulating maturation of specific metabolic pathways [29, 30].

However, in extremely premature infants, the combination of an immature antioxidant system plus a surfactant-deficient lung and the need for therapy with oxygen supplementation and mechanical ventilation together predispose to oxidative stress, lung-stretch damage, inflammation, and impairment of alveolar development, predisposing to chronic lung disease [31, 32].

However, generalized use of antenatal steroids has significantly reduced mortality and the incidence of severe complications in preterms younger than 34 weeks' gestation. Extremely low gestational age (ELGA) neonates with antenatal steroids spend less days on oxygen, on mechanical ventilation and have less severe complications such as bronchopulmonary dysplasia (BPD), patent ductus arteriosus (PDA), intra-periventricular hemorrhage (IPVH) or retinopathy of prematurity (ROP). Moreover, in spite of the increased antioxidant enzyme (AOE) activity and reduced oxidative stress and damage to proteins and DNA after antenatal steroid administration, the level of AOE activity was significantly lower than assessed in term infants or adults. Intriguingly, the response to antenatal steroids is conditioned by timing of administration before birth and by gender, with female neonates having a significantly increased response compared to male neonates [33].

Non-enzyme antioxidant factors are reported to be lower in the fetus and newborn than in adults and older babies [34]. One of the most studied antioxidant deficiency of fetus and newborn is tissue and erythrocyte low α-tocopherol. Other factors are important. Reduced glutathione (GSH) is the most abundant intracellular non-enzymatic antioxidant and is involved in the GSH-P and GSH-T enzyme activity. It has also complex interactions with environmental factors triggering oxidative stress [35]. Since in the cell the glutathione tripeptide is assembled from cysteine and glycine and then glutamate by consecutive actions of enzymes such as γ-cystathionase, γ-glutamylcysteine synthetase and glutathione synthetase, the possible problems with this mechanism may be due to recognizable inborn errors of metabolism or nutritional deficiencies [35, 36]. Several observations have shown that preterm infants have lower and age-related plasma concentrations of GSH and higher concentrations of glutathione disulfide (GSSG) than adults [37]. This occurrence may due to low GSH and low activity of GSH synthetase in the VLBW infants [36].

In this regard, there have been conflicting reports in the literature as to whether L-cysteine is an essential amino acid for the preterm infant as the result of the low activity of hepatic γ-cystathionase. Thus, studies performed in preterm infants revealed that plasma cystathionine concentrations in ELBW infants were significantly higher than in term infants, whereas cysteine concentrations were higher in term than in preterm. Furthermore, erythrocytes from preterm infants synthesize glutathione at a much lower rate than term infants when incubated with methionine, a process dependent on the γ-cystathionase pathway. These findings underscore the immaturity of the trans-sulphuration pathway and the conditional essentiality of L-cysteine in the parenteral and enteral nutrition of very preterm neonates. Moreover, it also explains the tendency toward oxidative stress [38].

Iron binding proteins have major antioxidant activity, protecting against metal induced $OH^{\bullet}$ production [39]. Therefore, among non-enzyme antioxidant factors the metal transporter proteins have an important function. In particular the transferrin concentration has a key role in protecting against the non protein bound iron (NPBI) promoted oxidative stress due to $OH^{\bullet}$ release [40, 41]. In this regard, low ceruloplasmin and transferrin may play an important role in neonatal susceptibility to oxidative stress and particularly to metal-induced $OH^{\bullet}$ production [42]. The finding of increased bleomycin-detectable iron in premature and some full-term infants is evidence of the real risk of increased pro-oxidant effects of iron in neonates [43]. High saturation of transferrin is therefore probably a risk factor for oxidative stress. It is generally accepted that NPBI is a pathological manifestation and it is extremely rare in adults [40]. Levels of NPBI in plasma of newborns are correlated with other markers of oxidative stress and are higher in hypoxic newborns [44]. Interestingly, plasma esterified F2-isoprostanes not only correlate with NPBI in the samples of cord blood of newborns but they increased after incubation of plasma with ammonium iron sulphate [45]. This observation strongly suggests the role of NPBI in enhancing oxidative stress in the neonate. High plasma NPBI has been found in hypoxic newborns with poor outcome [46]. Increased markers of oxidative stress such as hypoxanthine, total hydroperoxide and advanced oxidation protein products have been reported in hypoxic newborns and in preterm neonates at birth and on the seventh day of life [47, 48]. Increased F2 isoprostanes have been also found in growth restricted fetuses suggestive of oxidative stress and hypoxia [49]. These observations demonstrate that oxidative stress follows hypoxia with a mechanism of hypoxia re-oxygenation, NADP oxidase reactions or, paradoxically, by release of ROS by hypoxic cells.

Oxidative stress is involved in tissue damage induced by infection and sepsis. Although there is general agreement that neonatal phagocytes, especially those of premature infants, have abnormalities of various functions, active neonatal secretion of pro-inflammatory cytokines suggests a very complex situation in which oxidative stress following infection may be more dangerous in newborns, especially if premature, than in adults [50].

The key role of oxygen toxicity in the development of the retinopathy has been recognized from more than half a cen-

tury. The complex mechanism of oxygen toxicity is also discussed in Chapter 146.

Oxygen toxicity is particularly harmful for the lungs. The mechanism of damage is complex. Lung injury may be caused directly by ROS production in response to hyperoxia or indirectly by ROS due to phagocyte activation and inflammation. The two mechanisms seem to be integrated. The particular toxicity of ROS in the immature lung is mainly due to the low antioxidant capacity of premature infants, as well as to the possibly high toxicity of ROS in rapidly developing tissues [51]. Increased production of ROS under certain conditions may also play a role. The main sources of ROS production in the immature lung are ischemia, reperfusion, phagocytosis and hyperoxia [52–54].

The lung is highly susceptible to high oxygen concentrations especially when administered with positive pressure. In a prospective clinical study ELGA neonates were randomly assigned to become ventilated with higher (90%) and lower (30%) oxygen concentrations as initial inspiratory fraction of oxygen. Of note is that those neonates receiving more oxygen load during fetal to neonatal transition had a higher oxidative stress as detected by a decreased GSH/GSSG ratio. Moreover, urinary determination of ortho-tyrosine/phenylalanine ratio and 8-oxo-dihydroguanosine/2 de-oxyguanosine ratio revealed that premature infants who received more oxygen had increased oxidation of circulating proteins and higher damage to nuclear DNA. In addition, markers of inflammation (interleukin-8 [IL8] and tumor necrosis factor-α [TNF-α]) were evenly increased. Interestingly, infants with increased markers of oxidative stress and inflammation in the first days of life developed with significantly higher incidence of BPD and stayed more days on oxygen and mechanical ventilation [54].

Effects of hyperoxia in the lung and a close relationship between oxidative stress and inflammation have been demonstrated [55, 56]. Magnetic resonance studies have confirmed the previously reported experimental data on the consequences of hyperoxia in the lungs of premature newborn animals, namely edema, congestion, immune cell infiltration and decreased number of alveoli per square meter [57]. The finding of a large number of neutrophils and high concentrations of IL-8 and leukotrienes in bronchopulmonary lavage of infants with severe chronic lung disease (CLD) demonstrates the role of inflammatory reactions and ROS production in the development of this disease [58].

Oxidative stress is involved in the increased hemolysis and anemia of the newborn and particularly of the premature. The red cells of newborns appear to be more susceptible to the toxic effects of oxidative stress than those of adults [22] and the free iron content of red cells, a risk factor for hemolysis, is higher in newborns in comparison with the adults [59]. It is interesting that during aerobic and also hypoxic incubation, increased O_2^- production, free iron release and senescence antigen production showed the highest significant differences between adults and neonates [60]. This finding suggests that hyperoxia and hypoxia may generate red cell damage via ROS and possibly have a role in the increased hemolysis in the neonate.

In conclusion, experimental studies and clinical observations demonstrated high susceptibility of the fetus and newborn to oxidative stress. Increased release and decreased detoxification in the newborn appear to be negatively correlated with the gestational age.

39.3 Clinical Aspects and Prevention

39.3.1 Diagnostic Procedures

ROS have an important role in the development of retinopathy, chronic lung disease, necrotizing enterocolitis, renal failure, hemolytic anemia, septic shock and also brain damage. The clinics of these pathologies are treated in the corresponding chapters.

Several methods have been proposed in the attempt to detect the presence and the severity of the oxidative stress. Some frequently used approaches such as the measurement of erythrocyte antioxidant defenses are not accurate since the red cell enzyme activities are age dependent and values may be an expression of an old or young red cell population [61].

39.3.2 Lipids

The thiobarbituric acid (TBA) test should not be used to measure lipid peroxidation because most of TBA-reactive material is not related to lipid peroxidation. Measurements of malondialdehyde (MDA) by HPLC, 4-hydroxynoneal and particularly isoprostanes are more accurate [61]. The most work has been done with F-2 isoprostanes which arises from arachidonic acid non-cyclo-oxygenase (COX) peroxidation. Neuroprostane or F-4 isoprostanes has also been measured [61].

39.3.3 Proteins

Detection of oxidation of proteins can be obtained by measurement of carbonyl groups and the use of proteomics appears to a promising method in order to identify specifically oxidized proteins [61]. Assay of total hydroperoxides represents a measure of overall oxidative stress given that they are the intermediate oxidative products of lipids, peptides and amino acids [61]. Allantoin and 8-hydroxydeoxyguanosine can be measured in plasma and urine and the levels are high in conditions of oxidative stress [62, 63]. Nitrosyn levels have been reported as a marker of $ONOO^-$ production from leukocyte

activation [64]. A very specific, useful and non-invasive mean to monitor oxidative damage to circulating proteins and amino acids is the measurement of ortho-tyrosine. Oxidation of phenylalanine produces three different metabolites, ortho, para and meta-tyrosine, which can be detected in urine by high performance liquid chromatography coupled to mass spectrometry [65]. Interestingly, only ortho-tyrosine is produced by non-physiologic metabolic pathways and derives from hydroxyl derived oxidation of phenylalanine. In recent work, a significant correlation between the amount of oxygen given during resuscitation and the urinary elimination of ortho-tyrosine been detected; moreover, the increased antioxidant capacity of preterm human milk has also been assessed by this methodology [66, 67].

39.3.4 Intracellular Redox Status

A major marker of oxidative stress is the GSH/GSSG ratio which directly reflects alteration of intracellular redox status since when the oxidative stress exceeds the reductive capacity of GSH reductase the cell loses glutathione exporting the excess of oxidized glutathione [35]. NPBI levels appear to be a very reliable marker of oxidative stress, particularly in the newborns as previously indicated. Measurements of ethane in expired air may be useful in detecting oxidative stress [61].

39.3.5 DNA Damage

Determination of oxidized bases of DNA have been carried out by HPLC coupled to MS/MS [67].

39.3.6 Prevention of ROS Tissue Damage

Avoidance of conditions such as infections, asphyxia, hyperoxia and retinal light exposure, under which excessive free radical release occurs, are the best defense against development of imbalances in pro-oxidant and antioxidant factors in the neonate. Frequent reports of NPBI in plasma of neonates suggest that indiscriminate iron supplementation should also be avoided.

The concept of optimal oxygenation of newborns has recently been revised in order to clarify whether the optimal oxygen saturation unanimously accepted for normal infants and adults is also the best for sick neonates, especially if premature.

In an attempt to avoid the risk of tissue damage caused by ROS in the first hours of life, when susceptibility to oxidative stress is particularly high, the effects of O_2 were investigated. As previously reported, hyperoxia-induced lung injury has been demonstrated. Indications on the use of oxygen were recently reported by Cow et al [68] in a 5-year study in a tertiary neonatal center where oxygen therapy was adjusted to optimize neonatal care and decrease the incidence of ROP. They recommended avoidance of repeated increase and decrease in FiO_2 in response to the oxygen saturation monitor and maintenance of oxygen saturation within "acceptable" limits. They also recommended setting an alarm for oxygen saturation below 85% and above 93% for newborns under 32 weeks of age. More recently, comparison of two populations of high risk newborns kept at O_2 saturations of 88–98% and 70–90% showed a significant reduction in ROP in the group at lower O_2 saturation but no differences in mortality or poor outcome [69]. Data from clinical outcome seem to demonstrate that low birth weight infants cared for with liberal approaches had more cognitive disability compared with those cared for with more restrictive approaches after 10 years [69]. Data collected from the Oxford Vermont Network in extremely low birth newborns demonstrate significant lower incidence of chronic lung disease and ¾ ROP among babies carried with target oxygen saturation of <95% compared to those kept at more than 95% [70]. Shulze et al [71] did not observe signs of mismatch between systemic oxygen delivery and demand in low birth weight infants kept at 93–96% O_2 and 89–92% saturation. However, Poets et al [72] reported higher incidence of ROP in infants < 30 weeks' gestation using oxygen saturation limits of 80–92% in comparison with 92–97%. Therefore, the relationship between Hb oxygen saturation, risk of oxidative stress and oxygen toxicity is still a problem. Even a recent Cochrane review failed to define the target range for maintaining blood oxygen levels in preterm/LBW infants [73]. A subsequently repeated Cochrane review declares that "the question of what is the is the optimal target range for maintaining blood oxygen levels in preterm LBW infants was not answered by the data available for inclusion in this review" [74].This is presumably due to the complex mechanism of oxygen toxicity which may be expressed at different percentages of O_2 saturation under different conditions.

Conventional indications suggest that optimal oxygen tension should be maintained between 50 and 70 mmHg [75]. However, it should be taken into account that the ability of pulse oximetry to reliably detect hyperoxia remains controversial and it has been shown that oxygen saturation more than 90% can be associated with an arterial oxygen tension of more than 80 mmHg [69].

Hyperoxia and oxidative stress may occur during neonatal resuscitation (see Chapter 38).

39.3.7 Protective Effect of Human Milk in the Preterm Infant

The antioxidant properties of human milk are reported widely in the literature.

In a recent study Friel et al [76] confirmed that human milk of term and of preterm mothers provided better antioxidant protection. They found that human milk produced less ascorbate whether or not oxidative stress was present. Elevated concentrations of ascorbate are prooxidant in the extracellular milieu. Moreover, the antioxidant enzyme activity of catalase, superoxide dismutase, and glutathione peroxidase increased with time in human milk. Additional studies have shown that human milk-fed neonates had a higher plasma total antioxidant and vitamin C content. Biomarkers of oxidative status, such as total peroxide and oxidative stress index, were higher in formula-fed neonates at 3 to 6 months' postnatal age [77]. Human milk of preterm mothers at 35–36 weeks' post-conceptional age also seemed to have a positive effect on the oxidant status of their infants. In a recent study, preterm infants fed preterm human milk have significantly lower elimination of markers of hydroxyl radical aggression to protein and DNA, meaning that they produce lower amounts of free radicals.

Thus, in the clinical setting even in the acute stage preterm infants should be fed early with human expressed milk, which offers an additional protection against free radicals [78].

39.3.8 Antioxidants

Substances inhibiting phagocyte activation or xanthine oxidase and arachidonic acid metabolism, or decompartmentalizing free iron and making it available for the Fenton reaction, have also been investigated, together with those scavenging ROS directly or repairing ROS-induced membrane injury, like calcium antagonists and beta-blockers. The subject has been reviewed by Buonocore and Groenendal [79].

On the whole, the results obtained in newborns have been uncertain. Several antioxidant substances have been used in newborn animals and humans in an attempt to improve the worst prognosis of damage, presumed to be due to ROS. Many, such as superoxide dismutase (SOD), showed the same disadvantages in newborns. Other drugs, such as allopurinol and desferrioxamine have shown good results in animals, but no advantages in human newborns.

Among the antioxidants, melatonin has a special place since it has been reported to have several interesting effects such as enhancement of antioxidant enzyme activities and neutralization of H_2O_2 singlet oxygen and peroxynitrite; it appears to scavenge $OH^{\bullet}$ [80]. Administration of melatonin has been reported to decrease the concentrations of pro inflammatory cytokines and markers of oxidative stress in RDS and in septic newborns [81, 82]. In the animals, a study of Carloni et al [83] demonstrated that melatonin has a long-lasting beneficial effects on brain damage following hypoxia ischemia occurring during the development. However, the effects of the melatonin may be due to a combined actions since the melatonin in addition to the antioxidant effects, possesses also endocrine, autocrine and paracrine activity and appears to decrease the inflammation.

Vitamin E is a powerful, widely tested antioxidant. Conclusions of a recent Cochrane review are that vitamin E supplementation to preterm infants reduces the risk of intracranial hemorrhage but increases the risk of sepsis; in very low birth weight infants it seems to reduce the risk of retinopathy and blindness [84]. There is no evidence to support the use of vitamin E at high doses or the aim of keeping serum tocopherol levels above 3.5 mg/dL [85]. It should be remembered that some formulations of vitamin E are poorly adsorbed [86].

Peroxidation products in stored lipid emulsions have been shown to increase lipid peroxidation *in vivo* in newborns and adults. Since parenteral nutrition has been associated with increased formation of ROS, it is necessary to protect intralipids from light and add vitamins [87]. Finally, although hyper-bilirubinemia can be regarded as a natural antioxidant factor, the risk of brain damage due to high plasma levels of this molecule, particularly in premature babies, should not be underestimated.

39.4 Conclusions

The mechanism by which the oxidative stress is deeply involved in the development of several diseases of the fetus and newborn is complex and probably not yet fully understood. However, multiple observations strongly suggest that increased free radical and ROS play a considerable role as well as the deficiency of antioxidant agents. In particular, hyperoxia and inflammation as well as the episode of hypoxia reoxygenation appear to be a source of increased ROS release which may cause tissue injury, particularly in the preterm infant, either by direct effect or as a consequences of endothelium dysfunction.

Physical Examination of the Newborn

Claudio Fabris and Alessandra Coscia

40.1 Introduction

A complete physical examination of every newborn should be performed by a trained neonatology care provider within 24 hours of birth. Although there is no international standard, routine examination is regarded as a good practice in the guidelines for postnatal care [1–4].

Aims of the routine neonatal examination are:

1. to detect problems arising from maternal or familial diseases or from complications of labor and delivery;
2. to check for conditions suspected during antenatal period (e.g., congenital malformations) and to provide information about management;
3. to detect any acute condition requiring urgent diagnosis and therapy;
4. to diagnose congenital problems not already identified at birth (e.g., congenital heart disease, developmental dysplasia of the hip);
5. to screen some specific conditions, such as developmental dysplasia of the hip and congenital cataract;
6. to provide initial health and educational advice for the parents (e.g., breastfeeding, SIDS prevention, hemolytic disease of the newborn (HDN) prevention, safe transport in cars, vaccination).

The first quick examination should be performed immediately after birth, in the delivery room. This first step, mainly based on inspection, should check that the infant looks well and there are no pathological conditions requiring parents to be informed (e.g., congenital malformations or any doubt about the baby's gender) or immediate management (e.g., respiratory distress). A careful examination of the newborn should be routinely performed in presence of the mother or both parents, in a quiet warm room, with adequate lighting.

40.2 Full Examination

Before introducing himself to the mother, the health care provider must check basic information regarding maternal (e.g., maternal age, socioeconomic status, smoking, drug or alcohol abuse, any chronic disease) and family history and previous obstetric history. It is very important to inquire if there were any complications in the pregnancy and to know the results of pregnancy screening tests and diagnostic procedures (e.g., ultrasound examinations, amniocentesis). It is necessary to get information about problems during labor and delivery, as well as about the baby's gender, birthweight and gestational age. All these items should be documented in the infant's medical record.

The newborn can be properly examined clothed only in the nappy. There is not any strict rule regarding the order of the examination, but some tips can be given. It would be better first to perform a general "gestalt", whole inspection and then continue with a systematic review (e.g., from head to foot), as well take advantage of any period of quiet or sleeping to check the anterior fontanelle, to examine the eyes, to perform the auscultation of the heart and the lungs and the

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

palpation of the abdomen. It is better to leave the examination of the hips until the end, because the Ortolani-Barlow test is unpleasant for the newborn. Regardless the order of examination, the health care provider must make sure he has not omitted any item and he must record all findings. A suggested sequence is given in Table 40.1.

Many conditions observed during the examination are very common and they have little clinical importance or usually resolve spontaneously. On the other hand, there are some conditions, less frequent, that require further investigation or urgent therapy.

40.2.1 General Observation and Measurements

General observation includes weight, length and head circumference measurement: percentiles have to be ascertained from weight charts. If there is any doubt regarding gestational age, it should be determined by a scoring scheme [5, 6]. Simple observation allows short arms and legs to be noticed; these can indicate the presence of skeletal dysplasia.

Healthy term babies spend most time in quiet or active sleep, but transition between behavioral states can be rapid: crying is an usual finding during the examination [7]. A healthy full-term infant usually lies in flexion position (flexion of the arms at the elbows and of the legs at the knees), with a relatively symmetric limb position and posturing: however, the presentation at birth can influence posture in the first days of life. Asymmetric tonic neck reflex can be noted if the head is turned to one side: in this case, there is extension of the ipsilateral arm and leg and flexion of the controlateral extremities. Infants manifest spontaneous motor activity, which consists of moving their limbs in an alternating fashion [8].

40.2.2 Skin

The skin of a healthy newborn should be reddish pink, but peripheral cyanosis (hands, feet and circumoral area) is a common finding during the first 48 hours, as well traumatic cyanosis, often associated with petechiae, affecting the presenting part. Some conditions may be present:

- *Central cyanosis*: this is best observed on the tongue and it requires urgent investigation for pulmonary disease or congenital heart malformations. Plethoric newborns can appear cyanotic because they have more than 5 g per 100 mL of reduced hemoglobin.
- *Pallor*: when generalised it can be associated with anemia or shock.
- *Jaundice*: appearing within the first 24 hours of life, jaundice most often indicates hemolysis and requires further investigation and treatment.
- *Capillary hemangioma* (stork bites): these pink macules appear on the upper eyelids, the mid forehead and the nape of the neck: those on the forehead and eyelids disappear or fade over the first year, whereas those on the neck are covered with hair.
- *Neonatal urticaria* (erythema toxicum neonatorum): white papules appear on erythematous skin, usually on the second or third day of life and migrate to different sites.
- *Milia*: retention of keratin and sebum may cause these benign white cysts distributed on the nose and cheeks.
- *Mongolian blue spots*: they are blue-black maculae, more frequent in African-American or Asian babies, located at the base of the spine or on the buttocks, and in some cases also on the legs or in other parts. They fade slowly over the first few years of life.
- *Harlequin color change*: this is a vasomotor instability which causes a longitudinal reddening down one half of the body and a blanching down the other side.
- *Edema*: this may be generalized or localized: if present, it is always pathologic in the newborn. Pedal edema may be a sign of Turner syndrome.
- *Port-wine stain* (nevus flammeus): a vascular malformation of the capillaries in the dermis and usually evident at birth, whereas strawberry nevi (cavernous hemangioma) appear only after 1–2 months of life. When port-wine stain affects distribution of the trigeminal nerve, it may suggest underlying intracranial vascular malformations (Sturge-Weber syndrome), whereas large lesions on the limbs may be associated with bone hypertrophy (Klippel-Trénaunay syndrome).

40.2.3 Head and Face

Head dimensions and shape should be evaluated and fontanelle and sutures should be palpated. The head can be considerably moulded during labour and delivery. Babies in the breech presentation in utero often have the so-called "breech head" (prominent occipital shelf).

There may be some transient phenomena:

– bruising and abrasions from the use of forceps, vacuum extractor or scalp electrodes;
– caput succedaneum, edema and bruising of the presented part, that extends beyond the sutures;
– cephalhematoma, a collection of blood between the periosteum and the skull bone that does not extend beyond the sutures and usually affects parietal bone.

The anterior fontanelle can measure up to 3 × 3 cm, but its dimension can be variable: its tension (when the baby is not crying) may indicate raised intracranial pressure, from cerebral edema, intracranial hemorrhage, hydrocephalus or meningitis. After delivery the coronal sutures are often overriding, but ridging at the suture lines implies premature fusion of the sutures (craniosynostosis).

Asymmetry is a frequent finding due to pressure in utero and during labor and delivery. Palpation of the skull bones can reveal areas of craniotabes, caused by pressure in utero from maternal pelvis, that occur in 2% of normal full-term newborns and more frequently in the preterm baby. Cutis aplasia (small defect of the scalp) is a congenital malformation with risk of bleeding or infection of the dural venous sinuses and it may be a clue to the presence of a syndrome. Most newborns resemble one or other parent, but when the face appears unusual, the examiner should search for other dysmorphic manifestations, to exclude a syndrome.

40.2.4 Ears

General shape, size and position of the ears have to be evaluated. Malformations can be associated with hearing loss and require a hearing check. Preauricular pits, skin tags anterior to the ear and accessory auricles may be associated with an increased risk of renal abnormalities [9, 10]. Low-set ears (when the top of the pinna falls below a line drawn from the outer canthus of the eye at right angles to the face) are a characteristic of several syndromes.

40.2.5 Nose

Newborns have to breath through their nose, so complete nasal obstruction (i.e., from choanal atresia) causes intense respiratory distress and requires prompt investigation and treatment. If there is any doubt, a fine catheter should be passed through each nostril to ensure that both nares are patent. Flaring of the alae nasi is always abnormal and indicates the presence of respiratory distress that requires further investigation.

40.2.6 Eyes

The eyes should be examined both by inspection and with an ophthalmoscope. If the lens is opaque from a congenital cataract or glaucoma, the red reflex cannot be elicited: any abnormality of the red reflex requires urgent evaluation by an ophthalmologist. Congenital cataract is the commonest form of preventable childhood blindness. Swelling of the eyelids is common, a mucoid discharge ("sticky eye") is often present in the first 2 days of life and usually resolves spontaneously. A purulent discharge, accompanied by redness and swelling of the eyelids, requires microbiological investigation and treatment. Subconjunctival hemorrhages are very common due to delivery and usually resolve within 1–2 weeks. The iris is normally blue or grey in the newborn. Partial defect is called "colobomata" and it could be associated with a defect in the retina, complete absence is called "aniridia" and it is associated with an increased risk of Wilms' tumor. Size of the cornea has to be checked: if the corneal diameter is greater than 13 mm, there might be a congenital glaucoma.

40.2.7 Mouth

Direct inspection of the inside of the mouth is important, in order to exclude cleft palate, even mild defects (submucous cleft or posterior cleft palate). Other harmless findings may be seen, including Epstein pearls (small white pearls of microkeratosis along the midline of the palate), mucus-retention cysts of the gums (epulis) or on the floor of the mouth (ranula), short frenulum ("tongue tie"). These conditions usually do not need treatment. Natal teeth (rare in Caucasian race) are best removed.

40.2.8 Neck

The newborn has a relatively short neck, but a very short neck may indicate abnormalities of the cervical spine (Klippel-Feil syndrome). A webbed neck is one of the characteristics of Turner syndrome, and posterior redundant skin may suggest Down syndrome. Palpation of sternomastoid muscle may be evidence of "tumors", caused by bleeding or ischemia, sometimes resulting in fibrosis. Clavicle fractures may occur during delivery with shoulder dystocia: it is possible to palpate a lump on the clavicle that results from a callus around the fracture and usually recovers without treatment.

40.2.9 Examination of Chest and Auscultation of Heart and Lungs

A certain degree of breast enlargement is normal in newborns of either sex and a few drops of milk ("witch's milk") may be discharged.

Neonatal routine examination detects only a half of the infants with congenital heart disease, even if the baby has significant structural heart lesion. At birth, the pressure difference between left and right side may be still low and then newborns with ventricular septal defects might not have a heart murmur. Moreover, ductus-dependent lesions can present symptoms only a few days after birth, and femoral pulses are often palpable at first examination [11, 12].

Cardiorespiratory state can be deducted by simple inspection (respiratory rate and signs of respiratory distress, such as retractions or grunting). If cyanosis is present, pulse oximetry should be performed: pulse oximetry is currently not recommended as routine practice [13–15]. Normal respiratory rate

is 40–60 breaths/min: if a baby has a rate persistently above 55 breaths/min, he needs to be carefully evaluated. In a full-term newborn, there should be no grunting, no retractions and no flaring of the alae nasi: if present, they are symptoms of respiratory distress.

Palpation of the precordium may detect thrills or a pronounced ventricular heave. Peripheral pulses, in particular femoral pulses, should be always palpate: patent ductus arteriosus produces a bounding pulse, whereas absence or difficulty to feel femoral pulses suggests coarctation. If coarctation is suspected, it can be confirmed by comparing blood pressure in the arms and legs: a difference of 20 mmHg or more suggests coarctation. A heart murmur may be heard, but most are innocent: 60% of normal newborns have a systolic murmur at 2 hours of life: the origin of an innocent murmur may be the acute angle at the pulmonary artery bifurcation, patent ductus arteriosus, or tricuspid regurgitation [16]. Features that suggest a significant murmur are as follows [17]: pansystolic; ≥ 3/6; harsh quality; best heard in the upper left sternal border; abnormal second heart sound; and difficult to feel femoral pulses.

Electrocardiogram or chest X-ray rarely change the clinical diagnosis [18]. Due to the availability of ultrasound evaluation, this evaluation, with expert consultation, should be performed in any infant with a suspected significant murmur.

40.2.10 Abdomen

Simple observation may reveal any anomaly. The umbilicus is a common source of infection, so any discharge or reddening of the skin requires attention. A single umbilical artery occurs in 0.3% of newborns and is associated with an increased risk of congenital malformations, in particular renal abnormalities. Ultrasound of the renal tract should probably only be reserved for babies who have other problems, other than a single umbilical artery [19]. An umbilical hernia is a common finding, especially in African-American babies.

A diastasis of the recti is frequently appreciated by palpation, the liver edge is usually palpable 1–2 cm below the right costal margin. Also the spleen tip and the kidney are palpable: it is important to detect abnormal renal mass or enlargement of the bladder, which may be a sign of urinary outflow obstruction in a male infant.

40.2.11 Genitalia

The position and the tone of the anus must be checked and passage of meconium should be recorded.

Male Hydroceles occurs very frequently in the neonatal period, and usually resolves spontaneously. Inguinal herniae are common, in particular in preterm babies. The penis should be checked for length (usually about 3 cm) and position of urethral meatus. Sometimes the penis looks short, but a normal organ is buried in sovrapubic fat. An abnormal position of urethral meatus indicates hypospadia (glandular, coronal, mid-shaft or perineal): ventral curvature reveals the presence of a chordee. Glandular hypospadia without chordee does not require any treatment. In a full-term baby, testes should be palpable, but about 6% of newborns have one testis undescended at birth: if at 3 months of age the testis is still undescended, a pediatric surgeon or urologist should be consulted. Neonatal testicular torsion usually occurs before birth: neonatologists should consult a pediatric surgeon, although the testis has usually already undergone infarction [20].

Female At full term the labia majora cover the labia minora, in preterm babies the clitoris and the labia minora appear prominent. There is often a white or bloodstained discharge, due to maternal hormone withdrawal. Small hymenal skin tags, mucoid cysts or a ring of vaginal mucosa are common.

40.2.12 Spine

Swelling, dimples, a hairy patch or a nevus along the spine or over the base of the skull might indicate underlying vertebral, spinal cord or brain anomalies. Simple sacrococcygeal pits are common and harmless, simple dimples (less than 2.5 cm from the anus, less than 5 mm wide, without other cutaneous signs) do not indicate occult dysraphism [21–23].

40.2.13 Limbs

Extremities are examined to inspect shape, posture, symmetry and size. About 45% of individuals with Down syndrome have single transverse palmar creases, but the same finding may occur in 4% of the Caucasian and in 16.8% of the Chinese population. Polydactyly is often a familial trait, but it may be caused by a dysmorphic syndrome. Digital remnants should be removed surgically.

Observation of spontaneous arm movements and testing passive movements may indicate a fracture or a brachial plexus lesion. Lack of active movement and pain on passive movements indicates a fracture or an infection. In a brachial plexus lesion there is initially a lack of movement in the arm. After 48 hours, in an upper root palsy (Erb's palsy: C5, C6 and sometimes C7), the arm is internally rotated, without active abduction. In a complete palsy of upper and lower roots (Klumpke's palsy: C5, C6, C7, C8 and T1) the arm flails and there may be ptosis and Horner's syndrome, the hand may be clawed [24]. Most brachial plexus lesions

recover spontaneously: if recovery doesn't occur by 3 months of age, the baby should be referred to a specialist [25, 26].

40.2.14 Hips

The incidence of developmental dysplasia of the hip (DDH) and instable hip is about 1–2 per 1000 births and 10 per 1000 births respectively. The risk of DDH is increased in some conditions: female sex, breech presentation, positive family history, oligohydramnios, any abnormality of the lower limb, any other anomaly suggesting intrauterine compression (i.e., torticollis) [27]. Clinical screening of DDH (Ortolani's and Barlow's tests) has not reduced the number of babies requiring surgery (0.7 per 100 live births) [28]: moreover, most infants with abnormal neonatal examination have normal hips. Clinical examination by an unexperienced examiner is only little better than no screen [29].

There is another screening strategy, ultrasound screening, which is best performed by a skilled operator before 3 months of life: this can also detect clinically stable but anatomically abnormal hips. No universal agreement exists concerning the best DDH screening method. Many clinicians suggest that clinical neonatal examination is the best strategy, if performed by properly trained examiners and followed by selective ultrasound, based on risk factors [30]. In the Ortolani-Barlow manoeuvres, the baby lies supine, with the legs relaxed. For Ortolani's test, first the examiner should straighten out the legs and then flex the hips to a right angle: after placing the middle finger over the greater trochanter of each leg and the thumbs over the internal aspects of the thighs, the examiner slowly abducts and externally rotates the hips: a definite "clunk" indicates that a previous dislocated femoral head has slipped into the acetabulum [31]. The next manoeuvre is Barlow's test, which allows dislocation of an unstable hip. Holding the hips and knees as in Ortolani's test, with the hips at about 70° abduction, the examiner presses forward and medially each hip in turn: if the hip is dislocated, the femoral head slips into the acetabulum with a "clunk" [32].

40.3 Neurological Examination

Formal testing is only required in newborns with neuromuscular problems. The evaluation should be performed with minimal discomfort to the infant and the main goal is to exclude any suspicious neurological signs [8].

Neonatal neurological evaluation includes the following tests (see also Chapter 130):

- general observation
- level of consciousness and behavioral states
- mechanical signs: head, spine, limbs
- motor system: muscle strength and tone, spontaneous movements
- reflexes (deep tendon reflexes and primitive reflexes i.e., Moro, grasp, suck, root)
- autonomic function (heart and respiratory rate, bladder and bowel function).

Motor system function can be assessed by testing skeletal muscle posture, tone and movements.

Full-term infants usually exhibit flexion of the limbs. Muscular tone consists of an active or passive resistance to stretch and it results from a complex interaction between agonistic and antagonistic muscles: then any alteration in muscle tone could represent a sign of a variety of underlying neurological diseases.

The assessment of muscle tone includes the observation of posture and movement, the evaluation of resistance to passive movements and the production of active or passive movement by specific maneuvers, such as pull-to-sit manoeuvre and ventral suspension. In the pull-to-sit manoeuvre, as the infant is pulled up from the supine position by his wrist, there should be some flexion of elbows and slight flexion of neck, with the head coming up almost in line with the body. In the ventral suspension, as the newborn is hold in the air with the examiner's hand under the chest, flexed arms and the head lie almost on a plane with the body for a few seconds.

Increased resistance to passive movement may indicate hypertonicity, often associated with an opisthotonic posture and obligate extension during ventral suspension.

Babies with reduced resistance to passive movements and unrestricted movements usually tend to drape over the examiner's hands in the horizontal plane: these findings indicate hypotonia, whereas weakness is a reduction in muscle power or strength, and it may occur together or not with hypotonia. Hypotonia combined with weakness usually indicates an involvement of peripheral nervous system, whereas hypotonia without weakness indicates an involvement of the central nervous system (brain or spinal cord).

Rooting, sucking, grasp and Moro responses are the most important primitive or developmental reflexes: they should disappear in the first months of life. When they persist, an underlying central nervous system dysfunction should be suspected.

Crossed extension, placing and stepping reaction are other primitive reflexes.

The main aim of the neurological evaluation in the routine examination is to exclude the presence of suspicious neurological signs. The findings that require further evaluation are the following:

- persistent hypotonia, paucity of spontaneous movements
- abnormal posture (frog posture, opisthotonus, excessive fisting, fisted thumbs)
- asymmetric movements
- failure to suck
- high-pitched cry
- persistent and extreme irritability
- convulsions
- lesions over the spine.

40.4 Assessment of Gestational Age

The most reliable guide for assigning gestational age is an early antenatal ultrasound, combined with the mother's last menstrual period: early antenatal ultrasound has 95% confidence intervals of less than 7 days. Several methods can be used to assess gestational age: those based on physical criteria, those based on neurological development and those that combine physical and neurological examination.

Physical criteria progress in an orderly fashion with increasing gestational age and can be assessed immediately after delivery. Neurological criteria include the assessment of posture, passive and active tone, reflexes and righting reaction, and require the infant to be in an alert rested state, not so easy to obtain until the second day of life.

The most accurate method to assess gestational age is to combine the physical criteria and the neurological assessment: Dubowitz and Dubowitz scoring system involves 11 physical criteria and 10 neurological findings [5], whereas simplified Ballard system includes six physical and six neurological criteria to shorten the time taken (Fig. 40.1). The new Ballard score is valid for extremely premature infants [6, 33].

In any case, these methods are accurate only to ± 2 weeks, with an overestimation in extremely premature infants.

41

Primary Investigations in the Term and Preterm Newborn

Ignazio Barberi, Eloisa Gitto and Diego Gazzolo

41.1 The Term Newborn

41.1.1 Newborn Screening

Newborn screening, started in 1960, is primarily directed at disorders in which clinical complications develop during the immediate postnatal period.

41.1.1.1 Metabolic Screening

Metabolic diseases result from biochemical abnormalities that are manifest during the first days after birth [1]. Phenylketonuria (PKU) was the first metabolic disorder known to benefit from early diagnosis and immediate dietary treatment. Infant with PKU were identified early, in large numbers, and developed normal while receiving treatment [2]. The success of such screening led to further progress in the investigation of additional tests for metabolic diseases, such as galactosemia, maple syrup disease (MSUD), and homocystinuria. These tests could be applied to the same blood specimen obtained for PKU screening. In 1990, tandem mass spectrometry (MS/MS) started a new era in newborn screening [3]. The technology allows for the detection of more than 30 biochemical genetic disorders with a single assay with high specificity and with a very low of false positive rate. Currently, the disorders detected by most MS/MS newborn screening programs can be divided into three major categories: amino-acid disorders (including urea cycle defects), organic acid disorders and fatty acid oxidation defects [3].
In 1999, the American Academy of Pediatrics (AAP) Newborn Screening Task Force recommended that Human Resources and Services Administration (HRSA) developed and implemented nationally recognized newborn screening system standards and policies in collaboration with the Maternal and Child Health Bureau (MCHB) of HRSA and the American College of Medical Genetics (ACMG) [4]. Criteria included: 1) the current availability of an effective and rapid screening test; 2) an efficacious treatment and adequate understanding of the natural history .

Metabolic screening varies from country to country and each nation applies its own program of neonatal screening. A multidisciplinary report by the ACMG, HRSA and AAP recommended a panel of 29 tests and there is universal newborn screening for metabolic disorders in, many developed countries [5] (Table 41.1).

Conditions most commonly screened for are congenital hypothyroidism, galactosemia, adrenal hyperplasia (cah), biotinidase deficiency, sickle cell disease, cystic fibrosis are performed by immunoassays, radioimmunoassay (RIA), fluoroimmunoassay (FIA), and enzyme-linked immunosorbent assay (ELISA) techniques. The topic is considered in more detail in Chapter 120.

41.1.2 Infections

A wide variety of infectious agents may affect newborn such as bacteria, viruses, fungi, protozoa, and mycoplasmas. This topic is considered in more detail in Chapters 112–118.

Several laboratory tests have been evaluated for their ability to predict which at risk infants may develop symptomatic or culture–proven sepsis, but there is at present no single test that is sufficiently reliable. Investigators have proposed different combinations of laboratory tests but these various combinations were not more diagnostic than single laboratory tests although more predictive for negative cases [6].

Newborns at risk of sepsis need careful physical examination and standard laboratory investigation may be useful such as: WBC differential count, immature-to-total neutrophil (I:T ratio) and C reactive protein (CRP) [6]. Although

Table 41.1 Newborn screening panel recommended by ACMG expert panel [4]

MS/MS detectable disorders
Organic acids
– Isovaleric acidemia
– Glutaric aciduria 1
– 3-Hydroxy-3-methylglutaric aciduria
– Multiple carboxylase deficiency
– Methylmalonic acidemia due to mutase deficiency
– 3-Methylcrotonyl CoA carboxylase deficiency
– Methylmalonic acidemia due to cobalamin A and B defects
– Propionic acidemia
3-Ketothiolase
Fatty acid oxidation
– Medium chain acyl-CoA dehydrogenase
– Very long chain acyl-CoA dehydrogenase
– Long chain 3-hydroxyacyl-CoA dehydrogenase
– Trifunctional protein deficiency
– Carnitine uptake defect
Amino acids/urea cycle
– Phenylketonuria
– Maple syrup urine disease
– Homocystinuria
– Citrullinemia
– Argininosuccinic aciduria
– Tyrosinemia type 1
Disorders detected by other methods
Hemoglobinoathies
– Hb SS-Sickle cell anemia
– Hb S/Beta-thalassemia
– Hb S/C disease
Others
– Congenital hypothyroidism
– Biotinidase deficiency
– Congenital adrenal hyperplasia
– Galactosemia due to GALT deficiency
– Congenital hearing loss
– Cystic fibrosis

sensitivity/specificity is limited, total WBC count and differential and I:T ratio can indicate bacterial infection. Taken together: 1) an elevated WBC is not predictive of infection in newborn infants; neutropenia is more common than neutrophilia in severe neonatal sepsis, but also occurs in association with maternal diseases (PIH, IUGR); 2) thrombocytopenia is a nonspecific indicator of infection; 3) longitudinal WBC monitoring in the first 24 hours from birth is more predictive of infection than a single determination [7–9].

CRP is an acute-phase reactant that increases in the presence of inflammation caused by infection or tissue injury. Raised levels of CRP are found in bacterial sepsis or meningitis. After inflammation onset, CRP synthesis increases within 4–6 h, doubling every 8 h, and peaks at about 36–50 h. Levels remain elevated with ongoing inflammation, but with resolution they decline rapidly due to a short half-life of 4–7 h. CRP demonstrates high sensitivity and negative predictive value. A single normal value of CRP at birth cannot rule out infection because the sampling may have preceded the rise in CRP. Serial CRP measurements may be helpful [10–12].

For asymptomatic term infants with positive laboratory tests, blood culture and antibiotic therapy are recommended until cultures are negative. Asymptomatic infants born before 35 weeks with risk factors for sepsis should have blood cultures before antibiotic therapy is started and before the results of laboratory tests. The duration of therapy should be guided by the baby's clinical condition and the results of the tests [13].

41.2 The Preterm Newborn

Preterm birth affects more than 500,000 babies in the United States each year [14]. In Italy the incidence of preterm birth is 6.7 % at <36 weeks of gestation, 5.2% between 32 and 36 weeks of gestation and 0.9% <32 weeks [15]. Preterm birth is one of the leading causes of infant mortality and morbidity [16]. It accounts for more than 70% of neonatal deaths and almost half the children with long-term neurological disabilities were born prematurely [17]. Since 1981, the US preterm birth rate has increased from approximately 9% to 12% [14, 18]. Research indicates that preterm birth is a multifactorial disease caused by genetic, social and environmental factors, which most likely interact to increase risk [19–26]. There are striking disparities in the rates and consequences of preterm birth across racial and ethnic groups in the US that are unexplained [18].

41.2.1 The Problem of Preterm Labor

The factor(s) controlling the spontaneous onset of labor are not known. This is frustrating from a physiological point of view, and also a major clinical problem. The last trimester of pregnancy is necessary for the maturation of the fetal lungs and other organs in preparation for extrauterine life. If this process is interrupted by an early delivery the chances of survival of the newborn are severely decreased. The mortality rate according to different countries still remains higher and constant, at lower gestational ages, with a wide range morbidity and disability in the surviving infants [27, 28]. The factors responsible for parturition in women remain unknown and the endocrine paradigms described above do not fit primates. Therefore, more research is necessary to identify the physiological trigger for parturition and to understand why the process may be activated prematurely in some pregnancies. It is also necessary to investigate the biochemical mechanisms regulating uterine smooth muscle activity in order to develop more effective and selective therapy to control uterine contractions when this is indicated. Critical clinical findings are reported in Table 41.2.

Table 41.2 Critical assessment findings for hypo- and hyperthermia

Hypothermia
- Pale, mottled skin that is cool to touch babies
- Acrocyanosis
- Respiratory distress
- Apnea, bradycardia, central cyanosis
- Irritability initially
- Lethargy developing as hypothermia worsens
- Hypotonia
- Weak, cry and suck
- Gastric residuals, abdominal distension, emesis
- Shivering in more mature
- Metabolic acidosis
- Hypoglycemia
- *And temperature measurement*!!

Hyperthermia
- Reddened skin that is warm to touch
- Tachypnea
- Tachycardia
- Irritability, lethargy, hypotonia, weak cry
- Poor feeding
- Apnea
- Sweating in more mature babies
- Dehydration

41.2.2 Neonatal Assessment at Birth

Based on potential multiorgan damage due to prematurity, close monitoring, in the early phases after birth, is essential. Primary investigations include vital signs recordings such as temperature determination, heart and respiratory rates, oxygen saturation monitoring in parallel with blood pH assessment.

41.2.2.1 Temperature Determination

Temperature determination is always required and might be recorded at 30 minutes intervals up to thermostability achievement. Furthermore, it is suggested that temperature be recorded at 1–3 hour intervals by continuous monitoring with axillary determinations every 1–2 hours [29]. In this regard, recordings should include environmental temperature (i.e., air temperature in the incubator or radiant warmer settings). Measuring the skin and core temperature simultaneously may be of help differentiating between fever as a result of disease and environmental overheating. Noting that the baby's servo-controlled skin temperature is relatively stable but that the environmental temperature has dropped also may be indicative of fever as the incubator responds to the high probe reading by cooling the infant's environment.

41.2.2.2 Cardiorespiratory Monitoring

The electrical activity of an infant's heart is picked up by chest leads (usually three), placed on the infant and recorded by a cardiorespiratory monitor. The recording is displayed on a visual screen as the infant's electrocardiographic pattern. The infant's respiratory pattern also is recorded, because the chest leads electronically detect movement of the infant's chest with each respiration. The oxygen saturation monitor relies on adequate perfusion to the site and the ability to detect arterial pulsation; thus if it is placed distal to a blood pressure cuff, there will be an inaccurate reading while the cuff is inflated. Newer models of pulse oximetry reduce the artefact that results from motion and low perfusion [30, 31]. These newer models also are indifferent to ambient light whereas older models were affected by light sources such as phototherapy.

41.2.2.3 Blood Pressure Monitoring

Monitoring of blood pressure is essential for the optimal management of premature infants. Blood pressure is one of the most important physiological parameters to evaluate clinical stability in critical care. Several medical conditions in premature infants determine changes in blood pressure (i.e., infections, drugs, dehydration, blood loss etc.). The recognition and treatment of abnormal blood pressure states has significant prognostic implications in neonatal intensive care [32]. Blood pressure in the newborn is related to weight and gestational age. Blood pressure rises with postnatal age, 1–2 mmHg/day during the first week and 1 mmHg/week during next 6 weeks in the preterm infant, just as in the full-term infant. The measurement of blood pressure can be obtained by non-invasive or invasive methods. In stable infants or when only intermittent blood pressure measurements are required, non-invasive methods are preferred. Blood pressure invasive monitoring is obtained via catheter that has been introduced into an artery. This method is indicated in very small or instable infants, especially those with severe hypotension. For more details, see Chapter 78.

41.2.2.4 Transcutaneous Blood Gas Monitoring

PCO_2 and PO_2 are important monitoring parameters in neonatal intensive care units (NICU). Compared to conventional blood gas measurements that cause significant blood loss in preterms, transcutaneous (tc) measurements allow continuous, non-invasive monitoring of blood gas levels [33]. Preterm infants are vulnerable to alterations in arterial oxygen or carbon dioxide tension . Changes in oxygen supply contribute to the subsequent development of retinopathy of prematurity or bronchopulmonary dysplasia. Hypocarbia has been associated with the subsequent development of periventricular leucomalacia and cerebral palsy, and may cause retardation of retinal vascularization [34]. Transcutaneous measurement of oxygen ($PtcO_2$) and carbon dioxide ($PtcCO_2$) tension is a non-invasive method that has recently offered some promise. Several studies have shown a good correlation between tc and arterial values [35, 36].

41.3 The Preterm Baby

41.3.1 Specific Risks for the Preterm Neonate

Preterm infants usually show multiorgan failure in reverse proportion to the gestational age.

The main target-organs are:

- central nervous system (CNS): including apnea of prematurity, intracranial hemorrhage, development disability, and cerebral palsy;
- retinopathy of prematurity (ROP);
- cardiovascular complications may arise from the failure of the ductus arteriosus to close after birth: Patent ductus arteriosus (PDA) is typical in preterm babies. Other congenital cardiac malformations will further analyzed in Chapter 76;
- respiratory problems that can range from lung malformations (pulmonary hypoplasia, see Chapter 66) to wet lung and finally to chronic lung disease (see Chapter 65);
- gastrointestinal and metabolic issues can arise from glycemia and ion disorders, feeding difficulties, and finally necrotizing enterocolitis (NEC). However of particular interest are kidney diseases that are extensively described in Chapters 124 and 125;
- hematologic complications including anemia of prematurity, thrombocytopenia, and hyperbilirubinemia, and (jaundice) that can lead to Kernicterus (for review see Chapter 83);
- neonatal sepsis including viral and bacterial forms that can be characterized by general (septicemia) or localized sepsis (pneumonia, urinary tract infection, meningitis etc.).

41.3.2 Patent Ductus Arteriosus (PDA)

The ductus arteriosus' function in the unborn baby is to allow blood to bypass the lungs, because oxygen for the blood comes from the mother and not from breathing air. In full-term babies, the ductus arteriosus closes shortly after birth, but it frequently stays open in premature babies. When this happens, excess blood flows into the lungs and can cause breathing difficulties and sometimes heart failure. More details about PDA and other congenital cardiac disorders are analyzed in Chapter 80.

41.3.3 Respiratory Distress Syndrome

Clinical, diagnostic and therapeutic strategies in RDS management are described in Chapter 62. One of the most common and immediate problems facing premature infants is difficulty breathing. Although there are many causes of breathing difficulties in premature infants, the most common is called respiratory distress syndrome (RDS). Its incidence is inversely proportional to gestational age and occurs most frequently in infants of less than 1200 g and 30 weeks' gestation. RDS affects male infants twice as frequently as in female infants (2:1) In RDS, the infant's immature lungs fail to produce surfactant and its administration is highly required according to RDS severity. Prophylactic and or rescue surfactant administration modalities are reported in Chapter 70.

In RDS respiratory drive recording is generally irregular in rate and depth, and is chiefly abdominal, rather than thoracic, with a rate of 30–60 breath/min. Tachypnea, a rate above 60 breaths/min after the first hour of life, is the earliest symptom of respiratory diseases. Periodic respirations are cyclic respirations of apnea (5–10 seconds) and ventilation (10–15 seconds) [37]. Apnea is a non-breathing episode lasting longer than 20 seconds and accompanied by physiologic alterations. Use of accessory muscle of respirations is indicative of a marked increase in the work of breathing. Retractions reflect the inward pull of the thin chest wall on inspiration. Retracting is best observed in relation to the sternum (substernal and suprasternal) and the intercostals, supracostal, and subcostal spaces. The increased negative intra-thoracic pressure necessary to ventilate the stiff, non-compliant lung causes the chest wall to retract. This further compromises the lung's expansion. The degree of retraction is directly proportional to the severity of the disease. Nasal flaring is a compensatory mechanism that attempts to take in more oxygen by increasing the size of the nostrils and thus decreasing the resistance (by as much as 40) of the narrow airways. Grunting is forced expiration through a partially closed glottis.

Because the clinical presentation of many respiratory and non-respiratory diseases is the same, a chest X-ray examination may be the only way to differentiate cause and establish the proper diagnosis. Measurement of arterial blood gases is used to demonstrate alterations in oxygenation and acid-base balance and to differentiate between respiratory and metabolic components.

41.3.4 Hyperbilirubinemia

A common treatable condition of premature babies is hyperbilirubinemia, which affects 80% of premature infants. Although mild jaundice is fairly common in full-term babies (about 60%), it is much more common in premature babies. In premature infants, the bilirubin peak usually is on the fourth–fifth day of life and may be 10–12 mg/dL, possibly rising to greater than 15 mg/dL without any specific abnormality of bilirubin metabolism. Therefore for bilirubin screening it is enough to take sample blood on the fourth–fifth day of life. Neonatal jaundice is completely analyzed in Chapters 81 and 82.

Table 41.3 Indications for routine monitoring of blood glucose for prevention of neonatal hypoglycemia

Maternal conditions
– Presence of diabetes or abnormal glucose tolerance test
– Preeclampsia and pregnancy-induced or essential hypertension
– Previous macrosomic infants
– Substance abuse
– Treatment with beta-agonist tocolytics
– Treatment with oral hypoglycemic agents
Neonatal conditions
– Prematurity
– Intrauterine growth restriction
– Perinatal hypoxia-ischemia
– Sepsis
– Hypothermia
– Polycythemia-hyperviscosity
– Erythroblastosis fetalis
– Iatrogenic administration of insulin
– Congenital cardiac malformations
– Persistent hyperinsulinemia
– Endocrine disorders
– Inborn errors of metabolism

41.3.5 Hypoglycemia and Hyperglycemia

Recognition that preterm newborn are at risk for disturbances in glucose homeostasis is the most important step in preventing both hypoglycemia and hyperglycemia (Table 41.3). Maintenance of a neutral thermal environment is especially critical to minimize energy expenditure in those infants at risk for hyperglycemia. Other conditions associated with hypoglycemia, such as asphyxia and hypothermia, may be avoided through appropriate obstetric and neonatal intervention. When hypoglycemia is suspected, the plasma or blood glucose concentration must be determined immediately. Ideally this determination should be made with one of the laboratory enzymatic methods, such as the glucose oxidase or hexokinase method, but even bedside reagent test strip glucose analyzers (i.e., glucometers) can be used if the test is performed carefully with awareness of the more limited accuracy of these devices. A number of current references use 40–45 mg/dL as the lower limit of "normal" plasma glucose concentrations in the first 72 hours of life [38].

41.3.6 Intracranial Hemorrhage

Intracranial hemorrhage (ICH) can affect newborns of all gestational ages and often is clinically "silent". Among ICH, germinal matrix hemorrhage and intraventricular hemorrhage (GM-IVH) are the most common in the premature population (see Chapter 138). Routine screening for GM-IVH is performed in infants < 30 weeks or < 1250g at birth. The timing of hemorrhage occurrence is mostly within the first three days of life. "Late" hemorrhage (i.e., after 3 days of age) may be associated with pneumothorax and its restriction of venous return to the heart.

Indications for cerebral ultrasound scan are discussed in Chapter 132.

Physiology of the Gastrointestinal Tract

Arieh Riskin, Carlo Agostoni and Raanan Shamir

42.1 Development of the Gastrointestinal Tract: Organogenesis and Function

The gastrointestinal tract develops from the primitive digestive tube that originates from the dorsal part of the yolk sac. Initially the yolk sac is attached to the midgut of the digestive tube, but as early as the fourth week of gestation the gut becomes distinct from the yolk sac. The yolk sac is connected to the digestive tube through the omphalomesenteric (vitteline) duct. The dorsal mesentery separates the digestive tube from the dorsal wall of the embryo, and at this stage there is also a ventral mesentery that separates the anterior part from the ventral embryonic wall. Continuity with the exterior environment is formed only after the rupture of the buccopharyngeal and cloacal membranes. The anatomic formation of the esophagus, stomach, intestine, pancreas and liver is achieved by the fourth week through a series of evaginations, elongations and dilatations. Further development through cell proliferation, growth and morphogenesis then follows.

The pharynx, esophagus, stomach, liver, gallbladder, pancreas and upper duodenum originate from the foregut. The distal portion of the duodenum, the jejunum, ileum, cecum, appendix, ascending colon and two-thirds of the transverse colon arise from the midgut. The hindgut differentiates into the third distal part of the transverse colon, the descending colon, the sigmoid colon, the upper two-thirds of the rectum and the urogenital sinus [1]. Arterial supply delineates the boundaries: the celiac axis supplies the foregut, and the superior and inferior mesenteric arteries supply the midgut and hindgut, respectively.

The rapid elongation of the gut during the first trimester leads to its herniation into the umbilical cord. The gut reenters into the abdominal cavity and rotates counterclockwise around the superior mesenteric artery to reach its final position by 20 weeks of gestation (Fig. 42.1). Failure of this process results in malrotation.

By the second trimester all the anatomic structures of the gastrointestinal tract are well formed and recognizable. The process of maturation involves rapid increase in the mucosal surface area followed by folding forming the villi and microvilli. However, functional maturation, including the appearance of digestive enzymes in the villi and the development of swallowing and mature motility patterns, occurs much later than structural development; some functions are not fully established until 2-4 years of age. Maturation tends to follow a cephalocaudal progression from the proximal to the distal part of the gastrointestinal tract (Table 42.1).

The regulation of timing and nature of growth and maturation of the gastrointestinal tract is complex and involves many factors. These include not only intrinsic factors like signals arising from gene expression [2], biologic clock or regulatory hormones and peptide growth factors, but also extrinsic environmental factors acting at the molecular level. The gastrointestinal tract is in continuity with the environment; the fetal gut is thus exposed to the amniotic fluid content as the neonatal gut is exposed to enteral feedings, nutrients and even microbes. This is related to the advantages of breast milk with its immunologic and trophic growth factors to the newborn [3]. At the cellular level regulation occurs by homeodomain transcription factor genes [1] and cell to cell interactions, especially epithelial-mesenchymal interactions [4]. The pluripotent stem cell located in the crypt of the villus continuously differentiates into the 4 gut cell lineages: absorptive enterocytes, mucous (goblet), Paneth and endocrine cells [5]. This process that involves continuous proliferation, migration and loss of epithelial cells along the mucosal surface is also regulated genetically by homeodomain transcription factors [1].

For detailed aspects on structural anatomic development of the different parts and organs along the gastrointestinal tract, refer to Chapter 90, where congenital malformations of the gastrointestinal tract are discussed.

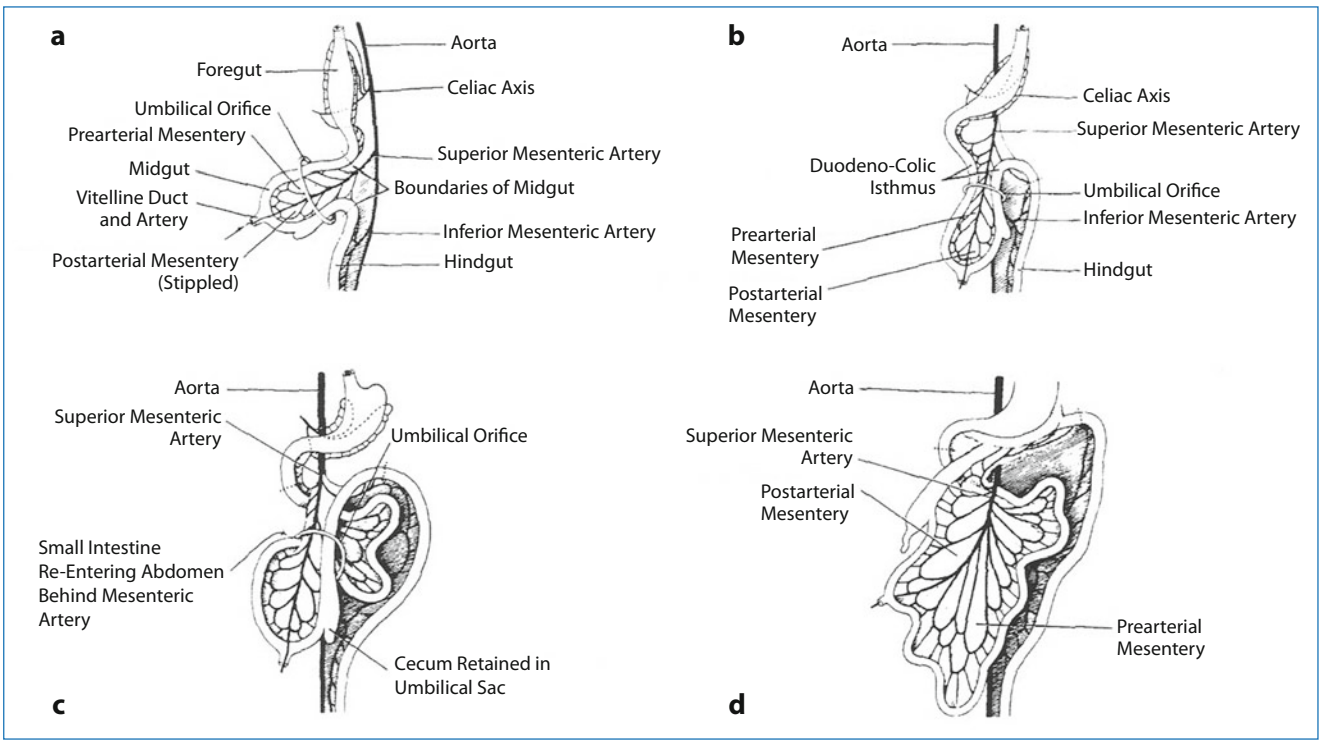

Fig. 42.1 Diagram showing normal rotation of alimentary tract. **a** Fifth week of intrauterine life (*lateral view*). The foregut, midgut, and hindgut are shown with their individual blood supply supported by the common dorsal mesentery in the sagittal plane. The midgut loop has been extruded into the umbilical cord. **b** Eighth week of intrauterine life (*anteroposterior view*). The first stage of rotation is being completed. Note the narrow duodenocolic isthmus from which the midgut loop depends and the right-sided position of the small intestine and left-sided position of the colon. Maintenance of this position within the abdomen after birth is termed *nonrotation*. **c** About the 10th week of intrauterine life, during the second stage of rotation (*anteroposterior view*). The bowel in the temporary umbilical hernia is in the process of reduction; the most proximal part of the prearterial segment entering the abdomen to the right of the superior mesenteric artery is held forward close to the cecum and ascending colon, permitting the bowel to pass under it. As the coils of small intestine collect within the abdomen, the hindgut is displaced to the left and upward. **d** Eleventh week of intrauterine life at the end of the second stage of rotation. From its original sagittal position, the midgut has rotated 270 degrees in a counterclockwise direction about the origin of the superior mesenteric artery. The essentials of the permanent disposition of the viscera have been attained. 42.2 Vascularization

Vascular supply to the intestine develops concurrently with its anatomic development. The arterial supply develops as 3 ventral outbuddings of vessels from the aorta: celiac trunk supplies the stomach, pancreas and duodenum via its splenic, left gastric and hepatic branches; superior mesenteric artery supplies the jejunum and ileum; inferior mesenteric artery supplies the colon and rectum. Smaller branches of the superior mesenteric artery form arcades before entering the intestinal wall that along with anastomoses with branches of the inferior mesenteric artery provide rich collateral flow. Watershed areas of marginal blood supply however exist in the distal transverse colon and upper rectum. Since there is high metabolic activity in the intestinal mucosal layer, it has rich vascular supply, yet it is still the most sensitive layer to any derangements in blood supply.

Based on animal studies it is assumed that intestinal basal vascular resistance decrease in the immediate postnatal period, thus doubling blood flow and oxygen delivery in the neonate to compensate for the higher metabolic activity related to nutrient absorption that was not needed in fetal life. However, later on between postnatal days 12–30 vascular resistance increases again due to maturation of the intestinal extrinsic adrenergic innervation, as well as changes in the geometry of the intestinal vasculature in response to the rapid increase in size (length and surface area) of the gut that happens concomitantly [6].

Basal vascular resistance is mediated by nitric oxide (NO) that is continuously produced by the endothelial cell NO synthase isoform (ecNOS) or is increased in response to mechanical or chemical stimuli. NO causes vasodilatation of the adjacent vascular smooth muscle via production of cGMP by activated guanylate cyclase. Rates of NO production and its relaxing effect on the mesenteric artery bed are maximal immediately after birth. Its role in determining vascular tone lessens over the first month of life. The essential role of endothelial production of NO in maintaining newborn intestinal hemodynamics may be important in the pathogenesis of necrotizing enterocolitis (NEC), because endothelial dysfunction that would limit NO production may lead to vasoconstriction and substantial intestinal ischemia [6].

Individual vascular smooth muscle cells respond to stretch stimulus by contracting via stimulation of calcium-induced phosphorylation of myosin light chain kinase [7]. This intrinsic myogenic response is the second mechanism mediating vascular response in the neonatal intestine, and it has an important role in setting basal intestinal vascular resistance in the first days of life [6]. It causes vasoconstriction in response to increases in intravascular pressure in some of the blood vessels.

Endothelin, the third mediator of vascular resistance, is a vasoactive peptide mainly produced by the vascular endothelium. ET-1, the intestinal form, is continuously produced by the intestinal vascular endothelium in an age-specific manner. Its production is greater in young subjects, especially in newborns, probably reflecting its essential role in angiogenesis at this time of exceptionally rapid growth of the intestine. Endothelin binding to ET_A receptors on vascular smooth muscle induces potent sustained contraction, while its binding to ET_B receptors causes NO-mediated vasodilatation. The force of ET_A-induced vasoconstriction exceeds the modest ET_B-induced NO-dependent vasodilatation, thus the net effect of constitutive ET-1 production is vasoconstriction [8].

The significance of these three mechanisms regulating intestinal vascular resistance in the neonate is markedly diminished after the first postnatal month of life. Thereafter, the greater degree of extrinsic adrenergic innervation causes increased basal vascular resistance with more robust responses to baro- and chemo-reflexes.

Mesenteric blood flow is regulated by changes in the tone of the arteriole and the pre-capillary sphincter. Control of blood flow is intrinsic and extrinsic [6]. Intrinsic control is achieved by local factors that react to changes in arterial pressure (pressure-flow autoregulation) and tissue oxygenation, such as functional postprandial hyperemia in response to feeding or reactive hyperemia in response to vessel occlusion. Modest arterial hypoxemia (PO_2 around 50 mmHg) causes vasodilatation and increased perfusion to the gut, yet profound hypoxemia (PO_2 <40 mmHg) causes vasoconstriction and gut ischemia. These different responses probably reflect NO regulation of vascular tone [6]. Extrinsic regulation is mediated by sympathetic input from the splanchnic nerves. However, the vasoconstriction response to adrenergic nerve stimulation is short-lived, and gut blood flow is slowly restored to its baseline by a process termed autoregulatory escape.

Circulating endogenous and exogenous factors (e.g., hormones, histamine and prostaglandins) can also modulate vascular tone. The presence of nutrients in the gut triggers the postprandial hyperemic response with brisk vasodilatation and increased blood flow and oxygen delivery. Postprandial hyperemia in the newborn is mediated by dilatation of the intestinal circulation in response to substance P, which is a peptide neurotransmitter in the enteric nervous system [9]. Both postprandial hyperemia and autoregulatory escape phenomena are present in newborns. However, unlike term infants, healthy preterm infants require compensatory systemic hemodynamic changes in response to feeding and postprandial hyperemic response because the increased mesenteric flow causes cardiac output increase and systemic blood pressure decrease [10]. Drugs used in neonatal care such as indomethacin [11], dopamine and caffeine [12], as well as other treatments (e.g., hyper alimentation and CPAP) [13] may diminish intestinal mesenteric blood flow thus disrupting compensatory mechanisms.

42.3 Neural Control of Motor Function and Gastrointestinal Motility

A major function of the gut is motor activity that moves the content forward along the gastrointestinal tract. This includes sucking, swallowing, gastric emptying, propagation of the food along the small intestine and evacuation of wastes from the colon. Neural crest cells migrate into the developing gut, and with muscle cells differentiate to form three layers of muscle that surround the mucosa (by 14 weeks of gestation) and a neural network that controls motor activity (by 20-24 weeks of gestation). This neural network comprises the enteric nervous system (ENS). The phasic contractions of the gastrointestinal tract are regulated by a complex interplay between the myogenic, neural and chemical control mechanisms [14].

Peristaltic activity allows intestinal contents to move along the intestine and can occur through a variety of mechanisms. Phasic contractions are responsible for the mixing and propulsive movements of the gut after a meal. These are called migrating action potential complexes (MAPCs), and they are prominent postprandially [14, 15]. During fasting, organized groups of contractions called cyclic motor activity and migrating motor complex (MMC) keep the upper digestive tract clean of residual food and debris [14, 15]. MMC cyclic motor contractions originate from the antrum and progress to the ileum. They are characterized by periods of quiescence followed by irregular contractions, then a period of regular contractions and return to the quiescent state. In addition, the small intestine and the colon generate giant migrating contractions, which are several-fold stronger than the postprandial phasic contractions and migrate uninterrupted over long distances. The giant migrating contractions are effective in rapid propulsion. The upper small intestine and the gastric antrum may also generate retrograde giant contractions that generally precede vomiting [14]. Movements of MMCs and MAPCs are orchestrated by the ENS.

42.3.1 Myogenic Control

Contractile activity can also propagate toward the anus in association with propagating slow-wave activity [16], expressing myogenic control. Muscle cells generate this spontaneous electrical activity through fluctuations in resting membrane potential, and these periodic depolarizations are called slow waves, electrical control activity, basic electrical rhythm or pacemaker activity. This myogenic pacemaker slow wave activity originates from specialized smooth muscle cells, the interstitial cells of Cajal (ICC) [17], that form an electrical syncytium with the smooth muscle layers. The network of ICC is also associated with the Auerbach's plexus [18]. There is evidence that absence of an ICC network may contribute to abnormalities in intestinal transit in humans, including infantile hypertrophic pyloric stenosis and Hirschsprung's disease [19, 20]. The fact that ICC are always very intimately associated with neural structures suggests a close co-operation between myogenic and neural control. Contractions occur when a slow wave under the influence of a neural or chemical stimulation exceeds the excitation threshold necessary for an action potential called electrical response activity or spike potential. Following this depolarization of the smooth muscle cell, intracellular calcium levels increase, calcium binds to the regulatory protein calmodulin, and this permits the binding of the contractile proteins actin and myosin, resulting in a contraction. It can be seen that the contraction caused by the electrical response activity occurs on the background of the electrical control activity, i.e., the slow waves of myogenic control [21]. This background slow wave activity controls timing, speed and direction of the intestinal contractions. There is probably co-operation between the neural and myogenic control of intestinal motility to ensure proper transit [15]. Denervated gut muscle cells have therefore a basal contraction rate like cardiac muscle cells.

42.3.2 Enteral Nervous System

The ENS is a subsystem of the autonomic system that includes two major nerve plexuses situated in the bowel wall. The myenteric (Aurbach) plexus lies between the external circular and longitudinal muscle layers, and the submucosal (Meissner) plexus lies between the circular muscle layer and the muscularis mucosa. The ENS also includes six minor plexuses located in the different layers of the bowel wall (Fig. 42.2). The ENS is integrated within the central nervous

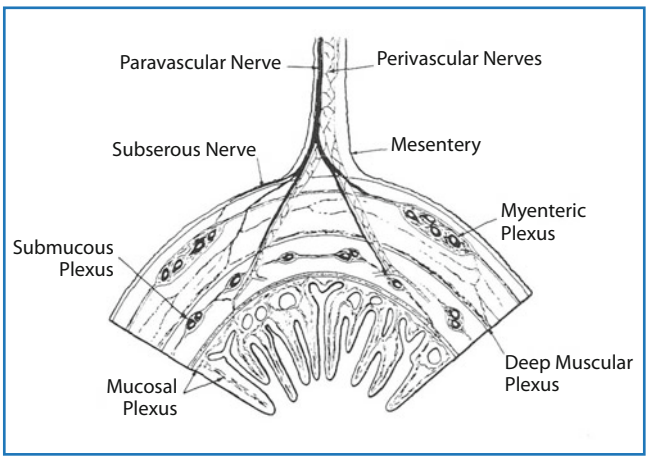

Fig. 42.2 Arrangement of enteric plexuses in whole mounts of intestine. In addition to the large myenteric and submucosal plexuses, several smaller plexuses are shown. Reproduced with permission of Elsevier from: Furness JB, Costa M, Arrangement of enteric plexuses. In: Furness JB, Costa M (eds) The Enteric Nervous System. Churchill Livingstone, New York, 1987

system (CNS) control of the gut, but it also provides the final regulation, and is even able to regulate gut motility, secretion and vascular flow independent of the CNS and spinal nervous control. The ENS with its large number of neurons compared to the relatively sparse central innervation of the gut is thus termed the "little brain of the gut", stressing its uniqueness compared to other peripheral nerve systems [22].

The basic unit of the ENS is the nerve cell. Neurotransmitters are released to other neurons or directly act upon striated or smooth muscle cells. Acetyl-choline is the main excitatory neurotransmitter mediating smooth muscle contractions [23]. Glutamate is also an excitatory neurotransmitter acting on N-methyl-D-aspartate (NMDA)-type receptors in the myenteric plexus in conjunction with cholinergic stimuli [24]. Glutamate can be synthesized from exogenous L-glutamine in myenteric neurons, and be released in response to neuronal depolarization [24]. Norepinephrine is a main inhibitory neurotransmitter. Nitric oxide (NO) mediates non-adrenergic non-cholinergic (NANC) relaxation of gastrointestinal smooth muscle [25]. NO synthase (NOS) and NO-containing enteric neurons have been demonstrated in the ENS [23]. Vasoactive intestinal peptide (VIP), another inhibitory neurotransmitter, may mediate NO effects [26]. Absence of NO has been implicated in the pathogenesis of infantile hypertrophic pyloric stenosis [27] and Hirschsprung disease [28].

Enteric neurons and glial cells of the ENS originate from the neural crest [29]. Cells from the vagal region migrate to the whole length of the gastrointestinal tract, but cells from the truncal and sacral regions populate only the foregut and the post-umbilical hindgut, respectively [30]. Like intestinal smooth muscle development, neural cells from the vagal region develop in a cranio-caudal direction, as opposed to neural cells originating from the sacral region that migrate into the distal bowel in a caudo-cranial direction. Neural cells that migrate from the outer mesenchyme of the gut to the inner mucosa proliferate. At this stage the cells are pluripotent and transiently express catecholamines [31]. Later in gestation the neural cells in the gut wall mature and differentiate into enteral neurons that do not express catecholamines anymore. Differentiated neurons express serotoninergic and peptidergic (e.g., substance P and neuropeptide Y) neurotransmitters. Some of the neural crest-derived cells that colonize the fetal bowel cluster and form ganglion cells that form the two ganglionated plexuses, described above [32]. These ganglion cells are distributed normally by 24 weeks gestation, although their density continues to change over the first years of life [33]. In the human fetus by the 10th week of gestation the circular muscle layer is formed, followed by the appearance of a primitive myenteric plexus, and the longitudinal smooth muscle layer in the 12th week of gestation. Most neurons in the myenteric ganglia at the 10th week of gestation are undifferentiated neuroblasts. The time between the 10th and 18th week of gestation is important for both morphological and functional maturation of the ENS. In the 18-week-old human fetus most neurons in the myenteric ganglia are already differentiated and mature, and the organization of smooth muscle cells and the primary strands of the myenteric plexus provide a satisfactory basis for an integrated peristaltic movement that is already seen in the gut [34]. Neurotransmitters are evident by 24-26 weeks, although their distribution along the gut may change and reach adult pattern only close to term.

Abnormalities in migration and differentiation of neural crest cells may cause a number of gastrointestinal disorders [35, 36], the main one is Hirschsprung disease that results from the absence of enteric ganglia in the distal hindgut.

42.3.3 Central Nervous System Control

CNS and ENS that control gastrointestinal motility, secretion and vascular flow consist of afferent sensory neurons, efferent motor neurons, synapses to the effector (e.g., muscle) cells and interneurons that integrate the messages. Sensory afferent fibers travel with parasympathetic preganglionic fibers in the vagus nerve and sympathetic postganglionic fibers in the splanchnic nerves. Vagal afferents conduct impulses from the mucosal and muscular layers of the whole gut, from the soft palate to the distal colon [37]. They reach the liver, gallbladder and pancreas too. Splanchnic afferents innervate the mucosal and muscular layers, the serosa and the bowel mesenterium. Motor innervation is made of sympathetic and parasympathetic components of the autonomic nervous system. Preganglionic sympathetic neurons are found in segments T2-L2 of the spinal cord. Postganglionic sympathetic neurons are found in the pre-vertebral sympathetic trunk (celiac, superior and inferior mesenteric ganglia). Preganglionic parasympathetic neurons are present in the medulla and in the sacral region of the spinal cord. Postganglionic parasympathetic neurons are located within the gastrointestinal tract. Most of the parasympathetic innervation of the gut comes from the vagus. Vagal efferents end up in the enteric ganglia of the ENS [38]. Sacral nerves innervate only the distal colon from the middle of the transverse colon. Since the vagus innervates most of the gut and has both afferent and efferent fibers it needs precise central viscerotopic organization of inputs and outputs. Afferent fibers reach the nucleus tractus solitarius and the vagal sensory nucleus. Efferent fibers originate from the motor nuclei and dorsal motor nucleus of the vagus and the nucleus ambiguous [37, 39]. The nucleus tractus solitarius is an important synaptic site where interneurons coordinate afferent inputs with efferent outputs delivered to the nucleus ambiguous and the dorsal motor nucleus of the vagus in order to control esophageal and gastrointestinal motility. Glutamate, an excitatory amino acid, is considered one of the neurotransmitters involved in this brain-stem synaptic transmission via NMDA receptors, specifically involved in esophageal motor activity in response to swallowing [40].

42.3.4 Gastrointestinal Motility

The motor activity of the gastrointestinal tract is critical not only for feeding but also for digestion and absorption of nutrients, because it promotes mixing of the nutrients with pancreatic, biliary and intestinal secretions, and transit of the intestinal content forward. Smooth muscles of the intestine are arranged in outer longitudinal and inner circular layers. They develop in a cranio-caudal direction that resembles the development of the vagal neural crest derived ENS. By the end of the first trimester longitudinal and circular muscles are detectable in the ileum. During the rest of gestation, muscle thickness increases. By 28 weeks gestation contraction of the gut can produce 60% of the intraluminal pressures measured at term. These pressures are sufficient for preterm infants to be able to move intestinal content forward. There is a gradual maturation of gut motility during fetal life that continues in the first years of postnatal life [41]. The gradual maturation of gut motility is the result of muscular and neural maturation. Motor activity is immature in preterm infants. Normal propulsive motility of the gut is evident by 30 weeks gestation. The classical MMC (migrating motor complexes) are demonstrated by 33 weeks but at slower propagation rates and without being abolished by feeding as happens in older children and adults.

Sucking and swallowing involve skeletal and smooth muscles. Although sucking and swallowing reflexes appear early in gestation their maturation is not complete until after birth. Fetuses can swallow amniotic fluid by 15-17 weeks gestation. Exposure to swallowed amniotic fluid including its growth factors such as the epidermal growth factor (EGF) is important for gastrointestinal development [42]. Close to term the fetus swallows 450-750 mL of amniotic fluid each day. Esophageal or intestinal atresia results in polyhydramnios. Non-nutritive sucking appears between 18-20 weeks, but nutritive sucking that involves coordinated mechanisms of sucking, swallowing and breathing develop only by 34-35 weeks of gestation [43], but has been described earlier (as early as 30-32 weeks) in preterm infants after early oromotor stimulation of nonnutritive sucking and use of pacifiers in preterm infants [44]. The maturation of nutritive sucking is parallel to the rapid growth in gastric size and maturation of gastric emptying, gastric antral and small intestinal motility and stimulation of secretion of gastrointestinal enzymes and peptides that enhance weight gain as well. Early introduction of oral feeding to preterm infants accelerates maturation of nutritive sucking and the transition time from tube to full oral feeding [44]. Maturation of sucking skills correlates better with postmenstrual gestational age than with postnatal age in preterm infants [45]. Lau et al characterized five developmental stages of sucking in preterm infants that were found to be in correlation with postmenstrual age, feeding progress, and the number of daily oral feedings. Rythmicity of sucking and rate of transfer of milk into the posterior pharynx were enhanced when infants reached the more mature stages of sucking, and general oral feeding performance improved as infants' sucking skills matured [46]. The first stage of swallowing is an involuntary reflex in preterm and term infants induced by the presence of milk in the posterior pharynx. At term, sucking is followed in an orderly manner by swallowing, esophageal peristalsis, relaxation of the lower esophageal sphincter (LES) and relaxation of the gastric fundus.

The esophagus serves as a connecting tube between the oropharynx and the stomach, but its peristaltic activity is essential for adequate passage of nutrients and for adequate clearing of refluxed materials. Coordinated esophageal peristalsis is present by 32 weeks of gestation and by that time upper esophageal sphincter (UES) tone is already present. Esophageal sphincters are not anatomic but rather functional. The LES is an area of increased muscular tone in the distal esophagus. Its main functions are to prevent gastric acid reflux and to propel food into the stomach. In term infants LES tone is 20-40 mmHg. However, contraction amplitudes, propagation of pressure waves and LES tone are lower in preterm compared to term infants. LES tone in a preterm infant less than 29 weeks gestation is lower than 5 mmHg [47]. Gastroesophageal reflux (GER), which is more common in preterm infants, is probably related to low LES tone and poor regulation of its relaxation [48]. Using impedance pH monitoring, non-acid as well as acid GER has been demonstrated [49], though norms for premature as well as term infants are yet to be established . The esophagus also provides aerodigestive defenses that exist in the healthy term infant and prevents aspiration of bolus feed or secretions. These mechanisms include: basal UES and LES tonic contraction, primary persitalsis of the esophagus triggered by swallowing, and secondary peristalsis with increase in UES tone in response to esophageal provocation. These defenses may not function in infants with neurodevelopmental abnormalities or mal-development of the foregut. Also, these defenses may not be fully mature in preterm infants, especially those with chronic lung disease [50].

Gastric emptying of liquid feeds is regulated by the fundus and proximal third of the stomach, which dilate to accommodate the milk volume, and is dependent on the pressure gradient between the proximal stomach and the duodenum. Accommodation of large volumes of milk in the fundus is poor immediately after birth. During the first three postnatal days, the newborn stomach becomes more compliant and develops more receptive relaxation, associated with a larger volume capacity. This is in accordance with the small feedings that neonates ingest in the first days of life [51]. Gastric emptying of more solid contents is regulated by the distal portion of the body of the stomach, the antrum and the pylorus where mixing is taking place. Gastric emptying requires adequate and coordinated antral and duodenal motor activities. As opposed to antral motor activity that seems to be mature as early as 24 weeks gestation [52], the coordination and the level of duodenal motor activity are decreased in preterm infants. In half of the preterm infants duodenal contractions cease in response to feeding resulting in delayed gastric emptying [53]. Reduced

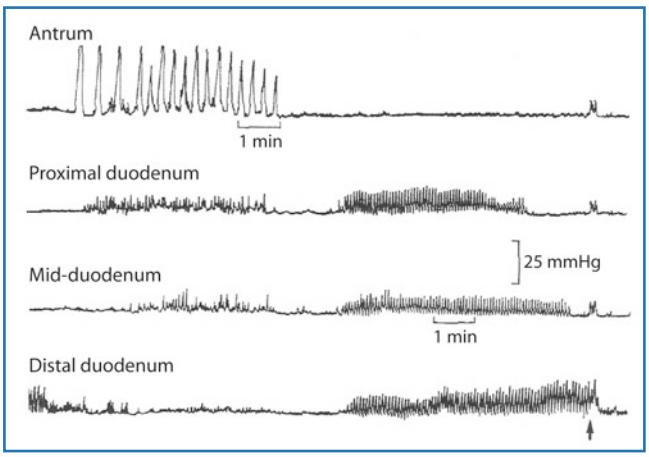

Fig. 42.3 Migrating motor complex in a term infant. Upper tracing: motor contractions recorded from the antrum. Lower three tracings: motor contractions recorded from the duodenum. Phasic activity present in the antrum is temporally associated with the appearance of intense phasic activity that migrates distally to the three duodenal leads. osmolality and increased feeding volumes seem to increase gastric emptying, but gastric emptying remains strongly related to gestational age at birth even at age of one month [54].

Maturation of gastrointestinal motility with increasing gestational age is most evident in the small intestine. This is shown by longer transit times as infants are more immature, especially before 30 weeks when ineffective gut motility may interfere with enteral feeding. The Migratory Motor Complexes (MMCs), described above, act as "housekeepers" that propel luminal content caudally along the small intestine. Term and late preterm infants born after 36 weeks gestation present organized MMC pattern [52] with periods of quiescence followed by irregular contractions, then regular contractions and return to the quiescent baseline (Fig. 42.3). This pattern is rarely found in preterm infants. Between 24-28 weeks gestation only unorganized irregular contractions are recorded with few quiescence intervals [41, 52]. By 28-32 weeks periods of quiescence appear alternating with short bursts of phasic activity called clusters. Between 32-36 weeks motor patterns become more organized and the periods of quiescence and clusters lengthen. MMCs are first seen around 33 weeks (Fig. 42.4) [41, 52]. Feeding should normally disrupt MMC pattern by creating strong contractions originating from the gastric antrum and pylorus that mix gastric content and propagate it through the pylorus and along the small intestine. These contractions are the migrating action potential complexes (MAPCs), discussed above. Berseth suggested that early feeding may accelerate the maturation of gut motility in preterm infants [55]. Composition and caloric content of the food, but not its volume, also has an effect on the maturation and intensity of the gut motor response, suggesting that diluted formula may not provide an optimal stimulant for the preterm intestinal functional responses to feeding [56].

94% of term newborn infants pass meconium within the first 24 hours and close to 100% do so within the first 48 hours. Passage of meconium may be delayed in preterm infants, up to 10 days and more in the very-low-birth-weight preterm infants [57]. Normal colonic function is necessary for successful defecation. However, not many studies were done on colonic motility, especially in preterm infants. The colon transports non-absorbable substances for excretion and facilitates exchange of water and electrolytes. Transit is slow and is achieved by mass movements that sweep the colon. Colonic motility is characterized by irregular alterations of quiescence with non-propagating and propagating contractions [58]. Colonic propagated events are defined as low and high-amplitude propagated contractions (LAPC and HAPC), and HAPCs are responsible for the mass movements. A colonic motor

response to a meal is comprised of segmental contractions, increased colonic smooth muscle tone and possibly also HAPCs. These were described in children as well, HAPCs being more frequent [59]. The only colonic cyclic activity is distal to the rectosigmoid junction. It is called recto motor complex and it is not synchronous with the small bowel MMCs. It keeps the rectum empty, especially at night, and thus helps maintaining continence [60]. It seems that colonic motility in term neonates is similar to that found in older children. However, colonic motility is immature in preterm infants. This is supported by the fact that term newborns that develop hypoxemia pass meconium in utero, while preterm infants rarely do so, suggesting the production of contractions that create mass stool movements are immature in preterm babies. Hirschsprung disease is the most common motility disorder affecting the colon. Neuronal Intestinal Dysplasia (NID) of the colonic submucous plexus is considered a congenital malformation of the enteric nervous system causing symptoms resembling those of Hirschsprung's disease. It is a poorly understood colonic motility disorder that is often associated with Hirschsprung's disease and is also associated with chronic intestinal pseudo-obstruction, anorectal malformations and the Multiple Endocrine Neoplasia (MEN) II syndrome [61]. Anal sphincter function is mature in term infants, but may be immature in less than 30 weeks gestation premature infants. However, delayed meconium passage in preterm infants could not have been related to the absence of a recto anal inhibitory reflex [62].

42.4 Digestion and Absorption

Three steps can be defined in the process of nutrient absorption: digestion, which is the processing of nutrients within the intestinal lumen and at the terminal digestive sites of the brush border membrane of the mucosal epithelial cells; absorption in the epithelial absorptive surfaces, which involves the membrane transport systems of the small intestinal epithelium; and transport of nutrients into the circulation [63].

42.4.1 Fat Digestion and Absorption

Fat is the major source for energy (provides half of the caloric intake) [64] and polyunsaturated fatty acids in newborns [65]. It is an essential cell membrane component [65], and it facilitates the absorption of fat soluble vitamins. Most of the lipids are absorbed in the proximal two thirds of the jejunum.

Digestion and transport of fat in the lumen of the gastrointestinal tract requires solubilization of the dietary lipids, mostly triglycerides, in the aqueous medium of the gut content, i.e., emulsification. This involves mechanical actions of mastication and gastric mixing to form fat droplets, as well as coating by phospholipids (mostly phosphatidylcholine in food with the addition of bile phospholipids in the duodenum) to stabilize the emulsion. Emulsification allows exposure of a large surface area to the action of the lipolytic enzymes. Hydrolysis of fat to form mono- or diglycerides and free fatty acids begins, especially in newborns, in the stomach by lingual lipase secreted from Ebner's glands near the circumvallate papillae [66] and by gastric lipase secreted by gastric glands. Lingual and gastric lipases are essential for the digestion of milk fat in the newborns because they can penetrate into the milk fat globule and initiate the digestive process, contrary to the pancreatic or milk digestive lipases [67]. In newborns, lingual lipase contributes significantly to lipid hydrolysis, and non-nutritive sucking stimulates its release from the posterior part of the tongue. Lingual and gastric lipases that are present as early as 26 weeks gestation compensate for the limited action of bile acids and pancreatic lipases that are found in low amounts, especially in preterm infants [68]. The contribution of lingual lipase significantly declines later in life.

Gastric hydrogen ions enter the duodenum and stimulate the release of secretin that enhances bicarbonate secretion from the pancreas. This process that raises the intraluminal pH to 6.5, which is more suitable for further fat digestion, is less effective in newborns. The optimum pH of lingual lipase, which is 3.5-6.0, is compatible with its continued activity in the upper small intestine, especially in newborns, where the luminal pH is under 6.5 [68]. The initial gastric phase of lipolysis generates modest amounts of diglycerides, monoglycerides, and free fatty acids that are required with bile salts for optimal activity of the intestinal phase of lipolysis. The bile salts further enhance fat emulsification rendering it more susceptible to the action pancreatic lipase that degrades it to monoglycerides and fatty acids. The co-activity of the enzyme colipase is critical to facilitate its attachment to the triglyceride droplets and to prevent bile salts from deactivating pancreatic lipase. All pancreatic lipases levels are low after birth, especially in preterm low birthweight infants [68], and increase to adult levels only by six months of age. The colipase-dependent pancreatic lipase catalyzes the intraduodenal phase of triglyceride digestion in formula-fed infants. However, in breast-fed infants this process is also mediated by the bile salt-stimulated lipase (BSSL), the main lipase in breast milk that is capable of hydrolyzing all three ester bonds of triglycerides, thus shifting the final products of triglyceride digestion to glycerol and free fatty acid that promote efficient fat absorption [69]. BSSL is identical to the pancreatic bile salt stimulated lipase that is responsible also for hydrolyzing intestinal cholesteryl esters and phospholipids [70], and its presence in human milk may serve as a bridge until the pancreas secretes it in adequate amounts. BSSL is not destroyed and does not lose its activity in the stomach, thus it can reach the duodenum and be activated by the concentrations of bile acids as found in the infant's duodenum. Breast milk also contains lipoprotein lipase (LPL) that has been described as related to the

prolonged neonatal jaundice in breast-fed infants. Lingual, gastric and milk lipases compensate for the low pancreatic lipase activity in term and preterm newborns [68], and since they all function well also in the presence of low bile acids concentrations they can also function well in preterm infants where bile acids synthesis in the liver is decreased and their intraluminal concentration is half of the critical micellar concentration required for fat absorption [68].

The source of dietary fat influences absorption [71], human milk being the best source for term and preterm newborns [72]. Unsaturated fatty acids are absorbed better than saturated ones, and short- medium-chain triglycerides are absorbed better than long-chain triglycerides [71]. Yet, long-chain fatty acids (≥16C) may have a growth promoting effect on intestinal cells, as can be seen in short-bowel syndrome [73]. Intraluminal calcium concentration also influences fat absorption. High calcium intake, as found in cow's milk, can impair fat absorption in term and preterm newborns. In human milk, palmitic acid esterified at the sn-2 position of the triacylglycerol molecule is well absorbed as 2-monopalmitin [74]. Lower digestibility of fat in bovine milk based infant formulas compared to human milk is related to the different position of palmitic acid in both fat sources [75].

After the luminal phase of digestion and processing of the lipids is completed, the mixture of all lipolytic products in the lumen is mixed with bile salts to form small aggregates of mixed micelles or liposomes, which are larger aggregates that are ready for the next mucosal phase of absorption. The bile salts that have both lipid- and water-soluble domains allow the passage of micelles through the water layer at the mucosal cell surface and the lipid rich microvillus membrane. The bile salts that are not absorbed remain in the intestinal lumen and are actively reabsorbed at the terminal ileum and into the portal system to be re-secreted into the bile. This enterohepatic circulation plays an important role in the pathogenesis of neonatal hyperbilirubinemia. Monoglycerides and free fatty acids diffuse into the cells. A significant proportion of this phase of lipid absorption is not by passive diffusion, but involves active, protein-mediated, transport [76, 77]. The major fatty acid protein transporter so far identified is FATP4 that is mainly involved in long-chain fatty acids absorption [78]. These fatty acids transporter proteins are located on the apical side of the enterocyte [76]. Inside the absorptive cells of the villus fatty acids are transported to the smooth endoplasmic reticulum where the triglycerides are re-synthesized. The triglycerides along with cholesteryl esters, phospholipids and apoproteins are packed together as chylomicrons that bind to the basolateral membrane and are transported via the intestinal lymphatics into the circulation [77]. Fat absorption seems to be fully developed at birth to suit the high fat intake of newborn infants [64]. This seems to be true for preterm infants too, thus suggesting that the relative inefficiency of fat absorption in preterm infants (40-90%) is mostly attributed to immaturity of the intraluminal digestive mechanisms, as described above.

42.4.2 Protein Digestion and Absorption

Although proteins encompass 10-15% of the caloric intake, they are important for somatic growth and synthesis of intracellular structures and enzymes. Adequate protein intake is critical for the premature infant, especially for brain development [79]. The initial step of protein digestion takes place in the stomach, and includes denaturation by gastric acidity and proteolysis mostly into large polypeptides by gastric pepsins. Pepsinogen 1 and 2 are the pro-enzymes of pepsin that are activated in low pH. Proteolysis in the stomach is affected by gastric content and motility and most importantly by gastric acidity. The pH of gastric juice is neutral or slightly acid at birth and decreases within hours. Gastric acid flow doubles within the next two months [80]. Parietal cell activity is noted in the body, antrum and pyloric regions of the fetal stomach as early as 13 weeks [81]. However, although the fetus has the capacity to produce gastric acid from the middle of the second trimester, gastric acid secretion is significantly reduced in preterm infants [82], and increases with growing postnatal and gestational age. Parietal cells disappear from the antrum of the stomach in the third trimester of pregnancy, but this process fails to occur in approximately 20% of the population [81]. Milk entry into the infant's stomach sharply raises gastric pH followed by slower return to lower pH compared to older children [83]. The outflow of pepsin is also diminished in the newborn infant and increases until 3 months of age [80]. Thus, gastric proteolysis is limited in term and especially in preterm infants because of low pepsin levels combined with low gastric acidity. However, gastric proteolysis does not seem to be critical for further digestion and absorption of proteins.

In the duodenum, several proteases act together to digest proteins into amino acids and oligopeptides (di- or tri-peptides). Pancreatic enzymes are secreted as inactive pro-enzymes that are activated by hydrolysis of a peptide bond. Bile salts in the duodenum induce enterokinase release from the microvillus membrane of the absorptive cells. Entrokinase converts trypsinogen to trypsin that in turn activates all the other pancreatic proteases and the release of more trypsinogen. The concentrations of the proteolytic enzymes (e.g., trypsin, chemotrypsin) excreted from the exocrine pancreas only modestly increase during the first hours to months after delivery, and they are fairly efficient in proteolysis from birth on. This is true for premature infants as early as 23 weeks gestation [84]. However, feeding preterm infants with a high-protein diet stimulates increased trypsin secretion into the duodenum. Lower chymotrypsin concentrations are found in infants who are small for gestational age (SGA) [84] suggesting a deleterious effect of intrauterine growth restriction on pancreatic exocrine function, which may limit postnatal catch-up growth. Concerns regarding protease inhibitors in human milk and colostrum that may interfere with the digestion of proteins in the intestine of breastfed babies [85] were disputed by others [86].

Following the digestion by pancreatic proteases, amino acids and oligopeptides are passively absorbed at the brush

border membrane by secondary active transport via sodium-dependent amino acid co-transporters [87]. The low intracellular sodium concentration creates a gradient for sodium entry that drives the absorption of the coupled amino acid. The energy is indirectly provided by the sodium-potassium ATPase pump. There are different classes of amino acids transporters as well as transporters for oligopeptides. There are also peptidases on the brush border membrane, as well as in the cytoplasm of the absorptive cell. In the embryonic period (4 to 8 weeks) the activity of proteases is mainly detected on the luminal surface of the fetal intestine. Later on, villi are formed from the duodenum up to the ileum. After 9 weeks of gestation differentiation of Lieberkuhn crypts can be observed. The activity of proteases is high in the differentiating microvillous zone of the primitive enterocytes [88]. Thus, the peptide transport system, as well as the brush border and cytosolic peptidases are well developed and functional in preterm infants. In addition, preterm and term newborns have increased small intestinal permeability that allows them to absorb intact macromolecules by active pinocytosis [89]. Amniotic fluid proteins are swallowed in utero and food and other proteins are ingested during the neonatal period. These include albumin, beta-lactoglobulin, immunoglobulins (A and G) and other immunologic factors, hormones (chorionic gonadotropin and growth hormone) and even intact lactoferrin of maternal origin.

42.4.3 Carbohydrate Digestion and Absorption

Carbohydrates provide about 40% of the caloric intake of the newborn. Lactose is the major source of carbohydrates in human milk. Lactase activity appears in the differentiating brush border of the fetal small intestine along with other disaccharidases (mainly sucrase) as early as 12 weeks of gestation [88], although in low levels. Lactase activity exhibits relatively higher levels at 37 weeks of gestation [90]. Lactase activity is still decreased during the first weeks of life, and this is reflected by the limited capacity of term and especially preterm infants to digest and absorb lactose in the small intestine [91]. Nevertheless, preterm infants fed lactose-containing milk or formulas grow well and have no diarrhea. The elevation of breath hydrogen in these infants apparently represents a successful adaptation of the colonic microflora that converts malabsorbed lactose to volatile organic acids that are subsequently absorbed [92]. Glucose polymers are polysaccharides that require hydrolysis by amylase. Since pancreatic alpha-amylase levels are low in young infants and increase only later during postnatal life, glucose polymers are either hydrolyzed by salivary alpha-amylase whose activity increases earlier, or by the intestinal brush border enzyme, glucoamylase. Alpha-amylase in breast milk probably also participates in digestion, because it can survive the mild acidity [93] and low pepsin levels in the stomach of newborn babies.

Glucose and other monosaccharide products of hydrolysis are then absorbed from the jejunum and illeum either by active sodium-dependent D-glucose co-transport carrier system (SGLT1) or by the GLUT family of facilitative glucose transporters [94]. The sodium-dependent D-glucose co-transport carrier systems demonstrate early differentiation of a functional heterogeneity in glucose transport capacity along the human fetal small intestine [95]. These brush border co-transport systems develop in the jejunum and ileum of the fetus as early as 17-20 weeks gestation, and can be differentiated not only by their kinetic properties but also by their differences in both substrate and inhibitor specificities [96]. The facilitative glucose transporter isoforms GLUT2 and GLUT5 are also developmentally modulated with highest levels in adult small intestine. By contrast, GLUT1 expression is higher in the fetal small intestine. In adult small intestine, GLUT5 is localized to the luminal brush-border surface of mature enterocytes. Yet, in the fetal small intestine, GLUT5 is localized along the intercellular junctions of the developing villus. Thus, both the expression and localization of GLUT 5 are developmentally regulated. In mature absorptive epithelial cell GLUT5 is localized to the luminal surface [94]. Postnatal glucose absorption in infants is less efficient than in adults, and the kinetics of glucose absorption is related to gestational and postnatal ages, as well as to the diet and exposure to glucocorticoids [97].

Carbohydrates that are not digested and absorbed in the small intestine reach the colon where they are degraded by colonic bacteria. The last step of this degradation is fermentation that results in the formation of short-chain fatty acids, methane, carbon dioxide and hydrogen. These short-chain fatty acids, particularly butyrate [98], are the preferred energy source for the colonic epithelial cells. In the premature infant, colonic fermentation serves as a major important route for lactose carbon absorption (as discussed above) [92]. Developmental aspects of colonic fermentative activity, effects of systemic antibiotic treatment on colonic micro flora, the effects of various fermentation pathways on energy balance, the capacity for absorption of sugars, short-chain fatty acids, and electrolytes by colonic epithelia, and the effects of fermentation products on metabolism and mucosal cells are all important to premature infants especially in relation to colonic disease or surgical resection [92].

42.4.4 Micronutrient Absorption

The absorption of the different micronutrients matures at varying rates during infancy.

42.4.4.1 Water and Electrolytes

Water is absorbed passively following the gradients of sodium and other electrolytes. Stimulation of intestinal sodium ab-

sorption by adding solutes (sugars or amino acids) that are absorbed by sodium-coupled mechanisms increase net fluid absorption [99].

The intestinal epithelium is more susceptible to diarrhea in young infants. Protracted diarrhea of infancy (PDI) describes infants with loose and frequent stools of sufficient severity to require nutritional support, often in the form of parenteral alimentation [100]. The most common cause for PDI is post-infectious diarrhea with failure of the injured gut to recover rapidly. The causes of PDI can be classified into two categories based on the findings of intestinal biopsy: PDI with normal villi and PDI with villus atrophy. The most common cause of protracted diarrhea with villous atrophy is microvillus inclusion disease, an autosomal recessive disorder that is present upon birth with striking secretory diarrhea. Diagnosis is based on typical electron microscopy findings including the diagnostic finding of microvilli inside involutions of the apical membrane [101]. During pregnancy, ultrasounds demonstrate multiple fluid-filled dilated intestinal loops and polyhydramnios. Other causes of congenital diarrhea with villus destruction include tufting enteropathy, autoimmune enteropathy, and IPEX syndrome [100], as well as carbohydrate-deficient glycoprotein syndrome [102], and enterocyte heparin sulfate deficiency [103].

In the category of normal villous PDI, congenital ion transport defects cause secretory diarrhea presenting at birth. The most common congenital ion transport defect is in the chloride-bicarbonate anion exchanger that is located in the distal ileum and colon. This trans-membrane protein belongs to the sulfate transporter family that have three known members in humans, all associated with a distinct genetic disease [104]. Members of the gene family can transport other anions as well (chloride, sulfate, and oxalate) [105]. In these cases of congenital chloride diarrhea, HCO_3^- is not secreted into the gastrointestinal tract lumen, leading to alkalosis. Fecal chloride concentration exceeds the sum of fecal sodium and potassium levels, establishing the diagnosis [104]. Congenital sodium diarrhea, a disorder of the intestinal H^+/Na^+-exchanger located in the small intestine and colon, is characterized by hyponatremia, alkaline diarrhea, and a high concentration of stool sodium [106]. In the other congenital ion transport defects (sodium co-transporters), abnormal reabsorption of sodium is involved, which usually results in hyponatremia [100].

The colon has an important role in absorbing sodium and water from the intestinal lumen. Active absorption of sodium ions can be increased 3-4 fold by the presence of aldosterone [107], suggesting that colonic absorption of sodium is central to maintaining salt and water homeostasis. Colonic mucosa in the fetus has well-developed villi that allows it to be involved in nutrient absorption in contrast to the adult [108]. Thus, in addition to its role in salt and water homeostasis, it can also absorb essential nutrients by active (sodium-coupled) transport of glucose and amino acids that may also compensate for decreased absorption in the developing small intestine.

42.4.4.2 Minerals and Trace Elements

Trace elements and mineral absorption depends on the milieu in which they are presented to the intestine. The bioavailability of iron, calcium and other minerals for absorption is better from human breast milk [109]. Preterm infants may absorb as much as 50% of the iron in breast milk, as opposed to formulas. This is true for other minerals that are more bioavailable for preterm infants in human milk. This does not alter the need to supplement some of these nutrients (mainly calcium and phosphorus) to preterm infants to compensate for their increased demands [110].

Calcium and phosphorus absorption and requirements are further discussed in Chapter 49.

42.4.4.3 Vitamins

Human milk is a good source for most vitamins. In healthy breastfed infants of well-nourished mothers, there is little risk of vitamin deficiencies and the need for vitamin supplementation is rare. The exceptions to this, to avoid deficiencies, is a need for vitamin K supplementation in the immediate newborn period and vitamin D in breastfed infants with dark skin or inadequate sunlight exposure [111, 112]. Most vitamins appear to be absorbed adequately in term and preterm infants.

Fat Soluble Vitamins

Fat soluble vitamins include vitamins A, D, E and K. Vitamins A (retinoids) and E (tocopherols) are two potent antioxidant nutrients that also play a significant role in immune function.

Vitamin D (calciferol) plays a major role in intestinal calcium absorption and bone mineralization [112]. Cholesterol derived precursor uses UV sunlight to convert to previtamin D_3, which is then converted to an inactive form of vitamin D_3. Vitamin D_3 is then hydroxylated in the liver (25-(OH)D) and in the kidneys to make active vitamin D (1,25-$(OH)_2$D). Vitamin D crosses the placenta mainly in the form of 25-(OH)D. The transport is passive or facilitated, with lower values in the fetus, and therefore fetal 25-(OH)D concentrations correlate with those of the mother. Exogenous vitamin D_3 (from animal source), or D_2 (ergocalciferol, synthesized by plants) can also be absorbed in the duodenum and the jejunum, although vitamin D_2 appears to be absorbed to a much lesser extent than vitamin D_3 [113].

Vitamin K intervenes in the synthesis of coagulation factors particularly in prothrombin synthesis. Fat-soluble vitamins are totally dependent on micelles in order to be presented to the brush border membrane. Absorption is also dependent on the presence of bile salts in the small intestine [114]. Ingested carotene and dietary retinyl esters are converted to free retinol in the proximal small intestine by pancreatic hydrolases and are the dietary sources for vitamin A. Retinol absorption

into the intestinal cells is facilitated by retinol binding protein, RBP II, which is found almost exclusively in absorptive cells. In the enterocyte, fat soluble vitamins are re-esterified, and incorporated into the developing chylomicron. Chylomicrons travel through the lymphatic system and then enter the bloodstream. Some of the vitamins use protein carriers for transport in the bloodstream (retinol binding protein, RBP I for carrying retinol to target tissue and D-binding protein to take hydroxylated vitamin D from the liver to the kidney for further hydroxylation). Excess is stored in liver and adipose tissue, and released as needed by the body. Risk of toxicity may be relevant for high doses of vitamin D, A and E and is less relevant for vitamin K. Disorders affecting fat absorption, such as short bowel syndrome, cholestasis and other diseases associated with bile acid deficiency may cause fat-soluble vitamin deficiency. Vitamin K2 (menaquinones) is synthesized by bacteria in the large intestine. Because the transfer of vitamin K across the placenta during pregnancy is poor and the sterile gut of the infant is unable to produce menaquinones, newborn babies are routinely given supplements of vitamin K [114].

Water Soluble Vitamins

Water-soluble vitamins are required as enzyme cofactors in a wide variety of metabolic reactions. Riboflavin (vitamin B2), niacin, and vitamin C (ascorbic acid) are essential for oxidation-reduction reactions. Thiamine (vitamin B1) and biotin are involved in macronutrient metabolism. Folate, vitamin B12, pyridoxine (vitamin B6), and riboflavin play important roles in the regulation of S-adenosylmethionine production and DNA synthesis. Each of these water-soluble vitamins requires its own membrane transport process for absorption across the enterocyte. Most of the water-soluble vitamins are absorbed from the proximal small intestine [114, 115]. Folate, biotin, and riboflavin can be transported across colonic epithelial cells as well, although the clinical significance of this is uncertain [115]. Riboflavin is light sensitive and is rapidly photodegraded. Phototherapy is a possible cause for riboflavin deficiency in neonates [116]. This may affect antioxidant mechanisms in preterm infants. The absorption of vitamin B12 (cobalamin) is complex and unique in requiring multiple steps from the stomach to the ileum and the involvement of at least four different binding proteins [115]. In the gastric acidic environment it is released from the food to form complexes with R-binders that are proteins found in the saliva, gastric juice, bile and milk and have high affinity for vitamin B12. At the alkaline environment of the duodenum pancreatic proteases degrade R-binders allowing vitamin B12 to bind to the intrinsic factor that is produced by the parietal cells of the stomach. The complex of vitamin B12 and intrinsic factor is absorbed intact in the distal ileum. Inside the ileal mucosal cells, vitamin B12 is released from the intrinsic factor and binds to a specific transport protein, transcobalamine II, to be delivered to the liver via the circulation. It is excreted mainly in the bile, but has a very long half-life due to very effective enterohepatic circulation. It is actively transported across the placenta so that newborns have concentrations twice as high as mothers [114]. Hepatic stores correlate with the duration of pregnancy and are thus large in full-term newborns, but lower in preterm infants. Clinical manifestations of vitamin B12 deficiency appear only in late infancy, because of the hepatic stores and the long half-life [114]. There are several congenital defects that can affect the complex absorption of vitamin B12, but they are rare compared to dietary deficiency that is not evident in the neonatal period.

42.5 Host Defense

Colonization of the gastrointestinal tract of newborn infants starts immediately after birth and occurs within a few days. Initially, the type of delivery (passage through the birth canal versus cesarean section) and the type of diet (breast milk versus formula feeding) affect the colonization pattern [117]. Other environmental factors such as developed versus developing countries and use of antibiotics in the neonatal period may also affect the microflora composition [118]. The immune system of preterm infants is immature. Thus, preterm infants are prone to a delayed gastrointestinal colonization, reduced microbial diversity in the bowel, acquisition of antibiotic-resistant strains, loss of strains associated with antibiotic treatment, and increased intestinal bacterial translocation [119]. The gut of extremely low birthweight infants is colonized by a paucity of bacterial species [120]. This can favor the overgrowth of microorganisms such as *Enterobacteriaceae* and *coagulase-negative staphylococci*, which are the most frequent pathogens of nosocomial infection in neonatal intensive care units [121]. These factors also make the preterm infant more susceptible to antibiotic-resistant infections, systemic inflammatory response syndrome and necrotizing enterocolitis (NEC) [122]. Breast milk and reduction of antibiotic exposure have been found to be important in increasing fecal microbial diversity in these premature infants [120]. Microbes of the intestinal tract serve several roles, including nutrition, growth, and maintenance of function and development of the immune system [123].

The gut is in continuity with the environment and thus exposed to bacteria and antigens. The gastrointestinal tract presents the largest surface area in the body exposed to microbes and other antigens. On the other hand, it needs to allow the entrance of nutrients and other beneficial molecules. Host defenses include non-specific and specific components. The innate immune system responds in a non-specific way, and the adaptive immune system responds specifically by humoral and cellular components that specifically react to particular antigens.

Defense factors in human milk include antimicrobial agents (secretory IgA, lactoferrin, lysozyme, glycoconjugates,

oligosaccharides, and digestive products of milk lipids), anti-inflammatory factors (antioxidants, epithelial growth factors, cellular protective agents, and enzymes that degrade mediators of inflammation), immunomodulators (nucleotides, cytokines, and anti-idiotypic antibodies), and leukocytes (neutrophils, macrophages, and lymphocytes). The presence and function of immunomodulatory and anti-inflammatory factors present in human milk help protec the mature newborn as well as the premature infant against infections. Some of these factors present in human milk may actively modulate the synthesis and maturation of the recipient immune system. This complex interactive system of bioactive substances in human milk seems to be designed to operate in a complementary manner with other non-inflammatory mechanisms in order to resist digestion of these factors in the recipient gastrointestinal tract, and to supplement the infant with developmentally delayed immune factors. This is consistent with the theory of the evolution of the mammary gland from the immune system [124]. In addition to the well-known passive protection against infections during lactation (mainly via secretory IgA antibodies, and also via several other factors like bactericidal lactoferrin), breastfeeding may also actively stimulate the immune system of the infant (via anti-idiotypic antibodies, cytokines, growth factors, T and B lymphocytes and macrophages) with other long-term positive effects (e.g. better immunological response to infections and vaccines) [125, 126].

Gastric acidity and pancreato-biliary secretions also decrease the load of viable microorganisms and intact dietary protein antigens. These defenses are all decreased in the newborn, especially the preterm infant, as described above. The use of H2 blocking agents or proton pump inhibitors that further decrease gastric acidity contribute to a decreased defense and may result in higher rates of infections [127].

Mechanical factors that appear early in gestation are also involved in the a host defense by creating a physical barrier of mucous secretion and by gastric emptying and intestinal peristalsis that prevent stasis and bacterial overgrowth. In preterm infants gastric emptying, MMCs and peristalsis may be delayed, as discussed above. Intestinal mucus secreted into the lumen from storage vacuoles in the goblet cells, found throughout the small and large intestine, plays a significant role in intestinal defense. It contains mucins, glycoproteins, immunoglobulins, glycolipids and albumin that form a slippery gel over the intestinal surface that enhances forward propulsion. Mucous gel can also trap large foreign antigenic molecules thus preventing their diffusion into the gut wall. Mucin secretion changes in amount and composition during development and maturation of the newborn infant and in response to stress and hypoxia [128]. Microvilli also constitute a significant barrier because of their size and negative charge that prevent large macromolecules from penetrating.

The intestinal single-cell layer of columnar epithelial cells is present by the end of the first trimester. It is the cellular site of innate immunity of the intestine separating the host from the intestinal lumen. It is arranged in crypts and villi. Stem cells at the base of the crypts proliferate and differentiate into enterocytes that migrate to the villus tip. They eventually slough into the lumen by physiologic apoptosis (anoikis), thus allowing reconstitution of the epithelium every 5 days [129]. This renewal mechanism serves as a defense mechanism against epithelial injury. Epithelial integrity is further protected by intracellular contacts of membrane proteins and cytoskeletal anchor proteins that form the apical junction complexes (AJCs) that are the basis for the series of tight junctions between the cells. The AJCs and their cytoskeletal connections are dynamic structures that closely regulate the flow of fluids, electrolytes ions and even small molecules between the cells but prevent passage of larger molecules [130]. Epithelial cells also regulate transcellular permeability to ions and small molecules through alterations in the expression of selective membrane ion channels and pores. Control of water and chloride secretion through the channels can result in secretory diarrhea that can flush away toxins and pathogens from the lumen [131].

In addition to mechanical barriers and mucin secretion, the gut elaborates chemical defenses secreted by the absorptive enterocytes and Paneth cells. Paneth cells are specialized secretory enterocytes located at the base of the small intestinal crypts, where they can control microbial populations and protect neighboring stem cells. Paneth cells secrete lysozyme, phospholipase A2, and antimicrobial peptides. Antimicrobial peptides are divided into defensins (alpha and beta), which are the predominant class, and cathelicidins. These small cationic peptides are able to insert into the membranes of a broad range of microbes (including bacteria, fungi and enveloped viruses), where they play an active role in oxygen-independent killing. It is possible that low levels of Paneth cell defensins, characteristic of normal intestinal development, may predispose preterm infants to necrotizing enterocolitis (NEC) [132].

An important nonconstitutive defense component of the gut innate immunity is the carefully programmed and regulated inflammatory response that is activated when potentially injurious stimuli cross the barrier of the intestinal epithelium. This activated inflammatory response induces recruitment of leukocytes (polymorphnuclear and macrophages) as well as complement, defensins and cytokines to aid in defense. Multiple endogenous or exogenous signals can start the inflammatory process by inducing the local release of soluble inflammatory mediators and chemotactic agents that increase vascular permeability and attract inflammatory cells, resulting in edema and inflammation [133].

The human genome contains evolutionary ancient components of innate immunity that are transmitted in the germ cells without exposure to the microbes, and encode at least 10 toll-like receptors (TLRs). TLRs are trans-membrane receptors that recognize pathogen-associated molecular patterns (PAMPs) or microbial associated molecule pattern (MAMPs) that are found only on microbes, like lipopolysaccharides, peptidoglycans and lipoproteins. The binding of MAMPs to TLRs or intracytoplasmic NOD proteins results in the activation of cytoplasmic signaling circuits. These pathways include the

classic nuclear factor kappa-B (NF-kappa-B), the mitogen-activated protein kinase (MAPK), and the interferon regulatory factor (IRF) pathways. During the initial events of bacterial perception by the intestinal epithelial cells all these three pathways are activated within minutes, leading to nuclear translocation of transcription factors and transcriptional activation of a battery of effector molecules [134]. This results in induction of the expression of enzymes important for bacterial killing and wound healing, as well as antibacterial peptides, cytokines, adhesion molecules, chemotactic messengers and antiapoptotic proteins [135]. The sterile fetal gut is naïve to MAMPs in utero. Within the first days the neonatal gut is challenged by multiple MAMPs as the luminal flora is introduced. TLRs are expressed at the basolateral aspects of fetal intestinal crypts as early as 20 weeks of gestation [136].

Membranous or microfold cells, commonly referred to as M cells, are specialized epithelial cells of the gut-associated lymphoid tissues (GALT) that play a major role in the intestinal immune system by delivering luminal antigens to the underlying immune cells. M cells in the intestine lack well-developed microvilli and allow macromolecular transport, as opposed to the absorptive enterocytes with their developed villi. M cells are present only in follicles overlying lymphoid tissue to which they can immediately present foreign antigens and microorganisms that they transport as macromolecules [137].

Subepithelial cells include follicular dentritic cells that are located in the lymphoid follicles and are important in nonphagocytic presentation of antigens to T-cells as well as B-cells. Peyer's patches are aggregates of lymphoid tissue that are present by 19 weeks of gestation, but become more prominent in the jejunum and ileum between 24-40 weeks. M cells occur in follicle-associated epithelium over areas of Peyer's patches [137]. Mast cells bind immunoglobulin E and subsequently release histamine and serotonin that stimulate mucus production by adjacent goblet cells, increase enterocyte permeability, chemotaxis of granulocytes, contraction of smooth muscle cells and lymphocyte function.

The immune system of host defense is composed of cellular and humoral components. T and B lymphocytes are produced as early as 12 weeks gestation, and are present with macrophages in the fetal intestine by 20 weeks gestation. Interspersed between the intestinal epithelial enterocytes are blood-derived intraepithelial lymphocytes (IELs) that are immune components of the host defense. They are located in the basolateral side of the epithelial layer where cells are exposed to various food and microbial antigens. They are cytotoxic and capable of producing cytokines in order to protect the host from invasion of microorganisms through the gut. Immature human enterocytes react with excessive pro-inflammatory cytokine production after inflammatory stimulation in premature infants exposed to initial colonizing bacteria and this may lead to necrotizing enterocolitis (NEC) [138]. On the other hand antigenic stimulation of the lymphoid tissues cannot be demonstrated before 46 weeks of postmenstrual age, which poses a challenge for preterm infants whose gut can absorb macromolecules directly by pinocytosis. Secretory IgA is present by 22 weeks of gestation, although in small amounts, because the newborn intestine has few IgA-producing plasma cells. In addition preterm infants are not able to form antibodies in response to exogenous food proteins.

Enteral nutrients and food supplements may also contribute to host defense. These include amino acids (glutamine and arginine), nucleotides, long-chain fatty acids, probiotics and prebiotics.

Glutamine contributes to maintenance of small intestinal inter-epithelial junctional integrity [139], intestinal epithelial cells growth and proliferation [140], inflammatory responses and active healing. Glutamine deficient diet increased bacterial translocation *in vitro* by altering intestinal tight junctions [139, 141], and glutamine supplementation decreased the incidence of sepsis in very-low-birth-weight infants [142]. Glutamine and glutamic acid together with taurine are the only free amino acids whose concentrations are increased in human milk during the first 3 months of lactation [143].

Arginine also plays an important role in immune function. Low plasma arginine levels in preterm infants were associated with increased risk for subsequent NEC [144], and its supplementation may prevent NEC [145].

Exogenous nucleotides influence cell proliferation, differentiation and apoptosis in the crypt and villus epithelium of fetal and neonatal small intestine [146]. Nucleotides in infant formulas also enhance humoral antibody responses to immunizations [147], and have a favorable effect on the lipid profile of preterm infants [148].

Long-chain polyunsaturated fatty acids (LCPUFA), Arachidonic Acid (AA) and Docosahexaenoic Acid (DHA), which are metabolites of the essential n-3 and n-6 fatty acids are known to modulate inflammation. Supplementation of preterm infants' food with LC-PUFA may reduce the risk of NEC [149, 150] and also has beneficial effects on the developing visual system and cognitive development during the first year of life [151].

Probiotic bacteria have been shown to reinforce the different lines of gut defense, which are immune exclusion, immune elimination, and immune regulation. They also stimulate nonspecific host resistance to microbial pathogens, thereby aiding in pathogen eradication. Documented effects include the alleviation of intestinal inflammation, normalization of gut mucosal dysfunction, and down-regulation of hypersensitivity reactions. Thus, modification of gut microflora by probiotic therapy may be suitable for clinical conditions associated with gut-barrier dysfunction and inflammatory response [152]. Consequently, probiotics are used in the treatment of acute diarrhea in children [153]. Probiotics modify the fecal flora, can reduce the overgrowth of pathogens in the bowel of preterm infants, and thus contribute to the reduction of the incidence of nosocomial infections in neonatal intensive care units [154]. *Bifidobacterium* species are the most common bacteria in human milk fed infants. Infants consuming

Bifidobacterium breve supplemented feedings had higher rates of fecal bifidobacteria colonization with some clinical advantages including decreased gastric aspirates and improved weight gain and feeding tolerance with no identified side effects [155]. Significant reduction in the incidence of NEC and NEC-associated fatalities was shown by Hoyos et al in preterm infants given daily doses of live *L. acidophilus* and *B. infantis* with no documented complications [156]. Dani et al found that the incidence of NEC (Bell stage ≥ 2) was lower in preterm infants supplemented with *Lactobacillus* GG (LGG) [154]. Lin et al have shown that supplementation of human milk [157] or formula feedings [158], with a mixture of *Lactobacillus acidophilus* and *Bifidobacterium infantis* [157] or *bifidum* [158], significantly reduced the combined incidence of NEC or death in very-low-birth-weight (VLBW) infants. There was a significant effect on NEC (Bell stage ≥ 2) itself as well. Bin-Nun et al showed that a probiotic mixture (*Bifidobacterium infantis*, *Streptococcus thermophilus*, and *Bifidobacterium bifidus*) had a significant protective effect on NEC of any Bell stage in VLBW infants, even when Bell stage ≥ 2 NEC was only considered [159]. Recent meta-analysis suggests that probiotics could significantly reduce the risk of NEC in VLBW preterm infants born after less than 34 weeks gestation [160], yet current available data are not sufficient to define the most suitable probiotic product or to settle the issue of the safety [161] of routine use of probiotics in young premature infants with immature defense systems [162].

Another approach is to use prebiotic supplementation. Prebiotics are defined as non-digestible substances that, when ingested, selectively promote the growth and establishment of beneficial probiotic-like bacteria normally present in the gut [163]. There are few studies on the use of oligosaccharide prebiotic products in preterm infants that have been shown to increase the counts of fecal bifidobacteria, reduce stool pH, reduce stool viscosity, accelerate gastrointestinal transport and improve mineral absorption [164–167] with no negative impact on weight gain. More randomized trials in preterm infants are needed to support their potential beneficial effects on feeding tolerance and on the reduction of the incidence of NEC and hospital acquired infections [166, 168]. Currently there is not enough data available to recommend the general use of prebiotics or probiotics in preterm infants [162, 163].

Hormones and Gastrointestinal Function

Flavia Prodam, Simonetta Bellone, Silvia Savastio, Arianna Busti, Carla Guidi, Alice Monzani and Gianni Bona

43.1 Introduction

Development is a continuous process. Nutrition, environment and stress modulate development through gene expression in an epigenetic manner. Prenatal and perinatal nutrition can be imprinting factors and turn on different genes that provide different phenotypes, such as the thrifty phenotype [1]. Indeed, the nutritional support of gastrointestinal growth and function is an important tool in the clinical care of newborn babies, in particular preterm neonates. Before birth, although amniotic fluid is not the main source of nutrition for the fetus, it contributes up to 15% of fetal nutritional requirements and plays a key role in its development and maturation [2, 3]. Accordingly, by 20 weeks of gestation, the anatomy of the fetal gut resembles that of the term neonate. However, the process of intestinal absorption is only partially mature before 26 weeks of gestation: gastro-entero-pancreatic peptides are secreted at a basal rate and can be completely stimulated or inhibited after delivery, in particular through contact with nutrients [4, 5]. At the age of 2 years, the intestine is fully functional [6]. Gut hormones, peptides, and growth factors clearly have a role in gut growth after birth and directly and indirectly mediate the trophic actions of enteral nutrition in a manner that is still incompletely understood [5]. By contrast, hormones and growth factors, which are present in breast milk, also seem to exert trophic activities on gut development and immune function. The interplay is complex [1, 3]. Little is known about the development of these regulatory systems in the human neonate and, as a consequence, premature infants experience significant morbidity and mortality associated with feeding problems [6]. Present clinical nutritional support for preterm babies consists of enteral and parenteral nutrition but both have associated complications [6, 7]. Since enteral feeding is important for gut development, acute or chronic gastrointestinal diseases could be caused by feeding with formula rather than human breast milk. Formula milks contain higher amounts of proteins and lack many endogenous hormones and growth factors [5, 6, 8]. A better understanding of factors linked to gastrointestinal function and energy metabolism could result in improved strategies for supporting nutrition of preterm newborns as well as their later development.

The aim of this chapter is to review the state of knowledge about gut peptide secretion during the neonatal period. It has to be emphasized that much information remains anecdotal and conflicting, probably due to small sample sizes, various methods of measurements or distribution of subjects.

43.2 Etiology, Pathogenesis and Clinical Aspects: Gut Peptides

In recent years, many peptides produced by the gut have been discovered that are closely involved in the development of gut function as well in the acute and chronic regulation of weight and energy balance. They are also affected by nutrient ingestion and could influence pancreatic secretion and beta-cell proliferation and survival. There is considerable data about the relationship between gut peptides and obesity and the development of type 2 diabetes during adulthood. However, investigations of their role during the neonatal period are ongoing.

43.2.1 Peptides from Proglucagon

43.2.1.1 Glucagon-like Peptide 1 (GLP-1)

GLP-1 is a peptide of 30 amino acids expressed and secreted by endocrine L cells of intestinal mucosa in the ileum and colon. GLP-1 derives from the same precursor as glucagon. Proglucagon is also expressed in the brain, in particular in the arcuate and paraventicular nuclei. Three hormonal products,

GLP-1, GLP-2 and oxyntomodulin (OXM) are derived simultaneously from the processing of proglucagon by neurons. In the gut, truncated peptides of proglucagon (GLP-1 7-36amide or GLP1 7-37) are the active forms, while the full-length native GLP1 is inactive [9]. Almost all secreted GLP-1 from L cells is amidated resulting in improved stability. Only 10-15% of the secreted GLP-1 is intact when it reaches the systemic circulation. This rapid initial whole body clearance is due to metabolism in the liver and to the activity of DPP-IV, which is expressed by enterocytes and by endothelial cells of capillaries of the lamina propria [9].

GLP-1 has several actions, including increasing insulin and suppressing glucagon postprandial secretion, thus modulating the pancreatic glucose-response [10, 11]. The amplification of insulin secretion in response to glucose levels by gut hormones has been termed the incretin effect [9].

GLP-1 levels have been shown to be modulated by ingested macronutrients through direct activation of secretion by L cells, probably by an interaction with microvilli [9]. The meal size and composition seem to be key factors for GLP-1 secretion in adulthood, where there is a correlation with gastric emptying. Small meals, particularly when nutrients were rapidly absorbed, did not result in a measurable secretion of GLP-1 but did stimulate large amounts of glucose-dependent insulinotropic polypeptide (GIP). By contrast, large meals containing more complex nutrients particularly lipids, were rapidly followed by high GLP-1 secretion [9, 12].

GLP-1 plays a role in mediating appetite and feeding behavior. A reduction in hunger coupled with the sensation of fullness, has been reported after its administration [13]. Consistent with animal studies, in humans GLP-1 induces a mild but significant dose-dependent inhibition of food intake in both lean and obese subjects as well as in patients with type 2 diabetes [14]. A role for GLP-1 in the development of gut function was hypothesized because of its incretin action and its regulation by nutrients.

There are limited studies of GLP-1 in relation to the developing fetus and gut maturation from prenatal to postnatal life. GLP-1 has been implicated in the regulation of pancreatic beta-cell mass during the neonatal period [9, 15]. Preterm and term neonates also have higher fasting and post-feeding GLP-1 levels, probably because of immaturity of dipeptidyl peptidase-IV (DPP-IV, which degrades GLP-1) or a reduced glomerular filtration rate. Increased activity of GLP-1 could also regulate entero-endocrine systems by increasing beta-cell mass and regeneration. However, it is not known whether increased GLP-1 levels are also derived from a higher gut or pancreatic production rate [16]. GLP-1 levels during feeds have recently been shown to be higher in preterm neonates than in older children or adults without being linked to hypoglycemic episodes. Most infants of this study were fed by nasogastric tube, suggesting direct stimulation of enteric pathways without activation of cephalic vagal tone [7]. It has been suggested that GLP-1 has a key ontogenic role in the regulation of the immature gut [7]. There are few data for other populations, in particular small for gestation age (SGA) subjects who are at a higher risk of developing glucose intolerance or diabetes mellitus, although a preliminary study involving adults born SGA described fasting and postprandial GLP-1 levels similar to healthy controls [17]. No studies have measured GLP-1 secretion in SGA or AGA subjects at birth or during the first two years of life.

43.2.1.2 Glucagon-like Peptide 2 (GLP-2)

GLP-2 is a 33 amino acid peptide also produced by the endocrine L cells by post-translational processing of proglucagon and secreted with GLP-1 in response to food ingestion [9]. It is also produced in the brain [18]. It is rapidly cleaved by DPP-IV with a half-life of 7 minutes, which is longer than that of GLP-1 [7]. It binds and activates its own receptor, the GLP-2 receptor, which is homologous to those of GLP-1, GIP, and glucagon [5, 7]. Like GLP-1, it is also modulated by ingested macronutrients, namely carbohydrates and lipids [19] and short chain fatty acids [5]. In adults, after an oral feed, GLP-2 secretion shows a biphasic increase with a first peak within 15 minutes and a second one after 1 hour, suggesting not only a direct stimulation by nutrients but also the involvement of other factors, in particular GIP and vagus nerve [5, 18].

In contrast to GLP-1, the role of GLP-2 in the regulation of feeding and during fasting is unclear. There is no evidence that the systemic injection of GLP-2 affects food intake in animals. However, the intracerebroventricular administration of the peptide suppresses food intake in rodents in a similar fashion to GLP-1 [20]. In humans, no variations in feeding behavior or gastric emptying have been observed after its administration [21].

Unlike GLP-1, GLP-2 is mainly a trophic peptide of intestinal mucosa and seems to slow gastric motility during fasting [5, 7]. Its administration inhibits gastric secretion [5]. GLP-2 increases gut epithelial absorptive capacity and mucosal growth by acting both on endocrine pathways and enteric neurons [7, 18, 22]. Several studies have suggested that GLP-2 is involved in controlling the absorptive capacity of the proximal bowel. Thus, following gut resection in both animals and humans, the residual bowel secretes higher amounts of GLP-2 after feeding , suggesting a process of adaptation [22]. Dietary carbohydrates stimulate the production of short chain fatty acids and it has been suggested that their malabsorption may trigger increased GLP-2 secretion [5, 23]. GLP-2 has been shown to also act on gut barrier functions by reducing bowel permeability to macromolecules, decreasing bacterial translocation and suppressing the local expression of proinflammatory cytokines [5, 15, 18, 22].

A trophic role for GLP-2 in the development and maturation of gastrointestinal function has been investigated, although its specific functions remain largely unknown. It is active in the immature bowel, with a peak of secretion during the late weaning period [5, 18]. However, studies of mutant mice have demonstrated that GLP-2 is not necessary for

bowel development during fetal life [24], despite its secretion mechanism being established by 24 weeks of gestation in humans [25]. In addition, GLP-2 levels in utero would be expected to be lower respect than during postnatal life because of higher levels and DPP-IV activity in the placenta [26].

Both fasting and postprandial levels of GLP-2 are higher in neonates when compared to older children or adults. As with GLP-1, these findings could be due to either an increase in production and/or a decrease in metabolism by DPP-IV immaturity or lower glomerular filtration [7, 25]. Increased GLP-2 levels in preterm babies may stimulate gut development. It is notable that normal infants aged 48 weeks have lower postprandial GLP-2 levels compared with delivery at 40 weeks. These data suggest that gestational age may influence GLP-2 secretion and that its peak of secretion could correspond to the time of the most rapid growth of gut, which ranges between 30 and 40 weeks of gestational age [7]. However, unlike animals and adults, infants with intestinal dysfunction or residual small bowel with intact colon do not appear able to produce GLP-2 in response to stimulation by feeding [27]. The reason of these discordant findings remains unexplained. The lack of GLP-2 secretion could be due to resection of the L cell bearing ileum as well as an age-related inability to produce an appropriate response or to ischemia that may alter GLP-2 secretion in the remnant gut [27]. These observations suggest that stimulation of GLP-2 secretion or GLP-2 supplementation may have therapeutic roles for infant gut dysfunction or for preterm newborns and further studies to address the ontogeny of the GLP-2 axis are needed.

43.2.1.3 Oxyntomodulin (OXM)

OXM is a 37 amino acid peptide derived from post-translational processing of the tissue-specific proglucagon molecule in intestinal cells, in particular in L cells in the distal portion of small bowel [16, 28]. OXM co-localizes with GLP-1 and Peptide YY (PYY) expression and secretion [16, 28]. Limited data are available about a possible feedback system among these peptides in adults as well as in neonates. OXM is also produced in the brain [29]. Like GLP-1 and GLP-2, it is inactivated in large amounts by DPP-IV [30]. The only known receptor for OXM is the same as for GLP-1, but the existence of other unknown receptor subtypes has been suggested [16, 30].

Similarly to GLP-1, OXM is released into the circulation after food ingestion in proportion to the caloric intake [29]. It has a lower incretin effect than GLP-1 [16, 30]. OXM also acts as an anorectic peptide [16, 28, 30]. Its administration induces a prompt decrease in the sensation of hunger, food intake and gastric emptying [31, 32]. However, the mechanisms of action for OXM have not been fully investigated. The reduction in energy intake after OXM administration is followed by weight reduction in both animals and humans [33]. This effect is not only due to the OXM anorectic action but also to an increase in energy expenditure [30]. OXM levels also increase after gastric bypass, in a similar fashion to GLP-1 [34]. No studies have compared activities of OXM with those of GLP-2.

Although the role of OXM is intriguing, no studies have been performed during the neonatal period or childhood. This proglucagon-derived peptide, which shares both effects of GLP-1 and GLP-2, could be a good marker of nutritional status and gut development in infants [35].

43.2.2 Glucose-Dependent Insulinotropic Polypeptide (GIP)

GIP is a peptide of 42 amino acids, which is synthesized by K cells located mainly in the proximal small intestine (duodenum and jejunum) [9]. GIP is frequently found to be colocalized with GLP-1, but rarely with PYY. As with other incretin hormones, GIP is cleaved and inactivated by DPP-IV with a half life of approximately of 5 minutes [36, 37]. GIP receptors are expressed in several tissues, including alpha- and beta-cells, stomach, adipose tissue, pituitary, heart, and brain [36, 37].

GIP secretion rises 15 minutes after the ingestion mainly of glucose and fats [36] and is also inhibited by glucagon [36, 38]. GIP can be considered as another incretin hormone [9]. However, it is clear that GIP alone cannot account for the full incretin effect normally associated with a mixed meal, with the main effect exerted by GLP-1 [9, 39]. GIP, like GLP-1 is also able to promote beta-cell neogenesis, proliferation and differentiation [36].

The administration of GIP improves glucose tolerance and insulin sensitivity in animals [40, 41]. However, GIP receptor knockout mice subjected to a high fat diet do not gain weight and have a preserved insulin sensitivity [42]. The marked weight decrease after gastric bypass seems to depend on surgical ablation of duodenal GIP secretion [43], suggesting it acts rather as an obesiogenic agent than having an anti-obesity or incretin hormone role [44–46].

There are few data relating to the major incretin hormones, in particular GLP-1. Studies on GIP in children investigated the integrity of its response during early life. In both term and preterm neonates, the enteroinsular axis has a functional role, responding to glucose with an increased plasma GIP concentration, which partially and progressively contributes to an enhanced insulin response to enterally infused glucose as well as to oral feeding [17]. One preliminary study has shown that GIP levels are lower in both term and preterm neonates in cord blood at birth than in adults. Moreover, its bloodstream concentration increases 2 hours after birth [47]. Basal GIP levels increased progressively when babies were fed orally and also increased after meals by the 24th day of life [48]. SGA and AGA babies have similar fasting and post-prandial GIP levels [49].

The infants of diabetic mothers and large for gestational age (LGA) newborn babies have a more rapid insulin response

to oral glucose without differences in GIP levels when compared to AGA controls [50]. Moreover, there is a higher GIP/insulin ratio in the amniotic fluid of diabetic pregnant women who delivered overweight infants compared with non-diabetic pregnant women or those who delivered normal weight babies [51]. These data suggest that the role of GIP on fat accrual is precocious and linked to glucose metabolism.

43.2.3 Peptide YY (PYY)3-36

PYY, a member of the NPY family, is a 36 amino acid peptide that is secreted during feeding from the L cells of the small and large bowel. It is released into the circulation in two forms, PYY1-36 and PYY3-36, which is most abundant in the bloodstream [11, 16, 51]. PYY has been defined as an orexigenic peptide. In particular PYY3-36 shows anorectic effects after both peripheral and central administration acting on Y2 receptor at the hypothalamic level [51, 52].

Plasma PYY3-36 levels increase after a meal [52]. In humans the administration of PYY3-36 is followed by a 30% reduction of ingested nutrients and is coupled with fullness sensation [53] and nausea at higher doses [9]. PYY is also involved in regulating glucose homeostasis. Unlike other gut peptides, it directly inhibits glucose-mediated insulin secretion [54]. These effects are associated with an improved insulin action on glucose disposal independent of effects on food intake and weight (55). PYY also directly promotes higher fat combustion in animals [56]. Fasting plasma PYY3-36 levels are lower in obese than in lean subjects [16], suggesting an involvement in the long-term control of weight.

There are increasing data relating to the role of PYY in neonates [57, 58]. In newborn babies, PYY3-36 levels seem to account for almost half the total circulating PYY [59, 60]. It correlates negatively with gestational age and anthropometric measures and is higher in the cord blood of preterm than full-term babies or adults, possibly to compensate for poor growth [59–61]. PYY also increases after enteral feeding with formula milk in preterm babies affected by necrotizing enterocolitis [61, 62]. Its fasting concentration decreases in 9 month old infants [63], suggesting that a postnatal surge is a feature of early adaptation to extrauterine life with possible effects on energy homeostasis and on the gut, including absorptive, trophic and proliferative actions [59, 60, 63]. More data are needed to confirm this hypothesis.

43.2.4 Peptides from Preproghrelin

43.2.4.1 Acylated (AG) and Unacylated (UAG) Ghrelin

Ghrelin is a 28 amino acid peptide, recently isolated from the stomach, but also expressed by other tissues such as pancreas, testes, placenta, pituitary and hypothalamus [64]. Ghrelin has been identified as an endogenous ligand of the orphan GH Secretagogue (GHS)-receptor type 1a [65, 66]. It circulates in blood in two forms, acylated (AG) and unacylated ghrelin (UAG) [64, 65]. The acyl group which binds ghrelin at the serine-3 residue, seems to be essential for the binding to GHSR1a and the resulting neuroendocrine functions, namely GH secretion [64, 65]. UAG, which is devoid of the acyl group, represents the most abundant circulating form [67, 68]. UAG is biologically active, although it does not have direct neuroendocrine actions [64, 65, 69] suggesting the existence of some GHS-R subtypes [64, 68, 70]. The mechanism of acylation of the preproghrelin or UAG is largely unknown although the acyltransferase that octanoylates ghrelin has recently been identified [71].

AG was identified first followed by UAG, then ghrelin was found to be involved in the regulation of food intake and energy expenditure, with AG the most potent peripheral orexigenic hormone known to date [64, 68, 70]. In animals and humans, AG has been shown to induce appetite and food intake differently to other anorectic gut peptides [68]. Despite these clear orexigenic effects of AG, the actual physiological role of UAG in the regulation of appetite is still a matter of debate [72]. Both forms of ghrelin also influence energy metabolism at the periphery, most likely influencing fat oxidation [73, 74]. Reduced cellular fat oxidation and promotion of adipogenesis both contribute to an increase in fat mass induced by AG and UAG [68, 75, 76].

Consistent with its effects on food intake and its involvement in energy balance, circulating ghrelin levels are negatively associated with body mass index in humans [68, 77, 78]. Several studies indicate that ghrelin hyposecretion in essential obesity is a functional impairment in response to body weight alteration [79]. Roux-en-Y gastric bypass has been shown to be associated with altered glucose kinetics and glucoregulatory hormone secretion likely secondary to the anatomic rearrangement of the foregut, with increased PYY and GLP-1 concentrations and decreased ghrelin levels [80, 81].

The majority of the data comes from studies that have exclusively analyzed total ghrelin levels. Recent findings have also shown that UAG is decreased in obesity, while there are no data for AG [82–86]. Ghrelin is implicated in the regulation of glucose homeostasis by modulating insulin secretion and action as described previously for other gut peptides with incretin action [64, 68]. During childhood, adolescence and adulthood, insulin modulates ghrelin levels through inhibition [64, 68, 87]. Ghrelin secretion is also affected by nutrients, namely carbohydrates, whereas the role of fats and proteins is not completely understood [64, 68, 88]. It is however noteworthy that the administration of mixed meals in children does not inhibit total ghrelin levels unlike adults, suggesting a modulation by age [64, 68, 89].

Ghrelin regulation and secretion during the fetal and neonatal periods is not fully understood yet but has been intensively investigated in the last seven years. Ghrelin is produced during fetal life, starting at 20 weeks post-conception and increases during the first years [86, 90–93]. These ghrelin

levels are directly produced by the fetus. Arterial and venous concentrations are similar and its expression in the placenta is almost absent during the third trimester [83, 94]. SGA newborns show higher ghrelin levels than AGA or LGA neonates [45, 86, 95]. Moreover, lower cord blood ghrelin levels are associated with slower weight gain from birth to 3 and 12 months of age, at least in breast fed infants [96, 97]; this evidence, however, does not definitely rule out a role of ghrelin in the control of somatotroph secretion but clearly suggests an involvement in both short-and long-term energy balance [94, 97]. Moreover, preterm AGA newborns have higher total ghrelin levels at birth [83, 94, 98, 99]. It is still not known whether ghrelin levels at birth in preterm neonates are independent or determined by gender, body weight and type of delivery [94]. What is clear is that ghrelin levels increase between birth and the fourth day of life and negatively correlate with weight and anthropometric parameters at that time [86, 94]. Ghrelin secretion is refractory to feeding in preterm AGA neonates during the first days of life, suggesting that it could represent an anabolic drive in newborns [94, 96]. However, ghrelin positively correlates with the enteral nutrition intake in both preterm and full-term babies on the second day after birth [100]. Blood ghrelin concentrations are affected by feeding, progressively increasing with prolonging fasting in full-term AGA infants from the first month of life [101].

Ghrelin secretion seems to be modulated by the type of enteral nutrition, suggesting a role of this peptide in gut development and maturation. At 4 months of age, formula fed infants have higher ghrelin and IGF-I levels without anthropometrical differences compared with breastfed ones [97]. At 6 months of age, ghrelin levels are higher in infants receiving a mixed diet of solids and milk compared with those exclusively milk fed [100]. It has been demonstrated that ghrelinaemia negatively correlated with weight gain at 12 months of age in breastfed but not in formula fed infants [97, 101]. These data suggest that a precocious derangement of ghrelin regulation could be linked to increased weight gain in children who are breastfed for less than 6 months [102]. Moreover, infant formula milks are devoid of many constituents, including ghrelin, which might influence gut maturation and fat accrual. Thus, both total ghrelin and AG increase in breast milk progressively during lactation during the first 6 months and their concentration in milk correlated positively with that in the plasma of breastfed infants [103].

Preliminary studies have also analyzed AG levels in newborns. AG is present in both fetal and neonatal circulation. AG and AG to total ghrelin ratio seem to be higher in venous cord blood, suggesting that the placenta is able to produce AG with a small part of it transferred to the fetal circulation [104]. AG is also higher in preterm and SGA newborns than full-term and AGA ones [104, 105]. Interestingly, umbilical cord AG concentration is lower than in maternal blood and the acylation process seems to be affected by cortisol partly through a placental role [99]. Any possible effect of AG on gut maturation has not yet been investigated.

43.2.4.2 Obestatin

In 2005, Zhang and coworkers identified a 23 amino acid peptide from a conserved region of preproghrelin sequence and named it obestatin, based on previous reported activities in animal models. Obestatin is amidated like GLP-1. It was initially characterized as the active ligand of the orphan receptor GPR39 [106] but more recently this has been debated [107, 108]. Obestatin, like ghrelin, is expressed in several tissues, including stomach, duodenum, pancreas, and brain [109]. Obestatin initially appeared to be a new regulator of appetite and body weight [108]. Subsequent studies, however, failed to reproduce obestatin's anorectic and anti-obesity effects and raised doubts about its existence simply as a ghrelin-associated peptide [110]. In contrast to other gut peptides, data regarding the modulation of insulin secretion are limited and controversial [107, 108]. However, preliminary *in vivo* studies observed that obestatin was reduced in subjects with type 2 diabetes, impaired glucose tolerance and in obesity, but increased in anorexia [111].

There have been some studies of the most recently identified gut peptide obestatin in pediatric subjects [89, 112], but there are no data relating to neonates.

43.2.5 Motilin

Motilin is a 22 amino acid peptide produced by the endocrine cells of the duodenum and jejunum. It binds and activates the receptor GPR38 through which it stimulates motility of digestive organs [113]. It regulates gastro-intestinal motility via migrating motor complex activity during phase III of contraction [114]. There are cyclical increases every 90-120 minutes during the interdigestive fasting periods [113, 114]. The mechanism by which motilin induces gut motility is still unclear. The gut motilin-containing cells and enteric neurons are only separated by a sheet of the basal lamina of mucosal epithelium. However, motilin receptor (GPR38) has not been demonstrated in the vagus nerve or nodose ganglion, although migrating motor complex activity is atropine sensitive and abolished by vagotomy [114, 115]. However, GPR38 is expressed in the brain, suggesting a role of motilin in feeding regulation [101]. It has to be emphasized that motilin and ghrelin precursors share almost 50% similarity in their sequences and, as a consequence, Tomasetto initially named it motilin-related peptide [116]. More recently, motilin has been included in the ghrelin peptide family. The GPR38 and GHS-R1a receptors are also part of the same family of G-protein coupled receptors with an overall sequence identity of the 53% [113]. Moreover, ghrelin and motilin are located in the same endocrine cells and in the same secretory granules at duodenum and jejunum level [117].

The role of motilin in gut development has been investigated during the neonatal period. Motilin secreting cells

appear at 8-11 weeks of gestation in the fetus, and at 12-15 weeks of gestation the distribution is similar to that seen in adulthood [118]. Motilin levels are higher in preterm and SGA infants after receiving enteral nutrition compared with levels in older children or adults [119–121]. Motilin is also present in human milk and its digestion in the stomach is retarded by milk itself, suggesting a biological role in the gut of newborns [101, 122]. Moreover, babies who have colic have higher motilin levels, which may have a role in this condition [123, 124]. Motilin-receptor antagonists could be a potential therapeutic agent for the treatment of colic when they become available for clinical trials [113].

43.2.6 Cholecystokinin (CCK)

CCK was the first gut hormone described as an inhibitor of food intake in rodents [125]. CCK is widely expressed at both central and peripheral levels, in particular in I-cells in the duodenum and jejunum mucosa [126]. CCK is detectable in the bloodstream in different forms, in particular CCK-8, CCK-33 and CCK-39 [16]. Two CCK receptor subtypes have been isolated: CCK_A receptor which is expressed in the vagus nerve, enteric neurons, pancreas and brain, and CCK_B expressed in the afferent vagus nerves, brain and stomach [126].

CCK has several activities on different tissues, including stimulation of pancreatic enzyme excretion and the induction of gallbladder contraction [10]. CCK has been shown to be a satiety signal, in particular in the short-term regulation of feeding behaviors [16, 126, 127]. It acts synergistically with leptin on the hypothalamic region [16, 126]. Its effect is reduced by vagotomy [16, 126, 127].

Peripheral CCK administration is followed by a rapid, but short-term effect on the inhibition of food intake, with an activity peak at 30 minutes [126]. High doses of CCK cause nausea, vomiting and taste aversion [128]. CCK mainly inhibits fat ingestion [129]. The inhibitory effect of CCK on food intake undergoes a functional desensitization after high dose administration as well as during continuous infusion [126]. When administered intermittently before meals, CCK maintains its anorectic effect, but a compensatory effect can be achieved by increasing the daily number of meals, however, there is only a mild effect on total food intake and body weight [128].

During the neonatal period, CCK has been shown to increase immediately after breastfeeding; this peak is followed by a decline 10 minutes later. There is a secondary rise 30 and 60 minutes later. The first increase of CCK levels may exert stimulatory effects on digestion while the secondary increase could have an anorectic effect [130]. Higher CCK levels correspond to a higher volume of ingested milk during breastfeeding [131]. CCK levels are negatively correlated with age in full-term infants [130]. Preterm infants show a similar increase in CCK concentration in cord blood 1 hour after delivery in both AGA and SGA babies [132, 133]. Plasma CCK concentrations appear to increase after nasogastric-tube feeding only in preterm neonates receiving kangaroo care and these results are still under investigation [134]. Furthermore, CCK prophylaxis for high-risk neonates seems to help with the prevention of parenteral nutrition-associated cholestasis [135]. However, the role of CCK on gut maturation has not yet been investigated.

43.3 Therapy and Treatments?

Bioactive peptides, hormones and factors in human milk and produced by the gut have been shown to stimulate gut development and function and to be modulated by nutrients. Most findings come from studies on preterm or SGA infants. However, there is a knowledge gap because many studies were performed 20 years ago and abandoned, while others have been linked to gut peptides discovered in recent years. Substances derived from these hormones might be used for the treatment of preterm newborns and colonic dysfunctions. However, further physiological and pharmaceutical studies are needed. In the future, more detailed studies will be needed to elaborate completely the functions of these peptides and the interaction of breast and formula milk and solids with the gut. Investigation of the signaling systems between neonates, mothers and nutrients could offer a physiological basis for appropriate nutritional support for preterm infants, as well as treatment options for necrotizing enterocolitis.

Feeding the Term Infant: Human Milk and Formulas

Silvia Fanaro and Vittorio Vigi

44.1 Introduction

Breast milk represents the natural food for infants, and is universally recognized as the optimal feeding choice for every infant. The American Academy of Pediatrics (AAP), and the European Society for Pediatric Gastroenterolgy, Hepathology and Nutrition (ESPGHAN) recognize that feeding at the breast is the advisable way of supporting the natural growth and development of all infants [1, 2].

The health benefits of breastfeeding are particularly relevant under conditions of poor hygiene and low socio-economic status: in these instances receiving own mother's milk can be a matter of life or death [2]. In developed countries there is no precise evidence that breastfeeding has a substantial impact on infant mortality, even if it has a certain role in the reduction of gastrointestinal infections and acute otitis media [2]. The promotion and support of breastfeeding must be regarded as one of the fundamental role of the pediatrician. Unfortunately, the commitment of many people involved in the field of child care has not been sufficient in expanding the initiation and, above all, the duration of breastfeeding, which remains still unsatisfactory in many countries. Exclusive breastfeeding for the first six months of life is still not a common practice in both developed and developing countries. Pediatricians, who play a key role on child health, must promote and encourage breastfeeding, also taking in due account mothers' wishes.

Recommendations for the duration of exclusive breastfeeding are still debated. According to the WHO [3], human milk should represent the exclusive nutrient for full tem infants during the first 6 months of life. This recommendation is not generally fulfilled, because complementary foods are often introduced before the 6th month. However, breastfeeding should be continued through the first year of life and thereafter, as long as possible and wished [1].

44.2 Breast Milk

Human milk is characterized by a peculiar species-specificity, with a composition that partially changes over time, during lactation, throughout the day and within a single feed (hind/fore milk), and that to some extent varies among different women. These variations are genetically determined, or induced by different lifestyles or dietary habits, mother's age and parity, as well as by the time of delivery. The most evident modifications take place in the first few days of lactation, when human milk changes from colostrum (0–5 days) to transitional (6–14 days), and then to mature milk (0.5–6 months; >6 months) [4].

Colostrum, the thick fluid produced during the first few days, is yellowish because of the high β-carotene content and contains more protein, fat-soluble vitamins and minerals, but less fats than the transitional or mature milk [5]. It is particularly rich in immunoglobulins and mononuclear cells [5]. During the transitional phase, from 7 to 10 days post partum to 2 weeks post partum, the composition gradually changes, with increasing concentrations of fats and lactose, into mature milk, whose composition remains relatively stable until weaning [5].

Maternal diet may influence milk composition, particularly for some components (fat quality and vitamins); although, it is important to point out that even extreme malnutrition does not induce consistent alterations in protein and lactose content, although it affects milk volume [5].

44.2.1 Nutritional Properties

Mature human milk is about 88% water and its osmolality is around 286 mOsm per liter [6].

The energy content of human milk varies during lactation and during a single feed, because it is mainly (~50%) determined by its fat content. Estimations for mature milk vary from 51 to 69 kcal/100 mL, but real values may be even

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

lower, as some components, mostly proteins and oligosaccharides escape digestion exerting non-nutritive effects [6].

Carbohydrates are the main component of human milk, and are mainly represented by lactose and oligosaccharides. Lactose is the prevalent nutrient in human milk, with an average concentration of 7 g/100 mL (6.7–7.6 g/100 mL) in mature milk [7]. Lactose is also the major determinant of milk osmolality and its concentration remains relatively stable once lactation is established [8]. Lactose, which is synthesized by the mammary gland, is a prompt source of galactose, which is essential for the production of galactolipids in the central nervous system (CNS) [5]. Oligosaccharides, the third largest component after lactose and lipids (2.4 g/100 mL in colostrum and 1.2 g/100 mL in mature milk), are non digestible carbohydrates which play a number of functional roles on intestinal health and host defenses, as will be more extensively described later [9].

Fat accounts for about 50% of the energy content of human milk and represents the second most abundant component after lactose, with a concentration of 1.5–2 g/100 mL in colostrum and 3.5–4.8 g/100 mL in mature milk [7]. The content is, however, extremely variable from woman to woman, during the course of lactation, during the day and, above all, during a single feed [10]. Lipids are a rather heterogeneous group of compounds, mainly represented by triglycerides (TGs, 98%) and in a small percentage by phospholipids, sphingolipids and cholesterol [7]. Lipids are secreted in a complex structure represented by the "milk fat globule", characterized by a core of TGs and cholesterol esthers, coated with bipolar substances such as phospholipids, proteins and bile salt-stimulated lipases. This unique system is effective in emulsifying milk fat and in improving the digestion and the absorption in the infant. Some of the substances included in the fat globule, such as lactadherin and MUC1, seem to play a role in host defense [11]. Fatty acids in human milk are for the main part estherified with glycerol and only in a small part are present in a free form [7]. While maternal diet does not influence the total fat content, which is however affected by body composition, it plays a significant role on the quality and on the proportion of the various fatty acids. More than 200 different fatty acids have been identified in human milk, represented by saturated (32–52%), cis-monounsaturated (30–50%), trans-monounsaturated (2.5–13.8%) and polyunsaturated fatty acids (11–27%) [6, 12]. The percentage of trans-fatty acids, as well as that of polyunsaturated acids, varies greatly worldwide, in relation to dietary habits. For example, the concentration of linoleic acid (18:2 n-6) may vary from 6% in omnivorous women to over 30% among vegan ones [13]. This aspect is even more evident for the n-3 eicosaenoid metabolite, docosahexaenoic acid (DHA, 22:6 n-3), whose content in human milk varies from 0.1% in women with vegan diets to 2.8% in Asiatic women with an high intake of fish and other marine foods [12]. The n-6 and n-3 fatty acids and their metabolites are essential for optimal growth and development of the brain and retina as for the synthesis of eicosanoids and leukotrienes [12].

Nitrogen content of human milk declines in the first two weeks of lactation from 300 mg/100 mL to 190 mg/100 mL, corresponding to a total protein content of about 1.2 g/100 mL (Kjeldahl's conversion factor = 6.25) [6]. Nearly 25% of this nitrogen is non-protein nitrogen (NPN), which includes urea, creatinine, sugar amines and free aminoacids; for this reason the real protein content is as low as 0.9 g/100 mL [6]. The milk protein fraction consists of casein and whey. The whey protein/casein ratio changes from 90:10 in early milk to 60:40 in mature milk and 50:50 in late lactation. Casein is made of four major families of protein: α, β, γ, and $\varkappa$ casein, among which β and $\varkappa$ are the most represented. Besides its function as a source of amino acids, casein serves as the precursor of several peptides with functional activities on intestinal motility and calcium absorption [14]. However, the whey fraction is the most characteristic and interesting component of human milk. It includes alpha-lactalbumin (αLA), lactoferrin, lysozyme, albumin, immunoglobulins, enzymes, hormones and growth factors [6]. The predominant whey protein in human milk is αLA, which provides a well-balanced supply of essential amino acids and is digested into peptides with antibacterial, immunostimulatory and antitumoral properties [15]. Some of the non-nutritional aspects of whey proteins of human milk will be further discussed later.

The vitamin content of human milk from well-nourished mothers is adequate to meet the needs of healthy infants with a few exceptions, represented by vitamin D and vitamin K [16]. In particular, vitamin D, whose production is almost exclusively dependent from sunlight exposure, is extremely low in human milk (0.4–4 IU/100 mL; 0.01–0.1 μg/100 mL) [17]. Thus, even breast fed infants born to mothers with normal vitamin D status are at risk of vitamin D deficiency in the first months of life. For this reason the American Academy of Pediatrics (AAP) recommends supplementing all breastfed infants with 400 IU/day of vitamin D from the first few days of life and to continue supplementation throughout childhood [18]. Vitamin K, which is essential for the synthesis and function of blood clotting factors and the structure of bones, is present in human milk at marginal concentrations. Measurements with advanced techniques have confirmed rather low levels, corresponding to 0.2–0.7 μg/100 mL [5, 19]. This is the reason why breastfed infants, receiving an oral dose vitamin K only at birth, undergo a serious risk of late-onset severe hemorrhagic disease. Although, even infants who had received intramuscular vitamin K at birth present low serum levels of vitamin K, with detectable proteins induced by vitamin K absent (PIVKAs) [20]. Notwithstanding this, very few cases of late hemorrhagic disease have been reported in breastfed infants who had received an intramuscular injection of vitamin K soon after birth. The AAP still recommends a single intramuscular dose of 0.5–1 mg to be given to all newborns [21]. At the same time, the AAP recommends that additional research should be conducted to test the safety and bioavailability and optimal dosing regimens of oral formulation of vitamin K [21]. Some authors and pediatric societies have proposed

to continue supplementation with physiological oral daily doses of 25 μg, recently revised to 50 μg, for the first three months of life in every breast fed infant [22, 23]. Human milk supplies adequate levels of the other fat-soluble and water-soluble vitamins with the exception of vitamin B12 in the case of mothers with vegan diet or with gastric by-pass [6].

Minerals are generally independent of maternal mineral status and do not significantly respond to supplementation [24]. In general, the concentration of macro-minerals, in particular calcium and phosphorus, is particularly low, but at the same time their bioavailability is particularly high [25]. With the exception of magnesium, all macro-minerals decline progressively during lactation [5]. The concentration of iron, zinc, and other trace elements also declines during lactation to very low levels; however, their bioavailability is much higher (20-50%) than that of cows' milk or infant formulas [26]. For this reason, breast milk provides sufficient intakes of trace elements to healthy term infants until the sixth month of life [27].

44.2.2 Non-Nutritional Properties

The supremacy of breast milk in the nutrition of the human infant results from both unique nutritional aspects and several valuable protective properties on the gastrointestinal function, the resistance to infection, as well as on the immunity, the neurodevelopment and the general well-being. Epidemiological data have clearly evidenced the preventive effect of human milk on infections (gastroenteritis, upper and lower respiratory tract illnesses, urinary tract infections, and sepsis) [28]. Although the impact of breastfeeding on the development of allergies remains controversial, some data indicate a transient, protective effect of exclusive breastfeeding, for at least 4 months, on atopic eczema, wheezing, and asthma in the first years of life [29, 30]. Other advantages on immune system regulation that have been investigated include the prevention of type 1 diabetes, celiac disease and inflammatory bowel disease, in particular Crohn's disease [2]. Breast milk may also exert a biological advantage on adult diseases, such as obesity, hypertension, hypercholesterolemia, cardiovascular disease and type 2 diabetes [2, 31–33]. The modulation and stimulation of the immune system could also partly explain the preventing effect of human milk on various malignant diseases, such as lymphocytic and myelogenous leukemia and breast cancer [34, 35]. However, the evidence of this preventive effect is at the moment rather weak [2]. Many studies have been performed on the effects of breastfeeding on neuro-development; most of them have evidenced an advantage, even if limited, on cognitive function, after also adjusting for potential confounders [2].

As a general rule, human milk is considered the cheapest and easiest way of feeding an infant. The economic advantages of breastfeeding are not limited in saving the costs of formula milk and go well beyond the familiar interest. The reduction of episodes of illnesses, fewer hospital admissions, medical visits and drug use, together with fewer absences of parents from work, associated with the reduction of chronic diseases in childhood and adulthood, represent an evident social and economic benefit.

44.2.3 Bioactive Components of Human Milk

A variety of heterogeneous agents with different beneficial activities on infants' health have been identified in human milk (Table 44.1) [36]. The value of these substances, pertaining to protein, lipid and carbohydrate fractions, is far beyond the nutritional aspect, which is frequently negligible. For reasons of space, our attention will be focused on few elements whose benefits are well recognized.

44.2.3.1 Oligosaccharides

Oligosaccharides (OS), carbohydrates made up of 3–9 monomer units, are synthesized in the mammary gland by specific enzymes (glycosyltransferases), by adding monosaccharide units (galactose, N-acetyl-glucosamine, fucose, sialic acid) to a molecule of lactose, forming either linear or branched structures [37]. More than 200 different forms of acidic or neutral oligosaccharides have been described, and their composition is related to maternal genetic expression of different fucosyltransferases [9, 37]. Oligosaccharides are important prebiotics and may represent a relevant component of the so-called "bifidus factor" of human milk. They resist the enzymatic digestion in the gastrointestinal tract, thus reaching the colon intact. At this level OS are mainly utilized in bacterial fermentation, leading to the production of short-chain fatty acids (acetate, propionate, and butyrate) and gases (hydrogen, carbon dioxide, and methane), and so selectively promoting a bifidogenic flora [38, 39]. The intestinal flora of breastfed infants is, in fact, typically characterized by a prevalence of bifidobacteria, while the growth of several other organisms is somehow reduced [40]. Lactic acid bacteria, in particular bifidobacteria, are widely recognized to positively influence human health, both at local and systemic levels, and are certainly involved in many biological advantages that breastfed infants have over formula fed counterparts [39].

44.2.3.2 Lactoferrin

Lactoferrin (LF) is an 80 kDa, natural defense iron-binding glycoprotein, which is present in several exocrine secretions, including tears, nasal and bronchial mucus, saliva, intestinal and genital secretions [41]. Its concentration in colostrum is up to 600 mg/100 mL and progressively decreases in mature milk to 140 mg/100 mL, while in standard infant formulas it is 10 fold lower [42]. Thus, in human milk lactoferrin accounts for about 10–15% of the total protein content [43].

Table 44.1 Bioactive factors of human milk

Adaptive immunity compounds	Immunoglobulins sIgA (11S), 7S IgA, IgG, IgM, IgE, IgD, free secretory component, antiidiotypes
Innate immunity agents	Complement, chemotactic factors, properdin factors, interferon, α-fetoprotein, antistaphylococci factors, mannose binding lectin, β-defensin-1, antiadherence substances (oligosaccharides, mucins, lactadherin, glycolipids and glycosaminoglycans, ϰ-casein), milk fat globule, hormones and growth factors (prolactin, cortisol, insulin, thyroxin, prostaglandins, vascular-endothelial growth factor, nerve growth factor, TGF, erythropoietin), antiviral factors (fatty acids and monoglycerides), migration inhibition factor, α-lactalbumin
Cytokines, chemokines, and receptors	IL-1β, IL-2, IL-4, IL-5, IL-6, IL-8, IL-12, IL-13, IL-16, IL-18, IFNγ, TNFα, G-CSF, M-CSF, GM-CSF, GROα, monocyte chemotactic protein-1, TGFβ1 and -2, sCD14, Toll-like receptor, sFas, sFasL
Antiinflammatory factors	IL-10, TGFβ2, glucocorticoids, antioxidants (α-tocopherol, β-carotene, lutein, vitamin E, catalase, glutathione peroxidase), lactoferrin, IL-1Ra, soluble TNFα receptors I and II, CD59
Prebiotics	"Bifidus factor", oligosaccharides, lactoferrin
Histocompatibility antigens	
Carrier proteins	Lactoferrin, transferrin, vitamin B-12 binding protein, steroid binding protein
Enzymes	Lysozyme, lipoproteinlipase, leukocyte enzymes, antiproteases, platelet-activating factor-acetyl-hydrolase
Others	Nucleotides, long-chain polyunsaturated fatty acids
Cellular	
Total counts	Colostrum, $1–3 \times 10^9$/L; mature milk, ~1×10^8/L
Cell types	Macrophages, ~60%; neutrophils, ~25%; lymphocytes, ~10%; epithelial cells

Modified from [36].

Lactoferrin has a marked bacteriostatic and bactericidal effect on a wide range of microorganisms, not only because of the iron deprivation of the pathogens, as believed in the past, but also because of its metabolite lactoferricin, a potent bactericidal peptide [44, 45]. In addition, lactoferrin shows a serine protease activity, which degrades the bacterial structures necessary for the attachment and the invasion of the bacteria to the mucosa [46]. Other valuable properties of lactoferrin are antiviral and fungistatic activities. Another precious effect of lactoferrin is the promotion of a bifidus flora. In fact, lactoferrin resists digestion by pepsin, trypsin and chymotrypsin and shows a bifidogenicity 100 fold stronger than N-acetylglucosamine [45, 47]. In addition, lactoferrin presents an antineoplastic action *in vitro* and a dual effect on immunity response, mostly anti-inflammatory [44, 48, 49].

44.2.4 Growth of Breastfed Infants

Several studies published in the last 20 years have repeatedly indicated different growth patterns in breastfed and formula-fed babies; the former show, in fact, a reduced rate of weight and length accretion from the 3rd–4th month to the 12th month of life [50]. In the past years this downward trend has somewhat worried some pediatricians and health care providers, leading to the erroneous conclusion that growth faltering was connected to inadequate breast milk intake or even to breast milk inadequacy. This conclusion has often led to the premature introduction of complementary foods and/or to the use of supplementary milk formulas. New growth charts based on thousands of breastfed children from 6 different countries were released in 2006 by the WHO [51]. The subjects examined, aged 0–5 years, were living in socio-economic conditions and in environments supportive of growth [51]. All the children studied were breastfed for at least 12 months [51]. These new curves reflect the growth when the subjects are fed optimally to achieve their genetic growth potential [52]. The use of these new standards avoids the risk of unnecessary formula supplementations. There is no evidence that individuals who are fed at the breast becomes shorter adults, but there is growing evidence that they may be protected from obesity later in life [52].

44.2.5 The Practice of Breastfeeding

According to the indication of AAP, in the first few weeks an infant may require 8 to 12 feedings a day, avoiding night intervals longer than 4 hours [1]. The postnatal weight loss should never be more than 8-10% and the birth weight should be regained within the 14th day of life [1]. The adequacy of milk intake may be judged on the basis of several indicators such as the number of wet diapers and the number, quantity and color of stools. During the first weeks of life the infant should produce six wet diapers/day, with yellow pale urine, and almost one yellow stool after each feeding [1]. Criteria are available when an intervention is necessary because the baby is undernourished [53]. Any infant who is not gaining a minimum of 20 g/day in the first months of life should be closely scrutinized and evaluated.

44.3 Infant Formulas

Infant formulas have tended for many years to be as close as possible to human milk, approximating its macro and micro

nutrient composition [54]. Although, the consistent variations of breast milk composition during lactation, within the day and within a single feed (hind and fore milk) have indicated that the figures relative to the composition of human milk cannot be taken as absolute values, but may only represent a general guide for the biochemical formulation of human milk substitutes. Thus, in the last few years it has been generally accepted the concept that milk formulas should approach the results obtained by breast milk, more or less independently by a strict adherence to its chemical composition. In other words, the adequacy of an infant formula is determined by a comparison of its effects on physiological (e.g., growth patterns), biochemical (e.g., plasma markers) and functional outcomes (e.g., immune responses) in infants fed formulas with those found in healthy breastfed infants [55]. Cow milk based infant formulas are the only acceptable alternative when human milk is not available. Although, cow milk has an unbalanced fat composition and an excessive concentration of proteins and minerals; for these reasons it represents only the matrix, which must be largely modified and adapted to the needs of human infants. New formulas are continually developed and new ingredients are added to existing formulas, as long as new components and biological activities of human milk are identified. At present, our scarce knowledge of the real functions of many substances present in human milk, such as hormones, immune and growth factors, enzymes and viable cells, makes it practically impossible to add them to current milk formulas [56]. Although, positive results of recent investigations have made the introduction of new important substances possible, such as Lc-Pufas, nucleotides, oligosaccharides, lactoferrin and the favorable modification of the protein fraction.

At present, human milk substitutes can be considered as the most regulated and controlled commercially available foods. The European Community has issued a Commission Directive on Infant Formulas, last amended in 2006, which has been implemented by member states [57]. In the United States the infant formula Act of 1980 has set up quality control procedures, minimum requirements and maximum permissible levels of nutrients contained in milk formulas [58]. A milk formula has been defined as "a food which purports to be or is represented for a special dietary use solely as a food for infants by reason of its simulation of human milk or its suitability as a complete or partial substitute for human milk" [58].

One aspect that deserves particular attention is the safety of preparation, storage and handling of infant formulas, especially if in powdered form. In fact, there is a serious risk of contamination of milk powder with *Cronobacter* (*Enterobacter*) *sakazakii*, which represents a possible etiologic agent of severe infections and sepsis in infants, especially if younger than 3 months, preterm, and immunocompromised [59–62]. For this reason, special attention should be paid giving parents appropriate instructions concerning the preparation of powdered milk formulas, as recommended by WHO: wash and sterilize bottles, wash and dry hands properly, use hot water (70–80°C), then add powder, quickly cool to 40°C to safely feed the infant, and finally discard the remaining [63]. If parents need to prepare feeds in advance for later use, reconstituted milk formula, as previously indicated, should be rapidly cooled and placed in a refrigerator (temperature ≤ 4°C) for a maximum of 24 hours [63]. In care settings the use of liquid milk formulas, as well as of sterile disposable bottles is obviously strongly recommended; it is advisable to reconstitute the milk immediately before feeding the infant.

44.3.1 Lipids

Fats in infant formulas provide 40–50% of the total daily energy intake of an infant. Lipids currently employed in standard infant formulas are of vegetable origins. A great deal of discussion has been aroused over the last 20 years by the addition of long-chain polyunsaturated fatty acids (Lc-Pufa). The interest of Lc-Pufas is directly linked to the recognition of their important role in the development and maturation of the infant nervous system. DHA is preferentially accumulated in the membranes of photoreceptors, cells of the retina, and in neurons during the last trimester of pregnancy and the accumulation continues along the first two years of postnatal life [12]. Other Lc-Pufas, i.e., arachidonic acid (ARA, 20:4 n-6) and eicosapentaenoic acid (EPA, 20:5 n-3), are precursors of important regulatory molecules, such as prostaglandins, leukotrienes, and thromboxanes [12]. Term infants are able to synthesize Lc-Pufas from precursors, but endogenous synthesis may be insufficient to cover the infant's DHA and ARA requirements [64]. During the first months of life breastfed infants receive preformed DHA and ARA. Feeding a non-supplemented infant formula leads to significantly lower levels of the DHA contained in plasma lipids, in erythrocyte membrane phospholipids, and in the cerebral cortex [64]. Data concerning the importance of offering preformed DHA to the infant have shown variable results on visual function and neurodevelopment outcomes [65, 66]. However, a number of papers provide a strong rationale for supplementing formulas with DHA and ARA. For this reason the International Expert Group (IEG) of ESPGHAN, among other scientific organizations, supports their optional addition in infant formulas, specifying that the DHA content should not exceed 0.5% of total fat intake, that ARA content should be at least the same concentration as DHA, and that the EPA content should not exceed the DHA content [55]. The EU Commission Directive established the minimum and maximum levels of the different fatty acids:

- linoleic acid (300–1200 mg/100 kcal)
- alpha-linolenic acid (not less than 50 mg/100 kcal)
- linoleic/alpha-linolenic acid ratio (5–15)
- n-3 LCP (not more than 1% total fat, DHA should not exceed total n-3 LCP content)
- n-6 LCP (not more than 2% of total fat, for ARA not more than 1% of total fat)
- EPA not more than DHA [57].

44.3.2 Proteins

In the past years formula fed infants consumed 60–70% more protein than breastfed infants and their plasma aminoacidogram was markedly different from those found in breastfed infants. Even though it was demonstrated that a milk formula with a whey-casein ratio of 50/50 produced an amino acid pattern more similar to that of human milk, the amino acid profile remained substantially different from that of breastfed infants [67]. There has been considerable discussion regarding the optimal concentration of protein in infant formula and the risks of excessive protein intake. Even though there was strong motivation to develop formulas that ensure a protein composition closer in quantity and quality to human milk, practical problems were serious obstacles for this accomplishment. The protein content of infant formulas are not species-specific, so that if they are reduced below certain limits, several essential amino acids could fall below the desired levels. In the last few years the protein content of formulas has been substantially modified and reduced, employing two approaches: removal of the whey protein glycomacropeptide, thus reducing plasma threonine concentration, and addition of alpha-lactalbumin, a tryptophan rich protein, balancing the entire amino acid profile [68]. Infants fed a low protein infant formula enriched with alpha-lactoalbumin have serum amino acid patterns near those of breastfed infants [68]. Besides its positive effect on aminoacidogram, αLA is believed to exert several valuable effects on health, such as antimicrobial activity, enhanced immune function, prebiotic function, increased trace element absorption and anti-tumoral activity [45, 69]. These interventions may overcome the problem associated with high protein intakes, allowing normal weight gain, without suboptimal amino acid levels [70]. The EU Commission Directive stated that the protein content of infant formulas manufactured from cow milk proteins must range from 1.8 g/100 kcal to 3 g/100 kcal, specifying that the infant formula must provide an available quantity of all indispensable and conditionally indispensable amino acids at least equal to that contained in breast milk [57]. Thus, it is possible to reduce the protein concentration in formulas to 13 g/L, provided that high-quality protein sources are used. The IEG is doubtful regarding the adequacy of the minimum allowed protein level of formulas, in terms of growth and amino acids supplied and it reaffirms the necessity of measuring the true protein content of a formula utilizing the conversion factor of 6.25 ([Total N-NPN] × 6.25) [55].

Lactoferrin, (LF) is a multi-functional whey protein that represents 10–20% of the total protein content of human milk [43]. Lactoferrin has shown important activities both *in vitro* and *in vivo*, such as bacteriostatic and bactericidal, antiviral and fungistatic effects, bifidogenic activity, anti-oxidant and anti-neoplastic action and a dual effect on the immune response, mostly anti-inflammatory [44–49, 71, 72]. For these reasons there is a growing interest toward the clinical advantages deriving from its administration both to infants and adults. In particular, there is a growing consensus toward the addition of lactoferrin to infant formulas, as already done in Japan for many years. In addition, bovine lactoferrin (BLF) is characterized by a high (77%) amino acid homology with human lactoferrin (HLF) and this aspect may be helpful in improving the amino acid pattern of formula-fed infants. At the moment, in Italy, only two manufacturers have introduced LF in preterm formulas, while there is only one infant formula supplemented with a rather low concentration (14 mg/100 mL) of lactoferrin. At present, there is no official recommendation concerning the addition of lactoferrin to infant formulas.

44.3.3 Carbohydrates

Carbohydrates represent the most important source of energy for the infant after lipids. Minimum and maximum carbohydrate content are established at 9.0 and 14.0 g/100 kcal, corresponding to 36–56% of the total energy of infant formulas [55]. Lactose represents the main digestible carbohydrate milk formulas as well. No maximum level specific for lactose has been set, whereas the minimum content is set to 4.5 g/100 kcal [57]. Free glucose, even though it is highly absorbable, is not routinely added to formulas, because of its heavy effect on osmolality and because of the possible unpleasant Maillard reaction with proteins. The addition to infant formulas of sucrose is not recommended by the IEG of ESPGHAN because of possible severe reactions in young infants affected by hereditary fructose intolerance [55]. Although, both glucose and sucrose may be added to infant formulas manufactured from protein hydrolysates [57]. Maltose and malto-dextrins, generally produced by controlled hydrolysis of corn starch, are sometimes employed to improve the gastro-intestinal tolerance of milk formulas, without increasing the osmolality load. Starch may be added to infant formulas up to 2 g/100 mL (30% of total carbohydrates) [55, 57].

Oligosaccharides (OS), which are carbohydrates with a degree of polymerization (DP) ranging from 2 to 60 monomers, are non-digestible by human or animal digestive systems. As previously said, they represent the third largest component after lactose and lipids of human milk. Technologically, they can be extracted from natural sources or derived from hydrolysis of natural polymers or synthesized from monomers and/or small oligosaccharides. Different OS have been investigated for their prebiotic effect in infancy, such as neutral and acidic galacto-oligosaccharides (GOS), short- and long chain fructo-oligosaccharides (scFOS), inulin, and combinations such as a mixture of these substances [73, 74]. A recent systematic review of published randomized clinical trials on the effectiveness of prebiotic supplementation in term infants, has shown that formulas supplemented with prebiotics are well tolerated and result in various short-term beneficial effects, including increased stool colony counts of bifidobacteria and lactobacilli, decreased counts of pathogenic enteric bacteria, more

acidic stools, and softer and frequent stools, without adversely affecting weight gain [75, 76]. These are certainly interesting results; however, the importance of prebiotics in the defense against pathogens and in the modulation of the immune responses needs further experimental evidence and scientific substantiation. The effects of oligosaccharides on the prevention of atopic diseases are limited and still debated [77–79].

The EU Directive on infant formulae expresses no objection to the addition of a mixture of galacto- and fructo-oligosaccharides to infant formulas up to a maximum concentration of 0.8 g/100 mL, and of other oligosaccharides whose favorable effects in infancy have been proven with scientific criteria [57].

In conclusion, as observed several years ago by an eminent scientist and one of the greatest authority in infant nutrition, Samuel J. Fomon, milk formula "…is not as good as breast milk, and can never be breast milk. But it can be a healthy alternative and is always being improved".

Nutritional Recommendations for the Very Low Birth Weight Newborn

Ekhard E. Ziegler

45.1 Introduction

To ensure uninterrupted growth and development of the prematurely born infant, all nutrients must be provided in the necessary amounts at all times. Delivery of nutrients meets with a variety of obstacles in very low birth weight (VLBW) infants, which is why VLBW infants frequently receive less than the required amounts of nutrients. As a consequence they fail to grow like they would have in utero and, more importantly, suffer impairment of their neurocognitive development. The main obstacles to delivery of nutrients historically have been concerns regarding presumed risks attendant to the administration of nutrients. Recent years have seen a gradual dissipation of these concerns as scientific evidence of the safety of providing nutrients has accumulated. This reassessment of the risks of nutrient administration has nearly been completed in the area of parenteral nutrition but is an ongoing process in the area of enteral nutrition. The more realistic assessment of risks, together with a desire to prevent postnatal growth failure and thereby minimize the risk of impaired neurocognitive impairment has led to more aggressive regimens of nutrient administration.

There is principal agreement that postnatal growth of the premature infant should emulate that of the fetus in utero. Such "normal" growth would be proof of the absence of substantive nutrient deficiency and would provide assurance of unimpaired neurocognitive development. The American Academy of Pediatrics [1] recommends that "postnatal growth that approximates the in utero growth of a normal fetus of the same postconception age" should be the basis for estimating nutrient requirements. It is recognized that birth engenders a permanent contraction of body water spaces, amounting to about 10–15% of extracellular fluid space. However, there are no known reasons why other body components should not be accumulating in the premature infant as they would have in the fetus. The fetal model is therefore appropriate for the estimation of nutrient intakes needed for normal growth and development.

Nutrient needs of the premature infant have been determined principally by two methods, the factorial method and the empirical method. Although both methods are ultimately based on the fetal model, they use very different approaches. In the factorial approach, fetal accretion of body components is used as the starting point. After correction for inevitable losses, inefficiency of conversion of nutrients into body components (in the case of protein) and absorptive inefficiency, the required intake for a nutrient is obtained. An important advantage of this approach is that it yields requirements for all nutrients for which fetal accumulation is known, which includes, besides protein and energy, all major minerals and most trace minerals. The factorial approach can also provide needs specifically for parenteral administration of nutrients. In the empirical approach, the intake of a nutrient is experimentally manipulated and a response, such as weight gain or, in the case of protein, nitrogen balance is observed. This approach has been applied to protein end energy and yields energy and/or protein intakes that produce weight gain or protein accretion comparable to the fetus. Estimation of nutrient needs for catch-up growth is possible with the factorial as well as the empirical approach.

45.2 Protein Requirements Determined by the Factorial Approach

The factorial approach derives nutrient requirements as the sum of two (in the case of parenteral requirements) or three components (in the case of enteral requirements). The largest component, and the component that changes most with body size, is nutrient accretion. The other components are inevitable losses and, in the case of enteral requirements, efficiency of nutrient absorption.

Table 45.1 Estimated nutrient intakes needed to achieve fetal weight gain

Body weight (g)	500–700	700–900	900–1200	1200–1500	1500–1800	1800–2200
Fetal weight gain (g/d)	13	16	20	24	26	29
(g/kg/d)	21	20	19	18	16	14
Protein (g/kg/d)						
Loss	1.0	1.0	1.0	1.0	1.0	1.0
Growth (accretion)	2.5	2.5	2.5	2.4	2.2	2.0
Required intake						
Parenteral	3.5	3.5	3.5	3.4	3.2	3.0
Enteral	4.0	4.0	4.0	3.9	3.6	3.4
Energy (kcal/kg/d)						
Loss	60	60	65	70	70	70
Resting expenditure	45	45	50	50	50	50
Other expenditure	15	15	15	20	20	20
Growth (accretion)	29	32	36	38	39	41
Required intake						
Parenteral	89	92	101	108	109	111
Enteral	105	108	119	127	128	131
Protein/Energy (g/100 kcal)						
Parenteral	3.9	3.8	3.5	3.1	2.9	2.7
Enteral	3.8	3.7	3.4	3.1	2.8	2.6

Nutrient accretion is derived from body composition of the fetus. Going back to the 19th century, the chemical composition of a sizable number of term and preterm infants, who were stillborn or died soon after birth, have been reported by a number of investigators. Sparks [2] and Forbes [3, 4] have provided comprehensive summaries of the chemical data derived from whole body chemical analyses of over 160 infants. The data permit derivation of fetal accretion rates of the various body components [2–4].

Utilizing a different approach, Ziegler et al [5] used select data for the construction of a "reference fetus" and similarly derived fetal accretion rates. Accretion rates by the different approaches are similar and the fetal accretion rates in Table 45.1 represent a composite of the different approaches [2–5] in combination with contemporary fetal growth data [6]. Fetal accretion rates shown in Table 45.1 are corrected for presumed inefficiency (90%) of the conversion of dietary protein to body protein. Energy accretion values include the energy cost of growth, estimated by Micheli et al [7] at 10 kcal/kg/d.

Inevitable losses of protein (nitrogen) through desquamation of skin were assumed to be 27 mg/kg/d [8] and urinary losses in the form of urea to be 133 mg/kg/d [9, 10]. Energy losses in the form of resting energy expenditure were assumed to be 45 kcal/kg/d in infants <900 g and 50 kcal/kg/d in larger infants, and other expenditures, e.g., for occasional cold exposure and physical activity, were assumed to be 15 kcal/kg/d in infants <1200 g and 20 kcal/kg/d in larger infants [11, 12]. The requirements for parenterally administered protein and energy (Table 45.1) are calculated as the sum of accretion plus inevitable losses. Enteral requirements are derived from parenteral requirements by application of corrections for percentage absorption, assumed to be 88% for protein and 85% for energy.

Absolute fetal weight gain (g/d) increases with increasing body size, but fractional fetal weight gain (g/kg/d) decreases markedly with increasing body size. In spite of this, the rate of protein accretion remains constant up to a weight of 1200 g. This is so because the protein content of fat-free body mass increases with increasing body size/age, offsetting the effect of the decrease in fractional growth rate. Energy accretion, on the other hand, increases with increasing body weight due to a marked increase in fetal body fat content. As the accumulation of body fat is not an absolute necessity, lesser energy intakes do not limit growth of lean body mass as long as they are greater than 100 kcal/kg/d [7].

45.3 Protein Requirements Determined by the Empirical Approach

The empirical approach utilizes feedings (formulas or human milk) that provide precisely known intakes of energy and protein, with growth and/or nitrogen balance as outcomes. Because of the fragility of extremely immature infants, the necessary studies have been performed for the most part with infants weighing >1200 g. As requirements are strongly influenced by body size, estimates by the empirical approach are generally applicable only to infants weighing >1200 g. Data published before 1986 [13], showed that weight gain (g/day) increased with increasing protein intake all the way to the highest intake studied (3.6 g/kg/day) Weight gain did not seem to be influenced by energy intake. The high protein

Table 45.2 Protein requirements by the empirical method and recommended intakes for premature infants

	Weight <1200 g		Weight >1200 g	
	g/kg/d	g/100 kcal	g/kg/d	g/100 kcal
Ziegler (Table 45.1)	4.0	3.7	3.6	2.8
Kashyap & Heird [14–16]	–	–	3.0	2.5
Denne [19]	3.5–4.0	–	3.0	–
Klein et al [18]	3.4–4.3	2.5–3.6	3.4–4.3	2.5–3.6
Rigo [17]	3.8–4.2	3.3	3.4–3.6	2.8

intake of 3.6 g/kg/d was shown to produce a weight gain of about 30 g/day, which was more than the weight gain of the fetus and therefore represented catch-up growth. Kashyap, Heird and collegues [14–16] performed a series of growth and metabolic balance studies with feedings (human milk, formulas) that varied in protein and energy content. They used the data to derive equations predicting protein and energy intakes necessary to duplicate fetal weight gain. The authors estimated that protein intake necessary for infants with birth weight greater than 1200 g to duplicate fetal weight gain was about 3.0 g/kg/day (Table 45.2). Using a variety of endpoints, including growth, body composition and nitrogen balance, Rigo [17] estimated the protein requirements ("advisable recommendation") of infants born at 26–30 weeks gestation (corresponding to weight of about 800 to 1500 g) at 3.8–4.2 g/kg/d (3.3 g/100 kcal) and those of infants born at 30–36 weeks gestation (corresponding to weight of 1500 to 2700 g) at 3.4–3.6 g/kg/d (2.8 g/100 kcal) (Table 45.2).

45.4 Recommended Protein Intakes

Based on a review of published studies, the Life Sciences Research Office (LSRO) [18] concluded that the minimum protein intake of premature infants (weight not specified) was 3.4 g/kg/d with a protein/energy ratio of 2.5 g/100 kcal at the maximum energy intake of 135 kcal/kg/d. The LSRO also concluded that a protein intake of 4.3 g/kg/d (with protein/energy ratio of 3.6 g/100 kcal) was without adverse consequences, whereas intakes of 5. 0 g/kg/d or higher were likely to be associated with undesirable consequences. Denne [19] provided recommended intakes based mostly on the factorial approach.

Table 45.2 provides a summary of the different estimates of requirements and of recommendations for infants weighing less than 1200 g and those weighing more than 1200 g. It is apparent that there is reasonably close agreement among the different estimates in spite of differences in methods and endpoints used.

45.5 Requirements for Energy and Other Nutrients

Estimates of energy requirements are available by the factorial method (Table 45.1). However, estimates by the empirical method are considered more relevant with regard to energy. Empirical estimates [7] indicate that energy needs are 90–100 kcal/kg/day. Energy taken in excess of this amount is used for storage in adipose tissue.

Requirements for major minerals and electrolytes derived by the factorial method are summarized in Table 45.3. Because there is considerable uncertainty regarding the minimal urinary losses of electrolytes and phosphorus, and because there is large variation of the efficiency of intestinal absorption of calcium, the required intakes shown in Table 45.2 are somewhat uncertain. Since accumulation of less than the fetal amounts of bone mineral (Ca, P) seems to be compatible with reasonable bone health, there is even uncertainty with regard to the minimum amount of Ca and P that must be accrued. Nevertheless, fetal accretion rates are considered the norm and deviations from them need to be justified. Table 45.4 summarizes the minimum mineral and vitamin content of feedings for premature infants as recommended by the LSRO [18].

Table 45.3 Requirements for major minerals and electrolytes determined by the factorial method (all values per kg/day)

	500–1000 g		1000–1500 g		1500–2000 g	
	Accretion	Required intake	Accretion	Required intake	Accretion	Required intake

45.6 Catch-up Growth

Growth restriction, whether occurring before birth (intrauterine) or postnatally, is associated with impaired neurocognitive development. Although postnatal growth restriction may lead to lower cardiovascular and metabolic risks later in life [20], the overriding concern is with neurocognitive development. Therefore, in order to minimize the adverse effects of growth restriction, efforts should be made to allow infants to make up any growth deficit as soon as possible. Accelerated growth following a period of growth restriction is referred to as catch-up growth.

Most infants are capable of catch-up growth, and catch-up growth will occur if the requisite amounts of nutrients are provided. Nutrient needs for catch-up growth are above and beyond the needs for growth like the fetus. Since most premature infants will have incurred some growth deficit during the immediate postnatal period, it is advisable to provide all VLBW infants with sufficient nutrients for making up the growth deficit. Attempts to estimate nutrient needs of growth-restricted infants and needs for catch-up growth have been made [21].

Table 45.5 presents examples of nutrient requirements of hypothetical growth restricted infants. The first column gives nutrient requirements of a normally-grown 26-week gestation infant weighing 900 g. The next column shows requirements of a growth restricted infant of similar weight and growing at the same rate as the normally grown infant. Because the lean body mass of this infant has a more mature composition (lower water content), the infant's metabolic rate is higher and accordingly its energy requirement is higher than that of the normally grown infant. The hypothetical infant in the far right column is also growth restricted but is assumed to undergo catch-up growth. As shown, this increases the requirements for energy and, especially for protein, by a considerable margin. Unless these needs are met, the infant will not realize catch-up growth.

Table 45.5 Nutrient requirements of growth restricted VLBW infants without and with catch-up growth

Gestational age	26 wk	30 wk	30 wk
Weight (g)	900	900	900
Weight status	NG	GR	GR
Catch-up growth	no	no	yes
Weight gain (g/d)	20	20	34
Required intake			
Protein (g/kg/d)	4.0	4.0	4.9
Energy (kcal/kg/d)	119	126	141
Protein/energy (g/100 kcal)	3.4	3.2	3.5

NG normally grown, *GR* growth restricted.

45.7 Nutrient Delivery

Ideally, the flow of nutrients should continue without interruption and at the same level as the fetus transitions to become an infant. Although the goal of an uninterrupted flow of nutrients is at present unattainable, it should be the goal that the caretaker strives to achieve. After all, it is not known what degree of shortfall from the goal, if any, is safe in terms of neurocognitive outcome.

Nutrients are initially delivered to most VLBW infants parenterally. While nutrients are provided parenterally, trophic feedings are initiated with the objective of fostering maturation of the immature intestinal tract. When maturation has advanced to the point where full feedings can be administered, parenteral nutrition can be terminated. This marks the beginning of the late feeding period, during which enteral feedings are the exclusive source of nutrients. Growth similar to the fetus, or faster than the fetus, is by consensus optimal. Yet, growth frequently proceeds at a slower rate (postnatal growth failure).

The reason for growth failure is mainly inadequate protein intake, which in turn is caused by the low protein content of most feedings. Inadequate protein intake is thus ultimately responsible for the poor neurocognitive development with which growth failure is associated [22]. Therefore, the achievement of adequate protein intake is mandatory if neurocognitive impairment is to be minimized.

45.7.1 Parenteral Nutrition

Delivery of nutrients via the parenteral route should commence immediately at birth. Nutrients may initially be limited to amino acids, energy in the form of glucose, and certain minerals, such as calcium, phosphorus and magnesium. Full parenteral nutrition, including intravenous lipids, should be instituted within 24 hrs of birth. Parenteral nutrition starting within 2 hours of birth has been shown to be effective and safe [23]. Delivery of amino acids in the needed amounts (Table 45.1) presents no difficulty, whereas delivery of energy can usually not be achieved for some days without incurring hyperglycemia, even if lipids are provided. The best strategy is to start glucose at a rate of 4.2 mg/kg/min and to increase delivery stepwise as long as euglycemia is maintained. Lipid emulsions based on soy oil provide needed energy and deliver modest amounts of the essential long-chain polyunsaturated fatty acids, docosahexaenoic acid and arachidonic acid. Parenteral nutrition should be continued until enteral feedings provide >90% of the required nutrients.

45.7.2 Early Enteral Nutrition

While adequate amounts of nutrients are being delivered via the parenteral route, enteral feedings should be started soon after birth. The sole objective of early (trophic) feeding is to stimulate the immature intestinal tract to undergo maturation. A marker of the intestinal tract's immaturity are the frequent gastric residuals, which can therefore be used to follow the intestinal tract's maturation. The best trophic feeding is human milk because of its superior ability to mature the gut while keeping the risk of necrotizing enterocolitis to a minimum. Because it usually takes some days for the mother's milk to become available, donor milk may be used to initiate gut stimulation in a timely manner, i.e., on the first day of life.

Gastric residuals should be monitored and their size taken into account in advancing feedings. It is probably prudent to keep the volume of trophic feedings low (<10 mL/kg/d) until gastric residuals are substantially diminished. There is lack of consensus on whether feedings should be kept low for a fixed period, e.g., six days, or whether cautious advancement can begin sooner. Contrary to earlier perceptions, neither the age at which trophic feedings are started, nor the rate of advancement of feedings have an impact on the risk of necrotizing enterocolitis [24]. Regardless of how feedings are advanced, it is important not to withhold feedings for more than a few hours because persistent feeding is crucial for optimal bowel maturation. Vigilance for signs of necrotizing enterocolitis must be maintained at all times. However, gastric residuals are not an early sign of necrotizing enterocolitis and their monitoring is not of proven value in the prevention of necrotizing enterocolitis. Delays in reaching full feedings should be minimized as early achievement of full feedings offers relative protection against late-onset sepsis [25].

45.7.3 Late Enteral Nutrition

It is widely appreciated that human milk does not provide the nutrients required by premature infants (Tables 45.1 and 45.3). The nutrient content of human milk must therefore be increased by the addition of nutrient supplements (fortifiers). Infants fed unsupplemented human milk show slow growth, which carries the risk of impaired neurocognitive development. In addition, premature infants can develop deficiency states of specific nutrients, such as osteopenia (Ca, P) or zinc deficiency. Commercially available human milk fortifiers provide protein, energy and the necessary minerals and vitamins. The amounts of minerals and vitamins are designed to meet or exceed, together with the nutrients intrinsically present in human milk, the concentrations specified in Table 45.4. Fortifiers provide energy in the form of carbohydrates and lipids because this enables the meeting of energy needs while keeping feeding volumes low. The protein provided by fortifiers (1.0–1.1 g/100 mL) is insufficient to meet the needs for protein at all times. Protein intakes approach protein needs if and when the protein content of human milk is at its highest, i.e., in the first two weeks of lactation. But it becomes progressively more inadequate as the protein content of human milk decreases with the duration of lactation. Inadequate protein intake from fortified human milk is the main cause of postnatal growth failure. Adequate protein intakes can be achieved if, in addition to the standard amount of fortifier, additional protein is added in a fixed amount, either as such or in the form of additional fortifier. Additional protein can also be added as part of a targeted fortification regimen [26] or in an adjustable fortification regimen [27]. There is no consensus regarding which of these methods is preferred. There is, however, no question that the amount of protein provided by commercial fortifiers is inadequate and that additional protein must be provided in some form.

Enteral Feeding of the Very Low Birth Weight Infant

Johannes B. (Hans) van Goudoever

46.1 Introduction

Enteral nutrition is the natural way of feeding infants. The fetus receives enteral nutrition via the amniotic fluid. The amniotic fluid is largely composed of fetal urine, but lung fluids, nasopharyngeal secretions and intra- and trans-membranous fluids contribute as well. Amniotic fluid contains protein and carbohydrates. The amino acid concentrations of amniotic fluid resemble the fetal plasma amino acid concentrations. The fetus starts to swallow considerable amount of amniotic fluid in the last trimester. By term, the fetus swallows about 700 mL per day, corresponding with 170–230 mL/kg/d [1]. It is estimated that up to 10–15% of the nitrogenous requirement of the fetus can be met by swallowing amniotic fluid [2].

There have been concerns that preterm infants have limited capacity to process carbohydrates, fats and proteins. Peptidases, brush border enzymes and hydrolases are present in fetal life, with an increase in enzyme activity with the glucocorticoid surge just before birth [3]. Pancreas enzymes, such as trypsin, lipase and amylase are secreted into the duodenum by 31 weeks. From approximately 26 weeks of gestation, lingual and gastric lipases are present, which might help in digestion and absorption of lipids. Bile acids are already secreted by 22 weeks, although the synthesis is much lower in preterm compared to term infants.

The effect of extreme premature birth (<26 weeks) and antenatal steroids on digestion and absorption is not precisely known, but may enhance these processes. Lactase activity is also lower in preterm infants, but preterm infants display normal growth when they are fed lactose-containing milk. Preterm infants fed formula pretreated with lactase showed a modest increase in initial weight gain, an effect that disappeared at the end of the study [4]. Proteins are taken up rather efficiently in preterm infants, a process that might be facilitated by pinocytosis and also because of the increased intestinal permeability, demonstrated in several studies [5, 6], intact proteins such as lactoferrin can be absorbed [7]. Preterm infants fed hydrolyzed formula reached full enteral feedings approximately two days earlier than non-hydrolyzed formula [8], with similar protein metabolism indices [9]. Enteral nutrition itself may induce the maturation process of digestion and absorption and enhance tolerance to larger volumes of enteral nutrition [10, 11]. Altogether it follows that enteral nutrition should be installed as soon as possible, also to avoid the complications of parenteral nutrient administration. This chapter will focus on feeding mode and type of enteral nutrition.

46.2 Feeding Mode

46.2.1 Minimal Enteral Feeding

The most important reason for withholding enteral feedings is necrotizing enterocolitis (NEC). This serious gastro-intestinal problem affects approximately 5% of very low-birth weight (VLBW) infants, but the incidence may vary widely amongst centers. Mortality rates are high, ranging from 20-40%. The multifactorial etiology includes gut hypoxia, impaired intestinal host defense mechanisms and alterations in microbial intestinal content (in amount, diversity and timing of colonization). Enteral nutrition is considered a risk factor as well, since in preterm infants, NEC develops in the second or third week of life, after the introduction of enteral feedings [12]. However, prevention of NEC by withholding enteral nutrition has not been shown. On the contrary, withholding enteral nutrition to neonatal animals reduces intestinal cell proliferation and gut mass [13]. In rats, lack of enteral nutrition results in atrophy of the proximal gut mucosa [14]. On the other hand, introducing large amounts of enteral feeding is a way of establishing NEC in premature piglets, despite the

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

fact that in utero large amount of amniotic fluids are ingested [15, personal communication]. Large amounts of enteral feedings are frequently not tolerated by the VLBW infants. Poor motility, pathogenic microorganisms, and inflammatory processes are related to the differences observed in postnatal life compared to prenatal life [12].

Many trials have examined the effects of minimal enteral feeding in VLBW infants [11, 16–20]. Many different definitions exist, but in general these are considered relatively small enteral volumes of human milk or formula (<25 mL/kg/d). They can be started as early as day one of life, even in extremely low birth weight infants. In neonatal piglets, mucosal growth is not observed before 30% of the total amount of nutrition is administered enterally, so minimal enteral feeding is not intended to serve as a nutritional source [13]. The initially observed physiological effects were increased motility and subsequent improved feeding tolerance resulting in higher weight gain rates, but recent results do not confirm this finding [19–21]. Gut hormone levels are stimulated by minimal enteral nutrition, possibly explaining the improved motility [16]. Also less need for phototherapy and reduced rates of osteopenia and cholestasis have been reported, probably all related to a reduced time on parenteral nutrition [10, 11, 17, 18]. Minimal enteral nutrition does not affect the incidence of NEC [21].

Lack of any enteral nutrition is associated with an increase in neonatal late onset infections [22]. This might be due to bacterial translocation from the intestine. In addition, the intestinal immune/inflammatory response is affected by the route of feeding, with an altered balance of cytokines, lower IL-4 and IL-10 levels in the non-enterally fed state and subsequent lower IgA production [23, 24]. Enteral nutrition has been demonstrated to down regulate the intestinal inflammatory response [25]. However, clinical trials have not demonstrated a beneficial effect of minimal enteral feeding on invasive infections [20].

Although large clinical trials on minimal enteral nutrition in VLBW infants are lacking, many studies including animal studies show beneficial effects of minimal enteral feeding in growth and feeding tolerance and provide indications of improved defense mechanisms against bacterial infections and inflammatory processes. This favors initiation of minimal enteral feeding shortly following birth as no adverse effects are reported.

46.2.2 Bolus or (Semi-) Continuous Feeding

Bolus feeding results in a significant increase in blood flow to the portal-drained viscera (i.e., stomach, spleen, intestine and pancreas). There is a surge in gastro-intestinal hormones, which is higher than when neonates are fed continuously [26]. Clinical trials show that even very small preterm infants tolerate bolus feeding well. Smaller infants seem to benefit more from continuous feeding [27, 28] and a recent small trial showed that preterm infants underwent more behavioral stress when fed intermittently [29]. However, a large randomized controlled trial with 250 VLBW infants has just been finished and the preliminary results show that even infants less than 1000 g tolerate bolus feeding well [W. Rövekamp-Abels, personal communication]. Some older trials have demonstrated less tolerance to intermittent bolus feeds than continuous milk infusion. Bolus feeding may result in apnea, deteriorating respiratory mechanics with decreased tidal volumes and transient hypoxia [30, 31]. These complications might aggravate in the presence of blocking materials of the nostrils such as nasogastric tubes, or CPAP devices. In conclusion, there is still not enough evidence to recommend either bolus or (semi-) continuous feeding as the preferred method.

46.2.3 Oral Feeding

Oral feeding is possible when an infant is capable of an adequate suck-swallow reflex. In the term infant the full, complex, integrated mechanism of swallowing, with the movement of the bolus of milk into the stomach, protection of the airway, inhibition of respiration and appropriate relaxation of the esophageal sphincter and gastric fundus is achieved within two days of birth [32]. The swallow function is present from 16 weeks of gestational age, and gastrointestinal motor activity, in small bursts, from 24 weeks onwards. Organized motility is present from around 30 weeks of gestation and nutritive and swallowing function from 32 weeks. Enteral nutrition promotes postnatal maturation of intestinal motor activity. It follows that oral feeding is only possible from 32 weeks onwards. Non-nutritive sucking can start earlier and may result in more rapid weight gain or earlier discharge although the results are not consistent [33]. The preterm infant of less than 32 weeks may be put on the breast, but the likelihood that the infant will ingest a significant volume of milk is very small. However, it may offer the mother a considerable psychological benefit and should therefore be strongly encouraged.

46.2.4 Intragastric Feeding

As oral feeding is not possible in VLBW infants, most frequently gastric tubes are used. Either nasogastric or orogastric tubes can be installed, both checked in the right position by checking the aspirate for acidity with litmus paper or by injection a small amount of air while listening with a stethoscope placed over the stomach. The nasogastric tube has the advantage of easier fixation but has the disadvantage of (partially) blocking one nostril. With the use of some CPAP devices, a nasogastric tube is not possible. With the use of tubes and syringes, one should be aware of a potential loss of nutrients such as lipids and calcium that may not reach the infant [34].

46.2.5 Transpyloric Feeding

Although transpyloric feeding is frequently used in pediatric intensive care [35–37], it should not be used in neonatal intensive care. Mortality rates are increased in infants that received transpyloric feeding, although this study might have been affected by selective allocation of the less mature and sicker infants to transpyloric feeding. No proven benefits in tolerance, growth or in aspiration rates have been reported consistently [33, 38].

46.3 Type of Enteral Nutrition

The aim of the nutritional support of the low birth-weight infant is to mimic intrauterine growth rate and obtain a long-term functional development similar to the term infant. The nutrient requirements for the VLBW infant are described elsewhere (see Chapter 45), but in general nutritional support should be designed to compensate for metabolic and gastrointestinal immaturity, immunological compromise and other problems associated with prematurity.

Own mother's human milk is the preferred choice, even for preterm infants although it does not provide the required nutrients. Fortification is thus necessary, as unfortified human milk leads to suboptimal growth [39–41]. Human milk is superior to cow's milk based formulas because of the species specificity. This results in the availability of, for instance, proteins and oligosaccharides important for the host defense, which might explain the reduced rates of NEC observed in human milk fed infants [42, 43]. Interestingly, pasteurized donor milk does not seem to reduce the incidence of NEC, although for instance oligosaccharides are not influenced by pasteurization [44, 45]. Bio-availability of calcium and phosphorus is higher in human milk, but preterm infants still frequently need supplementation. Lipases are present in breast milk, which might enhance fat absorption. Bacterial flora in infants fed preterm formula differs markedly from those who have been fed human milk, although the recent improvements in preterm formula facilitate the growth of *Bifidobacterium* and *Lactobacillus* species as well [46–48]. Human milk is better tolerated than formula, with a faster gastric emptying [49], while human milk might reduce intestinal permeability as well [50]. Long-term benefits of human milk include lower blood pressure, lower LDL to HDL ratio and possibly a reduced risk of obesity and higher IQ [51–53]. Early feeding with a higher nutrient dense formula results in a similar IQ to that found in breastfed children [54].

46.3.1 Preterm Human Milk

The milk from mothers, who have delivered prematurely, so-called preterm human milk, varies significantly from milk from mothers who delivered at term. Concentrations of proteins, lipids (and thus energy), vitamins, calcium, sodium and trace elements are higher [1, 2]. However, the concentrations of these nutrients soon decline and do not meet the requirements after approximately two weeks. In addition, clinical problems such as patent ductus arteriosus and bronchopulmonary dysplasia often restrict fluid intake demand fluid restrictions with the consequent need for nutrient dense feedings. The adequacy of nutrient intake is further compromised by the variability in composition. For example, the within-feed change in lipid content is well known and can be 2-3 folds different between fore- and hind milk.

46.3.2 Expressed Mother's Milk

As most low birth weight infants are not able to drink from the breast directly, most mothers choose to express their milk and deliver the milk to the unit themselves. As human milk is not homogenized, the fat content may separate from the remaining milk. Fresh milk is favorable, since freezing and thawing reduces the function of some beneficial components in human milk. Light exposure of breast milk reduces the riboflavin and vitamin A content substantially within a few hours. Human milk, even when fortified, can be stored at refrigerator temperature for 72 hours [34].

46.3.3 Human Milk Banks

An alternative to own mother's milk is the use of milk from a milk bank. Setting up a milk bank may be costly and after setting up the average cost per liter is around €30/liter [55]. Many units around the world have such a milk bank, where mothers donate their milk to be used, most often without payment. Although some argue that banked milk does not need to be pasteurized, almost all banks do, due to fear of pathogens. Human milk can transmit infection. Donors should be screened for hepatitis B, hepatitis C and HIV, with counseling offered when needed. Pasteurization might destroy HIV [56]. HIV is the most well recognized viral pathogen, but transmission of cytomegalovirus is not uncommon, and raw breast milk can cause serious and even fatal illness in preterm babies [57]. Pasteurization, freezing and thawing lower antimicrobial factors and denature milk lipase [58]. It may reduce vitamin content as well. Therefore, benefits are not as clear as with non-pasteurized, own mother's milk. On the other hand, most of the lysozyme, IgG and almost all IgA remain intact. A meta-analysis of trials in preterm newborns, all conducted in the early 1980s, showed that exclusively donor breast milk reduced the risk of NEC—a serious inflammatory condition of the bowel—when compared with formula [59]. Donors have usually delivered at term or have been lactating for some time, both of which re-

sult in lower nutritional content. Nowadays commercial instruments are available that can screen the nitrogen and energy content of milk very easy, to be informed about some quality aspects of the donor milk.

46.3.4 Fortifier

Exclusively unfortified, human milk fed preterm infants show lower serum albumin, total protein and transthyretin concentrations as a result of an inadequate protein intake. Growth rates are lower than fetal growth rates [60, 61]. In addition, calcium and phosphorus content are too low to meet the preterm infants requirements, resulting in decreases in serum phosphorus and increases in alkaline phosphatase [62] in the short-term and linear growth reduction in the long term [63]. Hyponatremia may result in a later stage, especially when diuretics are used.

The protein related deficits that might occur using unfortified milk can be corrected with supplementation [60, 61, 64]. Protein fortification has been shown to increase weight gain [65, 66]. Both human milk protein sources as well as bovine protein supplementation has been used, with similar results [67]. A recent study showed that human milk based fortifier resulted in a lower NEC incidence than cow milk based fortifier and preterm formula although the NEC incidence in the formula group was very high (16%).

Supplementation with calcium and phosphorus is possible as well. Indices of bone health, such as urinary calcium and phosphorus excretion, normalize with supplementation. Length gain improves, as well as bone mineralization in the long term [68].

The vitamin K concentration of human milk is very low and for the newborn breastfed infant, a deficiency state has been described. Vitamin K is produced by bacteroides and *E. Coli*, bacteria that are usually not common in breastfed infants. However, if prophylactic vitamin K is given at birth, no signs of deficiency have been described for three months [69], although the addition of vitamin K in fortifiers is logical and current practice.

As human milk composition changes in time, even fortified milk might not meet the requirements of the rapidly growing preterm infant. Frequent monitoring of the administered amount of nutrients remains necessary. Milk analyzers should therefore be available on all units as standard of care. The policy of waiting to change the composition of the nutrient intake until growth is faltering should be considered as suboptimal therapy, which can seriously affect long-term outcome.

Human milk fortifiers have been criticized for possible side effects, such as a loss of intrinsic host defense. As described above, there is an indication that infants fed a human milk based fortifier with human milk might be less prone to develop NEC. In a study, comparing either preterm formula as supplement or bovine fortified pasteurized human donor milk, no differences in sepsis or NEC were noted. Both groups showed a higher incidence when compared to human milk fed infants fortified with human milk fortifier [44]. No effect of fortifier is noted on IgA concentration [70, 71]. Another fear of the use of fortifiers is a reduced tolerance. A recent meta-analysis has revealed no differences between infants fed fortified or unfortified human milk [68]. Also no differences were observed between infants fed preterm formula or fortified human milk [72].

46.3.5 Preterm Formula

Although the goal of providing nutrients to the preterm infant is to achieve a functional outcome similar to that of the breastfed term infants, it is obvious that the composition of preterm formula is different from term formula, since the requirements are much higher. Until now, the factorial approach has been used, with only moderate success. With the factorial approach, estimations of requirements are made based upon intrauterine accretion rates, while accounting for endogenous losses, incomplete digestion and absorption. Intrauterine accretion rates are obtained from carcass analyses of fetuses, with sometimes limited information of the nutritional status of the mother or possible diseases and on intrauterine growth curves. Subsequent modifications of such formulas were made following clinical studies. As stated above, this approach has yielded only limited success. Weight gain rates are lacking behind intrauterine rates, especially in the extremely low birth weight infants [73, 74]. Mainly retrospective studies have shown detrimental effects of weight gain rates that are suboptimal [75, 76]. Very recently, guidelines developed from the European Society for Paediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN) together with a group of experts have indicated major changes in requirements, which are discussed elsewhere (see Chapter 45). Readers are referred to these published recommendations for a detailed description.

46.4 Approach to Improve Enteral Feeding

As yet, current enteral feeding strategies fail to meet the requirements of VLBW infants. Many more clinical trials are needed to improve the quality of the nutrient supply. An alternative approach would be to determine the quantity and quality of intrauterine nutrition by measuring fetal intake and fetal metabolism. Obviously, there are many differences between life in or outside the uterus. Compared to the fetus, preterm infants are depending on their own metabolism, use their lungs, and are subject to more gravity forces. In addition they are frequently ill, with might demand specific nutrients to support defense mechanisms. Medication usage may alter

metabolism. Their intestines start to be colonized, and bacteria have their own nutrient requirements. However, intrauterine nutrition and metabolism might provide very valuable insight in to what the fetus is capable of with regard to metabolic activity, although the mother plays a role in the conversion to and excretion of metabolic end products.

Glucose is the major oxidative substrate in utero. The ovine fetus utilizes glucose at a rate of approximately 4-7 mg/kg/min, but has the capability to metabolize double [77]. Lactate is also important as energy source, especially when other sources of energy are lacking [78]. When born at term, the human baby has a large portion of fat. Fat deposition increases exponentially with gestational age. Near term the fat accretion is 7 g/day. In the fetal sheep, large quantities of amino acids are taken up by both the placenta and the fetus [79]. About half of the retained amount is used as fuel source and the ammonia produced in this process is converted into urea by the fetal liver. Recent studies show a very active amino acid transport in the human fetus as well [80]. Comparison of albumin synthesis rates, using stable isotope techniques, revealed that very immature fetuses produce large quantities of albumin, rates that are not reached following birth with the present nutritional strategies [81]. This information provides guidelines as to which extent anabolism can occur and to which extent postnatal nutrition should be provided.

Parenteral Nutrition

Jacques Rigo and Thibault Senterre

47.1 Introduction

Modern perinatal medicine has resulted in dramatic decrease of mortality in premature infants, especially very low birth weight (VLBW, <1500 g) infants. With the major advances in life-support measures, nutrition has become one the most debated issues in the care of low-birth-weight infants. In this regard, several reports have shown the major effect of quantitative and qualitative nutrition during the first period of life on early and late outcome.

Incidence of intrauterine growth restriction (IUGR) is relatively high in VLBW infants and postnatal growth restriction (PNGR) is frequently observed during the early weeks of life resulting in a major growth deficit at the time of discharge. According to population, clinical disorders and nutritional support, growth restriction affected 60–100% of VLBW and extremely low birth weight (ELBW) infants [1].

PNGR is mainly the result of the cumulative nutritional deficit occurring during the transitional period from birth to the time of full enteral feeding [2, 3] but additional effects during the stable growing period have also been suggested [4]. Therefore, several studies evaluated the effect of more optimal (aggressive) nutrition during the early weeks of life [5–8] and various international scientific committees reconsidered current nutritional recommendations in preterm infants focusing on ELBW and VLBW infants (Table 47.1) [9, 10].

Due to gastrointestinal tract immaturity, cardio-respiratory adaptation, clinical status and high nutritional requirements, VLBW infants require parenteral nutrition from the first days of life to promote early positive nitrogen retention and growth. In addition, parenteral nutrition could be required or prolonged during the stable "growing" period due to feeding intolerance, gastrointestinal disorders or surgery. Provision of parenteral nutrition (PN), total or suppletive, can be ordered using individualized prescription, homemade standardized parenteral solution or ready to use industrialized prepared multichamber bags.

In this chapter we discuss the most important features regarding parenteral nutrition that have been recently reviewed [11–14] (Table 47.1), outlining more recent practical aspects and guidelines particularly for ELBW and VLBW infants.

47.2 Nutritional Support in VLBW Infants

Nutrition of VLBW infants may be divided into two subsequent periods, firstly the immediate adaptive or "transitional" period after birth, and a stable "growing" period up to discharge from the NICU. Depending on birth weight (BW) and gestational age (GA) the transitional period may be prolonged, particularly in the more vulnerable infants with major clinical disorders. The more premature a neonate, the more challenging are the influences of immaturity and the accompanying morbidity on nutritional supply. Most of these infants receive parenterally delivered nutrients as their major source of nutrition for the first days, and sometimes weeks, of life.

Nutrition during the "stable-growing" period on PN is exceptional, used only when preterm infants are recovering from surgery and/or severe gastrointestinal problems, to prevent or limit the use of the gastrointestinal tract.

47.2.1 Parenteral Nutrition During the Transitional Period

The aim of the nutritional support in VLBW infants during the transitional period is:

1. to reduce protein catabolism providing an energy intake at least at the level of energy expenditure;
2. to provide amino acids (AA) at a level sufficient to induce a positive nitrogen retention;

J. Rigo (✉)
Department of Neonatology, University of Liège, CHR de la Citadelle Liège, Belgium

NP not provided.

3. to provide water and electrolytes to control hydration status and postnatal physiological fluid adaptation;
4. to progressively increase AA, energy and mineral intake to promote nitrogen retention and early growth and to limit a possible cumulative nutritional deficit;
5. to limit postnatal metabolic stress in this high-risk population.

Recent data suggest that provision of a more "aggressive" nutritional support from the first day of life reduces postnatal growth deficit and improves neurodevelopmental outcomes in VLBW infants [15, 18].

47.2.1.1 Fluids and Electrolytes

A number of adaptive processes occurring at birth affect nutritional support. During the early weeks of life, water, electrolyte and mineral homeostasis, and glucose control are more challenging. Placental clearance and placental supply of fluids, electrolytes, minerals and nutrients are discontinued. Thermoregulation and insensible water losses influence water metabolism, especially in VLBW infants. Subsequent adaptation and compensatory regulative processes need time to stabilize.

Fluid and electrolyte administration during the transitional period should allow contraction of extracellular fluid space without compromising intravascular fluid volume and cardiovascular function, maintain normal plasma electrolyte concentrations, without impairing urinary output (<0.5–1.0 mL/kg/h) for more than 12 hours.

Water balance may be very unstable, especially in ELBW infants, urinary output may be high (6–10 mL/kg/h) and insensible fluid losses can be huge, especially under a radiant warmer and/or with phototherapy.

A negative net balance for sodium is allowed and intakes should be less than 2 mmol/kg initially. Restricted sodium intake in VLBW infants has a positive influence on oxygen supply and risk of later bronchopulmonary dysplasia. However, high sodium urinary excretion (10 mmol/kg) may occur, especially in case of high fluid perfusion over 170–200 mL/kg/d compromising sodium balance.

This transitional phase may last for a variable period of several hours or days and result in initial weight loss. The end of the transitional period is usually characterized by a urine volume <2.0 mL/kg/h, urine osmolarity>serum osmolarity, fractional Na excretion diminishing from >3% to <1% and specific gravity above 1012. In preterm infants, these changes complete after 3–5 days and water and electrolytes intake will be progressively increased to replete the body losses.

During the transitional period, VLBW infants should be weighted twice daily and in/out balance, plasma sodium concentration and urinary excretion should be monitored attentively during first days of life. Fluid intake on PN should be 50–100 mL/kg/d in VLBW infants according to clinical and environmental conditions and sodium and potassium intake limited to less than 2 mmol/kg/d [12, 14].

47.2.1.2 Amino Acids

To reduce the temporary interruption of the transfer of nutrients, to limit the high protein catabolism up to 1.5 g/kg/d and to induce a positive nitrogen balance from the first day of life a high-protein supply (>2 g amino acids/kg per day) has recently been suggested in the so-called "aggressive" nutrition [6–8].

Although, long-term benefits were not clearly demonstrated, it has been suggested that high protein intake during the first week of life induces positive nitrogen balance, increases insulin secretion, improves glucose tolerance, promotes early weight gain and improves neurodevelopmental outcome at 18 months [17]. Thus, new recommendations [12, 14] suggest providing 2–3 g of AA on the first day of life using a parenteral solution with a high AA:energy ratio and to progressively increase the AA intake up to 4 g/kg/d at the end of the first week of life.

47.2.1.3 Energy

Energy intake is required for both protein metabolism and deposition. Theoretically, an energy intake approximating the resting energy expenditure (i.e., 40–60 kcal/kg/day) allows the minimization of protein catabolism to about 1.5 g of protein/kg/d in ELBW infants. If amino acid intake is adequate and energy intake is in excess of resting energy expenditure, weight gain is achieved. However, because of individual differences in energy expenditure, the resting energy requirement varies considerably in this population. New recommendations [12, 14] suggest providing 40 kcal/kg/d on the first day of life, to increase up to 75–85 kcal/kg/d during the transitional period and to reach close to 100 kcal/kg/d at the end of the first week of life.

47.2.1.4 Carbohydrates

Glucose homeostasis is still immature during the early days of life in VLBW infants who are subject to hyper or hypoglycemia. Glucose is the main carbohydrate in fetal life and approximately 7 g/kg/d (4 mg/kg/min) of glucose crosses the placenta in the last trimester of pregnancy. Glucose production around 8 mg/kg/min (11.5 g/kg/d) in preterm infants is maximal in the postnatal period and decreases gradually with age. Gluconeogenesis may be responsible for a part of glucose production. During high rates of glucose infusion, endogenous production is not completely suppressed in VLBW infants. By contrast, maximum glucose oxidation is relatively limited, 7–8.5 mg/kg/min (10–12 g/kg/d), but could be less in critically ill VLBW infants. The imbalance between glucose infusion rate and endogenous production on one hand and the maximum oxidation rate explain the increasing incidence of hyperglycemia in VLBW infants. In addition, due to their immaturity and their underlying diseases, VLBW infants are relatively resistant to insulin during the first week of life.

During the transitional phase, fluctuations in blood sugar levels are frequently observed resulting from an insufficient glucose and energy intake associated with low substrate reserves (hypoglycemia) or from a relative excess of glucose and energy intake associated with some degree of insulin resistance (hyperglycemia). Although the definition and the long-term consequences of neonatal hypo- and hyperglycemia remain controversial, plasma glucose concentration should be monitored to remain in a normal range for VLBW infants on parenteral nutrition between 50 mg/dL (2.75 mmol/L) and 150 mg/dL (8.3 mmol/L). Hyperglycemia can be decreased by reducing insensible water loss, glucose infusion rate and by providing exogenous insulin supply. Insulin administration may help to control plasma glucose concentration, to achieve increased energy intake and to promote nitrogen retention and growth, although there is need for more data on its safety and long-term consequences as a growth-promoting agent. More recently, it has been proposed that high AA intake from the first day (2–3 g/kg/d) improves glucose tolerance in ELBW infants by stimulating growth, by enhancing insulin and insulin-like growth factors secretion [6]. This approach requires further randomized control trials.

In practice, 6 g glucose/kg per day are generally well tolerated (4–5 mg/kg/min) even on the first day of life in VLBW infants. If this intake is tolerated, it may be increased progressively to 12–16 g/kg per day at the end of the first week of life. If it is not tolerated, progression of glucose intake will be reduced and insulin perfusion will be considered according to clinical and nutritional status with an initial dose of 0.05 IU/kg/h.

47.2.1.5 Lipids

Intravenous lipid emulsions are important constituents of total PN as they provide in an isotonic solution, high energy density and essential fatty acids to VLBW infants. Intravenous lipids play two separate roles in the PN of VLBW infants. The first role is as a high-density energy substrate to be readily utilized by VLBW infants. The other role is as a source of essential fatty acids as well as long-chain PUFAs. Essential fatty acid deficiency is avoided by infusions of 0.5–1.0 g lipid per kg per day. The importance of long-chain PUFAs for the development of the brain and the retina has also been recognized. Intravenous lipid emulsions contain small amounts of these fatty acids as part of the egg phospholipid used as a stabilizer. However, clearance of lipid emulsion could be impaired in ELBW infants particularly those with IUGR requiring the monitoring of triglyceridemia.

Actually, new recommendations [12, 14] suggest providing 1 g/kg/d on the first day increasing stepwise fashion to 3.0 g/kg/d at the end of the first week of age.

47.2.1.6 Minerals: Ca, P and Mg

Calcium and phosphorus transfer and retention is high during the last trimester of gestation. Combined with a relative immaturity of hormonal control (Vit D, PTH), VLBW infants particularly are at risk of early neonatal hypocalcemia and hypophosphoremia (see Chapter 49).

Calcium supply needs to be provided from the first day of life in combination with an adequate calcium phosphorus ratio to limit the risk of hypocalcemia and/or hypophosphoremia. Phosphorus plays a critical role in energy metabolism, and deficiency of phosphorus results in clinical disease, including muscle weakness. Early phosphorus deficiency is also potentiated by IUGR. Reference values for plasma phosphorus concentration differ in adults (>1.0 mmol/L, 3 mg/dL) and in preterm infants (>1.6 mmol/L, 5 mg/dL). Unfortunately, most neonatologists are unaware that the laboratory reports plasma phosphorus concentration of VLBW infants with regard to adult references and tolerates hypophosphatemia with

the risk of hypercalciuria and osteopenia. Optimal calcium to phosphorus ratio differs in parenteral and oral nutrition due to the bypass of the gastrointestinal tract; phosphorus retention is related to bone mineralization with a weight-to-weight calcium:phosphorus ratio of 2.15:1 but also to nitrogen retention with a weight-to-weight nitrogen:phosphorus ratio of 15:1. Therefore optimal Ca to P ratio in parenteral nutrition ranges between 1.5 and 1.3.

Magnesium is rarely adjusted even in the transitional period unless the infant has persistent hypocalcemia secondary to hypomagnesemia, or has abnormally high magnesium levels due to maternal levels. Serum magnesium levels should be checked in any small infant whose mother was treated for hypertension or preeclampsia.

Actually, new recommendations [12, 14] suggest providing around 25–40 mg (0.6–1 mmol) of Ca/kg/d, 18–31 mg (0.6–1 mmol) of P/kg/d and 2.5–4.0 mg (0.1–0.2 mmol)/kg/d of magnesium on the first day and to progressively increase the intake according to energy and AA supplies up to 65–100 mg (1.6–2.5 mmol) of Ca/kg/d, 50–78 mg (1.6–2.5 mmol) of Phosphorus and 7–10 mg (0.3–0.4 mmol/kg/d) of magnesium.

47.2.2 Parenteral Nutrition During the Stable Growing Period

The aim of the nutritional support in VLBW infants during the stable growing period is:

1. to induce growth rate and protein accretion in the range of the fetal weight gain considering the lean body mass gain as reference;
2. to abolish the development of a cumulative nutritional deficit during the first weeks of life;
3. to reach, at the time of discharge and/or of theoretical term, an anthropometric parameter in the range of reference values for term infants.

47.2.2.1 Fluids and Electrolytes

Intravenous fluid is the carrying vehicle for parenteral nutrition. A fluid intake about 140–160 mL/kg/d in both VLBW and VLBW preterm infants allows for covering the water requirement for replacing water loss and providing enough extra water to build new tissues during the stable growing period. Fat mass is relatively free of water content. By contrast, lean body mass content is about 80%. Thus a weight gain of 20 g/kg/d containing 40% of fat results in a net storage of 13 g of water and 1–1.5 mmol of Na^+/kg/d.

Sodium and potassium requirements are in the range of 3–7 mmol/kg/d for Na^+ and 2–5 mmol/kg/d for K^+ in VLBW infants respectively. A mean intake of 3 mmol/kg/day of sodium and 2 mmol/kg/day of potassium seem to be appropriate to maintain normal plasma concentration for most stable, growing infants. In parenteral solution, sodium is frequently provided with phosphorus in the form of sodium glycerophosphate and limitation of sodium content also limits the phosphorus content. Chloride supply requires particular attention in parenteral nutrition. Chloride requirement is generally considered similar to sodium requirement. Chloride content in parenteral solution is related to several potential components, AA solution, sodium chloride, potassium chloride or calcium chloride and is difficult to control. However, chloride intake plays a role in the acid-base homeostasis and imbalance between $Na^+ + K^+$ and Cl^- promotes metabolic acidosis or alkalosis [19]. Therefore, monitoring of plasma and urinary electrolyte concentrations and appropriate correction remains recommended, during parenteral nutrition.

47.2.2.2 Amino Acids

Nitrogen requirement in parenteral nutrition is close to 95% of the enteral requirement, but corresponds in terms of g AA/kg/g to the figure in g protein/kg/d recommended in enteral nutrition, due to a relatively lower nitrogen content. Protein requirement has been recently reviewed according to fetal nitrogen accretion, lean body mass gain and the need to compensate early cumulative protein deficits during the transitional period. 3.5–4.5 g of AA /kg/d is recommended during the stable growing period in ELBW and VLBW infants [9, 10, 20].

47.2.2.3 Energy

In contrast to what is generally suggested, the energy requirement in PN approximates to that of enteral nutrition. In fact, the gross energy content, measured by bomb calorimetry, of 1 g of amino acid is lower than that of 1 g of protein. Similarly, gross energy content of glucose is less than that of more complex carbohydrates. In contrast, while in parenteral nutrition the metabolizable energy of amino acid and fat solutions are identical to the gross energy, the metabolizable energy of dietary protein and fat in oral nutrition represents about 90% and 80% respectively [21]. Consequently, the recommendation for energy intake during the stable-growing period in VLBW infants on parenteral nutrition is relatively similar to that in oral nutrition and corresponds to 110–130 kcal/kg per day in VLBW infants.

47.2.2.4 Carbohydrates

Glucose contributes to most of the osmolality of PN solution (510 mOsm/L for a 10% solution) by contrast to lipid solutions. An excessive glucose intake increases CO_2 production and may be responsible for hyperglycemia, cause lipogenesis, steatosis and may contribute to liver dysfunction. The maximum glucose intake should not exceed the glucose oxidation rate in

parenteral nutrition of 13–18 g/kg/d and more than 60–75% of the non-protein energy during the stable growing period.

47.2.2.5 Lipids

Intravenous lipid emulsions are important constituents of total parenteral nutrition as they provide most of the energy intake and essential fatty acids (EFA). The CO_2 production is lowered compared to PN with a high proportion of carbohydrates and the nitrogen metabolism can be improved by adding lipid emulsions to PN. Lipid oxidation depends on the overall energy intake and consumption, intake of carbohydrates and triglycerides and the carbohydrate/lipid ratio. Lipid oxidation decreases as the carbohydrate intake increases and is replaced by lipid storage.

Maximum fat oxidation occur when lipid emulsions provide 40% of the non-protein energy in newborns so it is recommended that lipid intake should provide 25–40% of non-protein energy with a maximum of 3–4 g/kg/day [12]. An increase in the concentration of plasma triglycerides is to be expected if the infusion speed of the lipid emulsion exceeds the speed of triglyceride hydrolysis that depends on lipoprotein lipase activity. In all cases, the triglyceride infusion dose should be adjusted to maintain a serum triglyceride concentration not exceeding 200–250 mg/dL, especially in ELBW or severely ill infants who may have limited lipid tolerance.

Concerns had been raised on the potentially adverse effects of lipid infusion on hemodynamics, infections or hyperbilirubinemia. It appears prudent to avoid high lipid supplies in infants with sepsis, impaired oxygenation, or severe hyperbilirubinemia and lipid emulsion infusion should be continued at least at 0.5–1.0 g/kg/day, which is sufficient to prevent essential fatty acid deficiency.

Lipid supply may result in enhanced lipid peroxidation and the formation of free radicals. An increased lipid utilization by reducing the carbohydrate/lipid ratio results in a reduction of lipid peroxidation and free radical formation. PN should be supplemented with multi-vitamin preparations including both vitamin C and vitamin E (alpha-tocopherol), which have anti-oxidative effects. Excessive exposure of the bottle to light should be avoided.

Carnitine is necessary for the transportation of long-chain fatty acids via the mitochondrial membrane and its oxidative metabolism. Because carnitine synthesis and storage are not sufficiently developed at birth, particularly in preterm infants, and because no commercial intravenous solution has carnitine, parenterally fed infants present low plasma and tissue carnitine levels that decline with postnatal age [22]. Although a meta analysis (based on 14 randomised, controlled studies) showed there to be no effect of carnitine supplementation on the metabolism of lipids, lipogenesis or weight gain [23], a carnitine supplementation of 15 μmol/100 kcal could be advisible for infants on total parenteral nutrition for more than 4 weeks.

47.2.2.6 Minerals: Ca, P and Mg

Calcium and phosphorus cannot be provided through the same parenteral solution at concentrations needed to support in utero accretion, because of solubility. With a fluid intake range of 120–150 mL/kg/day, it is advisable to supply 65–100 mg (1.6–2.5 mmol) of Ca /kg/d, 50–78 mg (1.6–2.5 mmol) of iP and 7–10 mg (0.3–0.4 mmol/kg/d) of Mg, corresponding to a Ca/P ratio of 1.3:1 by weight and 1:1 by molar ratio in the TPN solution. It must be underlined that this quantity of calcium provided by parenteral route is about 55–80% of that deposited by the fetus during the last trimester of gestation (120 mg/kg/day) but similar or higher than that obtained in enteral nutrition with the available preterm formula (see Chapter 49).

47.2.2.7 Trace Elements and Vitamins

Vitamin mixtures for parenteral use have been available since the early time of parenteral nutrition and the amounts provided were (and are) determined to a large extent by the preparations available. Today, additives of all trace minerals for which a deficiency has been demonstrated are available. However, little definitive information is available concerning the parenteral requirements of either trace minerals or vitamins in VLBW infants. Research concerning the parenteral requirements of these nutrients by infants, of course, is hindered by the difficulties both of measuring plasma concentrations of the nutrients using small volumes of plasma and of interpreting the physiological significance of plasma concentrations.

47.3 Practical Aspects of Parenteral Nutrition in VLBW Infants

47.3.1 Basic Components Available for Parenteral Nutrition in Preterm Infant

47.3.1.1 AA Solutions

Considerable improvement of parenteral amino acid solutions have occurred from the late 1960s when the source of intravenous protein was casein hydrolysate. More specific pediatric amino acid solutions have been designed in the early 1990s with high essential/non-essential AA ratios and conditionally essential amino acid content for use in preterm infants. At least three different "gold standards" have been proposed for premature infants: (1) the amino acid concentrations from the umbilical cord obtained following fetal cord puncture or after birth, (2) the amino acid concentrations of rapidly growing preterm infants receiving their mother's milk or human milk supplemented with human milk proteins, (3) the amino acid

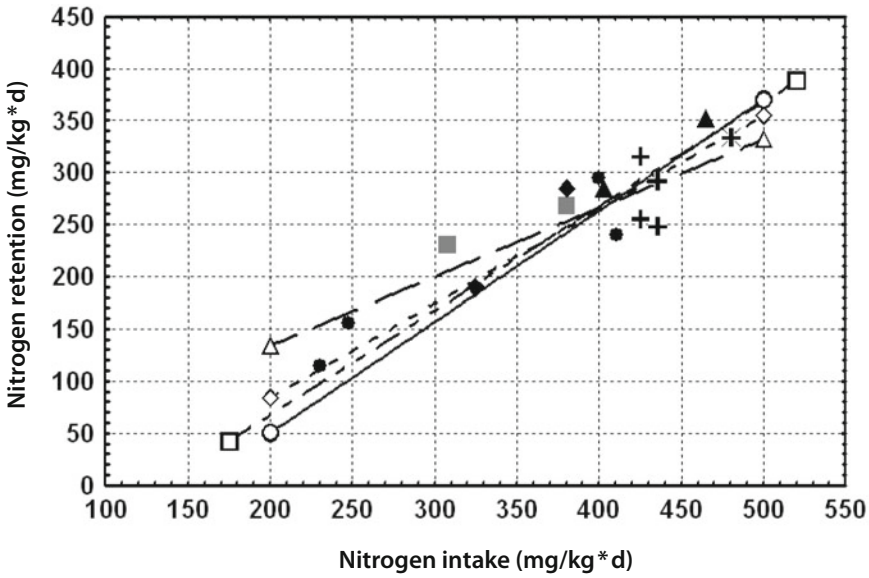

Fig. 47.1 Relationship between nitrogen retention and nitrogen intake in parenterally fed preterm infants computing of various studies (the different symbols represent individual studies)

concentrations of healthy breast-fed term infants. Nevertheless, despite the diverse composition of parenteral amino acid solutions used in pediatric care, nitrogen utilization does not change significantly (Fig. 47.1) [11, 20] (Table 47.2).

Therefore, optimal amino acid patterns for parenteral amino acid solutions in preterm infants still need to be determined and new solutions should be developed to potentially improve sulfur and aromatic AA imbalances and to provide additional glutamine. However, up to now, the use of cystein-HCl, acetyl-cystein, acetyl-tyrosine [24] and the supplementation with glutamine [25] have not demonstrated beneficial effects. The recent data evaluating the effect of bypassing the intestine on individual AA requirements has not been translated to designing and evaluating new AA solutions.

47.3.1.2 Lipid Emulsions

Intravenous lipid emulsions consist of different oils (soybean, safflower, coconut, olive and fish oils), egg yolk phospholipids and glycerol [reviewed in 12, 14, 26, 27] (see Table 47.3). Intravenous lipid emulsions provide high caloric, isotonic solutions and can also be given through peripheral lines. Traditionally, lipid infusions are prepared from soybean oil triglycerides emulsified with egg yolk phospholipids. Typical soybean oil contains about 45–55% linoleic acid (18:2n-6) and 6–9% linolenic acid (18:3n-3), but very little saturated or monounsaturated fat. Although clinically safe, experimental reports indicated that soybean oil based lipid emulsion could exert a negative influence on immunological functions. Those findings were related to its absolute and relative excess of ω-6 polyunsaturated fatty acids (PUFA) and the low amount of ω-3 PUFA and also to its high PUFA content with an increased peroxidation risk. The new lipid emulsion was basically designed in order to obtain balanced levels in polyunsaturated (ω-6 and ω-3), monounsaturated, and saturated fatty acids. They are differentiated by their fatty acid content, as well as fatty acid source of their origin, including soy, safflower, coconut, olive, and fish oil. Newer emulsions comprise physical mixtures of either a 20:80 mixture of soy ω-6 PUFA and ω-9 medium-chain monounsaturates (MUFA) from olive oil or a 1:1 ratio of LCT with coconut oil-derived medium chain triglycerides (MCT). Structured MCT/LCT emulsions formulated from a random combination of triglycerides synthesized on the same glycerol carbon chain are cleared faster from blood in moderately catabolic patients. The newer lipid com-

LCT long-chain triglycerides, *MCT* medium-chain triglycerides, *MUFA* mono unsaturated fatty acid.

binations with a smaller proportion of soy oil, have a much lower content of linoleic acid and linolenic acid, the potentially pro-inflammatory ω-6 PUFA, and less myristic, palmitic, and stearic acids. These long-chain SFAs are believed to have increased cardiovascular risk and can also have acute effects on cell growth and apoptosis. In MCT/LCT emulsions, MCT may be preferentially metabolized under certain clinical conditions and structured MCT may have a reduced tendency to accumulate in the reticulo-endothelial system. The olive oil-derived ω-9 MUFA appears less immunosuppressive and may inhibit release of pro-inflammatory cytokines. They are also less susceptible to peroxidation and well tolerated in critically ill neonates. Fish oil emulsions are predominantly ω-3 long-chain PUFA. Alone, they lack EFA and are formulated as a supplement to be administered with other nutritionally complete lipid products, or are manufactured as physical mixtures (10% fish:40% soy: 50% MCT or 30% soy:30% MCT:25% olive oil:15% fish). Fish oil-derived ω-3 PUFAs appear to alleviate symptoms of cholestasis, especially in neonates. Modern lipid products, based on olive, coconut, and/or fish oils, have demonstrable formulation and clinical benefits over traditional soybean and safflower IVLE and, when combined in the new multi-chamber bags, can also offer improvements in stability and safety [26–28].

47.3.1.3 Mineral Sources

In parenteral nutrition, calcium may be provided in the form of calcium gluconate, calcium chloride or calcium glycerophosphate. Due to aluminium contamination calcium gluconate was progressively abandoned by industry to meet the new FDA rule of 25 μg/L of aluminium in parenteral solution but remains frequently used in homemade hospital pharmacy preparations. Calcium chloride is easy to use but its high chloride content (2 mmol Cl^{-}/1 mmol Ca^{++}) limits its utilization in parenteral nutrition for VLBW infants [29, 30]. Calcium glycerophosphate with a 1:1 molar ratio is an adequate source of calcium and phosphorus, but is not registered for use in parenteral nutrition and needs to be prescribed from powdered anhydrous CaGlyP.

Phosphorus may be provided in inorganic (sodium or potassium phosphate) or organic form (glucose 1 phosphate, fructose 1-6 diphosphate, sodium glycerophosphate). Potassium phosphate is frequently preferred to sodium phosphate and used as the unique source of potassium in the parenteral solution. Potassium phosphate is easy to use but its high potassium content (1 mmol P^{3-}/1 mmol K for the monobasic form, 1 mmol P^{3-}/2 mmol K for the dibasic form or 1 mmol P^{3-}/1.7 mmol K for the mixed form) limit its utilization in parenteral nutrition for VLBW infants. Organic phosphorus in the form of disodium glucose 1 phosphate (Phocytan) is widely used in parenteral solution for VLBW infants. However, as for the use of sodium glycerophosphate, 2 mmol Na^{+}/1 mmol P^{3-}, or fructose 1-6 diphosphate (Esafosfina) the sodium content, 3 mmol Na^{+}/2 mmol P^{3-}, limits its utilization in VLBW infants particularly during the first weeks of life.

Magnesium is generally provided as magnesium sulfate in parenteral solution. Magnesium chloride has also been associated with the risk of inducing anionic-cationic imbalance in the parenteral solution.

47.3.1.4 Vitamins and Trace Elements

With the daily use of hydro- and lipo-soluble vitamins combined with trace elements clinical and biochemical evidence of deficiency were no longer reported.

47.3.2 Tailored or Standard Parenteral Solutions

Parenteral solutions can be prescribed using either of two formats: tailored or standard [31, 32]. Tailored solutions are formulated specifically to meet the daily nutritional requirements of the individual patient, whereas standard solutions are designed to provide a formulation that meets most of the nutritional needs of the stable biochemical and metabolic parameters. Both of these methods have advantages and disadvantages associated with their use.

Tailored solutions are based on the principle that no single parenteral regimen can be ideal for all patients, for a wide variety of pathological processes, all age groups, or for the

same patient during a single disease. The main advantage of tailored solutions is flexibility. Each solution is formulated for an individual patient and can be modified when the patient's nutritional needs and metabolic, electrolyte or clinical status changes.

The disadvantage of these solutions is linked to the time involved in calculation and label preparation, which today is nevertheless diminished with the use of specific computer programs. These solutions should be prepared with strict aseptic techniques, possibly in the pharmacy, not in the ward, and stored in a refrigerator at 4°C. The solutions thus prepared are stable for 96 hours and should be allowed to reach room temperature slowly and not warmed before infusion.

Standard solutions contain fixed amounts of each component per unit volume. In some hospitals there are a few types of fixed solutions to better cover the nutritional requirements of premature infants. The advantages of these solutions are that they include all the essential nutrients in fixed amounts, which eliminates the chances of inadvertent omission or overload. The disadvantage of standard solutions is their lack of patient specificity and the need of minimal adjustment particularly during the first days of life.

Very recently, it was suggested that the use of unique standard parenteral solution contribute to a significant improvement of nutritional support in both extremely and very preterm infants [33]. In addition, ready to use industrially manufactured multi-chamber bags (MCB) containing the 3 sterilized macro-nutrient solutions (amino acids, glucose, and lipids), in separate chambers of a single closed plastic system were evaluated in multicentric study and provides similar benefits [34]. Their guaranteed sterility and longer shelf life are major technological advances that minimize the risks of inadvertent contamination during compounding and storage.

47.3.3 Nutrient Intake

Table 47.4 shows the composition of a ready to use parenteral solution for VLBW infants used in our NICU and the daily nutrient intake (kg/d) given by total parenteral nutrition according to the new practice of "aggressive nutrition" for VLBW infants. In any case nutrient intakes are always indicative and may be modified according to each patient, his/her clinical picture, biochemical data and tolerance to nutrient intake. Thus, this standard solution could be diluted with free water according to fluid requirement and sodium intake could be adapted after a few days of life.

The following suggestions could be useful in the management of a parenterally fed VLBW infant.

- In the first days of life fluid intake should be increased if daily weight loss is > 5%, total weight loss> 12–15%, serum Na >150mmol/L, urinary osmolality >350 mOsm/L and if the infant is under phototherapy or managed in a radiant incubator. On the contrary fluid intakes should be reduced if daily weight loss <2% or there is a weight gain and serum Na <130 mmol/L.
- Glucose should be routinely administered after birth and progressively increased with the objective to increase energy intake. When a glucose infusion rate of 6 mg/kg/min or less leads to hyperglycemia, the use of insulin is advised. Insulin should be discontinued as soon as glucose tolerance is established and the energy supply necessary for growth can be delivered without hyperglycemia. If insulin is used, strict blood glucose monitoring is mandatory to avoid hypoglycemia.
- The starting dose of AA in the first day of life should be higher than what is currently advised. Intake should never

Table 47.4 Parenteral nutrition solution and daily nutrient intake (kg/d) of very low birth weight infants (<1500 g) in total parenteral nutrition according the "aggressive approach"

Day of life	Composition	D1 /kg/d	D2 /kg/d	D3 /kg/d	D4 /kg/d	D5 /kg/d	D6 /kg/d	>D6 /kg/d
Parenteral solution (mL)	100	50	70	100	120	140	150	150
Glucose (g)	12.5	6.3	8.8	12.5	15.0	17.5	18.8	18.8

Calcium (mg)	72	36	50	72	86	100	108	108
Phosphorus (mg)	55	27	38	55	66	77	82	82
Magnesium (mg)	8	4.0	5.6	8.0	9.6	11.2	12.0	12.0
Natrium (mmol)	1.6	0.8	1.1	1.6	1.9	2.2	2.4	2.4
Kalium (mmol)	1.5	0.8	1.1	1.5	1.8	2.1	2.3	2.3
Chloride (mmol)	2.0	1.0	1.4	2.0	2.4	2.8	3.0	3.0
AA supplement (g) *		1.0	1.0	0.5	–	–	–	–
Lipid emulsion 20% (g) *		1.0	1.5	2.0	2.5	3.0	3.0	3.0
Total fluid (mL)		65	83	110	132	155	165	165
Total energy (kcal) **	57	42	69	76	91	108	113	113
Total AA g		2.4	2.9	3.2	3.2	3.8	4.1	4.1

* Provided separately in Y route, ** Energy (kcal) = AA × 3.75 + Glu × 3.75 + lip × 9.3.
These nutrient intakes are a mere indication and have to be modified according to the clinical picture and biochemical data of the single patient.

be less than 1.5 g/kg/d and the starting dose should preferably be 2.0–3 g/kg/d. When energy intakes reach about 70 kcal/kg/d and there is no enteral protein intake, the dose should be increased progressively to 3.5–4.4 g/kg/d.

- Although many neonatal intensive care units start lipid infusion only after the first days, it seems logical to start parenteral lipid within the first day in order to avoid a prolonged interruption of essential fatty acids and LC-PUFA. The starting dose of 0.5–1 g/kg/d should be gradually increased to 3–3.5 g/kg/d. The lipid infusion should be adjusted to maintain a serum lipid <250 mg/dL. Using a similar approach allows to reduce the cumulative nutritional deficit and limit or abolish postnatal growth restriction in VLBW infants [15, 32].

Post-Discharge Nutrition in Preterm Infants

Richard J. Cooke

48.1 Introduction

The fundamental principle underlying nutritional support is that intake meets needs thereby ensuring the best outcome; in the case of the preterm infant, optimal growth and development. Achieving this goal is problematic and most, if not all very-low-birth-weight infants (VLBWI) are undernourished and under-grown at initial hospital discharge.

In term and preterm infants a clear relationship exists between poor growth and poor development. In preterm infants, the most rapid period of postnatal growth occurs between 37–38 weeks and 2–3 months corrected age. Infants who "recover" or "catch-up" during this period have better neurodevelopment while those who "fail to thrive" have poorer neurodevelopment. Precisely for these reasons preterm, particularly VLBWI, need close growth monitoring and specialized nutritional support after hospital discharge. In this chapter, we will review: a) the problem of undernutrition and postnatal growth failure (PGF) in preterm infants; b) the critical relationship between growth and development during infancy; c) studies examining growth and development in preterm infants fed nutrient-enriched formulas after hospital discharge; d) the breast fed infant; e) concerns about "recovery" or "catch-up" growth and the development of insulin resistance and visceral adiposity in preterm infants; f) outstanding issues about feeding preterm infants after hospital discharge.

48.2 Undernutrition and Postnatal Growth Failure in Preterm Infants

Several studies have examined postnatal growth in preterm infants during initial hospital stay and noted that most preterm, if not all very-low-birth-weight infants (VLBWI), are growth retarded at hospital discharge [1–7]. In studies where nutritional intake was measured, recommended dietary intakes (RDIs) took time to establish and infants accrued a significant nutrient deficit that was directly related to the growth deficit [1–5]. In studies where intake was not measured, poor growth was related to associated illness [6, 7]. This is not surprising because it takes time to establish RDIs in the smaller sicker infant. Once established, intake may be interrupted during episodes of clinical instability further increasing the nutrient deficit. However, other factors may underpin the development of growth failure in these infants.

Current recommendations are that the rate of weight gain parallel that of the fetus of the same gestational age once birth weight has been regained [8, 9]. Yet, a 26 weeks gestational age weighing ~ 850 g at birth who regains birth weight by 2 weeks of age and grows at the intrauterine rate will weigh ~550 g less than the fetus and be growth retarded at 36 weeks (Fig. 48.1). If current recommendations are met most, if not all, VLBWI will be growth retarded at hospital discharge.

Current recommendations assume that nutritional requirements are consistent throughout gestation for all preterm low birth weight infants [8, 9]. However, Ziegler et al have noted that protein and energy requirements change with advancing gestation [10] (Table 48.1). In effect, a formula containing a protein: energy ratio of 3.0 g/100 kcal, as is currently fed to preterm infants, does not meet the protein: energy needs of the infants weighing ≤1500 g at birth; i.e., the VLBWI.

Recommended dietary intakes are based on needs for maintenance and normal growth [8, 9], no allowance is made for recovery or "catch-up" growth [11]. In the study of Embleton et al, the accrued protein deficit at hospital discharge varied from 15 to 25 g/kg [3]. An additional protein intake of 0.5–1.0 g/kg/day would have been required to recoup this deficit before hospital discharge, further compounding the problem.

To further examine this issue, body size and body composition were measured in preterm infants at hospital discharge [12]. Weight, length and head circumference were measured using standard methodology [13]. Body

Table 48.1 Protein and energy needs in preterm infants

Weight (g)	500–700	700–900	900–1200	1200–1500
Protein (g/kg/day)	4.0	4.0	4.0	3.9
Energy (kcal/kg/day)	105	108	119	127
P:E (g/100 kcal)	3.8	3.7	3.4	3.1

composition was measured using dual-emission X-ray absorptiometry (DEXA) [14].

One hundred and forty nine infants (birth weight = 1406 ± 248 g, gestation = 31 ± 1.7 weeks) were studied. Post-menstrual age at discharge was 37 ± 1.2 weeks. However, z-score for head circumference was significantly greater than that for weight which in turn was greater that for crown-heel length ($-0.1 \pm 0.6 > -1.4 \pm 0.6 > -1.9 \pm 0.6$; $p < 0.0001$) [15]. Body composition results are compared to the reference infant at the same weight and same gestation in Table 48.2.

Global fat-free mass was less in study infants than the reference infant at the same weight (2062 < 2252 g; $p < 0.0001$) or gestation (2062 < 2667 g; $p < 0.0001$). Global fat mass was greater in study infants than the reference infant at the same weight (307 > 198 g, 13 > 8%) or gestation (307 > 273 g; 13 > 9%; $p < 0.0001$). At the same time, changes in central fat mass closely paralleled those in total fat mass ($y = 23 + 0.31x$, $r^2 = 0.77$, $p < 0.0001$) [12].

Table 48.2 Body composition of study infants compared to the reference infant at the same weight and same gestation

	Study infants	Reference at 35 weeks	Reference at 37 weeks
Body weight (g)	2369 ± 305	2450	2940
Fat-free mass (g)	2062 ± 277*	2252*	2667*
Fat-free mass (%)	87 ± 3.4	91.9	90.7
Fat mass (g)	307 ± 130**	198**	273**
Fat mass (%)	13 ± 3.4**	8.1**	9.3**

* Study infants < Reference infant at 35 or 37 weeks ($p < 0.0001$).
** Study infants > Reference infant at 35 or 37 weeks ($p < 0.001$).

A reduced body size that is paralleled by reduced linear growth and a reduced fat-free mass suggest that dietary protein needs were not met in these infants before hospital discharge, as has been previously suggested [10]. A reduced fat-free mass coupled with an increased global and central fat mass echoes concerns about visceral obesity and the development of insulin resistance in these high-risk infants [16, 17].

Although many factors contribute to the development of postnatal growth failure and the degree of failure will vary, depending upon the level of maturity of the infant [3], one point is clear; i.e., close attention must be paid to nutritional support and growth of these infants after hospital discharge. A reduced body size that is paralleled by a reduction in fat-free mass but a relative increase in fat mass indicate that particular attention be paid to dietary protein and energy intakes in these infants.

48.3 Growth and Development in Preterm Infants

Nutrients play a critical role the promotion of normal health and prevention of disease [18]. It is not surprising, therefore, that malnutrition can be directly related to alterations in organ structure and function which, in turn, are paralleled by an increased morbidity and mortality in adults and children [18]. However, the effects of malnutrition appear to be greater during early infancy than later on in life. There are several reasons for this. Requirements are a function of growth rate, the greater the rate the greater the requirement, the more likely that deficiency will occur. Growth rates are greater during infancy than later in life; i.e., the term infant will double birth weight by 4–5 months, triple birth weight by 12 months and approximately quadruple it by 24 months.

Studies have also suggested that growth is "pre-programmed" to occur at a certain time or "critical" epoch which if missed may not be recoverable [19]. In effect, even short periods of nutritional deprivation may not only affect somatic but also brain growth and development [19], the area of the brain that is "programmed" to grow fastest being the most affected [20].

Studies in term infants have shown that malnutrition during infancy is associated with permanent alterations in brain growth and function. Brain size is reduced [21–25], the brain cortex is thinner [26], neuronal numbers are decreased [27], myelination is reduced [28] and dendritic morphology is altered [29, 30], all of which can be related to poorer neuro-developmental outcome [31–39].

Concerns for the term are even greater in preterm infants. Growth rates are greater. A preterm infant is "programmed" to quadruple brain weight between 24 and 40 weeks gestation or 16 weeks [40], almost 6 times faster than the term infant. Preterm infants are more vulnerable to the effects of perinatal ischemia and inflammation, therefore the development of

periventricular intraventricular hemorrhage and periventricular leucomalacia [41]. They are also more likely to be fetally and/or postnatally malnourished. Up to 40% of preterm infants are growth retarded or small for gestational age (SGA) at birth [42], while up to 100% of VLBWI are SGA at hospital discharge [6].

Poor fetal growth is paralleled by reduced organ growth as well as altered structure and function [43] but not all organ systems are affected equally. This is nicely illustrated in the study of Myers et al [44]. In this study, 30% reduction in body weight in SGA monkeys was associated with an 8% reduction in brain weight but ≥35% reduction in lung, liver, pancreatic and spleen weights when compared to their AGA counterparts [44]. Thus, the brain is "spared" at the expense of other organs which; e.g., through the development of chronic lung disease, sepsis, etc [6], may amplify undernutrition by reducing intake and increasing requirements.

In the late 80's and early 90's, studies indicated that poor growth between birth–hospital discharge was associated with poorer neurodevelopment [45, 46] and that better growth, as achieved by feeding a nutrient-enriched formula, was associated with better developmental outcomes [47, 48]. More recently, early parenteral nutrition coupled with the early introduction and advancement of enteral feeds has been associated with better growth but many infants continue to be SGA at hospital discharge [49–52].

A clear relationship exists between "catch-up" growth and development in preterm infants but the time frame within which it needs to occur is not well delineated. In most studies, infants who "recover" or "catch-up" by 6–9 months corrected age (mca) have better neuro-developmental outcome [45, 53–56]. This is nicely illustrated in the study of Latal-Hajnal et al [56]. In this study, postnatal growth and neurodevelopment were studied in 219 VLBWI. Infants were stratified at birth into those who were appropriate size for gestational age (AGA weight ≥10th %tile) and SGA (weight <10th %tile). This process was repeated at 2 y of age. Four groups emerged: a) AGA at birth and 2 yrs (AGA-AGA), b) AGA at birth and SGA at 2 yrs (AGA-SGA), c) SGA at birth and AGA at 2 yrs (SGA-AGA) and d) SGA at birth and 2 yrs (SGA-SGA).

No differences were noted in development between the AGA-AGA and SGA-SGA infants. After adjusting for co-variables, infants who "caught-up"; i.e., SGA-AGA, had greater Bayley PDI (Psychomotor Development Index) scores than those who did not; i.e., SGA-SGA. Infants who "faltered"; i.e., AGA-SGA, had lower PDI's and MDI (Mental Development Index) scores, than those who continued to thrive; i.e., AGA-AGA. These authors concluded that the course of postnatal growth primarily determined later development.

To further examine this issue, our group examined postnatal growth and development in 119 preterm infants with a gestational age of <32 weeks [57]. It was hypothesized that the greater the degree of growth failure between birth–28 days; i.e., fall in z-score between birth and 28 days, the poorer the development at 18 mca. Body weight was determined at birth, 28 days, hospital discharge and serially until 18 mca. Developmental outcome was determined at 18 mca.

At 28 days, infants were stratified into those who were mildly (fall in z-score <–1.0 SD; MGR), or severely (fall in z-score ≥ –1.0 SD; SGR) growth retarded. At 18 mca, this process was repeated and 4 groups emerged; mildly growth retarded at 28 days and 18 mca (MGR-MGR), mildly growth retarded at 28 days but severely growth retarded at 18 mca (MGR-SGR), severely retarded at 28 days but mildly retarded at 18 months (SGR-MGR), severely retarded at 28 days and 18 mca (SGR-SGR).

The characteristics of the study infants are presented in Table 48.3. No differences were noted with the exception that gestational age was less (SGR-SGR < MGR-MGR, MGR-SGR, $p < 0.05$) and the frequency of cerebral palsy tended to be greater (SGR-SGR >MGR-MGR, SGR-MGR, $p < 0.10$) in infants with severe growth failure at 28 days and 18 mca.

Growth of the study infants is presented in Fig. 48.2. Between birth–28 days, all infants failed to thrive. Thereafter, all infants "recovered" or "caught-back" to some degree. However, recovery was more complete in the MGR-MGR and SGR-MGR than in the MGR-SGR and SGR-SGR infants. Infants who "recovered" (SGR-MGR) or "faltered", (MGR-SGR) did so between 28 days and 1–2 mca, a time when programmed growth velocity is greatest in the preterm infant [58].

Bayley's developmental scores are presented in Table 48.4. A 17-point difference in MDI ($p < 0.01$) and 14-point difference in PDI ($p < 0.05$) was noted between the MGR-MGR when compared to SGR-SGR infants supporting the hypothesis

Table 48.3 Characteristics of study infants

Group (N)	MGR-MGR (50)	MGR-SGR (18)	SGR-SGR (16)	SGR-MGR (24)

Cerebral palsy	4 (8%)	3 (17%)	5 (30%)**	2 (8%)

* SGR-SGR < MGR-MGR, MGR-SGR, $p < 0.05$.
** SGR-SGR > MGR-MGR, SGR-MGR, $p < 0.10$.

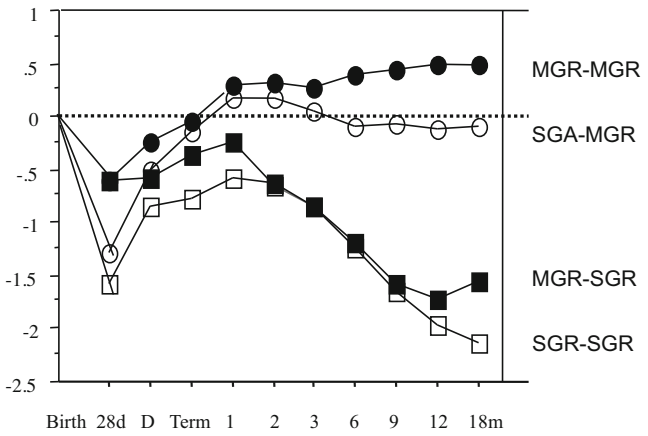

Fig. 48.2 Growth, i.e., change in z-score between birth and 28 days, term and one through 18 months corrected age, in study infants

Table 48.4 MDI and PDI in study infants

Group (N)	MGR-MGR	MGR-SGR	SGR-MGR	SGR-SGR
MDI*	93 ± 18	91 ± 18	95 ± 1	77 ± 19
PDI*	90 ± 17*	83 ± 19	87 ± 19**	77 ± 22*
MDI**	96 ± 15	93 ± 20	98 ± 16	88 ± 11
PDI**	94 ± 13	89 ± 15	91 ± 14	89 ± 16

* MDI ~ MGR-MGR, SGR-MGR > SGR-SGR. p < .05.
* PDI ~ MGR-MGR (p <.05), SGR-MGR (p <.10) > SGR-SGR.
** Infants with cerebral palsy excluded. MDI ~ MGR-MGR (p < .05), SGR-MGR (p < .10) > SGR-SGR.

that the greater the degree of growth faltering between birth–28 days, the poorer the developmental outcome. An 18-point difference was noted in MDI (p <0.05) and a 14-point (p <0.10) difference in PDI between SGR-MGR and SGR-SGR infants. When infants with cerebral palsy are excluded, differences in MDI but not PDI persist between the study groups.

Collectively, these data support the conclusions of Latal-Hajnal et al; i.e., it is the course of postnatal growth that determines later developmental outcome. These data also support the idea that a "critical window of opportunity" exists between 28 days and 1–2 mca during which "recovery" or "catch-up" growth to the original birth weight %tile is paralleled by better neuro-developmental outcome. If infants are to "recover", this is the time to do it.

48.4 Studies Examining Post-Discharge Nutritional Support in Preterm Infants

48.4.1 Effects on Growth

Several studies have examined post-discharge growth in preterm infants [36, 59–64]. Although some "catch-up" growth has been observed, preterm infants do not grow as well as their term counterparts and are smaller at 3 y [65], 8 y [66] and adulthood [67]. There are several possible reasons for this.

Current in-hospital feeding practices ensure that most, if not all VLBWI are undernourished and growth retarded at initial hospital discharge [3, 7]. A "critical epoch" of growth may, therefore, have been missed. Preterm infants also have greater morbidity than term infants during the first year of life [68–72] and inter-current illness will affect growth, irrespective of whether infants are admitted to hospital or not.

Until relatively recently, little attention had been paid to nutritional factors in the pathogenesis of this problem. For most early studies, infants were fed either human milk or a term infant formula after hospital discharge [36, 59–64]. Both feeding regimens were designed to meet nutritional needs of the term rather than the rapidly growing preterm infant. Infants, therefore, may have been partly underfed during the first 6–12 months of life.

More recently studies have examined the effects of feeding nutrient-enriched formulas; i.e., formulas with a greater nutrient density than a term infant formula, to preterm infants after hospital discharge [13, 14, 73–83]. The general characteristics of these studies are listed in chronologic order in Table 48.5.

Lucas et al randomized preterm infants (birthweight ≤ 1800 g, gestational age ≤ 34 weeks; n =16/gp) to be fed either a term formula or nutrient-enriched infant formula after hospital discharge. Those fed the nutrient-enriched formula grew better [73] and had better bone mineralization at 3 and 9 mca [74]. However, Chan et al were unable to show any differences in growth between preterm infants fed a term formula and those fed either a nutrient-enriched or preterm infant formula after hospital discharge [75].

Cooke et al randomized otherwise "normal" preterm (≤1750 g birth weight, ≤34 weeks gestation) infants to one of three feeding groups: one group (n = 49) was fed a nutrient-enriched infant formula between discharge–6 mca, the second group (n = 54) a term formula between discharge–6 mca and the third (n = 26) a nutrient-enriched formula between discharge–erm and a term formula between term–6 mca [13, 14, 77].

Infants fed the nutrient-enriched formula between discharge–6 mca, had lower volumes, similar energy but greater protein intake than the other groups (Fig. 48.3). Increased protein intake was paralleled by greater serum urea nitrogen and weight and length gains, which in turn, were reflected by greater body weight, length, lean mass and absolute (g) but not fractional fat (%) mass. No other differences were detected in growth or body composition between the groups. Initial analyses indicated that effects on growth were predominantly in boys. A subsequent analysis was performed when data were converted to z-scores (Fig. 48.4). Between birth and discharge, z-scores for body weight fell in boys in both treatment groups. Between discharge–6 mca, z-scores were consistently greater in boys fed the preterm formula. The pattern is the same in girls, indicating that girls also benefited when fed the nutrient-enriched formula.

Table 48.5 Characteristics of studies examining growth in preterm infants fed nutrient-enriched formulas after hospital discharge

Study	Protein content*	Energy content**	Sample size	Study duration	Benefit
Lucas et al [73, 74]	2.6 g	72 kcal	32	9 mca***	Yes[1]
Chan et al [75]	2.6 g	67 kcal	43	16 wca****	No
Wheeler et al [76]	2.7 g	67 kcal	43	12 wca	Yes[2]
Cooke et al [13, 14, 77]	2.8 g	80 kcal	129	6 mca	Yes[3]
Lucas et al [78]	2.6 g	72 kcal	229	9 mca	Yes[4]
Carver et al [79]	2.6 g	74 kcal	125	12 mca	Yes[5]
De Curtis et al [83]	2.4 g	74 kcal	33	2 mca	No
Agosti et al [80]	3.0 g	80 kcal	121	15 wca	Yes[6]

Koo et al [82]	2.6 g	74 kcal	89	12 mca	No

* Study formula /100 kcal ** Study formula /100 mL *** Months corrected age **** Weeks corrected age
[1] Increased weight and length at 9 months.
[2] Increased length and head circumference at 8 wca.
[3] Increased weight, length and head circumference at 6, 12 and 18 mca, predominantly in boys.
[4] Increased length at 18 months, boys only.
[5] Increased weight, length and head circumference at 12 months in infants weighing < 1250 g at birth, predominantly in boys.
[6] Increased weight at 6 months and 6 mca, boys only. Increased length at 12 mca, SGA infant boys only.
[7] Increased weight and bone mineral content at term.

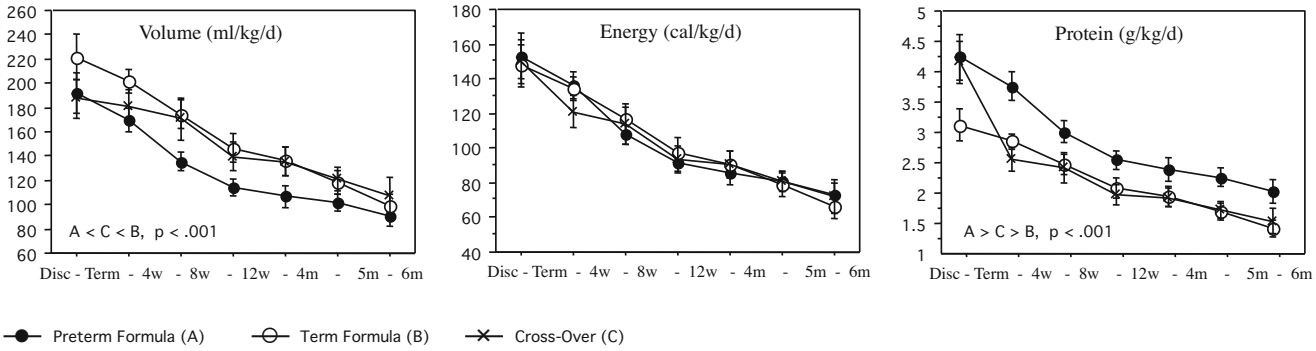

Fig. 48.3 Nutrient intakes between discharge and 6 months in study infants fed either a preterm infant formula (group A), a term formula (group B) or a preterm infant formula (discharge-term) and term infant formula (term–6 months; group C)

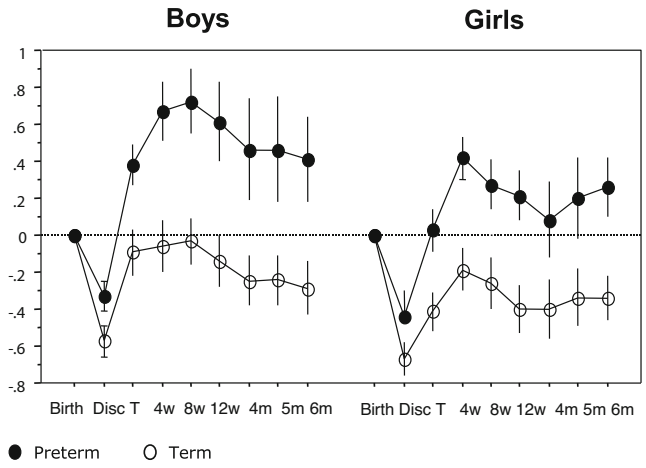

Fig. 48.4 Growth, expressed as weight z-score, in boys and girls fed either the preterm formula or the term infant between discharge and 6 months corrected age

Carver et al randomized preterm infants (<37 weeks, ≤ 1800 g) to be fed either a nutrient-enriched formula (n = 67) or a term formula (n = 56) between discharge and 12 mca [79]. Infants were stratified according to birth weight (< 1250 g, ≥ 1250 g). No differences were detected in energy intake but protein intake was greater in infants fed the nutrient-enriched formula. Growth was also better, particularly in infants <1250 g who were heavier, longer and had a greater head circumference at 6 mca.

Lucas et al randomized a group of preterm infants (< 37 weeks, < 1750 g) to be fed a either a nutrient-enriched (n = 113) or term (n = 116) formula between discharge and 9 mca [78]. Infants fed the enriched formula grew better; i.e., were heavier and longer at 9 mca and longer at 18 mca, than infants fed the term formula, an effect that was more marked in boys than girls.

De Curtis et al randomized a group of preterm infants (< 35 weeks gestational age; birth weight of < 1750 g) to be

fed either a nutrient-enriched formula (n = 16) or a standard term formula (n = 17) between hospital discharge at ~ 37 weeks and ~ 2 mca [83]. No differences were detected in volume of formula intake but protein and energy intakes were greater in infants fed the nutrient-enriched formula. No differences were detected in growth or body composition between the treatment groups.

Agosti et al randomized preterm infants (< 1500 g) to be fed either a nutrient-enriched (n = 62) or a standard term infant (n = 52) formula between term and 15 weeks corrected age (wca) [80]. A trend towards to increased weight and head circumference was noted at 12 mca, while weight increase was greater in boys at 15 wca and 6 mca in infants fed the nutrient-enriched formula. Length increase at 12 months was also greater in SGA infants fed the nutrient-enriched formula.

Lapillone et al randomized preterm infants (28–32 weeks gestation; 1000–1500 g) to be fed either a standard (n = 20) or a nutrient-enriched (n = 21) preterm formula during initial hospital stay until term corrected age, and then to ~ 3 mca [81]. The formulas differed in protein (2.5 v 2.7 g/100 kcal) and mineral content, plus 25% and 40% for calcium and phosphorus intake, for infants fed the nutrient-enriched formula. No differences were detected in growth but bone mineral mass was greater at term in infants fed the latter.

Koo et al randomized preterm infants (630–1620 g; 24–34 weeks gestation) to be fed a nutrient-enriched (n = 45, protein content 2.6 g/100 kcal) or term (n = 45, protein content 2.14 g/100 kcal) between hospital discharge and 12 mca [82]. Weight, length and head circumference were greater in infants fed the term infant formula. Lean, fat and bone mass were also greater in these infants.

Reviewing the results of studies published before 2005 Henderson et al concluded that feeding with nutrient-enriched formulas had little effect on growth [84]. As such, their conclusions on growth merit examination.

The first outcome variable evaluated was "growth during the trial period". The results of only one study were used; i.e. de Curtis et al [83] wherein the sample size was 33 and the end-point was gain in weight, crown-heel length and head circumference between 36 wca and 2 mca. Yet, growth velocity changes rapidly during this time (Fig. 48.5) and that which is averaged over a 12 weeks period may not reflect early but significant differences between the groups [13].

The second end-point was "longer-term growth"; i.e., weight, length and head circumference at 6, 9 and 18 mca. Data from only one study was used at 6 mca [85] and one at 9 mca [78], again not entirely representative. The conclusions drawn by Henderson et al on growth, therefore, must be questioned. However, a closer look at these studies is revealing.

In the study of Cooke et al, one group was fed the nutrient-enriched formula to term and no growth advantage was detected [13, 14, 77]. In the study of de Curtis et al, the nutrient-enriched formula was fed to 2 months and no growth advantage was detected [83]. Yet, in the studies with an adequate sample size, where the nutrient-enriched formulas were fed to 6 [13, 14, 77], 9 [78] and 12 [79] mca, growth was better, suggesting that duration of feeding is an important consideration.

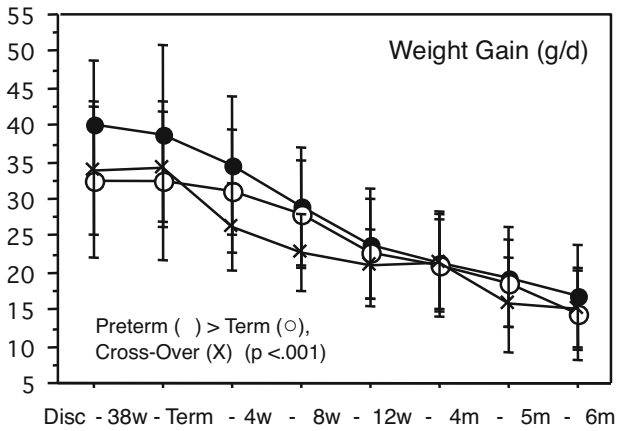

Fig. 48.5 Growth velocity, expressed as weight gain, in study infants fed either a preterm infant formula (*closed circle*), a term formula (*open circle*) or a preterm infant formula (discharge-term) and term infant formula (X)

In the studies of Cooke et al [13, 14, 77], Carver et al [79] and Lucas et al [78] infants were stratified according to sex. In these studies, the effect of diet was greatest in males. This may not be surprising because boys are programmed to grow faster and accrete more lean mass [86] and, therefore, benefit from a higher protein-to-energy ratio. This is illustrated in Fig. 48.6 where boys fed the nutrient-enriched formula had greater weight gain, lean mass gain, body weight and lean mass when compared to girls fed the same formula [14].

In the study of Carver et al infants were stratified according to birth weight, <1250 and 1250–1800 g [79]. Infants < 1250 g also seemed to benefit more from the nutrient-enriched formula. This also is not surprising. At hospital discharge, the more immature the infant the greater the accrued nutrient deficit the more likely the infant is to benefit from a post-discharge nutrient-enriched formula.

48.4.2 Effects on Development

Three studies have examined neuro-developmental outcome in preterm infants fed a nutrient-enriched formula after discharge in otherwise "normal" preterm infants [77, 78, 80] with another study assessing outcome in infants with perinatal brain injury [87].

Cooke et al also fed preterm infants (n = 113, ≤ 34 weeks gestation) either a nutrient-enriched or a term formula between discharge–6 mca [77, 78]. Although boys fed the nutrient-enriched formula had a greater head circumference at 6, 12 and 18 mca no differences were noted in MDI or PDI between the treatment groups (Table 48.6). However, boys

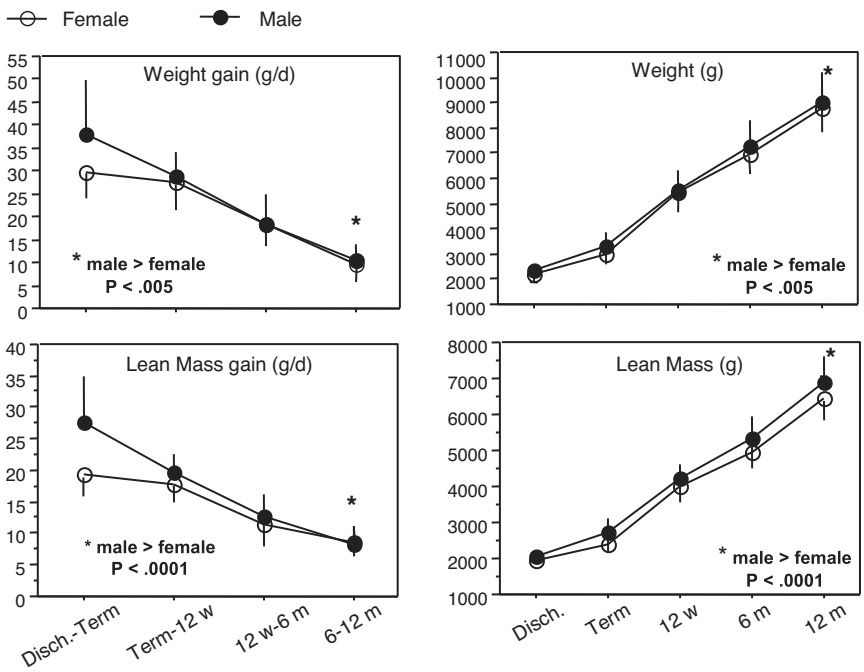

Fig. 48.6 Growth and lean body mass between discharge and 6–12 months corrected age in boys and girls fed the preterm infant formula

fed the term formula had the lowest head circumference [77]. Boys fed the term formula also had an MDI that was 10 points lower than girls fed the term formula (Table 48.6), suggesting that they were at a disadvantage when fed the term formula.

In the study of Lucas et al, preterm infants (n = 229, < 37 weeks gestation) were fed either a nutrient-enriched or a standard term infant formula between discharge–9 mca [78]. At 9 mca, no differences were noted in head circumference or development. At 18 months, no differences were noted in head circumference or development but infants fed the nutrient-enriched formula had a + 3 advantage point in PDI and it was concluded that they "could not reject the hypothesis that post-discharge nutrition benefits motor development" [78].

Agosti et al fed preterm infants (n = 121) either a nutrient-enriched (protein content = 3.0 g/100 kcal; energy content = 80 kcal/100 mL) or a term (protein content = 2.4 g/100 kcal, 70 kcal/100 mL) infant formula between term and 15 wca [80]. Development at 6 months, as assessed on the Griffiths Developmental Scale, was better in small for gestational age boys fed the nutrient-enriched formula.

Table 48.6 Bayley MDI and PDI scores in study infants

Formula group	Nutrient-enriched	Term	Nutrient-enriched + Term
MDI			
1. All	102 ± 14	103 ± 14	102 ± 11
2. Girls	103 ± 14	107 ± 14	104 ± 12
3. Boys	100 ± 15	97 ± 11	99 ± 11
PDI			
1. All	102 ± 8	103 ± 9	99 ± 8
2. Girls	103 ± 8	105 ± 9	98 ± 8
3. Boys	101 ± 7	101 ± 7	101 ± 7

Some insights can be obtained by comparing these three studies [77, 78, 80]. Although enrollment criteria and composition of studies formulas differed significantly between the studies and no overall differences were noted in development between control and treatment groups, all suggest that male infants are more likely to benefit from being fed a nutrient-enriched formula. Put in another way, male infants appear to be at a disadvantage when fed a term formula after hospital discharge.

More recently, Dabydeen et al prospectively randomized term and preterm infants with perinatal brain injury to either a control or high energy and protein diet during the first year of life [87]. Infants fed the high energy and protein diet had a greater head growth and axonal diameters when compared to the control group. It was concluded that infants with significant perinatal brain injury had increased nutritional requirements and that inadequate intake, as is commonly noted in neurologically impaired infants, may compromise subsequent brain growth and development [87].

Collectively, these data [77, 78, 80, 87] suggest that post-discharge nutrition may affect developmental outcome. In the case of the otherwise "normal" preterm infant, male infants appear most likely to benefit. In infants with perinatal brain injury, both term and preterm infants may benefit. Further appropriately "powered" studies are needed to examine both these issues.

48.5 The Breast-Fed Infant

Before hospital discharge, preterm infants fed human milk do not grow as well as infants fed nutrient-enriched formulas

[88, 89]. It is, therefore, recommended that human milk be fortified with additional nutrients [9]. Growth improves but it is still not as good as in infants fed a preterm infant formula [2]. The reasons for this are not entirely clear.

Fortifiers differ in nutrient composition and it is unclear which, if any, really meets requirements. The composition of human milk varies widely [90] and because it is not consistently measured there is no way of knowing what the infant is really receiving. In effect, intake less adequately meets requirements and growth is poorer. Nonetheless, because of lower rates of morbidity; e.g., sepsis and necrotizing enterocolitis [91], and improved developmental outcome [92] it is recommended that fortified human milk be fed whenever possible before hospital discharge [9].

After hospital discharge, breast-fed infants also grow more poorly than those fed nutrient-enriched formulas [75, 78, 93]. This also is not surprising. Before discharge, intake less adequately meets requirements, the accrued nutritional deficit and, therefore, needs for "recovery" are greater. Mature human milk is designed to meet the needs of the term infant and not the preterm infant and there are significant differences in nutrient content between mature human milk and formulas used to feed infants before and after discharge (Table 48.7).

Poorer growth after discharge is paralleled by alterations in bone mineral metabolism and body composition. Bone mineral accretion is less in infants fed unsupplemented human milk after discharge [75, 78, 93–95]. This, in turn, can be related to outcome on a short-term; e.g., osteopenia [96] and fractures [97], and long-term; e.g. poorer linear growth [98], basis. Infants fed human milk also have increased fat accretion when compared to those fed a nutrient-enriched formula [93].

These data support the idea that infants grow as they are fed. When mineral intake is inadequate infants are at-risk for deficit in mineral accretion. If the protein–to–energy intake is inadequate then, as in term infants [99], infants will accrete less lean but increased fat mass. Whether the latter in some way alters "programming" and, therefore, health in adult life remains to be determined.

In a recent stratified and randomized controlled pilot trial, preterm infants (750–1800 g) were fed unfortified (n = 20) or fortified (n = 19) human milk after hospital discharge–12 weeks [100]. A multi-nutrient fortifier, estimated to ensure an energy and protein density of 80 kcal and 2.2 g/100 mL, was added to 50% of feeds. Weight tended to be greater (all) while length (all) and head circumference, for infants ≤ 1250 g only, were greater in the fortified group. These data tend to support the idea that fortification, at these levels, promotes a proportional increase in lean and bone mass but further studies are needed in a larger group of infants to determine the best method to fortify human milk in these high-risk infants.

In the meantime, follow-up care and advisement of breast-feeding mothers after hospital discharge remains a critical issue. How often should these high-risk infants be followed up? What are acceptable growth rates and biochemical determinations in breast-fed infants? Schanler has suggested that human milk be fortified when weight, length or head circumference gains are < 25 g/day, 1.0 cm/weeks and 0.5 cm/weeks and or serum phosphorus, alkaline phosphatase or urea nitrogen levels are < 4.5 mg/dL (< 1.45 mmol), > 450 IU/L and <0.5 mg/dL (0.8 mmol) in the first 6–8 weeks after hospital discharge [101]. Given the relatively rapid rates of programmed growth [58] and critical importance that "catch-back" plays on brain growth and development during this period [57] infants should be seen every 2–3 weeks between hospital discharge and 3 mca.

Table 48.7 A comparison of nutrient content of human milk with preterm, nutrient-enriched post-discharge and term infant formulas

Per liter	Human milk	Preterm	Post-discharge	Term
Energy (kcal)	670	810	730	670
Protein (g)	10	23	20	14
Fat (g)	35	42	40	36
Carbohydrate (g)	70	88	78	73
Calcium (mg)	260	1400	850	530
Phosphorus (mg)	140	700	480	330
Sodium (mmol)	9	15	11	8
Chloride (mmol)	16	19	17	12
Zinc (mg)	3.2	12.1	9	6
Vitamin A (mg)	0.7	3	1	0.6

48.6 Catch-up Growth, Insulin Resistance and Visceral Obesity in Preterm Infants

Concern has been expressed about "catch-up" growth and the subsequent development of insulin resistance [102, 103] and metabolic syndrome X [104] leading to the idea that "bigger might not be better", even in preterm infants [103]. However, a certain amount of confusion exists when the term "catch-up" is used to describe growth during infancy.

In many instances, "catch-up" growth is related to weight gain and then to the subsequent risk of obesity [104]. It has been interpreted more as a pathologic rather than physiologic phenomenon and, therefore, best avoided. But weight gain "per se" reveals little information on the nature of the gain. It also fails to recognize that it is not preventable; i.e., after a period of growth faltering all infants "recover" or "catch-up" to some degree once the underlying cause is treated and more adequate nutrition is provided.

The extent to which "catch-up" occurs depends on many factors, including timing of the insult. Growth is thought to be programmed within a specific time frame or critical epoch which if missed my not be recoverable [43, 105]. It also depends upon the severity and duration of the insult, the more severe and prolonged the insult the greater the accrued nutritional deficit. Subsequent intake must not only replace the accrued nutritional deficit but also meet needs for maintenance and normal growth.

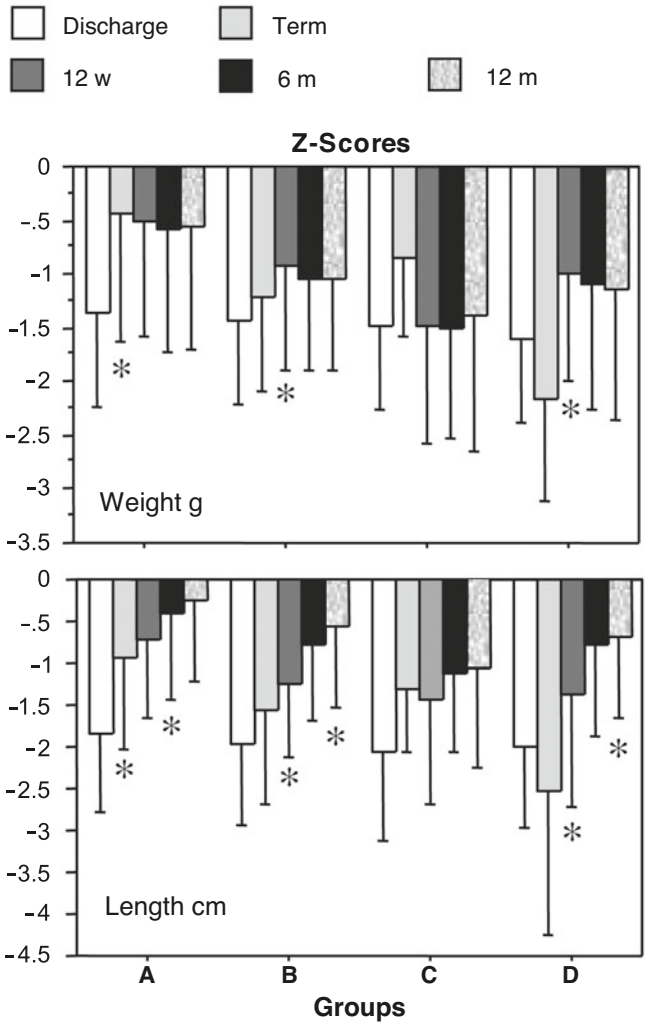

Fig. 48.7 Growth, expressed as weight and length z-scores, in study infants fed either a preterm infant formula (A), a term formula (B) or a preterm infant formula (discharge-term) and term infant formula (C) compared to a reference group of breast-fed infants (D)

With acute illness, infants develop a hyper-metabolic state and there is an acute depletion of body protein to meet energy needs [106]. With chronic protein-energy malnutrition during infancy visceral tissue is conserved at the expense of protein and fat [107]. Nutritional rehabilitation in these infants with high-energy intakes results in increased weight gain [108] and body fat [108, 109]. In effect, the nature of the gain is directly dependent upon the compositional nature of intake.

At hospital discharge, preterm infants have accrued a significant protein deficit [3] and are lighter, shorter and fatter that the reference infant at the same body weight or gestation [16]. After hospital discharge, a diet that is relatively high in energy may promote "catch-up" that is paralleled by increased and altered adiposity; i.e., central fat accretion. A diet that better meets protein needs may be paralleled by increased lean mass accretion.

Term infant formulas have a protein content of 1.8 g/100 kcal. Nutrient-enriched formulas, as fed to preterm infants after hospital discharge, have a protein content that varies from 2.5 to 2.7 g/100 kcal. In a prospective randomized controlled trial (Fig. 48.7), body size and composition were measured in preterm infants fed either a preterm formula (protein content 2.7 g /100 kcal, discharge–6 months; A), a term formula (protein content 1.8 g/100 kcal, discharge–6 months; B), a preterm formula to term then a term formula to 6 months; C) or unfortified breast milk (D).

"Catch-up" in weight and length were faster and more complete in infants fed the preterm formula (group A; Fig. 48.7). This was paralleled by an increase in non-fat mass and total fat mass but not % fat mass (Table 48.8). Changes in central fat mass (trunk + pelvis; $y = 41 + 0.30x$, $r^2 = 0.90$, $p < 0.0001$) and leg fat mass ($y = 034 + 0.40x$, $r^2 = 0.91$, $p < 0.0001$) were linearly related to those in total fat mass. Changes in central and leg fat mass accounted for 30% and 45% of the variation in total fat mass. No differences were detected in central fat mass between the groups but leg fat mass was greater in infants fed

Table 48.8 Body composition in study infants

	Group	Term (n = 148)	12 weeks (n = 141)	6 months (n = 145)	12 months (n = 138)
Fat-free mass* (g)	Preterm (A)	2745 ± 445	4270 ± 452	5208 ± 638	6872 ± 806
	Term (B)	2393 ± 276	4022 ± 411	5139 ± 515	6592 ± 738

Table 48.9 Regional fat accretion (grams) in study infants

	Group	Term	12 weeks	6 months	12 months
Trunk	Preterm (A)	172 ± 65	532 ± 168	651 ± 218	699 ± 249
	Term (B)	182 ± 71	485 ± 154	635 ± 170	613 ± 160
	Cross-Over (C)	186 ± 67	394 ± 136	579 ± 221	573 ± 162
	Breast-Fed (D)	147 ± 54	503 ± 183	688 ± 229	657 ± 230
Legs *	Preterm (A)	159 ± 58	500 ± 155	736 ± 270	975 ± 354
	Term (B)	133 ± 73	451 ± 168	652 ± 300	830 ± 271
	Cross-Over (C)	129 ± 75	458 ± 133	602 ± 247	822 ± 409
	Breast-Fed (D)	98 ± 58	454 ± 183	654 ± 289	897 ± 254

* A > B ($p < .01$), C ($p < .001$), D ($p < .10$).

the preterm formula (Table 48.9). Thus, more rapid "catch-up" or "recovery" growth was paralleled by an increase in linear growth, lean and fat mass accretion, the latter primarily reflecting increased peripheral rather central fat mass accretion.

These data do not support the idea that adiposity is increased or altered in preterm infants fed a nutrient-enriched formula after hospital discharge when compared to infants fed a term formula or infants fed unfortified human milk. However, the data must be interpreted with caution. Body composition was measured using DEXA, which does not differentiate subcutaneous and visceral fat and subtle differences in visceral fat mass may have gone undetected. Insulin sensitivity/resistance was not determined and it is unclear if any relationship exists between insulin responses and dietary protein intake and/or central obesity in these high-risk infants.

48.7 Outstanding Issues

In their recent review on feeding preterm infants after hospital discharge the ESPGHAN Committee on Nutrition concluded that "close monitoring of growth" was needed to "enable the provision of adequate nutrition support" and that infants with a "subnormal weight for gestational age" who are a) breast-fed be supplemented with a human milk fortifier, b) formula-fed receive a post-discharge formula with "high contents of protein, minerals, trace elements and long-chain polyunsaturated fatty acid, at least until 40 weeks but possibly until 52 weeks post-conceptional age" [110].

Yet, many questions remain about the feeding of nutrient-enriched formulas to preterm infants after hospital discharge. The first relates to formula composition. What is the ideal composition of these formulas? Will one formulation meet the varying needs of a heterogeneous group of growth-retarded infants?

There are major differences in energy, protein, mineral and micronutrient content between formulas used in previous studies. While most studies showed a growth advantage, the magnitude of effect varied, the formulation associated with the most consistent growth advantage was that closest to a regular preterm formula [13, 14, 77].

Will one formulation meet the needs of boys and girls? To date, it is assumed that nutrient requirements are similar. However, preterm boys grow faster in-utero and accrete more lean mass than girls during the fist 2–3 months of life [86]. They are more susceptible to even marginal levels of intake and benefit more when fed nutrient-enriched formulas before [48, 111–113] and after hospital discharge [14, 78–80]. Future studies must be "powered" to detect differences between the sexes.

How long should these formulas be fed? In studies where the nutrient-enriched formula was fed to term or 2 months no advantage was noted. However, in studies where a nutrient-enriched formula was fed to 6, 9 and 12 months the most consistent advantage was noted. Whether 6 months is better than 9 or 12 months or vice-versa remains unclear.

Breast-fed infants appear likely to benefit with additional nutrient supplementation, however achieving this is problematic. Fortifiers could be used. Alternatively, a nutrient-enriched formula might also be fed once breastfeeding is fully established. Breastfeeding during the day supported by nutrient-enriched formula at night may not only improve growth but also prolong breastfeeding in these infants.

How often should infants be followed-up after hospital discharge? A "critical window of opportunity" appears to exist between discharge and 2–3 mca. Future studies must focus on this time frame, a time when infants should be frequently evaluated, using anthropometry and biochemical investigations as indicated and intake adjusted accordingly. Body composition and endocrine status might also be considered, at least under study conditions.

Calcium and Phosphorus Homeostasis: Pathophysiology

Jacques Rigo, Catherine Pieltain, Renaud Viellevoye and Franco Bagnoli

49.1 Introduction

Ninety-eight percent of the calcium and eighty percent of the phosphorus in the body are in the skeleton; these elements are also constituents of the intracellular and extracellular spaces. The metabolic homeostasis of calcium, phosphorus, and magnesium and mineralization of the skeleton are complex functions that require the intervention of various parameters; an adequate supply of nutrients; the development of the intestinal absorption process; and the effects of several hormones, such as parathyroid hormone, vitamin D, and calcitonin, as well as optimum renal and skeletal controls [1]. Bone formation requires protein and energy for collagen matrix synthesis, and an adequate intake of calcium and phosphorus is necessary for correct mineralization. During development, nutrients are transferred mainly across the placenta. It has been calculated that during the last trimester of gestation the daily accretion per kilogram of body weight represents around 120 mg of calcium and 70 mg of phosphorus. Therefore, at birth the whole-body content of a term infant represents approximately 30 grams of calcium and 16 grams of phosphorus. After birth, the use of the gastrointestinal tract to provide nutrients for growth causes a reduction in calcium availability for bone accretion promoting the occurrence of relative osteopenia in preterm infants and to a lesser extent in term infants during the first weeks of life. In addition to their roles in bone formation, calcium and phosphorus play important roles in many physiologic processes, such as transport across membranes, activation and inhibition of enzymes, intracellular regulation of metabolic pathways, secretion and action of hormones, blood coagulation, muscle contractility, and nerve conduction. The 20% of phosphorus not complexed within bone is present mainly as adenosine triphosphate, nucleic acids, and cell and organelle membranes.

49.2 Calcium and Phosphorus Physiology

49.2.1 Calcium Physiology

49.2.1.1 Serum Calcium

Serum calcium is a fraction of total body calcium because only about 2% of calcium is present in extracellular fluid and soft tissues. Approximately 50% of total serum calcium is in ionized form at the normal serum protein concentration and represents the biologically active component of the total serum calcium concentration. Another 8% to 10% is complexed to organic and inorganic acids (e.g., citrate, lactate, bicarbonate, sulfate, and phosphate); together, the ionized and complexed calcium fractions represent the diffusible portion of circulating calcium. Approximately 40% of serum calcium is protein bound, primarily to albumin (80%) but also to globulins (20%) [2, 3]. Ionized calcium is the only physiologically active fraction.

The protein-bound calcium is not biologically active but provides a rapidly available reserve of calcium. Under normal circumstances the serum calcium concentration is tightly regulated by parathyroid hormone (PTH) and calcitriol (1,25-dihydroxy vitamin D_3; $1,25[OH]_2D_3$), which increase serum calcium (Fig. 49.1), and by calcitonin, which decreases serum calcium.

49.2.1.2 Placental Transport

During pregnancy there is an active calcium transfer from the mother to the fetus, reaching a peak of 120 to 150 mg/kg of fetal weight per day during the third trimester.

To meet the high demand for mineral requirements of the developing skeleton, the fetus maintains higher blood calcium and phosphorus levels than the ambient maternal levels. This process is the result of the active transport of calcium across the placenta by a calcium pump in the basal membrane that

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

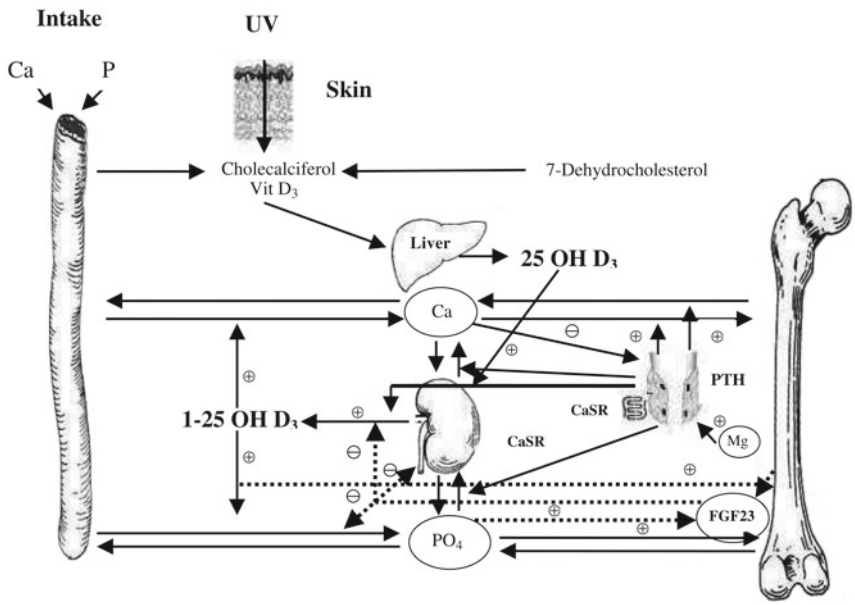

Fig. 49.1 Regulation of calcium and phosphate homeostasis. Parathyroid hormone (*PTH*) increases Ca release from bone, Ca resorption in the kidney, and $1,25(OH)_2D_3$ secretion from the kidney. PTH production is stimulated by low Ca and inhibited by low Mg and high $1,25(OH)_2D_3$. Vitamin D increases Ca release from bone and Ca and PO_4 absorption from the intestine. Vitamin D production is stimulated by high PTH and low PO_4. FGF23 production and release is stimulated by serum phosphate independent of PTH axis. FGF23 lowers phosphate concentration by inhibiting renal and intestinal phosphate transport as well as preventing activation of $1,25(OH)_2D_3$ which in turn controls levels of bone synthesis of FGF23. *CaSR* calcium-stimulating response, *UV* ultraviolet light

maintains a gradient of maternal to fetal calcium of 1:1.4. PTH has no effect on placental calcium transport.

By contrast, the main regulator of fetal ionized calcium appears to be the parathyroid hormone-related protein (PTHrP) produced by the placenta. PTHrP(1-141) or its midmolecule fragment, PTHrP(67-86), is the active form contrary to PTH (1-34) or PTHrP(1.34), suggesting that PTHrP stimulates receptor(s) distinct from the PTH/PTHrP receptor [4].

The role of vitamin D in fetal physiology is not well understood. Cord concentrations of 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D correlate significantly with those found in the maternal circulation, suggesting that the vitamin D pool of the fetus depends entirely on that of the mother. Fetomaternal relationships of 1,25-dihydroxyvitamin D concentrations are still debated.

Nevertheless, it has been demontrated that the placenta is able to synthethise and metabolize 1,25-dihydroxyvitamin D through the activity of 25-hydroxyvitamin D-1α-hydroxylase and 1,25-dihydroxyvitamin D-24 hydroxylase, two key enzymes for vitamin D metabolism [5]. In addition, it has been suggested that methylation of the vitamin D-24-hydroxylase gene plays an important role in maximizing active vitamin D bioavailability at the fetomaternal interface [6] and that active transplacental calcium and phosphate transfers are at least partly dependent on insulin-like growth factor-1 (IGF-1), itself a stimulating factor of fetal and placental 1,25-dihydroxyvitamin D synthesis.

Bone mass of the newborn may be related to the vitamin D status of the mother and studies of particular populations show that infants of mothers severely deficient in vitamin D may be born with rickets and can suffer fractures in the neonatal period [7, 8].

49.2.1.3 Intestinal Absorption

Calcium absorption is the main determinant of its retention; consequently, it has a significant impact on bone mineral content. Calcium absorption occurs in the small intestine by both active and passive processes. Vitamin D is essential for the active absorption of calcium, which involves carriers such as calcium-binding proteins.

After birth calcium absorption limits the rate of bone mineralization for growth although the absorption rate is higher than that during all other periods of life. The absorption of calcium occurs in the small intestine by two main routes – either through or between cells. Movement through the cell takes place by active transport dependent on vitamin D bound to a cytosolic calcium-binding protein (calbindin D_{9k}). The major role of vitamin D in transcellular calcium transport involves the biosynthesis of calcium-binding protein. Passive calcium transport is driven by chemical gradients that represent movement of calcium among the cells (paracellular transport). In addition to vitamin D status, various other factors affect calcium absorption [2, 9]. Ionization of calcium compounds, which requires an acid pH, occurs in the stomach and is a prerequisite for absorption. Therefore, low availability could be the result of an insoluble fraction of calcium intake or the precipitation of calcium in the gut. Calcium chloride, citrate, and carbonate have higher solubilities than calcium phosphate, which should be avoided in formulas. By contrast, the higher solubility of organic calcium, such as that found in calcium gluconate or glycerophosphate, improves its absorption. Fat intake and LCSFA (long-chain saturated fat acids) intake may also influence calcium absorption through the formation of calcium soap. It has been showed that the free palmitate content in the gastrointestinal tract after

the hydrolysis of triglyceride may impair calcium absorption. The higher bioavailability of calcium in human milk would be partly due to palmitate, which is predominantly esterified at the glycerol 2 positions (Sn-2), but also to the human milk bile salt-stimulated lipase that is not specific to the Sn-1 and Sn-3 positions. The improvement of calcium absorption with the use of medium-chain triglycerides is probably the result of the reduction of total LCSFA content in formula. At present, with the use of a well absorbed fat combination (±85% fat absorption), the influence of calcium soap formation and the B-palmitate content formula could be relatively minimal in clinical practice. A relatively low gastrointestinal pH content or the lactose and casein content of the formula may also have an additional positive effect on calcium absorption. In light of the considerable requirements of preterm infants, all of these factors probably play a significant role in the amount of calcium retained and deposited in the skeleton.

Medications also interfere with calcium absorption; for example, glucocorticoids inhibit intestinal transfer. Some anticonvulsants can also inhibit calcium absorption either directly (phenytoin) or indirectly through interference with vitamin D metabolism (phenobarbital and phenytoin). In newborn infants, a significant amount of calcium is secreted in the intestinal lumen through digestive fluid. With the use of stable isotopes, endogenous fecal calcium excretion and true calcium absorption may be evaluated. Considering that fecal calcium excretion may represent about 15 mg/kg per day in preterm infants, the true calcium absorption rate is significantly higher than the apparent rate measured by conventional metabolic balances.

Numerous metabolic balance studies have been performed in preterm infants fed human milk or a formula (Fig. 49.2) [1, 10, 11] to evaluate apparent calcium absorption. In preterm infants fed human milk, calcium absorption ranges from 60% to 70% depending on the calcium intake,

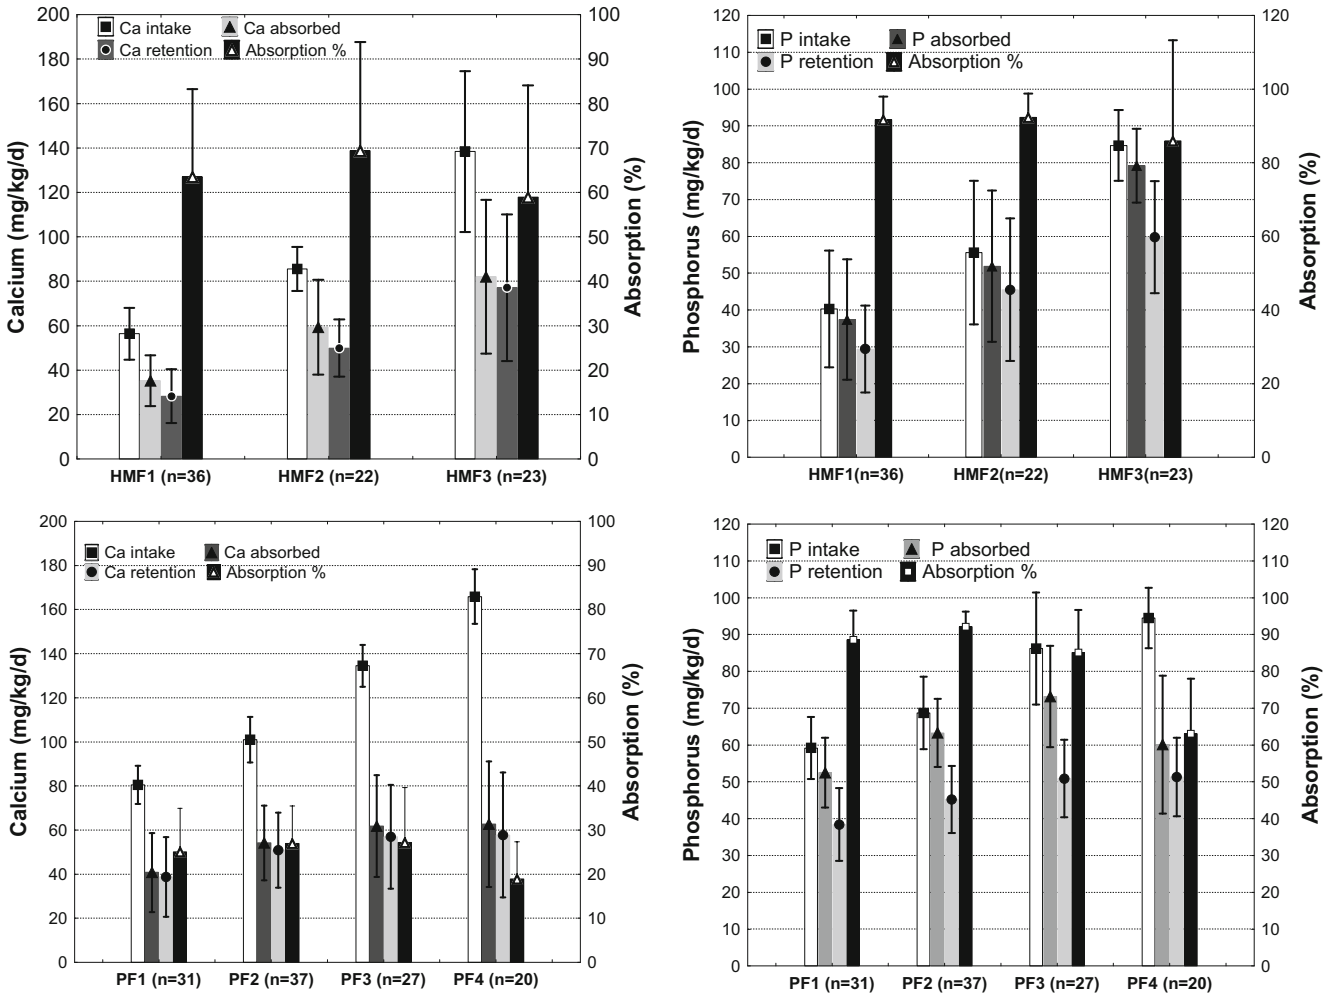

Fig. 49.2 Calcium and phosphorus absorption and retention in preterm infants fed human milk (without or with a human milk fortifier) and preterm formulas. In human milk groups, calcium and phosphorus absorption and retention are related to intake, in contrast to formula groups, in which a plateau is reached rapidly due to a decrease in net absorption (%). *HMF* human milk fortifier, *PF* preterm formula

whereas calcium retention is related to the phosphorus supply. Supplementation of human milk with phosphorus alone normalizes calciuria and allows calcium retention to reach about 35 mg/kg per day. When calcium and phosphorus are provided together or as human milk fortifiers, calcium retention and absorption rates parallel that of human milk, reaching 60 mg/kg per day. The use of new human milk fortifiers containing highly soluble calcium glycerophosphate improves calcium retention to 90 mg/kg per day (Fig. 49.2) [1]. In formula-fed infants, the percentage of net calcium absorption is less than that with human milk, ranging from 35% to 60%. Most of the difference probably results from the various factors affecting calcium solubility and absorption. At present, the use of a preterm formula with a high mineral content does not necessarily improve mineral retention [10]. Indeed, due to the poor solubility of calcium salts, especially calcium phosphate, the calcium content measured in formulas may be significantly lower than the claimed value, and an additional loss due to precipitation may occur before feeding [10]. In metabolic studies, the actual amount of calcium provided by feeding needs to be measured. As shown in Fig. 49.2, calcium retention limited to 90 mg/kg per day could presently be expected in preterm infants fed a preterm formula with a highly soluble calcium content. Nevertheless, those values are still relatively far from the reference values calculated during the last trimester of gestation (120 to 130 mg/kg per day), which is still considered the target mineral accretion rate for infants with very low birth weight (VLBW).

49.2.1.4 Renal Excretion

Under normal circumstances, calcium status is maintained by a balance between its intestinal absorption and renal excretion. Urinary excretion is the result of glomerular filtration followed by the sum of the processes of tubular reabsorption and secretion. Approximately 70% of the filtered load of calcium is reabsorbed in the proximal tubule and 20% in the thick ascending limb of Henle's loop in association with Na^+ reabsorption. Although it is responsible for only 5% to 10% of Ca^{2+} reabsorption, the major regulation of Ca^{2+} reabsorption occurs in the distal convoluted tubule by a mechanism independent of Na^+ reabsorption but regulated by PTH and $1,25(OH)_2D_3$. Calcium reabsorption is increased by both PTH and $1,25(OH)_2D_3$. It is also regulated by ionized calcium concentration, phosphate concentration, and acid-base status and increases with Ca^{2+} depletion and alkalosis but decreases with hypercalcemia, phosphate depletion, and acidosis. The effects of diuretics on renal calcium excretion vary considerably. Furosemide markedly increases renal calcium losses and is a risk factor for neonatal nephrocalcinosis. Thiazides increase renal tubular calcium reabsorption, thereby reducing calciuria [12].

The ability of the kidney to dispose of excess calcium represents a major homeostatic mechanism. Under normal circumstancs, nearly all filtered calcium (98%) is reabsorbed in the renal tubule. However, preterm and term infants differ from the adult in three main aspects: (1) Renal function is far from being completely developed, (2) Mineral requirements for growth are very high and (3) Renal calcium load results solely in the difference between net absorption and net bone and soft tissue retention. Considering that calcium soft tissue retention is negligible, renal calcium load is highly dependent on bone calcium deposition associated with phosphorus in the form of hydroxyapatite $[Ca_{10}(PO_4)_6(OH)_2]$ containing a molar calcium:phosphorus ratio of 1.67 (2.15 wt/wt). Therefore, the main determinant of the urinary loss of calcium in preterm and term neonates is relative to phosphorus depletion, which has been illustrated in balance studies performed in growing preterm infants fed human milk. When human milk is provided exclusively, there is an increase in the urinary excretion of calcium associated with very low urinary phosphate excretion. In contrast, when human milk is supplemented with phosphate, significant phosphaturia appears at the same time that calciuria decreases to a minimum level. Therefore, hypercalciuria can be explained by a relative phosphate depletion that cannot meet the phosphate demand necessary for skeletal mineralization (Fig. 49.3).

49.2.1.5 Requirement

For preterm infants, recommendations are based on fetal accretion rates. In 1985 the American Academy of Pediatrics recommended that formulas contain 140 to 160 mg of calcium per 100 kcal [13]. More recently, the Life Sciences Research Office recommended a calcium content of 123 to 185 mg/100 kcal for preterm infant formula, and an international expert panel suggested a similar value of 90 to 180 mg/100 kcal [14]. However, the ESPGHAN (European Society for Pediatric Gastroenterology, Hepatology, and Nutrition) committee of nutrition considers that those calcium needs are based on data obtained in infants fed preterm formulas with low calcium bioavailability. It suggests that after birth, bone metabolism is designed to accelerate bone turnover, reducing calcium requirements and that the relative osteopenia observed in preterm infants could be considered at least partially physiologic. As a calcium retention level ranging from 60 to 90 mg/kg/day assures appropriate mineralization and decreases the risk of fracture in VLBW infants, the ESPGHAN CoN recommended the use of highly bioavailable calcium salts providing a calcium content of 110-130 mg/100 kcal [15].

49.2.2 Phosphorus Physiology

Unlike calcium, phosphorus remains in the soft tissues, mainly in the form of phosphate esters, and in extracellular fluid in the form of inorganic phosphate ions. It represents approximately 15% of the whole-body content. Given its

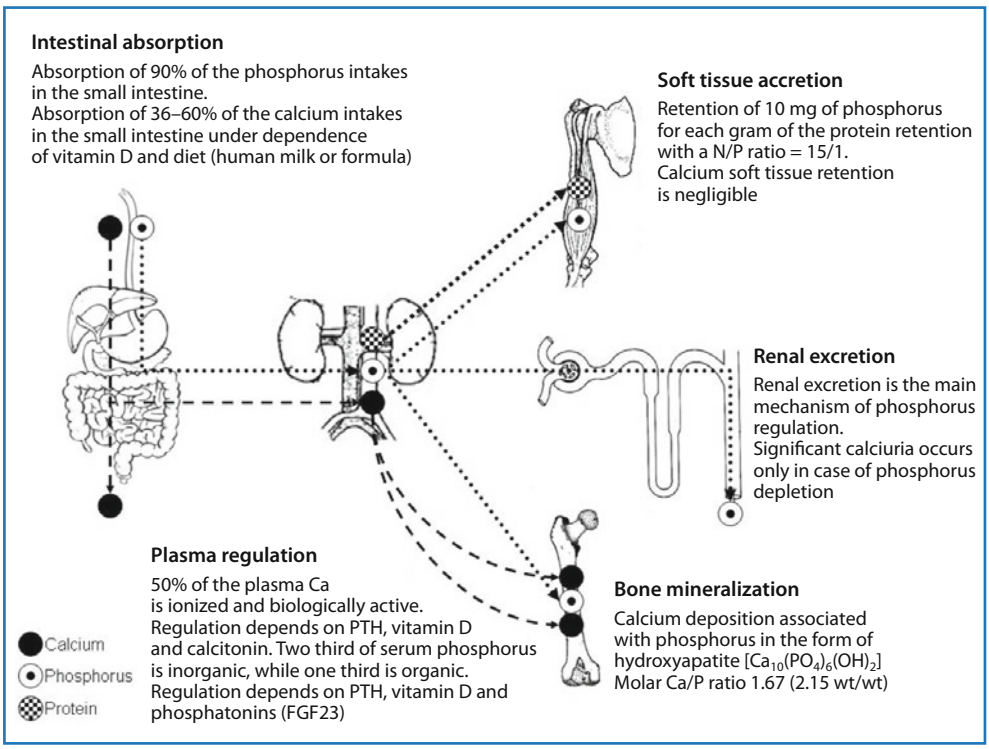

Fig. 49.3 Metabolism of calcium and phosphorus in term infants with feeding

widespread distribution, phosphorus plays a critical role in many biological processes, including energy metabolism, membrane composition, nucleotide structure, cellular signaling and bone mineralization. It is, therefore, not surprising that a deficiency of phosphorus results in clinical disease, including muscle weakness, impaired leukocyte function, and abnormal bone metabolization.

49.2.2.1 Serum Phosphorus

In serum about two thirds of phosphorus is organic (lipid phosphorus and phosphoric ester phosphorus) and one third inorganic. In routine clinical practice only inorganic phosphorus is measured. About 85% of the inorganic phosphorus is ionized, circulating as monohydrogen or dihydrogen phosphate; 5% is complexed with sodium, magnesium, or calcium; and 10% is protein bound [2].

Because so many phosphorus species are present, depending on pH and other factors, the serum concentration is conventionally expressed as the mass of the elemental phosphorus (mmol/L or mg/dL). In contrast to calcium, the serum phosphorus concentration varies widely depending mainly on intake and renal excretion but is also influenced by age, gender, pH, and a variety of hormones. At birth, the mean serum phosphorus concentration is relatively low (2.6 mmol/L, or 6.2 mg/dL) but thereafter rises rapidly to reach 3.4 mmol/L, or 8.1 mg/dL, owing to both endogenous phosphorus release and low renal excretion. Serum phosphorus subsequently varies. The diet partially determines the serum phosphorus content: it is higher in formula-fed than breast-fed infants. Serum phosphorus is inversely related to serum calcium concentration. After the neonatal period, the serum phosphorus concentration progressively decreases to 2.1 mmol/L, or 5 mg/dL, at the age of 1 to 2 years; 1.8 mmol/L, or 4.4 mg/dL, in middle childhood; and 1.5 mmol/L, or 3.5 mg/dL, at the end of adolescence [12].

49.2.2.2 Placental Transport

During pregnancy there is transfer of phosphorus from the mother to the fetus that reaches a peak of 60 to 75 mg/kg per day during the third trimester; 75% is retained for bone mineralization, and 25% is retained in other tissues. The transplacental transport of phosphorus is an active process against a concentration gradient and is sodium dependent. Both $1,25(OH)_2D_3$ and fetal PTH may be involved in the regulation of placental phosphorus transfer.

49.2.2.3 Intestinal Absorption

Intestinal phosphorus absorption takes place primarily in the duodenum, jejunum, and to a lesser extent in the ileum and colon. It occurs via two mechanisms: an active, sodium-dependent transcellular process localized to the mucosal surface

and passive diffusion through the paracellular pathway. It depends on both the absolute amount of dietary phosphorus and the relative concentrations of calcium and phosphorus (an excessive amount of either can decrease the absorption of the other). Vitamin D may stimulate active phosphorus absorption, although it is largely independent of vitamin D intake. The efficiency of this absorption is high (close to 90% of intake) regardless of the type of milk given [1, 2]. However, the use of poorly soluble phosphate salt such as calcium triphosphate in formulas is associated with a significant reduction in phosphorus absorption [1]. In contrast to calcium, only a small amount of phosphate is secreted in the intestinal lumen through digestive fluid.

49.2.2.4 Renal Excretion

The kidney contributes to a positive phosphate balance during growth by the reabsorption of a relatively high fraction of filtered inorganic phosphate (99% in newborns, 95% in infants fed human milk, and 80% in adults).

Preterm infants have an increased fractional excretion of phosphate and are at a greater risk of developing signs and symptoms of phosphate deficiency. The bulk of filtered phosphate is reabsorbed in the proximal tubule via a sodium-dependent transporter, the Na^+-phosphate cotransporter. The age-related decrease in phosphate reabsorption observed after the weaning period appears to be correlated with the smaller phosphate needs of adult and older animals than those of growing animals and is associated with a rapid downregulation of Na^+-phosphate cotransporter-2 mRNA and protein in the brush border membrane [16]. The kidney is the major determinant of the plasma phosphate concentration. Filtered load depends on the plasma phosphorus level and glomerular filtration rate (GFR).

Tubular reabsorption is an active and saturable process that gives rise to a maximum rate of tubular reabsorption (T_m). There is a plasma minimum threshold below which phosphorus reabsorption is almost complete and urinary excretion close to zero and a maximum threshold above which all tubular reabsorptive systems are saturated, so each additional increment in filtered load is associated with a parallel increment in excretion [2]. In preterm infants, the minimum and maximum threshold levels are 1.75 mmol/L (5.4 mg/dL) and 2.45 mmol/L (7.6 mg/dL), respectively (Fig. 49.4).

In the intermediate zone, there is a functional relationship between GFR and T_m, known as the glomerulotubular balance, in which a change in GFR is compensated for by a change in T_m in order to regulate phosphorus excretion. The total body phosphate metabolism is tightly regulated by three hormones, namely PTH, $1,25(OH)_2$ vitamin D and fibroblast growth factor 23 (FGF23) [17]. The level of PTH activity in plasma is an important physiologic regulator of phosphorus excretion. PTH inhibits phosphorus reabsorption, but its activity appears to be limited to the intermediate zone between the minimum and maximum plasma threshold levels. In contrast, $1,25(OH)_2$ vitamin D synthesis, stimulated by a decrease in plasma phosphorus concentration, has an indirect effect on phosphorus reabsorption by its effect on mineral absorption and mobilization from bone, resulting in an increase in plasma calcium concentration and the suppression of PTH release. During early postnatal life the phosphate response to PTH is blunted, whereas PTH increases tubular calcium reabsorption.

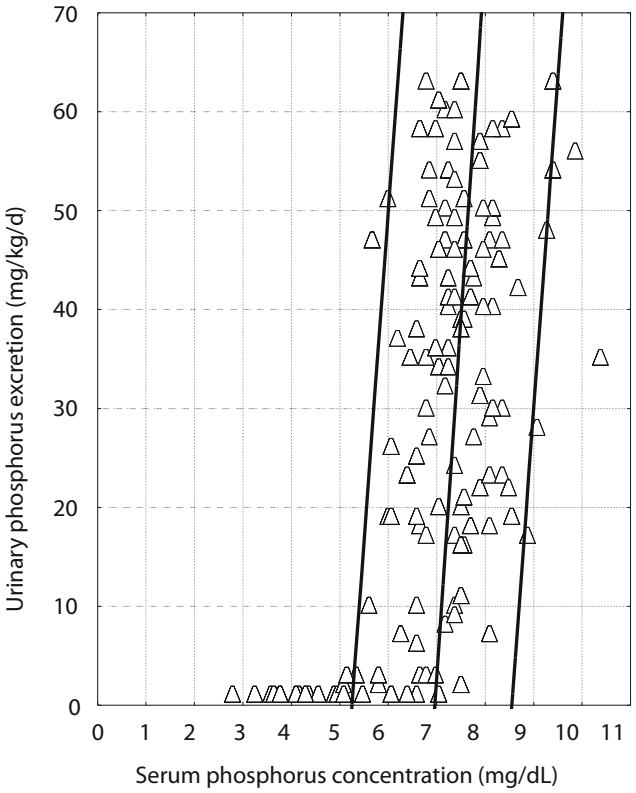

Fig. 49.4 Relationship between urinary excretion of phosphorus and serum phosphate level (n = 198) in preterm infants. Regression lines represent the minimum, mean, and maximum plasma phosphate concentration thresholds for tubular reabsorption of phosphate. Points to the left of the minimum threshold were considered hypophosphatemia associated with phosphorus depletion. Points to the right of the maximum threshold were considered hyperphosphatemia due to low glomerular filtration rates and relative phosphorus overload

Together, these actions result in the retention of both calcium and phosphate in infants, which is favorable for growth. The role of newly discovered phosphatonin peptides such as FGF23 in the regulation of phosphorus excretion during the early life remain to be established. FGF23 principally functions as a phosphaturic factor and counter-regulatory hormone for $1,25(OH)_2$ vitamin D production [17].

Absorbed phosphate enters the extracellular phosphate pool, which is in equilibrium with bone and soft tissue. In adults with neutral phosphorus balance, the amount of phos-

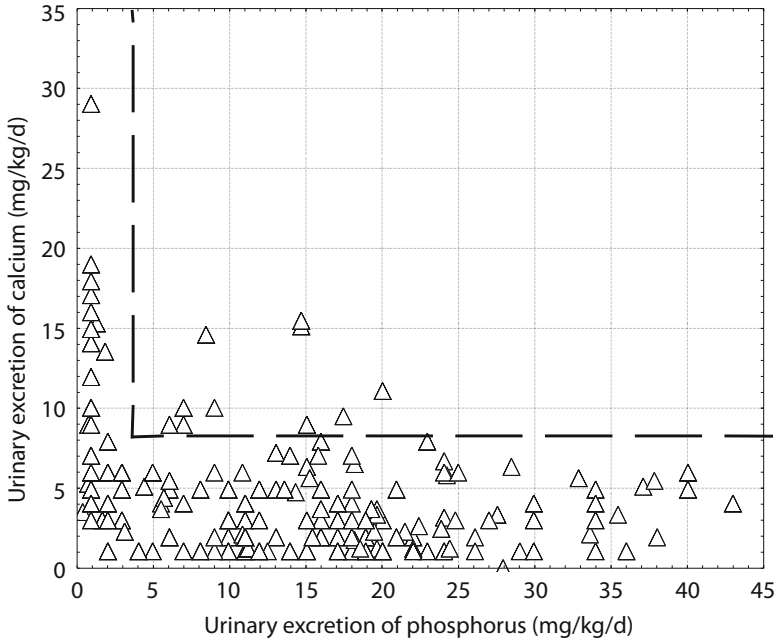

Fig. 49.5 Relationship between urinary excretion of calcium and urinary excretion of phosphorus in preterm infants (n = 198). Hypercalciuria (>8 mg/kg/day) is related to low phosphate excretion (<3 mg/kg/day). Conversely, urinary excretion of calcium below 8 mg/kg/day is usually observed in preterm infants with phosphorus excretion over 4 mg/kg/day

phorus excreted by the kidney is equal to the net amount absorbed by the intestine; in growing infants, it is less than the net amount absorbed due to the deposition of phosphorus in soft tissues and bone.

In growing infants, phosphorus will preferentially go to soft tissue with a weight-to-weight nitrogen:phosphorus ratio of 15:1 and to bone with a weight-to-weight calcium:phosphorus ratio of 2.15:1. The residual phosphorus constitutes the renal phosphorus load influencing plasma concentration and urinary excretion. In the face of a limited total phosphorus supply, bone mineral accretion may be limited, leading to significant calcium excretion associated with very low urinary excretion of phosphorus (Fig. 49.5). This particular situation is illustrated in Fig. 49.3, showing calcium and phosphorus metabolism in term infants.

49.2.2.5 Requirement

For preterm infants the recommendations are based on fetal accretion rates. The 1985 American Academy of Pediatrics recommended 95 to 108 mg of phosphorus per 100 kcal for preterm formulas [13], whereas more recently, the Life Sciences Research Office and the International Expert Panel recommended similar values, with a calcium-to-phosphorus ratio maintained over 1.7:1 but less than 2.0:1 [14]. Considering a nitrogen retention ranging from 350 to 450 mg/kg/day and a calcium retention from 60 to 90 mg/kg/day. The ESPGHAN CoN recommended an adequate intake of 65 to 90 mg/kg/day of a highly absorbable source of phosphate (90%) with a Ca to P ratio between 1.5 and 2.0 [15].

49.3 Hormonal Regulation

49.3.1 Parathyroid Hormone

PTH is synthesized as a larger (115-amino acid) precursor (prepro-PTH) but is stored and secreted mainly as an 84-amino acid peptide, with the 1-34,N-terminal portion conferring bioactivity. PTH regulates large calcium fluxes across bone, kidneys, and intestine (Fig. 49.1). PTH increases serum calcium concentrations directly by increasing bone resorption and renal calcium reabsorption and indirectly by increasing renal synthesis of $1,25(OH)_2D_3$, thereby increasing intestinal calcium absorption. PTH also lowers serum phosphorus concentrations through its phosphaturic action on the renal proximal tubule. This action minimizes the possibly adverse effect of hyperphosphatemia related to bone resorption on calcium homeostasis.

49.3.1.1 Regulation

Serum calcium concentration regulates PTH secretion; high concentrations inhibit the secretion of PTH and low concentrations stimulate it. Low or falling serum calcium concentrations act within seconds to stimulate PTH secretion, initiated by means of a calcium-sensing receptor (CaSR) on the surfaces of parathyroid cells. Slower regulation of PTH secretion occurs over a period of hours as a result of cellular changes in PTH messenger RNA (mRNA). Vitamin D and its metabolites 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D, acting

through vitamin D receptors, decrease the level of PTH mRNA and hypocalcemia increase it. The slowest regulation of PTH secretion occurs over days or even months and reflects changes in the growth of the parathyroid glands. Metabolites of vitamin D directly inhibit the mass of parathyroid cells; hypocalcemia stimulates the growth of parathyroid cells independent of the contrary action of vitamin D metabolites. In the kidney, the calcium-sensing receptor (CaSR) mediates the direct inhibition of the reabsorption of divalent cations in the thick cortical ascending limb of Henle's loop [18].

49.3.1.2 Fetal Parathyroid Function

Human parathyroid glands are functionally active as early as 12 weeks of gestation. However, fetal parathyroid glands are functionally suppressed by high intrauterine calcium concentrations, and PTH levels in cord blood are frequently below the detection limit. PTH does not appear to cross the placenta in either direction, and the role of PTH in maternal-fetal calcium transport is limited. In contrast, PTHrP acts during fetal life to promote calcium transfer, high blood calcium concentration, bone development, and matrix mineralization.

Maternal hyperparathyroidism results in maternal hypercalcemia, which leads to fetal hypercalcemia and suppression of fetal and neonatal parathyroid glands. Conversely, untreated maternal hypoparathyroidism leads to maternal hypocalcemia, fetal hypocalcemia, and secondary fetal and neonatal hyperparathyroidism.

49.3.1.3 Neonatal Parathyroid Function

After birth, with the abrupt termination of the maternal calcium supply, serum calcium in the newborn decreases and serum PTH increases correspondingly. Both term and preterm infants may show a PTH response to falling serum calcium. Nevertheless, plasma PTH levels are relatively low in the neonatal period and are minimally responsive to hypocalcemia during the fist 2 to 3 days of life leading to transient neonatal hypocalcemia. Infants with VLBW have a decreased PTH surge compared with full-term infants. Infants of diabetic mothers may have impaired PTH production during the beginning days of life. Infants with birth asphyxia may also have decreased PTH responses to hypocalcemia.

49.3.1.4 Parathyroid Hormone Reference Values

In full-term newborns, serum PTH concentrations tend to be low in cord blood but increase within the first 48 hours of life in response to the decrease in serum calcium. In preterm infants the serum immunoreactive, intact PTH (1-84) concentrations increase immediately after birth, indicating that the secretion of the hormone responds physiologically to the hypocalcemic stimulus. This increase in immunoreactive PTH concentration could be blunted when premature infants receive calcium by infusion, with the calcium load buffering the postnatal depression of serum calcium. By day 10, the serum concentrations of intact PTH return to euparathyroid values (Table 49.1) [7]. The multiplication factor for serum PTH from picograms per deciliter to picomoles per liter (pg/dL to pmol/L) is 0.11.

Table 49.1 Evolution of intact PTH (1–84), carboxy terminal PTH, and vitamin D binding protein concentrations in 15 preterm infants

	PTH(1–84) (pmol/L)	cPTH (pmol/L)	DBP (μmol/L)
Cord Serum	11 ± 3	48 ± 8	4.43 ± 0.37
Day 1	66 ± 11*	125 ± 15*	4.40 ± 0.34
Day 2	87 ± 11*	168 ± 5*	4.96 ± 0.23
Day 5	67 ± 9*	152 ± 16*	6.21 ± 0.26*
Day 10	23 ± 4	69 ± 6	6.03 ± 0.30*
Day 30	38 ± 7	80 ± 11	5.16 ± 0.23

* Significantly different from cord serum, $P < .05$.
PTH parathyroid hormone, *cPTH* carboxy terminal PTH, *DBP* vitamin D binding protein.

49.3.2 Vitamin D

49.3.2.1 Synthesis and Metabolism

Vitamin D is synthesized endogenously in the skin (cholecalciferol or vitamin D_3) after sunshine exposure or is absorbed from dietary sources as either vitamin D_3 (from animal sources) or vitamin D_2 (ergocalciferol [from vegetable sources]). Regardless of its origin, vitamin D_2 and D_3 are transported bound to the vitamin D binding protein to the liver, where it is hydroxylated at carbon 25 to form vitamin D_3 (25[OH]D_3, or calcidiol), the most abundant vitamin D metabolite. The circulating concentrations of 25[OH]D_3 provide a useful index of vitamin D status (reflecting both dietary intake and sunshine exposure). Subsequently in the kidney, 25[OH]D_3 is further hydroxylated at carbon 1 to form the final active metabolite, 1,25$(OH)_2D_3$, or calcitriol. This last transformation is tightly regulated and is the rate-limiting step in vitamin D metabolism. 1,25$(OH)_2D_3$ can also be synthesized by various cells as well as by the placenta during pregnancy. However, this local production of 1,25$(OH)_2D_3$ is not associated with calcium homeostasis but could contribute to regulating cell growth.

49.3.2.2 Effects

Normal vitamin D status is necessary to maintain calcium and phosphorus homeostasis. The effects of 1,25$(OH)_2D_3$

(calcitriol) on target tissues are initiated by its binding to a steroid receptor (vitamin D receptor) distributed in numerous tissues, leading to the synthesis of a variety of proteins. Therefore, $1,25(OH)_2D_3$ acts on the small intestine, increasing the absorption of calcium and phosphorus by the synthesis of calcium-binding (calbindin-D) proteins; on bone, mobilizing calcium and phosphorus by increasing the number of osteoclasts; and on the kidney, increasing calcium reabsorption in the distal nephron segments by increasing the expression of the epithelial calcium influx channel. There is a natural polymorphism in the genotype of the vitamin D receptor that contributes to skeletal metabolism in early childhood and to the genetic determinant of the peak bone mass.

49.3.2.3 Regulation of Secretion

In contrast to hepatic 25-hydroxylation, renal 1-hydroxylation, which leads to the active metabolite, appears to be tightly regulated. The main factors increasing the synthesis of calcitriol via stimulation of renal $25(OH)D_3$-1α-hydroxylase are PTH, PTHrP, hypocalcemia, hypophosphatemia, and other hormonal factors, such as insulin-like growth factor-1, estrogen, prolactin, and growth hormone. The production of calcitriol is inhibited by elevated serum levels of calcium and phosphorus, but also by the newly discovered phosphatonin peptides implicated in phosphorus homeostasis. Thus, an increase in FGF23 production suppresses $1,25(OH)_2$ vitamin D via inhibition of 25-hydroxyvitamin D-1α-hydroxylase and stimulation of 24-hydroxylase inactivating $1,25(OH)_2$ vitamin D in the proximal tubule of the kidney [17].

49.3.2.4 Fetal Vitamin D Function

Serum 25-hydroxyvitamin D concentration depends on vitamin D intake and production. The production of vitamin D is influenced by geographic location, season and latitude, and skin pigmentation. Vitamin D deficiency is very common during pregnancy, not only in areas with a prolonged winter season. In Belgium, vitamin D deficiency, < 50 and 80 nmol/L, represent respectively 80 and 90% of the pregnant women [19].

Cord concentrations of the major vitamin D metabolites are consistently lower than those measured in the mother's serum. Placental vein 25-hydroxyvitamin D concentrations correlate significantly with those found in the maternal circulation, suggesting that calcidiol easily diffuses across the placental barrier and that the vitamin D pool of the fetus depends entirely on that of the mother. The fetomaternal relations of 1,25-dihydroxyvitamin D concentrations are more complex, most of the 1,25-dihydroxyvitamin D in fetal plasma is due to fetal kidney activity, as suggested by studies in fetal plasma from infants with renal agenesis. Actually, the precise role of the placental 1,25-dihydroxyvitamin D activity in the mineral homeostasis during the fetal life remains to be evaluated.

Bone mass of the newborn may be related to the vitamin D status of the mother [20]. Comparison of the results of dual-energy X-ray absorptiometry from different countries shows that infant whole-body bone mineral content values are lower in countries in which milk products are not supplemented with vitamin D than in those where milk products are supplemented. In contrast, vitamin D supplementation of malnourished mothers results in improved growth of the fetus and child in terms of both birth weight and subsequent linear growth during infancy.

Therefore, during pregnancy a daily vitamin D supplement of at least 400 IU/day (10 μg/day) need to be administered, whereas for at-risk populations an increased supply to 1000 IU/day [25 μg/day]) should be given at least during the last 3 months of pregnancy.

49.3.2.5 Neonatal Vitamin D: Function and Recommendations

Plasma $25(OH)\ D_3$ concentration is a useful vitamin D biomarker reflecting vitamin D supply and usage over a period of time. Unfortunately, the cut-off used for serum $25(OH)\ D_3$ concentrations varies among researchers, leading to various prevalence of vitamin D deficiency and/or insufficiency. Nevertheless, several surveys show a high rate of poor maternal vitamin D status throughout the world, particularly in countries without vitamin D supplementation, with poor sun exposure, extensive clothing, or with deeply pigmented skin. Thus, the rate of cord blood vitamin D severe insufficiency (< 20 nmol/L; < 8.3 ng/mL) may reach up to 70% in European populations [19, 20].

The concentrations of vitamin D are low in human milk (20 to 60 IU/L) and lower than that in regular formulas (400 to 600 IU/L). In breast-fed infants not receiving vitamin D supplements, vitamin D stores could be depleted within 8 weeks of delivery, suggesting the need for vitamin D supplementation [21]. A minimum daily intake of 400 IU (10 μg/day) of vitamin D is recommended by the AAP for all infants beginning soon after birth, including those who are exclusively breastfed [22]. Moreover, in breastfed full-term infants born to mothers who are vitamin D deficient, maternal supplementation with vitamin D could be required to increase the human milk vitamin D concentration and in turn improve infant vitamin D status. In addition, vitamin D is metabolized in the liver, and anticonvulsants such as phenobarbital and diphenylhydantoin increase its hepatic catabolism and requirements.

In preterm infants, as a result of the decrease in serum calcium during the first days of age, the postnatal surge in PTH induces increased synthesis of $1,25(OH)_2D_3$ during the first days day of life. Provision of 1000 IU of vitamin D_3 increases the 25-hydroxyvitamin D pool of the newborn at

birth, followed by rapid renal synthesis of 1,25-dihydroxyvitamin D during the early postnatal days. In very low birth weight infants (<1500 g), immaturity of the vitamin D activation pathway, either alone or in combination with other abnormalities, particularly transient hypoparathyroidism, hypercalcitoninemia, and end-organ resistance to hormonal effects, may promote late neonatal hypocalcemia. However, after 28 weeks of gestation, activation of vitamin D is operative as early as 24 hours after birth. Vitamin D supplementation just after birth improves its nutritional status, as evidenced by rises in both plasma 1,25- and 25-hydroxyvitamin D concentrations.

In countries with high vitamin D status, plasma 25-hydroxyvitamin D remained normal for 6 months while infants received around 400 IU/day (<10 μg/day). By contrast, in Europe and other countries where dairy products are not enriched with vitamin D, sunshine exposure is restricted [7], and mean cord concentrations of 25-hydroxyvitamin D are low, the administration of vitamin D (from 1000 IU/day, or 25 μg/day) results in a rapid increase in circulating concentrations of total 1,25-dihydroxyvitamin D by 5 days of age, promoting calcium absorption and mineral accretion rates during the neonatal period. Therefore, vitamin D recommendations may differ significantly between North American (400 IU/day, 10 μg/day) and European countries (800 to 1000 IU/day, 10 to 25 μg/day) [15].

49.3.2.6 Reference Values

New informations on the additional role of vitamin D on glucose homeostasis, immune system, cardiovascular disease, and cancer has resulted in defining vitamin D deficiency in adults as a 25-OH-D concentration <50 nmol/L and vitamin D insufficiency as a 25-OH-D concentration of 50 to 80 nmol/L. At the present time, however, consensus has not been reached with regard to the concentration of 25-OH-D to define vitamin D insufficiency for infants and children [23]. Universal units of measure for 25-OH-D and 1,25-OH_2-D are nmol/L. Conversion to ng/mL is made by dividing the value expressed in nmol/L by 2.496. Thus, 80 nmol/L becomes 32 ng/mL.

49.3.3 Calcitonin

Calcitonin (CT) is a 32-amino acid peptide secreted by the thyroidal C cells. In addition, a group of peptide hormones, the "calcitonin family", including the calcitonin gene-related protein (CGRP), with structural similarities to calcitonin are also produced by several tissues. Although calcitonin has often been considered to be a vestigial hormone with no certain role in mammalian calcium and bone homeostasis, recent studies indicate that calcitonin has important roles in calcium and bone homeostasis that have not been previously recognized. It has been established that the major action of CT is the inhibition of bone resorption, and osteoclasts [24]. The regulation of calcitonin is opposite to that of PTH. Mediated by the CaSR, an increase in ionized calcium stimulates calcitonin secretion, whereas a decrease in ionized calcium leads to a fall in calcitonin. Thus, the CaSR has a dual physiological response to regulate PTH and calcitonin that in the long-term will influence the maintenance of skeletal mineral content [25].

At birth, serum calcitonin concentrations are higher in cord blood than maternal blood, and they increase further in the first 24 hours of life. The physiologic importance of the postnatal increase of calcitonin is unclear and it is uncertain whether calcitonin plays any specific role in calcium homeostasis and skeletal metabolism during the fetal and neonatal period [25]. In contrast, CT has an important physiological role during lactation protecting the maternal skeleton against excessive resorption and attendant fragility.

49.3.4 FGF23 and Phosphatonin Peptides

"Phosphatonins" represent a number of peptides which have been recently identified as a result of the study of various diseases associated with hypophosphatemia: fibroblast growth factor 23 [FGF23], secreted frizzled-related protein 4 [sFRP-4], fibroblast growth factor 7 [FGF7] and matrix extracellular phosphoglycoprotein [MEPE] [17, 26, 27]. FGF23 is predominantly produced by osteocytes in bone, and its principal actions are to inhibit sodium-dependent phosphate reabsorption and 1α-hydroxylase activity in the proximal tubule of the kidney, leading to phosphaturia and suppression of circulating 1,25$(OH)_2$D levels. Evidence that FGF23 is the principle phosphaturic factor comes from a variety of observations [27].

Fibroblast growth factor 23 regulates serum phosphate levels within a narrow range despite wide fluctuation in dietary intake via a series of classic negative endocrine feedback loops involving 1,25-dihydroxyvitamin D, parathyroid hormone, urinary phosphate excretion, and dietary phosphorus absorption. A sustained increase in dietary phosphorus intake stimulates FGF23 secretion that increases phosphaturia. At the same time, FGF23 inhibits renal synthesis of 1,25D. By contrast, a sustained reduction in phosphorus intake lowers FGF23 secretion, which enhances tubular phosphorus avidity and increases 1,25D production. A down regulation of FGF-23 could promote the relative hyperphosphatemia and the relative increase in 1,25$(OH)_2$ vitamin D promoting bone mineralization during early rapid growth in the neonatal period [17]. The targeting of FGF23 to the kidney is mediated by a coreceptor (klotho) that enhances the binding affinity of FGF23 to the widely expressed FGF receptor 1c [17].

Phosphatonins have been implicated in the pathophysiology of disorders of phosphate homeostasis such as Tumor-induced osteomalacia (TIO), X-linked hypophosphatemic rickets (XLH), autosomal dominant hypophosphatemic rickets (ADHR), autosomal recessive hypophosphatemia (ARHP),

tumoral calcinosis and renal failure [27]. However, the role of newly discovered phosphatonin peptides, such as FGF 23 in the regulation of phosphorus excretion during the early life, remain to be established.

49.4 Clinical Conditions Associated with Calcium Disturbances

49.4.1 Neonatal Hypocalcemia

Serum total and ionized calcium concentrations are relatively high at birth but decrease sharply during the first hours of life to reach a nadir at 24 hours and increase progressively thereafter up to the end of the first week of life (Table 49.2). Sudden changes in the distribution of calcium between ionized and bound fractions may cause symptoms of hypocalcemia even in children with functioning hormonal mechanisms for the regulation of the ionized calcium concentration (Table 49.3). Increases in the extracellular fluid concentration of anions such as phosphate, citrate, or bicarbonate increase the proportion of bound calcium and decrease ionized calcium. Alkalosis increases the affinity of albumin for calcium and thereby decreases the concentration of ionized calcium. In contrast, acidosis increases the ionized calcium concentration by decreasing the binding of calcium to albumin. Although it is conventional to measure the total serum calcium concentration, more physiologically relevant information is obtained by direct measurement of the ionized calcium concentration. This measurement is particularly important when evaluating patients who have abnormal circulating proteins and after blood transfusion for the correction of acidosis and hyperventilation. For example, total serum calcium decreases approximately 1 mg/dL, or 0.25 mmol/L, for each 1 g/dL of decrease in serum albumin, without any change in ionized calcium.

Neonates at the greatest risk for symptomatic or asymptomatic neonatal hypocalcemia, such as the infants of diabetic mothers or preterm or asphyxiated neonates, are frequently sick for a multitude of reasons, and the contribution of neonatal hypocalcemia to signs related to their primary illness can be easily obscured. From a clinical viewpoint, because Ca^{2+} concentrations are maintained within narrow ranges under normal circumstances, the potential risk for disturbances of physiologic function increases as the Ca^{2+} concentration

Table 49.2 Evolution of serum calcium concentrations (mmol/L*) during the first 10 days of life in term and preterm infants

	Term		Preterm	
Age	Mean	95% CI	Mean	95% CI
Birth (cord blood)	2.55	2.25-2.85	2.24	1.58-2.90
24 h	2.25	1.95-2.55	1.94	1.64-2.24
48 h	2.39	2.14-2.64	1.85	1.47-2.23
120 h	2.46	2.25-2.68	2.22	1.84-2.60
240 h	2.48	2.26-2.69	2.45	2.45-2.89

*Conversion to mg/dL: mmol/L × 0.2495.

Table 49.3 Causes of neonatal calcium disorders

Hypocalcemia	Hypercalcemia
Early Hypocalcemia (1-4 days of age)	*Iatrogenic*
Prematurity	Calcium salts, vitamin A
Maternal diabetes	Hypophosphatemia (prematurity)
Perinatal stress/asphyxia	Hypervitaminosis D
Intrauterine growth restriction	Thiazide diuretics
Maternal anticonvulsants	
	Disorders of Parathyroid Function
Late Hypocalcemia (5-10 days of age)	Maternal hypocalcemia, hypoparathyroidism
Hyperphosphatemia (high phosphate load, advanced renal insufficiency)	Mutation of the parathyroid hormone-related protein receptor
Hypomagnesemia	Jansen metaphyseal chondrodysplasia
Vitamin D deficiency	Calcium-sensing receptor defects
PTH resistance (transient neonatal pseudohypoparathyroidism)	Familial hypocalciuric hypercalcemia
Hypoparathyroidism	Neonatal severe hyperparathyroidism
Primary: parathyroid agenesis, 22q11 deletion, parathyroid hormone gene mutation	*Idiopathic Infantile Hypercalcemia*
Secondary: maternal hyperparathyroidism	*Hyperprostaglandin E Syndrome*
Calcium-sensing receptor defects; autosomal dominant hypocalcemic hypercalciuria	*Severe Infantile Hypophosphatasia*
Acquired or inherited disorders of vitamin D metabolism	*Other Causes*
Neonatal hypocalcemia associated with skeletal dysplasia	Congenital carbohydrate malabsorption
Other causes (alkalosis, citrated blood transfusions, phototherapy, viral gastroenteritis, lipid infusions)	Distal renal tubular acidosis
	Tumor-related hypercalcemia
	Congenital hypothyroidism
	Williams syndrome
	Subcutaneous fat necrosis
	Blue diaper syndrome

decreases. A useful approach to the classification of neonatal hypocalcemia is by time of onset. The early and late forms of hypocalcemia have different causes and occur in different clinical settings.

49.4.1.1 Early Hypocalcemia - Term Infants

Early neonatal hypocalcemia occurs during the first 4 days of life and represents an exaggeration of the normal fall in serum calcium concentration that occurs during the first 24 to 48 hours of life. At birth there is an interruption of maternal calcium supply, and the serum calcium concentration in infants is maintained by either the increased calcium flux from bone or sufficient exogenous calcium intake. Because intestinal calcium absorption is correlated with intake and dietary calcium is usually low on the first day of life, the serum calcium concentration decreases on the first day of life [3].

Normal serum concentrations for Ca^{2+} in full-term newborns reach a nadir at about 24 hours of age (1.10 to 1.36 mmol/L, or 4.4 to 5.4 mg/dL) and rise slowly thereafter. Neonatal hypocalcemia could be reasonnably defined as a serum total calcium below 2 mmol/L or a an ionized calcium of less than 0.9 to 1.1 mmol/L.

Early neonatal hypocalcemia apparently results from the abrupt interruption of the placental supply and the low intake provided by oral and parenteral nutrition and also by the slow release of PTH by immature parathyroid glands or the inadequate responsiveness of the renal tubular cells to PTH.

By contrast, exaggerated rise in calcitonin secretion may not play a contributory role in premature infants. In infants with VLBW the high renal sodium excretion probably aggravates calciuric losses, and relative end-organ resistance to $1,25(OH)_2D_3$ may exist additionally to an $25(OH)D_3$ deficiency. Hypocalcemia is temporary, and the serum calcium concentration gradually reverts to normal after 1 to 3 days. Factors contributing to serum calcium normalization include increased calcium intake with feedings, increased renal phosphorus excretion, and improved parathyroid function. Calcium supplementation may hasten the restorative process.

49.4.1.2 Early Hypocalcemia - Preterm Infants

The frequency of hypocalcemia varies inversely with birthweight and gestational age. In preterm infants, the postnatal decrease in the serum calcium level typically occurs more rapidly than it does in term infants, the magnitude of the depression being inversely proportional to gestation. Before routine calcium supplementation and the use of parenteral nutrition from the first day of age, many LBW infants and nearly all those with extremely low birth weight (ELBW) exhibited total calcium levels of less than 7.0 mg/dL by day 2. However, the fall in Ca^{2+} is not proportional to that in total calcium concentration, and the ratio of ionized to total calcium is higher in these infants. The reason for the maintenance of Ca^{2+} is uncertain but is probably related to low serum protein concentration and pH associated with prematurity. The sparing effect of Ca^{2+} may partially explain the frequent lack of signs in preterm infants with low total calcium levels. In preterm infants the reference values for ionized calcium are available only for large, moderately premature infants who show values very similar to those for full-term infants. These cutoff values might not apply to smaller infants, given insufficient physiologic data on ionized calcium. At present, the traditional cutoff point, a total calcium content of less than 1.75 mmol/L (7.0 mg/dL) and an ionized calcium of less than 0.9 to 1.1 mmol/L, remains reasonable in VLBW infants.

49.4.1.3 Perinatal Asphyxia

In asphyxiated infants, the following factors may contribute to early hypocalcemia: a decreased calcium intake due to delayed feedings and an increased endogenous phosphorus load resulting from the reduction of the glomerular filtration rate. Hyperphosphatemia may induce relative PTH resistance and a stimulation of FGF23 secretion. Theoretically, the correction of acidosis with alkali may further aggravate hypocalcemia by inducing decreased calcium flux from bone to the extracellular fluid and by lowering the ionized calcium concentration.

49.4.1.4 Maternal Conditions and Treatments

Maternal Diabetes

Infants of diabetic mothers (IDMs) demonstrate an exaggerated postnatal drop in circulating calcium levels when compared with controls of gestational age. Prematurity and birth asphyxia are frequently associated problems that independently increase the risk for hypocalcemia. In IDMs, hypocalcemia appears to be related to hypomagnesemia, the maternal form of which is caused by urinary magnesium losses with diabetes and leads to fetal magnesium deficiency and secondary functional hypoparathyroidism in the fetus and newborn. Hypocalcemia in IDMs is also correlated with the severity of maternal diabetes, which is classified by White's criteria. The natural history is usually similar to that of early neonatal hypocalcemia in preterm infants, but hypocalcemia sometimes persists for several additional days. Improved metabolic control for pregnant diabetic women has markedly diminished the occurrence and severity of early neonatal hypocalcemia in IDMs. The incidence of hypocalcemia is also increased in the infants of gestational diabetic mothers (IGDMs), and the role of hypomagnesemia has recently been demonstrated [28].

Maternal hyperparathyroidism with hypercalcemia, maternal chronic renal failure with secondary hyperparathy-

roidism, mothers with abnormal vitamin D homeostasis and mothers receiving anticonvulsants are additional factors increasing risk for neonatal hypocalcemia (Table 49.3).

49.4.1.5 Late Hypocalcemia

Hypocalcemia is conventionally defined as late when it occurs after the first 4 days of life. Late neonatal hypocalcemia usually develops at about 1 week of age (Table 49.3) and more frequently in term than preterm infants and is not correlated with maternal diabetes, birth trauma, or asphyxia. In some instances the clinical distinction between early and late hypocalcemia may not be clear.

Phosphate Loading

Hypocalcemia induced by an elevated phosphorus supply usually occurs at the end of the first week of life. Late-onset hypocalcemia is considered to be a manifestation of relative resistance of the immature kidney to PTH. In these infants the renal tubular cells are unable to respond appropriately to PTH, leading to renal retention of phosphorus and hypocalcemia. These biochemical features strongly resemble those of pseudo-hypoparathyroidism [3]. The normally low neonatal glomerular filtration rate may also play a role in limiting the ability to excrete the phosphorus load.

Late hypocalcemia was frequently observed in infants fed cow's milk or evaporated milk because of their high phosphorus content. With the introduction of adapted infant formulas, late hypocalcemia, though not abolished, has become uncommon. However, even with current formulas the formula-fed infants have lower serum ionized calcium and higher serum phosphorus in the first week of life than those of breastfed infants.

These differences correlate with the absolute phosphorus amount but not with the different calcium:phosphorus ratios in formulas. The phosphate load increases calcium bone deposition, leading to hypocalcemia. The normal response to hypocalcemia is an increase in PTH secretion, inducing an increase in both the urinary excretion of phosphate and tubular resorption of calcium. The pathogenesis of this "transient hypoparathyroidism" in late neonatal hypocalcemia is poorly understood. The inadequate secretion of PTH, immaturity of PTH receptors, or transient change in the threshold of CaSR may play an important role [29]. In these infants, serum calcium levels frequently increase when they are given human milk, lower-phosphate formulas, and calcium supplements. After several days to weeks, serum PTH usually increases and the infants are able to tolerate a higher dietary phosphate load. Some of these infants have a persistent or recurrent inability to mount an adequate PTH response to a hypocalcemic challenge and may have a form of congenital hypoparathyroidism.

Hypocalcemia Resulting from Vitamin D Disorder

Maternal vitamin D deficiency is the major risk for neonatal vitamin D deficiency presenting as hypocalcemia. Vitamin D deficiency is unusual in countries where it is common practice to supplement the diet with vitamin D dairy products and other foods. However, it occurs in women in whom both sunlight exposure and the dietary intake of vitamin D are inadequate and high incidence has been reported in most of the european countries [19]. Therefore, if daily vitamin D supplementation during the whole pregnancy can be undertaken, the amount given should be at least 400 IU/day (10 μg/day). In countries where dairy products are not supplemented with vitamin D and sunshine exposure is low, 1000 IU/day (25 μg/day) should be given during the last 3 months of pregnancy [7].

Breastfed infants of strictly vegetarian mothers are also susceptible to vitamin D deficiency and early-onset hypocalcemic rickets.

Hypomagnesemia

Neonatal hypocalcemia usually accompanies hypomagnesemia because magnesium deficiency inhibits the secretion of PTH and reduces responsiveness to its action. Depression of the serum magnesium levels in newborns is mainly due to transient hypomagnesemia or exceptionally to primary hypomagnesemia with secondary hypocalcemia [3].

49.4.1.6 Other Causes of Neonatal Hypocalcemia

Bicarbonate therapy, as well as any form of metabolic or respiratory alkalosis, decreases ionized calcium levels and bone resorption of calcium. Transfusion and plasmapheresis with citrated blood can form nonionized calcium complexes, thus decreasing Ca^{2+}. Furosemide and xanthine therapy promotes calciuresis as well as nephrolithiasis. Phototherapy appears to be an additional possible cause of neonatal hypocalcemia, although the mechanism is still uncertain. Lipid infusions may increase serum free fatty acid levels, which form insoluble complexes with calcium. Most of these effects are transient, and cessation of therapy is associated with a return to normal serum calcium levels.

49.4.1.7 Clinical Manifestations of Hypocalcemia

The clinical manifestations of neonatal hypocalcemia in infants may be easily confused with other neonatal disorders (e.g., hypoglycemia, sepsis, meningitis, asphyxia, intracranial bleeding, narcotic withdrawal). The neonate with hypocalcemia may be asymptomatic; the less mature the infant, the more subtle and varied the clinical manifestations. In the neonatal period the main clinical signs of hypocalcemia are

jitteriness (increased neuromuscular irritability and activity) and generalized convulsions, although focal seizures have also been reported. Infants may also be lethargic, eat poorly, vomit, and have abdominal distention. The degree of irritability does not appear to correlate with serum calcium values. Furthermore, hypocalcemia may be asymptomatic. Therefore, suspicion of hypocalcemia should be confirmed by the measurement of total serum calcium and Ca^{2+}.

The diagnostic workup for hypocalcemia includes a history, physical examination, and relevant investigations. In clinical practice, the diagnosis of hypocalcemia is based on the determination of ionized or total calcium. Serum magnesium should also be measured because hypomagnesemia may coexist and cause identical signs. The measurement of calcium-regulating hormones is not routinely recommended unless hypocalcemia is prolonged, refractory, or recurrent. Assays of calciotropic hormones and 25(OH)D may be useful in the diagnosis of uncommon causes of neonatal hypocalcemia, such as primary hypoparathyroidism, malabsorption, and disorders of vitamin D metabolism. If DiGeorge syndrome is suspected chest X-ray examination for a thymic silhouette is indicated and molecular genetic studies may be needed to confirm a microdeletion of chromosome 22q11.2.

49.4.1.8 Treatment

Early Neonatal Hypocalcemia

In asymptomatic newborns, treatment generally is indicated when the total serum calcium concentration is less than 1.5 mol/L (6 mg/dL) in the preterm infant and less than 1.75 mol/L (7 mg/dL) in the term infant. Calcium supplementation can be given either by the intravenous or oral route. Depending on the clinical status of the infant, treatment of newborns who have acute or symptomatic hypocalcemia is accomplished best by the intravenous infusion of calcium salts; 10% calcium gluconate (9.3 mg/mL of elemental calcium, maximum 2 mL/kg over 15 min followed by 75mg/kg per day up to normal range) is used most commonly. Effective oral therapy involves adding calcium glucobionate or calcium carbonate to human milk or a low phosphate formula (calcium to phosphate ratio of 2:1).

Additional therapy depends on the cause of hypocalcemia. Infants who have hypoparathyroidism require calcitriol in addition to calcium supplementation to restore and maintain eucalcemia. Infants who have vitamin D deficiency will benefit from vitamin D supplementation. If magnesium concentrations are low, treatment with intravenous or intramuscular magnesium sulfate is essential for correction as a 50% solution of magnesium sulfate in a dose of 0.1 to 0.2 mL/kg.

Complications of intravenous calcium therapy include extravasation into soft tissues (with calcium deposition and sometimes cutaneous necrosis) and bradycardia. Because of the many potential risks, arterial infusions of calcium in high concentrations should be avoided. However, parenteral nutrition solutions containing standard mineral (including calcium) content can be safely infused through appropriately positioned umbilical venous or arterial catheters. The direct administration of calcium preparations with bicarbonate or phosphate solution results in precipitation and must be avoided. The duration of supplemental calcium therapy varies with the course of hypocalcemia. As few as 2 or 3 days of therapy are usually required.

Late Neonatal Hypocalcemia

There is usually little debate regarding the treatment of late hypocalcemia. Because serum calcium is not routinely measured after the first few days of life, late hypocalcemia is usually symptomatic when diagnosed and the requirement for calcium therapy may be prolonged in the case of hypocalcemia caused by malabsorption or hypoparathyroidism. In phosphorus-induced hypocalcemia, a low-phosphorus formula (or human milk) and oral calcium supplementation are indicated to decrease phosphorus absorption and increase calcium absorption. In hypomagnesemia, the magnesium deficiency usually has to be corrected before hypocalcemia can be treated successfully

Hypoparathyroidism requires therapy with vitamin D or one of its metabolites; $1,25(OH)_2D_3$ (or 1 α-hydroxyvitamin D_3, a synthetic analogue that undergoes hepatic 25-hydroxylation) has the advantage f a shorter half-life, and treatment may be more easily tailored to the individual patient. Attention should be directed toward a number of concomitant treatments. Because thiazide diuretics can increase renal calcium reabsorption, the inadvertent institution or discontinuation of these drugs may increase or decrease, respectively, the plasma calcium level. In contrast, furosemide and other loop diuretics can increase the renal clearance of calcium and depress serum calcium levels. The administration of glucocorticoids antagonizes the action of vitamin D (and the analogues) and may also precipitate hypocalcemia. The development of hypomagnesemia may also interfere with the effectiveness of treatment with calcium and vitamin D [2].

49.4.1.9 Prevention of Neonatal Hypocalcemia

The most effective prevention of neonatal hypocalcemia includes the prevention of prematurity and birth asphyxia, the judicious use of bicarbonate therapy, and mechanical ventilation to avoid secondary metabolic alkalosis. Whereas, the pharmacologic prevention of neonatal hypocalcemia, especially in VLBW infants, is based on the prophylactic use of calcium salts, phosphorus salts, and vitamin D supplementation from the first day of life, with a regular survey of serum concentrations and urinary excretion.

49.4.2 Neonatal Hypercalcemia

Hypercalcemia is defined as a pathologic elevation in plasma ionized Ca^{2+} concentration greater than 1.35 mmol/L (5.4 mg/dL) with or without a simultaneous elevation in total calcium concentration of greater than 2.75 mmol/L (11.0 mg/dL) as total calcium is more related to serum albumin concentration [2, 18]. Neonatal hypercalcemia (Table 49.3) is relatively uncommon, but it needs to be recognized because it can result in significant morbidity or mortality. The clinical symptoms of sustained hypercalcemia are not specific. Infants with mild increases in serum calcium (2.75 to 3.25 mmol/L, or 11 to 13 mg/dL) often fail to manifest specific symptoms of hypercalcemia. Nonspecific signs and symptoms such as anorexia, vomiting, and constipation (but rarely diarrhea) may occur with moderate to severe hypercalcemia. Seizures, bradycardia, or arterial hypertension is very exceptional. On physical examination infants may appear dehydrated, lethargic, and hypotonic. Those with chronic hypercalcemia may present with failure to thrive as the principal source of physical distress. Renal function is generally impaired, and polyuria and hypercalciuria are observed. However, renal complications such as nephrocalcinosis, nephrolithiasis, and hematuria may be the earliest clinical manifestations of hypercalcemia.

49.4.2.1 Iatrogenic Hypercalcemia

Hypercalcemia may result from increased intestinal or renal calcium absorption, increased bone turnover or iatrogenic causes. Iatrogenic hypercalcemia is the most common type of hypercalcemia in the newborn and should be considered before starting extensive investigation of rare syndromes. It may result from excessive intravenous calcium administration during total parenteral nutrition or exchange transfusion but also of unbalanced calcium to phosphorus ratio in the oral or parenteral diet. Moderate hypercalcemia may also be the result of phosphorus deficiency in premature infants receiving unbalanced calcium and phosphorus regimens in oral and parenteral nutrition. In this situation, hypercalcemia is accompanied by hypophosphoremia. Infants with VLBW who are fed mineral-unsupplemented human milk may develop hypophosphatemic hypercalcemia. The low phosphorus concentration in human milk causes phosphorus deficiency, leading to an increased calcium concentration and hypercalciuria. Hypophosphatemia stimulates renal synthesis of calcitriol, which activates the intestinal absorption and skeletal resorption of calcium and phosphorus. The absorbed phosphorus is preferentially oriented for soft tissue formation, whereas the remaining phosphorus is insufficient to allow calcium deposition. Phosphorus supplementation and the use of human milk fortifiers can prevent hypophosphatemia and hypercalcemia. Similar situations have been reported in infants on parenteral nutrition, providing an unbalanced calcium:phosphorus ratio. Additionally, thiazide diuretics reduce renal calcium excretion and may represent a contributing factor. Other causes of iatrogenic hypercalcemia are the use of extracorporeal membrane oxygenation, which can cause transient hypercalcemia in up to 30% of infants, and vitamin D intoxication from the administration of excessive vitamin D supplements. Vitamin A toxicity increasing bone resorption is rare and can cause severe hypercalcemia.

49.4.3 Neonatal Hyperparathyroidism

Neonatal hyperparathyroidism frequently results in severe hypercalcemia. It may be hereditary primary hyperparathyroidism or be secondary to maternal hypocalcemia and is summarized in Table 49.3 with other more unusual causes of hypercalcemia.

49.4.3.1 Primary Hyperparathyroidism

Hereditary primary hyperparathyroidism manifested in neonates is associated with inactivating mutation of CaR. The serverity of hypercalcemia is related to the extent of CaR mutation, moderate with heterozygous mutation in patients with familial hypocalciuric hypercalcemia. It is an autosomal-dominant trait with a high degree of penetrance. More severe hypercalcemia occurs in neonatal hyperparathyroidism with homozygous inactivating germline mutations of the CaR gene [30].

49.4.3.2 Secondary Hyperparathyroidism

In many cases of secondary hyperparathyroidism, a thorough investigation of the infant's mother will disclose previously known but poorly treated hypoparathyroidism, pseudohypoparathyroidism, or clinically unsuspected hypocalcemia, as seen in mothers with renal tubular acidosis that had induced severe secondary hyperparathyroidism in the developing fetus during pregnancy. The clinical presentation is variable and may depend on the severity of maternal hypo- calcemia. Secondary hyperparathyroidism and neonatal hypercalcemia are transient conditions with a good prognosis provided that supportive measures are instituted.

49.4.3.3 Clinical Manifestations

Most infants are asymptomatic when diagnosed. Those with mildly elevated levels of calcium often fail to manifest specific symptoms of hypercalcemia. Infants with chronic hypercalcemia may present with failure to thrive as the principal source of physical distress.

There are nonspecific signs and symptoms such as anorexia, vomiting, and constipation (but rarely diarrhea); polyuria may occur with moderate to severe hypercalcemia. In severe hypercalcemia infants are often dehydrated, lethargic,

and hypotonic. Alternatively, they may present with seizures. Clinically, these infants can have bradycardia, a short QT interval, and hypertension. However, renal complications such as nephrocalcinosis, nephrolithiasis, and hematuria may be the earliest clinical manifestations of hyper- calcemia. Otherwise, the physical examination is usually normal except for the infants with subcutaneous fat necrosis, Williams syndrome, Jansen metaphyseal chondrodysplasia, and hypophosphatasia.

In clinical practice the practical approach is first to exclude the possibility of iatrogenic hypercalcemia. Secondly, a maternal history of calcium-phosphorus disease or excessive vitamin D intake during pregnancy should be investigated. Thirdly, the signs of clinical syndromes associated with hypercalcemia, such as blue diapers, fat necrosis, and elfin facies, should be sought. Finally, the initial laboratory evaluation should include serum calcium, phosphorus, alkaline phosphatase, PTH, the urinary calcium:creatinine ratio, and tubular reabsorption of phosphorus. In most cases, these tests allow the differentiation of hypercalcemia caused by parathyroid disorders from nonparathyroid conditions. In hyperparathyroidism the serum phosphorus concentration is low; renal tubular phosphorus reabsorption is decreased, usually to less than 85%; and the serum PTH concentration is elevated. Finally, additional tests may be performed: a serum $25(OH)D_3$ determination may be useful when an excess of vitamin D is suspected; long-bone X-ray films identify demineralization, osteolytic lesions, or both (hyperparathyroidism) or osteosclerotic lesions (occasionally with vitamin D excess); measurements of serum and urinary calcium in parents allow a diagnosis of familial hypocalciuric hypercalcemia; and renal sonography detects nephrocalcinosis.

49.4.3.4 Treatment

The treatment of neonatal hypercalcemia depends on the severity of the presentation. Conservative management is appropriate in the case of mild hypercalcemia in a preterm infant resulting from an inappropriate mineral supply, hypoalbuminemia, or chronic acidosis, with special emphasis on the phosphorus supply when hypercalcemia is associated with hypophosphatemia. Hypercalcemia seen in newborns exposed to maternal hypocalcemia is usually mild and transient, and treatment consists of no more than supplying the appropriate amounts of calcium and phosphorus in the milk.

Infants with moderate to severe hypercalcemia need more aggressive treatment. The initial steps are not specific: (1) Discontinue oral and intravenous calcium and vitamin D supplementation and dietary restriction; (2) increase the urinary excretion of calcium by maximizing glomerular filtration with the administration of intravenous fluids, which consist of standard saline at about twice the maintenance requirements; and (3) encourage calcium excretion with furosemide after rehydration but with particular attention to maintaining electrolyte homeostasis.

More specific therapy comprises the use of glucocorticoids, calcitonin, bisphosphonate, dialysis, and total parathyroidectomy. Glucocorticoids (2 mg/kg of prednisone) decrease intestinal calcium absorption, decrease bone resorption, and increase renal excretion. They may be useful during a short period, mainly in cases of an excess of vitamin D, but are relatively ineffective in cases of hyperparathyroidism. Calcitonin (4 to 6 IU/kg subcutaneously every 6 hours) reduces the serum calcium concentration, but its effectiveness declines after a few days. Bisphosphonate therapy is limited in newborn infants. However, pamidronate (0.5 to 2.0 mg/kg) has been used in the treatment of subcutaneous fat necrosis and could be an ideal agent to stabilize cases of neonatal severe hyperparathyroidism, as recently suggested. A calcimimetic drug that reduces PTH secretion, recently approved by the FDA for chronic secondary hyperparathyroidism in dialyzed patients, could be of major interest in primary hyperparathyroidism but needs to be evaluated during infancy [29]. Dialysis could be prescribed with a low-calcium dialysate (1.25 mmol/L) in the face of severe and unremitting hypercalcemia. Total parathyroidectomy with partial autotransplantation could be a rescue treatment in the severe form of neonatal severe hyperparathyroidism. In the chronic phase, dietary restriction with the use of a special formula without vitamin D supplementation is the mainstay of treatment. If the dietary regimen is insufficient, corticosteroids can be used with caution. Cellulose phosphate binders have been occasionally used in children, but there is limited experience in neonates and they may contain unwanted free phosphate.

49.4.4 Nephrocalcinosis in Preterm Infants

Nephrocalcinosis is defined as ultrasound evidence of bright reflections with or without acoustic shadowing, small flecks across to completely echodense pyramids which are reproducible in both the longitudinal and transverse direction, found within the cortex or medulla. Initially, nephrocalcinosis was attributed to long-term furosemide therapy. It is now known to be multifactorial and has been associated with low gestational age and birth weight; severe respiratory disease, transient renal failure; imbalance intakes of calcium and phosphate; long duration of total parenteral nutrition; as well as pro-calciuric medications such as furosemide, corticosteroids, aminoglycosides, and xanthines. In addition, in analogy to the pathogenesis of stone formation, nephrocalcinosis is considered to result from a spontaneous or therapy-induced imbalance between promoters (e.g., calcium, oxalate, uric acid, ascorbic acid) and inhibitors (e.g., citrate, magnesium) of crystallization in urine. The prevalence of nephrocalcinosis varies between studies from 7% to 41% in recent reports [31].

The short- and long-term evolution of nephrocalcinosis has not been clearly defined. Ultrasonographic abnormalities that develop during the first months of life disappear in the majority of patients within months to years. Earlier studies had raised

concerns regarding tubular function in affected patients. This has not clearly been substantiated in more recent larger studies where an unfavorable effect on renal function is seen in a small number of children [31]. Nevertheless, premature children with or without nephrocalcinosis when compared with non-premature children had lower kidney size and borderline blood pressure. In addition, children with intra- or extrauterine growth retardation had an impaired GFR compared to children with appropriate pre- and postnatal growth [32].

In summary, nephrocalcinosis is a high incidence disease in VLBW and ELBW infants but associated with a good renal outcome and a high resolution rate. However, it has been highlighted that there could be long-term sequelae in tubular dysfunction and hypertension. This warrants close monitoring in ex-premature babies.

49.5 Disorders of Phosphate Homeostasis

49.5.1 Neonatal Hypophosphatemia

In adults, moderate hypophosphatemia is defined as a serum phosphorus concentration between 3.0 and 1 mg dL^{-1}, and is usually asymptomatic. Severe hypophosphatemia is defined as serum inorganic phosphorus concentration below 1.0 mg dL^{-1}. In children, serum phosphorus concentrations below 5 mg dL^{-1} are often considered abnormal. This level corresponds to the threshold level of tubular resorption capacity and potential increase in urinary calcium excretion (Fig. 49.5). Hypophosphatemia may be caused by decreased intestinal absorption of phosphate, increased urine losses of phosphate, and an endogenous shift of inorganic phosphorus from extracellular to intracellular fluid compartments. It has also been reported in various rare hereditary diseases associated or not with neonatal hyperparathyroidism (Table 49.4). Early hypophosphatemia was observed in IUGR. Within the 1st week of life, a significant correlation between preeclampsia and 1st week inorganic phosphate deficiency was related in VLBW babies, whereas, the occurrence of hypercalciuria and low urinary phosphate was also observed in small-for gestational age (SGA) infants. These studies suggest that infants with extrinsic IUGR are probably insufficiently provided with phosphorus *in utero* and hence postnatally may suffer early-onset inorganic phosphate depletion from prenatal origin. This mineral imbalance has been delineated in newborns with chronic fetal hypoxia and malnutrition leading to disproportionate or type II IUGR. In those infants, hypophosphatemia as well as platelet count and high nucleated red blood cell count were closely correlated with the severity of IUGR in SGA type II.

A high incidence (i.e., 28%) of hypophosphoremia associated with a double mortality rate related to myocardial dysfunction is reported in adult intensive care patients. A short course of phosphotherapy improved the left ventricular function rapidly in inorganic phosphate depleted adults [33].

Table 49.4 Causes of neonatal phosphorus disorders

Hypophosphatemia	Hyperphosphatemia
Endocrine	*Endocrine*
Hyperparathyroidism	Hypoparathyroidism
VitaminD deficiency or resistance	Hyperthyroidism
Renal losses	Growth hormone excess
Congenital tubular disorders	Vitamin D toxicity
Secondary tubular disorders	*Renal*
Diuretics	Renal failure
Volume expanders	Volume depletion
Hypercalciuria	*Increased load*
Glucosuria	Enteral, Cow milk feeding
Hypomagnesemia	Rectal enema
Gastrointestinal	Parenteral
Decrease of intake	Blood transfusion
Decrease of absorption	
Calcium salt	
Malabsorption	
Antacid	
Gene mutation	
Others	
Metabolic acidosis	
Respiratory alkalosis	
Gram-negative sepsis	
Refeeding syndrome	
Hypercalcemia	
Carbonic anhydrase inhibitors	
Dopamine	

Therefore it is tempting to speculate that early-onset inorganic phosphate depletion could be an etiologic factor in myocardial dysfunction, leading postnatally to left heart failure and ensuing pulmonary hemorrhage in the most severely growth retarded VLBW-infants.

During the first weeks of life, hypophosphatemia related to low phosphorus intake occurs in low birth weight babies who were fed soy formulas and more frequently exclusive unsupplemented human milk [34]. With human milk addition of 5 to 10 mg/100 mL of inorganic phosphate equivalent corrects plasma concentration, reduces calcium excretion and improves calcium retention. In formula fed infants, similar hypophosphatemia is also observed in relation to an inadequate calcium phosphorus ratio resulting either from a relative phosphorus malabsorption or a relatively higher calcium absorption rate. In that situation, absorbed phosphorus is lower than that required for deposition in soft tissues and bone according to nitrogen retention and calcium absorption.

An inadequate calcium to phosphorus ratio is also observed in preterm infants with persistent metabolic acidosis or prolonged respiratory distress syndrome. In that situation, the acid-base disturbance, increased bicarbonate or hypercapnia reduced phosphorus tubular reabsorption inducing a relative hypophosphatemia and hypercalciemia associated with a concomitant urinary excretion of phosphorus and calcium increasing the risk of nephrocalcinosis.

Given its widespread distribution and critical role in vital cellular processes, it is not surprising that a deficiency of

phosphorus results in various clinical symptoms including hypotension and decreased stroke volume, impaired diaphragm contractility, dyspnea and respiratory failure, paresthesia, weakness, confusion, disorientation, lethargy, areflexic paralysis, seizures and coma, leukocyte dysfunction hemolysis and thrombocytopenia, as well as rickets or osteomalacia as reported in refeeding syndrome [35].

49.5.2 Neonatal Hyperphosphatemia

Hyperphospatemia is usually due to a decrease in renal function or a PTH absence (primary or secondary hypoparathyroidism) or phosphatonin deficiency. Hyperphosphatemia is most often the result of decreased renal excretion of phosphate anions as encountered in acute or chronic renal failure, particularly when glomerular filtration rate is reduced to less than 25% of normal. Hyperphosphatemia could also be the result of increased body phosphate load from blood transfusions and hyperalimentation. Increased renal tubular reabsorption of phosphate is responsible for hyperphosphatemia seen in neonatal hypoparathyroidism and associated disorders such as infants of diabetic mothers, transient neonatal hypoparathyroidism, neonatal pseudohypoparathyroidism or in babies born to mothers with hyperparathyroidism (Table 49.4). Hyperphosphatemia and secondary hyperparathyroidism have been extensively investigated as inducing factors in cardiovascular calcification. Together with passive deposition of calcium-phosphate in extraskeletal tissues, it has recently been demonstrated that inorganic phosphate induces arterial calcification directly through a real "ossification" of the tunica media [36].

49.6 Bone Mineralization

49.6.1 Factors Affecting Growth and Mineralization

During gestation, the fetus receives an ample provision of nutritional supply through the placenta. Nitrogen, energy, minerals, and vitamins allow a high velocity of body length growth, representing around 1.2 cm/week during the last trimester of gestation. The fetus maintains its hypercalcemic state in a high calcitonin and estrogen environment, promoting the modeling/remodeling ratio in favor of modeling and thus increasing endocortical bone. In addition, according to the mechanostat theory of bone development, fetal bone is also driven by the mechanical force applied to the fetal skeleton during the intrauterine resistance training provided by regular fetal kicks against the uterine wall [37, 38]. Consequently, at term the newborn skeleton has a high physical density (bone mass divided by bone volume), with elevated cortical thickness and relatively small marrow cavities.

Various factors influence the processes of growth, mineralization, and bone structure. Growth is directly related to protein and energy supplies but also to the hormonal environment comprising insulin, IGF1, and IGF2, among others. Bone formation, mineralization, and structure are related to mineral supply and hormonal factors such as PTH, PTHrP, vitamin D, and calcitonin as well as others, such as genetics and physical activity. Several factors have been found to have a significant impact on newborn bone mineral content and developing fetal bone. Reduced calcium supply, vitamin D deficiency, alcohol consumption, and smoking during pregnancy are all factors affecting fetal skeletal development in addition to low weight related to gestation and diabetes in the mother.

49.6.2 Osteopenia of Prematurity

Premature infants, particularly those born at <28 weeks' gestation, are at significant risk for reduced bone mineral content (BMC) and subsequent bone disease, variably termed metabolic bone disease (MBD), osteomalacia, osteopenia, or neonatal rickets [11, 39, 40]. Reduction in BMC and the development of MBD of prematurity are quite common among VLBW infants. However, due to the lack of widely adopted diagnostic criteria, the true incidence has not been determined. Fractures in premature infants typically occur several weeks after delivery and prior to the postnatal age of 6 months [41, 42]. Rib fractures, the most common type, usually occur silently and are diagnosed only if X-rays are performed. Therefore, the true incidence of fractures is difficult to determine, varying between 2.1% and 25% in 3 previous studies [41] conducted without the use of prospective, systematic skeletal surveys.

The risk factors commonly associated with fractures include extremely low birth weight, late (> 30 days) establishment of full enteral feeds or prolonged parenteral nutrition, exclusive use of unfortified human milk, necrotizing enterocolitis, conjugated hyperbilirubinemia, chronic lung disease, use of various medications, utilization of passive respiratory physiotherapy (i.e., chest percussion), and lack of physical activity, which may be enhanced by sedatives. Recent data on fractures among VLBW infants are still lacking, but some clinical evidence suggests that the risk for fracture is greatly reduced with the use of parenteral and enteral nutrition adapted to the special nutritional needs of the premature infant.

Risk factors for MBD are commonly encountered in the preterm infant. The majority of bone mineralization, along with calcium and phosphorus accretion, occurs during the third trimester of pregnancy. Infants born before this time thus have depleted stores of these minerals [42]. Data from bone density scans (dual-energy X-ray absorptiometry [DEXA]) performed at birth in preterm and term infants suggest that bone mineral accretion during the last trimester of gestation is higher than needed, with growth in bone volume leading to

a continuous increase in skeletal density. Preterm infants therefore have a large mineral deficit compared with term infants. Several factors increase the risk for severe MBD among VLBW infants, with the most important appearing to be an inadequate supply of calcium and phosphorus associated with the use of an enteral *vs* transplacental route. Newborn premature infants experience a diminished mineral uptake required for proper bone accretion, due, in part, to the reduced availability and to their compromised gastrointestinal (GI) absorption. Metabolic balance studies in preterm infants fed fortified human milk and formulas [1, 2] have reported that maximal calcium retention values may reach 60 to 90 mg/kg/day and maximal inorganic phosphate retention values may reach 50 to 75 mg/kg/day. The retention rates are relatively low compared with the fetal accretion rates. In total parenteral nutrition, similar data could be obtained with the use of organic phosphate supply and highly soluble calcium salt. In our unit, using calcium glycerophosphate, we provide up to 105 mg of calcium and 80 mg of inorganic phosphate/kg/day with a retention rate close to 95%.

Decreased bone mineralization and the development of osteopenia are the balanced result between two different factors, bone matrix growth directly related to energy balance and nitrogen retention on the one hand, and mineral accretion on the other hand [2, 10]. Data from DEXA scans [2, 10] performed during the first weeks after birth in both preterm and term infants suggest that bone growth, estimated by increase in bone area, is relatively higher than bone mineral accretion, leading to a continuous decrease in skeletal density (Fig. 49.6). Nevertheless, after a few weeks or months, with the continuous reduction in growth velocity, the balance is progressively reversed and the bone mass accrual compensates slowly for the early peak bone growth during the first few months of life. Physical activity appears to play a significant role in bone mineralization. During the neonatal period, mechanical strain on bone and joints stimulates bone formation and growth, whereas inactivity leads to bone resorption [37, 38]. This might be equally valid for preterm infants in incubators during the first weeks of life, who lack the *in utero* mechanical stimulation associated with regular kicks against the confining uterine wall [43]. During the initial hospitalization, the movements of preterm infants usually occur without much resistance. While in the NICU, these infants are handled with little tactile stimulation in order to reduce stressful events. Moreover, the use of drugs to reduce pain aggravates the reduction in mechanical stimulation during their stay. In order to obviate the effects of reduced mechanical stimulation, systematic physical activity programs administered several times a week by nurses, therapists, and parents have been evaluated. A number of recent studies, agree that physical activity either improves bone mineralization, as determined by single-photon absorptiometry, or increases bone formation, as estimated by the measure of serum collagen C-terminal propeptide [43]. These regimens either increased bone strength or attenuated its decrease, as evaluated by quantitative measurement of bone ultrasound transmission speed. Nevertheless, the last Cochrane review of this subject concluded that additional studies are needed before the general use of such physical activity programs can be promoted [43]. A number of other factors may also play a significant role in bone mineralization, including genetic polymorphism, mechanical stimulation, or the use of various medications that interfere with mineral absorption or retention, such as diuretics, caffeine, and corticosteroids.

Neonatal screening for MBD in preterm infants is still controversial [40]. Serum calcium levels are carefully regulated by hormonal secretion and are not a useful screening tool. However, a low serum phosphorus concentration <1.8 mmol/L) that is below the renal phosphate threshold has been related to insufficient phosphorus intake and to an increased risk for osteopenia. Urinary excretion of calcium and phosphorus has been proposed as a marker of adequate postnatal

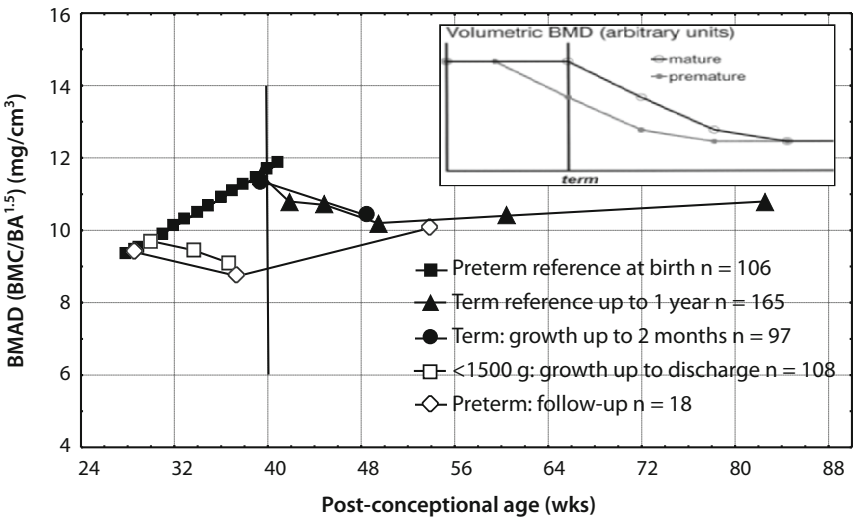

Fig. 49.6 Physiological evolution of DEXA apparent Bone Mineral Density during the last trimester of gestation and during the first year of life in healthy term infants (*dark symbols*) compared to that observed in premature infants (*open symbols*). Comparison to the evolution suggested by the mechanostat theory (*frame*)

mineralization when doses >1.2 mmol/L of calcium and >0.4 mmol/L of inorganic phosphorus are excreted simultaneously. However, these values are more appropriate for estimating the adequacy of the calcium to phosphate ratio than for estimating mineral accretion, especially when data on the mineral absorption rate are lacking.

In infants, 90% of alkaline phosphatase (ALP) is of bone origin and thought to reflect bone turnover. ALP concentrations usually increase during the first 2 to 3 weeks of life and may peak further if there are insufficient mineral supplies. Elevated levels of ALP have been reported in association with severe under mineralization based on radiologic evidence, low bone speed of sound (SOS) using quantitative ultrasound, or severe bone mineral density (BMD) deficit revealed on DEXA scans. Nevertheless, ALP is probably more sensitive for evaluating fracture risk than for assessing MBD or osteopenia.

Various radiologic investigations have been proposed for assessing bone mineralization and osteopenia among preterm infants. Plain radiography is poorly sensitive, detecting only a decrease of >20% to 40% of bone mineralization [42]. By contrast, DEXA technology, is sensitive, accurate, and precise, and its use has been validated in both preterm and term infants [1, 2, 44]. Normative data on bone mineral content, projected bone area, and BMD in healthy preterm and term infants close to birth were established in order to obtain surrogate intrauterine reference values. In addition, various indices have been proposed for reducing the anthropometric dependency of the various parameters and for facilitating group or individual comparison. Thus, data obtained from various groups allow for the determination of major changes in bone mineralization during the fetal life and postnatally in preterm and term infants. These results are in agreement with the predicted time course of volumetric bone mineral density in mature newborns and premature babies, according to mechanostat theory [39].

The use of ultrasound has been proposed for the evaluation of bone mineralization in newborn infants [40]. It is a simple, non-invasive, relatively inexpensive bedside procedure. Some machines have been designed to measure broadband ultrasound attenuation or SOS, commonly on the tibia. The propagation of sound waves in bone is determined by a number of factors, including mineral density, cortical thickness, elasticity, and micro-architecture, possibly providing a more complete picture of bone strength than measurements of BMD alone. In preterm and term infants at birth, there is a significant correlation among tibial SOS and gestational age, birth weight, birth length, and tibial length. However, the changes in SOS values during the last trimester of gestation are relatively small, accounting for only about 130 m/sec. This value is only ±1.5 times higher than the interindividual variability (standard deviation [SD] = 95 m/sec). After birth, a rapid decline in bone SOS occurs during the first days of life that cannot be completely explained by a nutritional deficit. Therefore, these data suggest that measurement of bone SOS has a lower sensitivity than DEXA for evaluating the various factors influencing bone mineralization during the neonatal period (Fig. 49.6).

In contrast to fetal bone metabolism, in which modeling is the main process inducing high net bone formation, with a rapid increase in trabecular thickness, neonatal bone metabolism is the result of a prevailing remodeling activity, defined as the cyclical succession of bone resorption and formation on the same bone surface [39, 40]. Therefore, the relative MBD of prematurity could be the result of a postnatal physiologic metabolic adaptation instead of the expression of a transitory MBD. Indeed, the relative osteopenia observed in preterm infants appears to be similar to that observed in healthy term infants during the first weeks after delivery or to that observed in early adolescence at the time of a growth spurt.

After discharge, catch-up mineralization is rapidly observed in VLBW infants [44]. At 6 months of corrected age, spine and total bone mineral density, corrected for anthropometric values, are in the range of normal term newborn infants. In fact, the catch-up mineralization observed after discharge is quite similar to that observed after the initial acceleration of growth during adolescence. Nevertheless, peak bone mass may be less during adulthood [45]. As suggested by Fewtrell and coworkers, at 8 to 12 years of age, formerly preterm infants were shorter, lighter, and had lower BMCs than controls. However, BMC was appropriate for the body size achieved and was not affected by early dieting or human milk feeding [46].

Thus, osteopenia or rickets of prematurity seems to be a self-resolving disease, although the potential long-term consequences on the attainment of peak bone mass are not clearly known. Even if BMC improves spontaneously in most infants, this discovery does not imply that a period of demineralization is acceptable. Although the long-term consequences are unclear, the benefits of prevention and treatment include avoidance of fractures and possibly improved linear growth and peak bone mass.

In summary, after birth, the development of relative osteomalacia or osteopenia is a physiologic event resulting from a mismatch of the mineral supply and the persistent growth velocity on the one hand, and from the stimulation of bone turnover as an adaptation to extrauterine life on the other. This phenomenon is enhanced in preterm infants born with low mineral stores, an immature GI tract, and reduced physical activity, who demonstrate higher growth rates than do term infants. Several of the conditions discussed above and in the articles reviewed in this chapter might increase the severity of MBD, leading to the development of severe osteopenia and the risk for fracture. Early optimal parenteral and oral nutritional support, combined with biologic neonatal screening and measurement of serum phosphorus and ALP concentrations, as well as mineral urinary excretion, appears to be helpful for the prevention of MBD. When available, DEXA is more sensitive than ultrasound for quantifying osteopenia in VLBW infants [40].

Micronutrients and Vitamins

Olivier Claris and Guy Putet

50.1 Micronutrients

Table 50.1 summarizes the most recent recommendations [1–4].

Iron Iron (Fe) is an important micronutrient implicated in DNA replication, cellular metabolism and oxygen delivery. It is mainly involved in erythropoesis and is the first sign of deficiency in anemia, it is also implicated in neurodevelopment, and cardiac and skeletal muscle function. On the otherhand, it is a potentially toxic nutrient and, as a powerful prooxidant, it may play a major role in the oxidative stress. Furthermore, iron overload has a direct impact on cardiac and liver function. For all these reasons, the range between requirements and toxicity is narrow.

Iron is absorbed in the duodenum as ferrous. Absorption rates depend on the iron status, the form of iron given and the age of preterm (PT) infants. Iron absorption is particularly enhanced by human milk feeding and vitamin C status, and is decreased after erythrocyte transfusion and competes with zinc and copper absorption.

Iron supplementation may be started as soon as 2 weeks of age, at a dose of 2 to 3 mg/kg/day [1]. Infants receiving erythropoietin treatment require higher intake, but too high an intake may cause intestinal side effects and increase retinopathy of prematurity. It is therefore why intakes above 5 mg/kg/d are not recommended [5].

Zinc Zinc (Zn) is an ubiquitous trace metal present in numerous enzymes and participates in carbohydrate (CHO) and protein metabolism. It is required for replication, transcription and repair of DNA, and plays an important role during embryogenesis and growth. Zn is absorbed in the distal duodenum and proximal jejunum, and this is impaired by high casein intake.

O. Claris (✉)
Department of Neonatology, Hôpital Femme Mère Enfant, Bron, and Hospices Civils de Lyon and Université Claude Bernard, Lyon, France

Zn deficiency is characterized by growth arrest, irritability, anorexia, alopecia, esophagitis, diarrhea and functional recommendations in immunity, skin lesions of the hands and feet and poor healing. True acrodermatitis enteropathica is rarely seen in PT infants but ELBW infants on TPN without Zn, SGA, and growing PT infants fed unfortified HM are at risk of Zn deficiency [6].

Copper (Cu) It is a component of numerous enzymes (superoxide dismutase) involved in oxidation and reduction. It helps to protect cell membranes from oxidative damage. Copper competes with Zn and iron for intestinal absorption. It is absorbed in the upper part of the intestine, and this decreases by high Zn and iron intakes. Deficiency is associated with hypochromic anemia not responding to iron supplementation, hypotonia, failure to grow, diarrhea, bone abnormalities, neutropenia. In the case of hepatic cholestasis, intake has to be reduced or stopped because of potential toxicity.

Selenium (Se) It is a glutathione peroxidase component, which protects cell membranes against peroxide induced drainage. Deficiency is only seen in infants on TPN without or with too little Se, or in Keshan disease (cardiomyopathy) areas where soil is Se deficient. Addition of Se to food or TPN must be cautious as most Se compounds are toxic if given in excess [7].

Iodine (I) It intervenes in thyroid function (T3 and T4 synthesis), and iodine deficiency (before or after birth) may impair growth and intellectual performance. Excess iodine may also create hypothyroidism. PT infants often have transitory hypothyroidism as their mechanisms to control iodine levels are immature [8]. Based on the mean content of iodine in HM some PT infants may be on negative iodine balance. Toxicity is more often due to percutaneous intake (antiseptic solution).

Chromium (Cr) It has a role in glucose homesostasis. Hyperglycemia and insulin resistance are part of Cr deficiency, never described in infants either breast or formula fed.

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

Table 50.1 Micronutrients: Human milk (HM) content and intake recommendations [1–4]

	HM content FT	Requirements [2]		Requirements [1, 3, 4]		
		Enteral PT	Parenteral PT	Enteral PT	Parenteral FT	Parenteral PT
Iron	0.5–1 mg/L	2–4 mg/kg	0.25–0.67 mg/kg*	2–3 mg/kg	0.5–1 mg/kg	0.2 mg/kg**
Zinc	0.5–2.5 mg/L***	1–2 mg/kg	0.4 mg/kg	1.1–2 mg/kg	0.25 mg/kg	0.45–0.5 mg/kg
Copper	600–800 µg/L	120–150 µg/kg	20 µg/kg	100–132 µg/kg	20 µg/kg	
Selenium	15–20 µg/L	1.3–4.5 µg/kg	1.5–4.5 µg/kg	5–10 µg/kg	2–3 µg/kg	
Iodine	70–90 µg/L	10–80 µg/kg	1 µg/kg	11–55 µg/kg	1 µg/day	
Chromium	0.3–0.5 µg/L	0.1–2.25 µg/kg	0.05–0.3 µg/kg	0.03–1.23 µg/kg	not necessary	
Manganese	5 µg/L	0.75–75 µg/kg	1 µg/kg	<27 µg/kg	1 µg/kg	<50 µg/day
Molybdenum	2 µg/L	0.3–4 µg/kg	0.25–1 µg/kg	0.3–5 µg/kg	0.25 µg/kg <5 µg/day	1 µg/kg
Fluorine				1.5–60 µg/kg		

* After 2 weeks of life. ** Unnecessary before 3 weeks. *** Decrease with postnatal days.

Manganese (Mn) It is a component of several enzymes acting in gluconeogenesis, mitochondrial membrane maintenance and in mucopolysaccharide synthesis. Mn deficiency has not been described in human conclusively, however Mn toxicity has been seen in adults with extrapyramidal symptoms. Advisable intakes are based on what is contained in human milk.

Molybdenum (Mo) It intervenes in the function of xanthine, aldehyde and sulfite involved in purine metabolism and sulfur excretion. Deficiency is only described in adults on very long term TPN. Advisable intakes are based on what is contained in HM.

Fluorine (F) It is found in bones and teeth mainly. There are no data to make any recommendation except that it is found in human milk and crosses the placenta.

50.2 Vitamins

Table 50.2 summarizes the most recent recommendations for vitamin intake.

Vitamin B1 (**thiamine**) Vit B1 is a coenzyme essential for CHO metabolism and lipids synthesis once transformed by the liver into thiamine pyro phosphate. It is absorbed in the proximal small intestine. Deficiency is known as "beriberi". A thiamine deficient total parenteral nutrition (TPN) may induce severe lactic acidosis and death.

Vitamin B2 (**riboflavine**) Vit B2 is implicated in energy metabolism (it forms flavin, adenine, dinucleotides). It is absorbed in the small intestine. Deficiency leads to stomatitis, dermatitis and anemia. Requirements are based on HM content and are related to protein intake. If protein supply is given without Vit supplementation, a deficit can occur [9].

Vitamin B3 (**niacin**) Vit B3 can be synthesized from tryptophane (Try) in the presence of B6, once this amino acid (AA) exceeds minimal intake (60 mg of Try → 1 mg of niacin expressed as Niacin Equivalent). It is also a cofactor for electron transport and energy metabolism. Absorption is effective in the small intestine. Deficiency is known as pellagra (dermatitis, diarrhea and neurological symptoms). It usually results from multiple deficiency and poor protein intake not observed in newborn infants.

Vitamin B6 (**pyridoxine**) Vit B6 has a role in the metabolism of AA, prostaglandins, CHO, in the development of immune system and neurologic function. Its requirement is related to protein intake (15 µg of B6 should be available per g of protein). It is absorbed in the small intestine. Deficiency leads to vomiting, irritability, dermatitis, failure to thrive, hypochromic anemia and neurological symptoms as convulsions.

Vitamin B9 (**folate**) Vit B9 is active in the biosynthesis of purines, pyrimidine and AA metabolism. Its activity decreases by Zn deficiency. Deficiency is associated with megaloblastic anemia, leucopenia, thrombocytopenia, growth insufficiency, and lesions in small intestine, mostly in context of malabsorption syndromes.

Vitamin B12 (**cobalamin**) Vit B12 is involved in DNA nucleotides synthesis. Absorption depends on gastric pH and occurs in the small intestine. Deficiency of cobalamin is known as leading to megaloblastic anemia, glossitis and neurologic signs, but although this is not seen in FT breast fed infants, it is well established in infants of vegetarian mothers.

Vitamin B5 (**pantothenic acid**) It is a precursor of Coenzyme A (energy metabolism). It is absorbed in the small intestine. Deficiency has not yet been reported as diet provides sufficient amounts.

Table 50.2 Vitamins: human milk (HM) content and intake recommendations [1, 2]

	HM content FT	Requirements [2]		Requirements [1]	Equivalents
		Enteral PT	Parenteral PT	Enteral PT	
Vit A	660–1000 IU/L	750–1500 IU/kg	750–1500 IU/kg	400–1000 µg RE/kg	1 RE = 1 µg all trans retinol 1 RE = 3.33 IU Vit A 1 RE = 6 µg β carotene 1 RE = 12 µg other carotenoids
Vit D	20–30 IU/L	200–1000 IU/day	60–400 IU/day	800–1000 IU/day	1 µg cholecalciferol = 40 IU Vit D
Vit E	3–4 IU/L	6–12 IU/kg	2.8–3.5 IU/kg	2.2–11 mg/kg TE	1 IU = 1 TE 1 IU = 0.67 mg α-tocopherol 1 IU = 1 mg dl-α-TA
Vit K	5–10 µg/L	8–10 µg/kg	10 µg/kg	4.4–28 µg/kg	

IU international units, *RE* retinol equivalent, *TE* tocopherol equivalent, *TA* tocopherol acetate.

Table 50.3 Vitamins: effect of temperature and light, and toxicity

	Temperature	Light	Toxicity
Vit A	↓	Photodegraded	Intra cranial hypertension if >5000 IU/day
Vit D	Stable	Stable	Hypercalcemia, hypercalciuria, anorexia, vomiting, failure to thrive, calcifications
Vit E	Stable	Slightly affected	Large doses associated with sepsis, NEC
Vit K	Stable	↓	Not reported

Table 50.4 Vitamins: daily intake recommendations [1, 2]

	Requirements [2]				Requirements [1]	
	Enteral FT	Enteral PT	Parenteral FT	Parenteral PT	Enteral PT	Parenteral FT
B1	30 µg/kg	300 µg/kg	1–2 mg/day	350 µg/kg	140–300 µg/kg	350–500 µg/kg
B2	40 µg/kg	450 µg/kg	150 µg/kg	150 µg/kg	200–400 µg /kg	150–200 µg /kg
B3	0.2 mg/kg	4.5–6 mg/kg	17 mg/day	5 mg/kg	0.3–5 mg/kg	4–6.8 mg/kg
B6	14 µg/kg	180–300 µg/kg	1000 µg/day	180 µg/kg	45–300 µg/kg	150–200 µg/kg
B9	9.4 µg/kg	45–50 µg/kg	140 µg/day	56 µg/kg	35–100 µg/kg	
B12	0.05 µg/kg	0.3 µg/kg	0.75 µg/day	0.3 µg/kg	0.1–0.77 µg/kg	0.3 µg/kg
B5	1.7 mg/day	2 mg/day	5 mg/day	2 mg/kg	0.33–2.1 mg/kg	1–2 mg/kg
B8	0.7 µg/kg	4–40 µg/kg	20 µg/day	6 µg/kg	1.7–1.65 µg /kg	5–8 µg /kg
Vit C	6 mg/kg	30–40 mg/kg	80 mg/day	25 mg/kg	11–46 mg/kg	15–25 mg/kg

Table 50.5 Vitamins: human milk (HM) content, effects of temperature and light, and toxicity

	HM	Temperature	Light	Toxicity
B1	165–220 µg/L	↓	Photo degraded	Only in adults
B2	350–575 µg/L		↓	Not clearly defined
B3	1.8–2.5 µg/L			No side effect with nicotinamide
B6	130–310 µg/L		Inactivated	Very rare only in adults
B9	80–135 µg/L	Destroyed	Inactivated	Very rare may mask Vit B12 deficit. May depress Zn absorption
B12	0.2–1 µg/L			Not reported
B5	2–2.5 mg/L			Not reported
B8	5–9 µg/L			Not reported
Vit C	35–85 mg/L	Inactivated		Rebound scurvy in newborn only after large doses during pregnancy

Vitamin B8 (biotin) Except in some metabolic diseases, deficiency is not seen in enterally fed infants as it is synthesized in gut, but is seen in TPN (pallor, anemia, dermatitis, lethargy, EEG abnormalities). It is also absorbed in the small intestine.

Vitamin C (ascorbic acid) Vit C has a role as a cofactor in hydroxylation reactions (proline, lysine, norepinephrin synthesis and Try) and as an antioxidant. It also has a role in folic acid conversion to folinic acid (active form) and in the oxidation of tyrosine (Tyr), and in iron absorption. 1 IU of L Ascorbic Acid corresponds to 50 μg. It is absorbed in the small intestine. Deficiency is known as scurvy. A transient elevation of plasma Tyr and Phenylalanine has been reported in VLBW infants fed high protein casein formulae.

Vitamin A This term refers to compounds (retinoids) having similar activities and structure as retinol (natural molecule derived from beta-carotene). Vit A activity is expressed as RE (retinol equivalent), 1 RE = 1μg retinol = 3.3 IU Vit A. Vit A is mainly stored in liver and circulates in blood linked to retinol binding protein (RBP), and is implicated in protein synthesis and epithelial cell functions, growth and immune functions. It has also strong antioxidant properties. It is absorbed in the upper part of the small intestine. No clinical deficiency is described in FT breastfed infants and precise requirements for PT infants are still unknown with recommended intakes are based mainly on biological data. Vit A supplementation may play a role as an antioxidant factor, and as a protective factor for bronchopulmonary dysplasia (BPD) [10].

Vitamin E The term of Vit E refers to 8 compounds having similar activities. The most active compound is α-tocopherol, which shows a strong antioxidant capability by protecting from lipid peroxidation. Vit E is entirely expressed as α-tocopherol equivalent (αTE), 1 mg αTE = 1 mg d-α-tocopherol = 1.49 IU, and 1 IU = 1 mg dl-α-tocopherol acetate. Vit E requirements depend on polyunsaturated fatty acid intake. It is absorbed in the small intestine. Hemolytic anemia is the main consequence of Vit E deficiency. Some controversy still persists upon the role of Vit E in BPD and retinopathy of prematurity. Large intakes of Vit E (above 50 mg/kg) have been implicated in gastro intestinal adverse effects and sepsis [11].

Vitamin K There are to 2 forms: Vit K1 (phyloquinone: plant form) and Vit K2 (menaquinone: synthesized by bacteria). Vit K is necessary for hepatic synthesis of coagulation factors (II, VII, IX, X, protein C and protein S). It is absorbed in the small intestine. It is needed in a very small amount and, as it is synthesized partly in the gut, synthesis is less pronounced with HM, and deficiency is seldomly seen, except in neonates and in cases of malabsorption or hepatic disease [10].

Vitamin D Along with calcium and phosphorus homeostasis (see also Chapter 49), Vit D plays a physiologic role in neuromuscular function and cell growth and differentiation. It is absorbed in the small intestine. As Vit D deficiency in pregnant women is still frequent, recommended supply for neonates needs to be given as soon as enteral feeding is established [12].

Safety of Medications During Pregnancy and Breastfeeding

Nada Djokanovic and Gideon Koren

51.1 Introduction

The use of medications during pregnancy has become a concern since the thalidomide tragedy. However, although avoiding medications during pregnancy and breastfeeding may be desirable, it is often not possible. Medication use during pregnancy and postpartum is often necessary and unavoidable in chronic conditions such as asthma, diabetes mellitus, hypertension, epilepsy or depression. Women can also develop acute illnesses or pregnancy-induced complications that necessitate drug therapy. In addition, because approximately 50% of pregnancies are unplanned, women are frequently exposed to therapeutic drugs not necessarily intended to be used during pregnancy. Epidemiological studies have determined that two-thirds of all pregnant women use at least one prescription drug during pregnancy [1, 2]. However, in a review conducted in 2001 it was estimated that more than 90% of the drugs approved by the FDA between 1980 and 2000 had insufficient human pregnancy data to determine whether the benefits of treatment exceeded the risk to the embryo and/or fetus [3]. This reality highlights the growing need for more and better data regarding medication use during pregnancy and breastfeeding.

To guide physicians in the interpretation of the teratogenic risk associated with prescription drugs, in 1979 the FDA created a rating system that classifies drugs on the basis of data from animals and humans, ranging from class A drugs, which are designated as safe for use during pregnancy, to class X, which are contraindicated during pregnancy because of proven teratogenicity. However, this system oversimplifies the issues relevant to prescribing a medication to a pregnant patient, and has been criticized as inconsistent, misleading and of limited value. The FDA has recognized the limitations of the current system, and a new approach to pregnancy and lactation labeling is under development. The proposed change to the FDA labeling system will provide more detailed, comprehensible, and practical information about the use and effects of drugs during pregnancy and lactation [4].

This chapter reviews the issues related to safety of medications use in pregnancy and breastfeeding describing the principles of teratogenicity assessment and providing practitioners with resources for obtaining up-to-date information regarding exposures during pregnancy and lactation.

51.2 Establishing the Risk – The Importance of Observational Data

When a drug is first marketed, there are usually no human data on drug exposure in pregnancy. Due to ethical concerns about possible harm, pregnant and breastfeeding women are traditionally excluded from clinical trials. Although animal studies function as a screen for potential human teratogenicity and are a required part of the drug development process, they do not necessarily predict the effects in humans because of considerable variations in species-specific effects [5]. In the absence of randomized controlled trials, the best and only ethical way to achieve better knowledge of possible teratogenic effect of drugs during pregnancy is collection and follow-up of observational data [6].

51.2.1 Case Reports and Epidemiological Studies

How do we establish that specific agents are teratogens? Evidence of teratogenicity in humans frequently starts from a single case-report or case series. Case reports can be very useful, or useless, depending on the relatively simple statistical consideration: If a specific, rare malformation occurs in

G. Koren (✉)
The Motherisk Program, Division of Clinical Pharmacology and Toxicology, The Hospital for Sick Children, Toronto, Canada

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

association with a drug that is taken rarely in pregnancy, then a few case reports may prove causation [7]. For example, the first few cases of anotia (lack of ears) and brain defects after isotretinoin have established causation, because the number of cases by far exceeded the rate of these rare malformations [8]. If, on the other hand, the drug is taken by many pregnant women or the malformation in question is common (e.g., ventricular septal defect), then case reports are useless, as they may simply reflect the spontaneous occurrence of malformations in the general population. Case reports have high sensitivity but low predictive value and are thus limited in proof of causation. Hence one must be careful to not rely solely on this type of published information.

At this point, epidemiological cohort and case control surveillance studies are the main methods for verifying an existing risk. Cohort studies are typically designed to determine whether women who took a specific drug during pregnancy have a larger number of malformed children than women who did not use the same drug. Cohort studies are usually prospective (i.e., subjects are enrolled before the outcome is known) and are commonly used for evaluating risk, but their size is frequently small and the selection of appropriate comparison groups (unexposed pregnancies) is important. Case-control studies are based on the ability to link specific malformations with gestational exposure to the drug in question. They are useful when there has been extensive use of a drug by pregnant women or when a drug is suspected of causing relatively rare malformations.

Pregnancy exposure registries are a type of cohort study that prospectively enroll pregnant women exposed to a specific drug of interest and evaluate the associated pregnancy outcomes. They are increasingly used for evaluating risk of newly marketed drugs, but sometimes are limited by the absence of important information such as the timing and dose of the exposure, and the lack of an appropriate comparison group [9].

Databases developed for administrative purposes are also frequently used for both identifying women who were exposed to a specific drug during pregnancy and the outcomes of their pregnancies. These data can be used to identify high-risk teratogens, although for recently introduced drugs they are likely to provide results more slowly than pregnancy registries [10].

Table 51.1 Drugs with potential teratogenic effects [25–27]

Drug	Teratogenic effect
Aminopterin	CNS, limb and skeletal malformations
Angiotensin-converting-enzyme inhibitors	Oligohydramnios, IUGR, neonatal renal failure, anuria, decreased skull ossification, pulmonary hypoplasia, joint contractures, death
Carbamazepine	Neural tube defects, facial dysmorphism
Cyclophosphamide	Skeletal, palate and ocular defects, IUGR
Danazol	Virilization of female fetus
Diethylstilbestrol	Vaginal/cervical carcinoma and other genitourinary defects in female and male offspring
Fluconazole (high doses 400-800 mg/day)	Brachycephaly, abnormal facies, abnormal calvarial development, cleft palate, arthrogryposis, CHD
Lithium	Cardiac defects, particularly Ebstein's anomaly of the tricuspid valve
Methimazole	Aplasia cutis, choanal atresia, esophageal atresia, hypoplastic nipples, scalp defects
Methotrexate (≥12.5 mg/wk)	Large fontanelles, abnormal head shape, craniosynostosis, ocular and skeletal defects
Misoprostol	Moebius syndrome, terminal transverse limb defects, arthrogryposis
Mycophenolate mofetil	Microtia, cleft lip/palate, hypoplastic fingers and toenails, heart defects, micrognathia
Penicillamine	Cutis laxa/connective tissue anomaly
Phenytoin	Fetal hydantoin syndrome: ocular hypertelorism, flat nasal bridge, hypoplastic nails/distal phalanges, microcephaly, developmental delay
Systemic retinoids (isotretinoin, etretinate)	CNS, microtia/anotia, craniofacial, cardiovascular, eye anomalies, limb defects
Tetracycline	Dental staining
Thalidomide	Limb-shortening defects, internal organ defects
Trimethadione/ Paramethadione	IUGR, facial and CNS defects
Trimethoprim	Neural tube defects
Valproic acid	Neural tube defects, fetal valproate syndrome (distinct craniofacial appearance, limb defects, heart defects, a cluster of minor and major anomalies, and developmental delay)
Warfarin	Skeletal and CNS defects, Dandy–Walker syndrome

CNS Central nervous system, *IUGR* Intrauterine growth restriction, *CHD* Congenital heart disease.

51.3 Human Teratogenesis

Teratogenesis is defined as structural or functional dysgenesis of the fetal organs [11]. Adverse pregnancy outcomes as a result of teratogen exposure include structural malformations, embryonic or fetal death, growth alteration, and functional/neurobehavioral deficits [11].

The incidence of major congenital malformations in the general population is 1–3% of all births. For the majority of birth defects (65–75%) the etiology is unknown [12]. In 15-25% of cases the cause is attributable to genetic or chromosomal abnormalities, while 10% of birth defects have an exogenous and potentially preventable cause, such as maternal diabetes, alcohol abuse and therapeutic drugs. The part played by drugs is low, and probably account for less than 1% of all birth defects [12].

One of the common misconceptions about a teratogen is that exposure to that agent during pregnancy will always result in abnormal fetal development. However, even high-risk teratogens, such as thalidomide and isotretinoin, do not inevitably cause birth defects and they typically affect one out of every four exposed fetuses. With the exception of thalidomide and isotretionoin, the other human teratogens are associated with ≥90% normal infants in exposed pregnancies. Fifty years after thalidomide-associated embryopathy, only about 20 drugs or groups of drugs have been established as human teratogens when used in clinically effective doses (Table 51.1).

51.4 Basic Principles of Teratology

An understanding of the principles of teratology is critical to determine if an agent may be the cause of an adverse outcome. These principles help provide the biologic plausibility component needed when one is assessing teratogenicity. Factors that may influence whether a teratogen will actually produce teratogenic outcomes in a particular case include the gestational timing of exposure, dose, route and duration of exposure, the nature of the agent itself, concurrent exposures to other agents, underlying maternal diseases, and genetic susceptibility of the mother and the embryo or fetus [13].

51.4.1 Timing of Exposure

Among the criteria of human teratogenicity, one of the mot important is that of time; that is, the evidence that exposure to teratogenic agents occurred during organogenesis of the given organ or part of the body. The most vulnerable period of organogenesis is from the third through to the ninth week after conception (embryonic stage). Each of the developing organ systems undergoes one or more critical processes during this stage and interference in these processes has the greatest likelihood of causing a structural anomaly. The vast majority of malformations seen in the newborn have already occurred by the end of 8 weeks.

A drug exposure that occurred after the critical period could not produce a birth defect. For instance, the neural tube defect results from events that occur before day 28 following conception. After day 28, the neural tube is closed, and malformations of closure can no longer occur. Thus, during the evaluation of a pregnancy affected by a NTD, it is essential to determine if potential exposures occurred before this time critical period. Examples of a few other anomalies and the post-conception days before which the causative event or exposure must have occurred are cleft lip (36 days), cleft palate (8 weeks), ventricular septal defects (6 weeks), and hypospadias (12 weeks) [11].

The fetal phase, from the end of the embryonic stage to term, is the period when growth and functional maturation of organs and systems already formed occurs. Teratogenic exposure in this period may affect fetal growth and the size or function of specific organs, rather than gross structural anomalies.

On the other hand, exposure to a teratogenic agent before implantation, which occurs 8–10 days after conception in most cases [14], is unlikely to result in malformation. This is known as the "all-or-none" period, as insults to the embryo are likely to result in either death of the conceptus and miscarriage (or resorption), or in intact survival. It is biologically plausible that exposure to teratogens during the preimplantation stage does not cause congenital malformations, unless the agent persists in the body beyond this period.

51.4.2 Exposure Dose

A broadly accepted principle of teratology is that there is a dose-effect relationship with developmental toxicity. There seems to be threshold levels for most human teratogens at which no adverse outcomes are known to occur if exposure is limited to subthreshold levels. An agent may be safe at one dosage, but induce birth defects at higher dosages. However, there are only few examples of drugs in which the dose has been proven to be a major determinant of their teratogenicity in humans. As an example we could use fluconazole, a triazole antifungal agent that has been used in the treatment of vaginal candidiasis and other fungal infections. A single fluconazole dose of 150 mg, usually prescribed for vaginal candidiasis, has not been associated with increased risk for malformations at any point during gestation [15]. On the other hand, five case reports describing multiple congenital anomalies (a distinct and consistent pattern of malformations) in infants born to mothers treated with high dose fluconazole (400–800 mg/day) during first trimester of pregnancy have been published [16, 17].

Although a precise dose-response curve cannot be determined, fluconazole is only teratogenic at these high, continuous doses.

Nevertheless, the basic principle of dose related teratogenicity of therapeutic drugs seems to be more complex, as illustrated by the axiom that "a teratogenic response depends upon the administration of a specific treatment of a particular dose to a genetically susceptible species when the embryos are in a susceptible stage of development" [11].

The teratogenicity of an exposure is influenced by both the maternal and fetal genotypes, which can result in differences in cell sensitivity, placental transfer, metabolism, receptor binding, or drug distribution. The mother metabolizes some medications extensively; their teratogenicity depends upon whether a toxic form reaches the embryo or fetus in sufficient quantities to produce adverse effects.

51.5 Teratogen Risk Counseling

It is important for pregnant women to know that even without any drug exposure there is 1–3% baseline risk of major congenital malformations among all pregnancies. Without appropriate evidence-based counseling, women may perceive the risk of taking a medication during pregnancy or lactation to be greater than the actual risk [18]. As a result, they may undermine their own health or that of their child by discontinuing needed medications, discontinuing breastfeeding despite its known health benefits, or terminating a pregnancy [19].

The selection of drugs for pregnant women or women planning pregnancy needs to be supported by the available relevant information about their safety in pregnant women [20]. Adequate knowledge on potential teratogenicity of a drug permits modification of therapy before conception. If the dilemma is between 2 or more drugs of the same group, the one with better evidence of safety should be selected. In general, the rule of thumb during pregnancy remains; choose an older agent for which there are more fetal safety data. A proactive teratogen risk counseling should include a critical appraisal of the published information and an evaluation of the consequences in the mother and her fetus if the treatment continues or if it stops. Evidence-based counseling ensuring that the potential risks of maternal drug therapy is balanced against the maternal-fetal risks of the untreated condition are the mainstay of teratogenic risk counseling [20].

Most physician and other health professionals receive insufficient training to answer all the questions pregnant women ask about the effects of chemical, physical, or infectious agents on the developing embryo or fetus. To receive up-to-date, evidence-based information on the safety and risks of drugs during pregnancy and lactation, physicians can consult a teratogen information services or on-line databases listed in Table 51.2.

51.6 Breastfeeding and Medications

Breast milk possesses nutritional and immunologic properties superior to those found in infant formula. World Health Organization actively promotes breastfeeding as the best source of nourishment for neonates and young infants and advises exclusive breastfeeding for the first 6 months of age, with continued breastfeeding along with appropriate complementary foods up to two years of age or beyond [21]. Breastfeeding has become more common in recent years, due in part to the many known health benefits to babies and mothers.

It is generally accepted that all medications transfer into human milk to some degree, although it is almost always quite low [22]. Although the majority of medications are considered to be compatible with breastfeeding [23], there have been many case reports of clinically significant toxicity in breastfed infants from some medications used by the mother [24]. Unfortunately there is a paucity of epidemiologic data regarding the risk of adverse effects in infants as a result of exposure to drugs in breast milk.

The transfer of medications across the basal membrane of the mammary gland alveoli depends on lipophilicity, protein binding, molecular weight and on the degree of substance ionization. The dose of a drug an infant receives during breastfeeding depends on the amount excreted into the breast milk, the daily volume of milk ingested, and the average plasma concentration of the mother. An important factor to consider is also the infant clearance, which is itself dependent on the ontogeny of elimination pathways and pharmacogenetics. One of the more popular methods for estimating exposure of the breastfed neonate to a specific drug is to determine the Relative Infant Dose (RID) which represents the weight corrected percent of the maternal dose ingested by an exclusively breastfed neonate. The RID gives the clinician a feeling for just how much medication the infant is exposed to on a weight-normalized basis. It is generally accepted that for drugs without excessive toxicity a relative infant dose of less than 10% is considered safe for full-term infants [22].

A practical view to take when prescribing drugs during breastfeeding is to choose drugs with short half-lives, high protein binding, low oral bioavailability, high molecular weight, and RID less than 10%, as well as drugs for which there are published data, rather than those introduced recently [22]. Greater precaution is advised when prescribing

Table 51.2 Resources for information on medication use in pregnancy and breastfeeding

Pregnancy Registries	www.fda.gov/womens/registries

medications for mothers of premature or otherwise compromised infants or newborns in the first weeks of life than for older, healthy infants. It is tremendously important to always evaluate the infant's ability to handle small amounts of medications. Because many drugs require renal and/or hepatic excretion, clearance may be slowed in preterm infants, who have immature renal and hepatic function.

The American Academy of Pediatrics publishes periodic statements on the transfer of drugs into breast milk [23]. Drugs are listed based on their safety for nursing infants. Most medications that are listed are included in the safest category - Maternal Medication Usually Compatible with Breastfeeding. Limitations of these recommendations include infrequent updates (last update is from 2001), little detail on the medications and omission of many medications. Table 51.2 lists resources that contain more comprehensive information. The on-line database LactMed can be especially useful in the office setting because it is regularly updated and easily accessible without subscription.

51.7 Resources and Accessibility of Information

Multiple resources for obtaining up-to date, evidence-based information regarding exposures during pregnancy and lactation are available, including books, on-line databases and teratology information services (Table 51.2).

Among books, *Drugs in Pregnancy and Lactation* by Briggs et al [25] is a highly used reference guide. A fetal and breastfeeding summary and recommendations are given for about 1200 medications. Another useful book is *Medications and Mothers' Milk*, a comprehensive reference on the impact of more than 1000 currently used medications on breastfeeding mothers and infants, written by Hale [22].

The online REPRORISK system (available from Micromedex) provides access to teratogen information databases REPROTOX and TERIS. Online access to these databases is available for a subscription fee. REPROTOX is an updated, comprehensive database providing summary information to health care professionals on the effects of chemical and physical agents on fertility, pregnancy and lactation [26]. There are summaries for more than 4000 agents, along with references for the data included.

TERIS is another online database designed to assist physicians or other healthcare professionals in assessing the risks of possible teratogenic exposures in pregnant women [27]. The database consists of a series of agent summaries, each of which is based on a thorough review of published clinical and experimental literature.

LactMed (Drugs and Lactation Database) is a peer-reviewed and fully referenced database of drugs to which breastfeeding mothers may be exposed. Among the data included are maternal and infant levels of drugs, possible effects on breastfed infants and on lactation, and alternate drugs to consider. It is available without subscription at: http://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?LACT

In addition to the cited resources, healthcare providers also may obtain information from, or refer pregnant and breastfeeding patients to, a teratology information service for information and counseling about medication exposures.

OTIS (Organization of Teratology Information Specialists), located in the United States and Canada, provides accurate, free, evidence-based, clinical information to patients and health care professionals about exposures during pregnancy and lactation. On the OTIS website (http://www.otispregnancy.org/hm/) is information about the organization, downloadable fact sheets on more than 70 common pregnancy exposures available in English, Spanish, and French, and access to current teratology research studies.

ENTIS is European Network of Teratology Information Services, similar to OTIS (http://www.entis-org.com/index.html).

A list of many of the existing postmarketing pregnancy registries is maintained by the Office of Women's Health, US Food and Drug Administration at www.fda.gov/womens/registries

51.8 Conclusions

When considering the safety of drugs in pregnancy and breastfeeding it is necessary to make a risk-benefit calculation with often insufficient data about the risk. The term "safety" implies the absence of risk, which is impossible to demonstrate conclusively with any kind of epidemiological studies. Nevertheless, only a limited number of drugs have been proven to cause malformations in humans, the vast majority of drugs taken by pregnant women do not pose a significant risk when used in recommended doses. Although decisions about medication use must take into account the potential risk to the embryo, fetus, and infant, consideration of the impact on the mother's health is equally important. Many maternal diseases can be markedly improved by appropriate therapeutic interventions. Withholding of treatment because of theoretical concerns for the fetus is justifiable for limited number of drugs, and even then it should be the mother's decision.

It is crucial that physicians provide women with balanced, evidence-based information concerning drug exposure during pregnancy and breastfeeding as misinformation and unrealistic perception of the teratogenic risk of medications may lead to inadequate treatment of maternal disease, discontinuation of breastfeeding or unnecessary termination of pregnancies.

For obtaining up-to date, evidence based and easy to access information we refer you to multiple resources listed in Table 51.2.

Developmental Pharmacology and Therapeutics

Erika Crane, Victoria Tutag Lehr, Merene Mathew and Jacob V. Aranda

52.1 Introduction

Developmental pharmacology and therapeutics is a broad field that includes the study of drugs during growth and development and the effect of these drugs on development itself. Development is a continuum that includes periods of conception, fetal stages and the neonatal and childhood phases of development. This chapter focuses on pharmacology and therapeutics in the newborn infant.

In practice, newborn infants are exposed to many drugs via transplacental transfer to the fetus, as well as neonatal exposure in newborn nurseries and intensive care units. Drug utilization surveys indicate at least 400 drugs are used in newborns, with pervasive polypharmacy use in sick newborns [1, 2]. Early pharmacologic surveys suggested that a neonate receives an average of about 7 drugs [2–4]. However, recent pharmacoepidemiologic surveys suggest that a sick newborn in the intensive care unit receives about 7 to 71 different drugs during their hospital course. At least 80% of these drugs have not been adequately studied in newborns and are used "off-label" in this population since the basic clinical pharmacology data including pharmacokinetics and drug elimination are not available [4–6]. Heterogeneity mainly due to fetal and post-neonatal maturity in the neonatal population complicates safe medication use. A term infant differs from a very low birth weight newborn in their ability to metabolize and eliminate drugs. Moreover, advancing age after birth influences drug clearance from the body and drug dosing regimens. Fig. 52.1 illustrates the changes in plasma half lives of a drug (theophylline) as a function of age. Another example is shown in infants less than 2 years of age with much slower valproate elimination (a commonly prescribed antiepileptic drug for pediatric patients) compared with adults and older children [7]. Children aged 2 to 10 years have plasma clearances of valproate, which are 50% higher than adults. After 10 years of age, pharmacokinetic parameters approach that of adult patients for this drug. Careful monitoring and titration of drug dosage, serum concentration, signs of toxicity and clinical effect are important as a child develops. Generalization that drug metabolism and elimination is markedly slower in the newborn infant relative to older children and adults is not always applicable. For instance, plasma clearance of a new echinocandin, micafungin, is much faster in preterm newborns than older children and adults [8] and hence will require substantially higher daily doses of micafungin [9, 10]. Drug dosages for many drugs used in neonates are indicated in other chapters of this book. However, changes in drug disposition, drug action and dosing requirements during the neonatal period are discussed in this chapter.

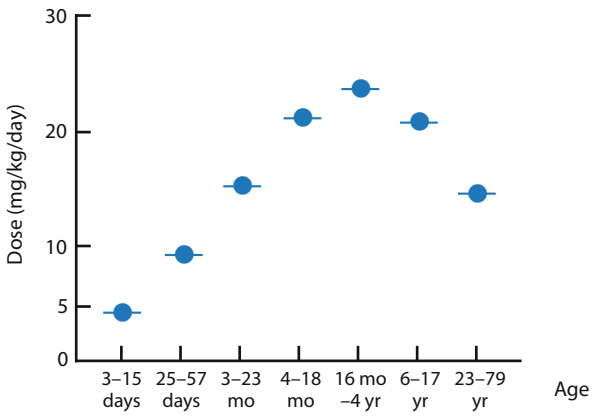

Fig. 52.1 Theophylline dose to mantain plasma concentration ≅ 10 mg/L

52.2 Developmental Pharmacokinetics

As neonates and children grow and mature, physiologic and biochemical developmental changes alter how the body handles and responds to a drug. These dynamic changes often do not have a linear relationship with such factors as age or

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

weight. Within the neonatal population, great variability in gestational age, development and weight results in highly varied dosing regimens of the same drug (Table 52.1) [11]. Developmental pharmacokinetics refers to these physiologic parameters, which define how an infant or child absorbs, distributes, metabolizes and eliminates drugs.

52.2.1 Absorption

Changes in absorptive surfaces can modify the rate and bioavailability of a drug [12]. At birth, the gastric pH is neutral and remains relatively high throughout infancy, which may effect the ionization and stability of the drug. Acidity is further decreased by the frequent ingestion of alkaline milk products and decreased gastric acid production [13]. Gastric acid production does not reach adult levels until 3 years of age [14]. Weak acids such as phenobarbital will have decreased absorption, while weak bases such as diazepam have increased absorption. Acid labile drugs such as penicillins are less likely to be degraded, therefore have increased bioavailability [14].

Most absorption of orally administered drugs occurs in the duodenum. Gastric emptying and intestinal transit time determine the rate at which a drug reaches the small intestine and for how long the drug stays in contact with the absorptive surfaces [12]. In general, gastric emptying is usually delayed in infants, not reaching adult rates until 6–8 months of age, which may delay drug absorption [14]. Intestinal motility is often erratic in childhood, with neonates and infants having a prolonged transit time and toddlers having relatively rapid intestinal motility compared with older children and adults [14]. Intestinal flora, ontogeny of intestinal metabolic enzymes and developing molecular transport mechanisms may also contribute to the erratic and often slower absorption of drugs in the neonatal gastrointestinal tract [12].

Alterations in neonatal drug absorption may occur with other routes of administration. Absorption is often enhanced for drugs administered topically, secondary to thinner stratum corneum and increased total body surface area to body mass ratio in the neonate [12]. Developmental changes affect the skin throughout infancy and childhood, influencing the rate and extent of absorption, metabolism, and bioavailability of topical medications. Skin accounts for up to 13% of an infant's total body weight compared with only 3% of an average adult's body weight [15]. This greater total body surface area ratio to body mass results in a much greater proportion of drug absorbed per kilogram of body weight for infants compared with adults [16]. Therefore, infants and young children may develop toxic drug serum concentrations with topical administration of medications [16]. Hydration of the stratum corneum is greatest in the axillae, diaper area, antecubital space and popliteal fossae, enhancing permeability. Absorption of intramuscularly administered drugs also varies in infancy, and is influenced by skeletal muscle blood flow and density of skeletal muscle capillaries [12]. The intramuscular route of drug administration is also painful and is best avoided.

Table 52.1 Neonatal dosing of gentamicin based on weight and age

Age	Weight (g)	Dose (mg/kg/day)	Interval (h)
Premature neonates	<1000	3.5	24
	<1200	2.5	18–24
Term neonates			
<7 days of age	1200–2000	2.5	12
>7 days of age	1200–2000	2.5	8–12
	>2000	2.5	8

Data from [11].

52.2.2 Distribution

Distribution of drugs within the body is greatly influenced by developmental changes in body composition. Neonates have a higher total body water content of 80%, which quickly declines by 4 months of age to the adult fraction of 60%. Neonates also have a higher fraction of extracellular water, which steadily declines throughout childhood. Hydrophilic drugs such as gentamicin or amikacin often have a higher volume of distribution in neonates, resulting in larger doses to obtain a therapeutic serum concentration. Fatty connective tissue is the major component of the subcutaneous layer and begins to accumulate around week 14 of gestation [17, 18]. The fat content in the neonate is relatively low, increasing significantly in early infancy and then steadily declining to near adult values by 3 years of age. Therefore, lipophilic drugs often have a higher volume of distribution in infants and toddlers compared with neonates, older children and adults [14].

Developmental changes in protein binding also effect drug distribution in the neonate. Neonates and young infants have decreased total plasma proteins, which may increase the free fraction of highly protein bound drug available for therapeutic effect. In neonates, presence of fetal albumin, which has reduced drug binding affinity, and increased bilirubin and free fatty acids may contribute by displacing bound drugs from the plasma protein [12]. (See Chapters 81-84 for further details.)

52.2.3 Metabolism

Metabolism and elimination determine the clearance of a given drug. Patients who have delayed clearance are at risk for drug accumulation and toxicity, and often require changes in dose or dosing interval. Developmental maturation of metabolizing enzymes occurs in both the phase I cytochrome P450 enzymes as well as the phase II conjugation reaction enzymes. For the cytochrome P450 enzymes, this activity matures in a predictable but heterogeneous pattern throughout infancy and childhood. While specific enzyme activity varies, in general the activity of CYP enzymes is decreased at birth and gradually increases over the first 3 months of life [19]. The non-oxidative metabolic reactions of methylation, acetylation, sulfation, glucuronidation, conjugation with amino

acids (primarily with glycine), glutathione conjugation and esterase hydrolysis function to detoxify and enhance the elimination of drugs and pro-drugs, many as phase II reactions subsequent to oxidation. Maturation of phase II conjugation enzyme activity occurs at a much less predictable pace [19]. These developmental changes in metabolism are likely to contribute to the unique toxicities seen in infants and children.

52.2.4 Elimination

Unlike the often irregular maturation of drug metabolizing enzyme activity, development of renal function is often predictable and directly applied in selection of drug dose and interval [19]. Premature infants have fewer glomeruli than term neonates. At birth, the term neonate has the same number of glomeruli as the adult, but the tubular system is less developed [13]. The glomerular filtration rate (GFR) is reduced in the neonate due to decreased renal blood flow and immature tubular structures [13]. The GFR in the term neonate is approximately 2 to 4 mL per minute per 1.73 m^2 [12]. Premature infants have an even lower GFR than the term newborn, with values as low as 0.6 to 0.8 mL per minute per 1.73 m^2 [12]. The GFR steadily increases to adult values by 5 to 12 months of age [12, 14]. Tubular secretion is also reduced at birth and steadily increases to adult values around 7 months of age [14]. Recent research in animal models suggests that ontogeny of renal drug transporters such as P-glycoprotein may also play a role in clearance of renally excreted drugs [20]. Failure to account for these developmental changes in clearance may lead to increased drug accumulation and toxicity.

52.3 Protein Binding

As mentioned above, protein binding plays a significant role in drug pharmacokinetics and can pose a unique challenge in the neonate. In plasma, a given drug is present in both unbound and bound states. The portion of a drug which is unbound to plasma proteins is described as the free fraction of the drug. It represents the portion of drug available for pharmacologic effect as well as clearance and elimination. The ratio of free to bound concentrations is unique to each drug, but can be influenced by physiologic and developmental factors. Highly protein bound drugs are confined to the vascular compartment and are considered to have a low volume of distribution. Drugs that are primarily unbound widely distribute to tissue, and have a large volume of distribution. Changes in total protein may alter the volume of distribution of a drug, requiring dosing adjustments to achieve optimal therapeutic effect. Free drug is usually eliminated through hepatic metabolism or renal excretion. Highly protein bound drugs may have delayed clearance and elimination, thereby prolonging the effect of the drug. Drug interactions may occur when drugs compete for plasma protein binding sites or when one drug displaces another drug from a binding site. Alterations in the free fraction of drug due to changes in total protein or drug interactions may lead to diminished therapeutic effect or toxicity.

Protein binding and drug distribution are influenced by age related changes in body composition [12]. Neonates have lower total protein levels (including albumin and alpha 1-acid glycoprotein) compared to older infants and children, which may decrease the bound portion of a drug. Fetal albumin also has a lower affinity for drugs, and the presence of endogenous substances such as bilirubin and free fatty acids compete for protein binding sites [15]. For highly protein bound drugs, these factors may contribute to an increase in the free drug fraction despite a normal total concentration (bound plus unbound), which may result in a greater pharmacologic drug effect or toxicity [15]. Examples of drugs that may be influenced by protein binding in the neonate include: phenytoin, salicylates, ampicillin, naficillin, sulfisoxazole, sulfamethoxyphrazine, furosemide, and phenobarbital [12]. These drugs tend to have an increased free fraction in the neonate, with a larger volume of distribution and may cause drug displacement or hyperbilirubinemia. In neonates, developmental changes in plasma proteins must be considered to achieve the optimal therapeutic pharmacologic effect.

52.4 Therapeutic Drug Monitoring

Therapeutic drug monitoring (TDM) is the practice of sampling drug concentrations in body fluids to optimize therapeutic effects and decrease toxicities by application of pharmacokinetics and pharmacodynamics [21]. Indications for TDM include suspected drug toxicity, subtherapeutic response to drug therapy, assessment of drug interactions, assessment of clinically unstable patients, or after initiating new drugs or changing the drug regimen [22]. Therapeutic drug monitoring can guide therapy for patients with previous toxicity or adverse drug reactions to a prescribed agent [23]. Many drugs are subject to interindividual variability, and therefore, the usefulness of TDM for these drugs has to be assessed individually [24]. Agents requiring TDM have a narrow therapeutic index, a high incidence of adverse effects, or are associated with clinically significant interactions [25]. Therapeutic drug monitoring is clinically useful for agents that have a known relationship between measured body fluid concentration and therapeutic effect. Neonates, with rapid developmental changes occurring in the handling of drugs and drug response [12, 19, 26], benefit from TDM for commonly prescribed medications such as aminoglycosides and vancomycin [27, 28]. Optimization of aminoglycoside serum concentrations to achieve a desired therapeutic range warrants therapeutic drug monitoring to achieve efficacy and avoid toxicity [29, 30]. Aminoglycoside efficacy is related to the ratio of peak serum concentration with the minimal inhibitory concentration (MIC) of the infecting microorganism and area under the time-versus-concentration curve (AUC) [31]. Peak minimal inhibitory concentration ratio

of >10 are considered to be essential, therefore adequate initial peak serum concentrations of 5 to 10 mg/L are targeted by TDM [32]. Toxicity has been related to high predose ("trough") serum concentrations, therefore trough target ranges are 0.5 to 2 mg/L. Large interindividual differences occur in pharmacokinetic parameters secondary to varying levels of gestation, concomitant medications and predictive performance of initial empiric regimens might be improved by TDM.

Traditionally, TDM sampling for aminoglycosides has been performed at steady-state, around the fourth dose. This may not be practical in neonates during the first week of life. Antimicrobial therapy in neonates is often "presumptive" and may be discontinued after 72 hours of negative blood cultures. Because of prolonged half-life and reduced clearance in premature infants, intervals of 24 to 48 hours are commonly recommended [33]. Many centers are using extended interval dosing of aminoglycosides for neonates typically 4–5 mg/kg per dose administered at intervals of 24 hours or longer compared with conventional dosing of 2–3 mg/kg per dose administered at 8 to 24 hours [28]. Steady state TDM in the neonatal intensive care unit would not be performed in time to be of practical use.

Vancomycin continues to be used extensively for newborns in neonatal intensive care units for treatment of gram-positive infections [34, 35]. Initial vancomycin dosage regimens are based on creatinine clearance, weight, and postconceptional age [11]. Vancomycin dosing guidelines often require clinician interpretation using infant specific parameters to attain serum trough ranges multifold the MIC [33, 36]. Peak serum vancomycin concentrations have not been consistently associated with toxicity or efficacy in neonates; therefore routine sampling of peak serum concentrations may not be necessary. The inadequacy of current vancomycin dosing guidelines for achieving therapeutic serum concentrations using empiric dosing regimens underscores importance of appropriate therapeutic drug monitoring in neonates. Rapid changes in physiology during the perinatal period accounts for wide variability in elimination and volume of distribution for many drugs, including vancomycin. The neonatal population is heterogeneous with respect to gestational age and weight. The large variability in pharmacokinetic variables observed in this population is possibly related to factors affecting volume of distribution such as administration of ante- and postnatal medications, volume expanders, comorbidities, renal function and protein binding. A challenge for clinicians is to individualize current vancomycin dosing for very low birth weight premature neonates and critically ill term infants. While pharmacokinetic parameters for vancomycin have been characterized in newborns of varying maturity, utilization of contemporary dosing guidelines frequently results in serum concentrations outside of desired therapeutic range. Peak serum vancomycin concentrations of 25 to 40 mcg/mL and 5 to 10 mcg/mL for troughs are generally accepted as therapeutic. However, the MIC's for vancomycin have been increasing [37]. Vancomycin serum trough concentrations greater 10 mcg/mL may be indicated for improved outcomes. The requirement for achieving aggressive target vancomycin concentrations is prompting re-evaluation of the current dosing guidelines.

Prospective dosing regimens are needed for targeting higher troughs in view of emerging resistance patterns. Further assessment of physiologic factors affecting variability is warranted. Individualization of dosing may result in less serum concentration sampling and decreased time to achieving desired steady state decreased serum concentrations, thereby minimizing risk and improving outcomes for these fragile infants.

52.5 Age Specific Drug Dosing

Drug dosing for children is often derived from adult dosing regimens. Using factors such as age, weight and body surface area to extrapolate from adult doses assumes a linear relationship between development and growth. None of these methods correlate well with pharmacokinetic parameters such as drug distribution. Body surface area correlates better than weight or age for certain parameters including cardiac output, extracellular fluid, blood volume, respiratory metabolism and GFR [14, 38]. In general, weight based dosing often results in the under-dosing of infants and children, while overdosing neonates. Medication dosing using body surface area often overestimates the dose for infants [38]. Ideal dosing regimens are based on pharmacokinetic and pharmacodynamic variables from studies in neonates, toddlers, children and adolescents.

Drug dosing in children is further limited by appropriate dosing formulations. Lack of a liquid formulation may present an administration barrier for infants and young children unable to swallow tablets or capsules. Tablets, which are crushed, or capsules, which are opened, often lack pharmacokinetic data on absorption and may be irritating to the stomach [11]. Suspensions, such as phenytoin, may deliver variable drug doses if the particulates settle and are not adequately shaken before administration. It is important to remember that bioavailability is often formulation dependent. For example, phenytoin suspension is free phenytoin acid, while phenytoin capsules are phenytoin sodium, which contains only 92% phenytoin. Switching between formulations without adjusting for differences in bioavailability may result in toxicity. Clinicians should consult with a pharmacist for bioavailability data and extemporaneous formulations that may be prepared for new medications [39].

52.6 Conclusions

Safe and effective use of medications during the neonatal period is challenging due to developmental changes in physiologic and biochemical processes, which govern pharmacokinetic and pharmacodynamic responses. Developmental

variations in absorption, distribution, metabolism and elimination influence the neonate's ability to handle a drug, must be considered when selecting a therapeutic regimen. The neonate's low total protein level and decreased affinity at protein binding sites further effect drug behavior, and may lead to subtherapeutic or supratherapeutic drug concentrations. Therapeutic drug monitoring is essential in achieving and maintaining optimal therapy in neonates, however pharmacokinetic parameters, post-conceptional age and neonatal weight must be taken into account. Ideally, drug dosing in a neonate is best based upon drug specific pharmacokinetic and pharmacodynamic parameters. However, many medications lack the rigorous testing required in neonates, and further research is needed. Infants of differing gestational ages and weights must continue to be enrolled in drug trials with appropriate safety and efficacy outcomes. Clinicians are urged to consult current literature and share their experience with new agents in this vulnerable population.

53

Infants of Drug-Addicted Mothers

Eunji Kim and Gideon Koren

53.1 Introduction

The wide variety of addictive substances share in common the reinforcing feature of individuals experiencing a persistent desire to administer the drugs and a strong obsession in obtaining them. Addiction to psychoactive substances is a complex issue, recognized as a class of mental disorders in the fourth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) [1]. DSM-IV defines addiction as manifested by the compulsion to take a drug with a loss of control on the intake, and continued use despite knowledge of adverse physical and psychological health effects.

The harm associated with substance use becomes increasingly alarming when women are addicted to drugs during pregnancy and mothering. The incidence of maternal substance use is difficult to assess with an estimate of 4% of women using illicit drugs and 12% of women using alcohol in pregnancy [2, 3]. The effects of maternal substance use on human development and growth are further exacerbated by behavioral and environmental factors surrounding the addiction.

Although society has a negative perception of women using recreational drugs during pregnancy, many addicted women are highly motivated and interested in the well-being of their unborn child. Reports indicate that a significant number of women seek treatment and support programs, or reduce their drug use upon discovering their pregnancies [4, 5]. Therefore, the child-bearing time offers a unique window of opportunity in engaging these women and addressing the concerns associated with their alcohol and substance use.

An understanding of the effects of perinatal drug consumption and the associated risks to the developing child is critical in providing an appropriate care to these women.

53.2 Alcohol

Alcohol is a mild CNS depressant with potential for abuse due to its reinforcing properties. In developed countries, approximately 1 in 12 women develop alcohol dependence [6], and the potential adverse effects of perinatal alcohol consumption cannot be overstated.

Alcohol readily crosses the placenta and enters the fetal circulation with a slower elimination rate than from the maternal circulation [7]. The teratogenic effects of alcohol have been widely documented with several suspected mechanisms of action [8–11].

Fetal alcohol syndrome (FAS) describes the full-blown symptoms following prenatal exposure to alcohol [12]. The occurrence of FAS is in 0.5 to 2 per 1000 live births, and may reach as high as 10% in some communities where problem alcohol consumption is more prevalent [13]. Although variability in the characteristic features of FAS exists among affected infants and children, the consistency of the characteristics has been generally reliable. The diagnosis of FAS includes confirmation of alcohol exposure in utero along with three major criteria [14, 15]:

1. Prenatal and postnatal growth restriction
   - slow growth, when corrected for other factors, such as age, nutritional status, pathology and genetic factors.
2. Craniofacial malformations
   - midface hypoplasia
   - short palpebral fissures
   - hypoplastic filtrum
   - thin upper lip
   - epicanthal folds
   - short upturned nose
   - wide depressed nasal bridge.
3. CNS abnormalities
   - microcephaly
   - learning disabilities
   - fine or gross motor problem
   - poor executive functioning and abstract reasoning
   - pervasive behavioral anomalies.

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

The growing understanding of the use of alcohol in pregnancy has led to the realization that FAS represents only a small portion of offspring exposed to heavy alcohol in utero. In fact, many individuals affected by prenatal exposure to alcohol do not display the classical features of FAS.

Fetal alcohol spectrum disorder (FASD) is a comprehensive terminology, which recognizes the broad range of symptoms exhibited by an individual injured by maternal drinking in pregnancy. Alcohol related birth defect is used to describe various physical malformations associated with prenatal exposure to alcohol, whereas alcohol-related neurodevelopmental disorder characterizes the specific neurobehavioral and cognitive impairments of FASD.

The lack of the physical symptoms may present difficulties in clinical identification of FASD. Studies suggest that 30 to 50% of children born to problem drinkers may exhibit the characteristic features of FASD [16]. The number is concerning since FASD is the leading preventable cause of mental retardation and neurobehavioral deficits in the developing world [17]. In addition to malformation, a quarter of newborns, whose mothers were intoxicated during delivery, may exhibit ventricular tachycardia, tremors, and in some cases seizure [18].

Although diagnosing an individual with FASD may lead to labeling and stigmatization, the importance of early identification must be recognized. The damage following prenatal exposure to alcohol persists into adolescence and throughout adulthood. The term secondary disabilities of FASD identifies the disruptive school experience, mental illness, drug issues, delinquency, inappropriate sexual behavior, dependent living, and unemployment, which result from the poor social adaptability and problematic behaviors in an FASD individual [19, 20]. Early diagnosis and intervention in childhood (before age 6) were determined to be critical factors in the prevention of the secondary disabilities.

Alcohol is a known teratogen, which results in significant, lifelong deficits in physical growth, psychological health and cognitive functioning of an individual. Due to the combination of lack of knowledge on a safe amount of alcohol in pregnancy, and the absence of specific treatment for FASD, women who are pregnant or planning pregnancy should refrain from alcohol consumption. Identification of women with problem drinking in the primary care setting is an important factor in the prevention and reduction of injury caused by alcohol exposure in utero. The screening includes asking all women of reproductive age on their use of alcohol as part of routine health examination, and adopting a validated screening tool such as TWEAK (Tolerance Worry Eye opening Amnesia Cut-down) or T-ACE (Tolerance Annoyed Cut-down Eyeopener) to further screen for women who may be at risk for alcohol dependence [21].

Women who are identified with problem alcohol consumption should be encouraged to discontinue their alcohol use since stopping at any time during pregnancy can improve child health. Furthermore, they should be referred to appropriate support and treatment programs to ensure a continuum of care. In order to facilitate the early identification and intervention of infants who may be affected by alcohol exposure in utero, the frequency and the amount of maternal alcohol consumption should be recorded in the child's health documents [21].

53.3 Cannabis

The dried leaves and flowering parts of the hemp plant are smoked recreationally, constituting the most commonly used illicit drug worldwide [22]. Cannabis plants contain numerous active agents with the primary psychoactive ingredient, the delta-9-tetrahydrocannabinol (THC). Estimates of marijuana smoking in pregnant women vary between 2% to 20% [23, 24].

Although THC crosses the placenta and reaches the fetus, marijuana has not been identified as a human teratogen [25–27]. A dose-dependent reduction in prenatal growth has been reported. The suggested mechanism is the increase in carboxyhemoglobin in marijuana smokers, which may impair fetal oxygenation [26]. This may be accompanied by a reduction in placental blood flow resulting from the increase in maternal heart rate and blood pressure. However, the impact of marijuana on fetal growth has shown weak association, and a meta-analysis could not replicate the data when the possible effects of cigarette smoking were controlled for [28].

Studies on the postnatal health of children exposed to marijuana in utero have been largely inconsistent. In general, prenatal marijuana exposure did not affect the offspring's cognitive abilities [29–31]. Subtle effects have been reported, which included abnormal sleep pattern in infancy, poor visual responsiveness and sustained attention. However, many of the studies recognized the possible confounding role of postnatal home environment of these children.

53.4 Cocaine

Cocaine is a potent, short-acting stimulant, which can be snorted or injected. The derivative form, known as crack, is smoked. Crack and cocaine are the second most common illicit drugs used by pregnant women. Cocaine freely crosses the placenta, and may reduce uterine blood flow via its vasoconstrictive effect [32]. Although cocaine has not been unambiguously identified as a human teratogen, many studies report adverse maternal and neonatal health following cocaine exposure. Cocaine use during pregnancy has been associated with an increased risk for intrauterine death, pregnancy complications such as placenta abruption, premature rupture of membranes and preterm birth [33–36]. Maternal dependence of cocaine in pregnancy has been associated to increase the risk for low birth weight and a small head

circumference [37, 38]. The use of cocaine near term may result in transient neurologic abnormalities of newborn including disrupted sleep, irritability, tremor and hypertonia [39].

Numerous neurodevelopmental studies conducted on children prenatally exposed to cocaine have largely resulted in conflicting results. The prevailing consensus is that maternal use of cocaine in pregnancy is not associated with global cognitive deficits [38–41].

Subtle effects such as language delays or behavior problems have been described. The inconsistent outcome of children exposed to cocaine in utero may in part be due to the difficulties associated with studying cocaine addicted women and their children.

Moreover, many cocaine users combine other substances, such as alcohol, a known teratogen. Importantly, the general consensus is that when children of cocaine dependent mothers are provided with appropriate care and support, the long-term assessments resulted in favorable outcome with a normal pattern of development.

53.5 Other Stimulants

Amphetamines have been used therapeutically for various purposes such as narcolepsy, appetite suppression, and attention deficit hyperactivity disorder (ADHD). These drugs may be purchased illegally on the street and used for recreational purposes.

Dextroamphetamine (Dexedrine), widely prescribed for obesity in the past, can be injected intravenously for its stimulatory effects. Methylphenidate (Ritalin), the first line treatment for ADHD, can also be used as a drug of abuse by oral or intranasal ingestion.

Methamphetamines are also produced in illegal laboratories and sold as speed, ice, crank and crystal meth.

Studies on the effects of stimulants other than cocaine have resulted in mixed conclusions. Numerous case reports suggest an association between amphetamine use in pregnancy and various malformations including congenital heart abnormalities, biliary atresia and oral cleft [42–44]. However these studies are often limited by small sample size and poor methodology. Some studies report no increased risk for malformation [45, 46], but possible increased risk of premature birth and intrauterine growth restriction [45, 47]. The suggested mechanism of action is its vasoconstrictive effect, which may impair oxygen flow to the fetus. However, the appetite suppressant characteristics of amphetamine, the energy surge experienced by the users, in combination with many cofounding risk factors make a definite conclusion impossible. Babies exposed to amphetamine close to delivery may experience transient jitteriness, drowsiness, and respiratory distress [47].

The neurotoxicity of amphetamine on a developing brain is currently unknown. The limited human data have reported reduced brain structure volume, poor performances on sustained attention, and verbal memory deficits [48]. However, the direct effect of methamphetamine exposure in utero and the postnatal home environment are difficult to differentiate.

In addition, children who live in methamphetamine home laboratories face health and safety hazards from explosions during manufacturing, and airborne exposure to toxic chemicals. The environments of amphetamine users are often characterized by violence, chaos, neglect, abuse, and criminal behavior [49].

53.6 Opioids

Reports indicate that the non-medical use of opioids is growing with current estimate of 2% of pregnant women users [50]. Opioid such as codeine, morphine, meperidine, oxycodone, hydrocodone, fentanyl and heroin can be ingested orally, injected intravenously or intramuscularly, snorted or smoked.

Although opioids do not increase the risk for birth defect, an increased incidence of obstetric complications in opioid dependent women has been reported with high rate of preterm birth and intrauterine growth restriction has been suggested [51]. It has been argued that the effects of opioids on growth may be related to confounding variables such as poor maternal nutrition and concurrent drug use.

The maternal use of opioids near term can result in neonatal abstinence syndrome with a reported incidence in 60-80% of infants born to opioid dependent women [52]. Withdrawal typically begins within 24 hours, but symptoms can be delayed for up to two weeks.

Clinical features include insomnia, irritability, hypertonia, tremor, vomiting, diarrhea, fever, high pitch crying, and seizures.

Studies have suggested poor developmental outcomes following prenatal exposure to opioid, which include sleep disturbances, short attention span and hyperactivity [53, 54]. The authors recognized the difficulty in separating cofounding factors such as maternal polydrug use and postnatal home environment from direct effect of maternal opioid use in pregnancy. Detoxification during pregnancy should be avoided as sudden withdrawal of the mother has been associated with adverse maternal, fetal and neonatal health.

Maternal symptoms of withdrawal include abdominal cramping and uterine irritability, which may increase the risk of miscarriage, preterm labor, and fetal death [55]. Therefore, if detoxification is to be undertaken during pregnancy, it should involve a slow tapering of the opioid under the supervision of trained health care professionals. Women should also be counseled on methadone or buprenorphine treatments, which have been reported to improve maternal and neonatal health.

53.7 Sedatives-Hypnotics

53.7.1 Barbiturates

Although the use of barbiturates has decreased dramatically over the last years, barbiturates are still prescribed for the treatment of seizure disorder unresponsive to standard therapy, and are included in headache preparations. Widely used barbiturates include mephobarbital, pentobarbital, phenobarbital and secobarbital. Barbiturates may be used recreationally for their intoxicating effects. Heavy stimulant drug users may use barbiturates to counteract the effects of large doses of amphetamines or cocaine. Early data suggested teratogenicity following maternal barbiturates use in human pregnancy.

However, results were confounded by the severity of maternal epilepsy and polytherapy [56]. More recent data on monotherapy does not suggest teratogenicity [57]. It is important to keep in mind that women were using barbiturates for therapeutic reasons, and positive findings may not apply to frequent use at high dosage in drug-addicted women. Infants born to mothers receiving barbiturates near term may show transient signs of restlessness, sleep disturbances, and respiratory depression [58]. These symptoms may be delayed up to two weeks postpartum due to the long half-life of barbiturates.

53.7.2 Benzodiazepines

Benzodiazepines have a wide clinical use ranging from treatment for anxiety, insomnia, and as muscle relaxants and anticonvulsants. Commonly used benzodiazepines include chlordiazepoxide, diazepam, lorazepam, and oxazepam. Although benzodiazepines in pregnancy have been suggested to increase the risk for oral cleft [59], a recent study on 1979 infants did not find an increased risk [60]. Combination of benzodiazepine with other substances and use at high dosage may result in distinctive neonatal outcome than that observed at therapeutic dosage. Maternal use of benzodiazepine near term has been associated with transient lethargy, poor muscle tone, and respiratory depression in neonates.

53.8 Club Drugs

Club drugs include a variety of psychoactive compounds, which are commonly used at nightclubs, bars, raves, or trance scenes. Ecstasy (N-methyl-3,4-methylenedioxyamphetamine, MDMA), gamma-hydroxybutyrate (GHB), ketamine, lysergic acid diethylamide (LSD), flunitrazepam (Rohypnol) are common examples.

MDMA belongs to the amphetamine family. Although isolated case reports suggest a possible increased risk for congenital heart malformations, small sample size, an inconsistent pattern of heart malformations, and poor methodology make it difficult to estimate the risk, if it exists [61].

GHB, a metabolite of the inhibitory neurotransmitter gamma-aminobutyric acid, is used for the treatment of narcolepsy and as a general anesthetic. It is also used as recreational drug due to its euphoric and sexually enhancing effects. A woman addicted to GHB delivered a healthy full-term birth followed by a mild maternal respiratory depression [62]. However, large studies are needed to identify perinatal risks of GHB use in pregnancy.

Ketamine, a dissociative anesthetic, has not been studied for its potential human teratogenic effect, although animal data do not suggest an increased risk for malformation [63]. All existing human data resulted from its use as an epidural for pain relief during labor [64].

A higher incidence of limb and eye defects has been described in isolated reports of LSD addiction in pregnancy [65], although larger prospective studies could not replicate these findings [66]. Possible increased risk of spontaneous abortions has been suggested, but more studies are needed before a definite conclusion can be drawn.

In general, club drug users have different pattern of use compared to other substance users with different risk factors. They are more likely to be teenagers or young women with a combination of different drugs, most commonly alcohol. The lifestyle factors associated with clubs and raves may also contribute to poor outcome of infants and children of these women.

53.9 Solvents and Inhalants

Solvents and inhalants are not commonly used by pregnant women. However, women using inhalants are often at a social disadvantage with the inability to obtain other substances. Solvents and inhalants contain gasoline or toluene, which are pharmacologically quite similar to alcohol. The reported effects on pregnancy include preterm birth, intrauterine growth restriction, microcephaly, neonatal electrolyte disturbances (hypobicarbonatemia or hypokalemia) and developmental delay [67]. There are reports of children with facial features similar to FAS, which was coined as toluene embryopathy.

53.10 Comorbidities

Drug addiction is a complex medical condition with many risk factors surrounding drug abuse. Studies on offspring of addicted women recognize the difficulty to disentangle the effects of numerous comorbidities from the direct damage of substance use on a developing child.

The postnatal period may in fact be the most critical point of a child's development.

Some of the challenges associated with maternal substance use include [68–70]:

- lack of prenatal/postnatal care and available resources
  - poor nutrition
  - inadequate housing
  - lack of access to health care
  - lack of education and employment skills
- low socioeconomic status
- lack of family and partner's support
  - disruptive family experience
- maternal ineptness
  - inadequate bonding and nurturing
  - lack of appropriate stimulation
  - inappropriate role model
- psychiatric disorders or emotional instability
- transmission of sexually transmitted disease
- history of violence, abuse and neglect
- genetic predisposition.

These factors have all been associated with impaired intellectual abilities and social behaviors of the children, and long-term outcomes improved significantly when women and their children were provided with prenatal and postnatal intervention services.

Maternal alcohol and illicit drug use in the perinatal time frame has been associated with physical and neurodevelopmental abnormalities in the offspring. Polydrug use and the risk factors surrounding substance use make it difficult to discern the specific impacts of a drug on the developing child. However, the consistent reports of adverse outcome of children born to addicted mothers emphasize the need to address the associated issues.

To reduce harm incurred by maternal substance use, it is important to routinely screen all women of reproductive age for their consumption of alcohol and illicit drugs. When women's problem alcohol and drug use is confirmed, it is important to engage and motivate them to change their risky behaviors. Furthermore, they should be referred to appropriate treatment and support services to assist them in their challenges. Programs may include shelters, employment resources, food banks, and childcare services.

Biological samples of the newborn, such as meconium and hair, is often requested in infants with suspected but unconfirmed exposure to alcohol and illicit drugs.

In case of significant level of exposures, women should be counseled on the benefits of discontinuing at any time. Their infants should be monitored routinely by a pediatrician and provided with facilitated access to support services to match the needs of the infant.

Infants of Smoking Mothers

Roberto Paludetto and Francesco Raimondi

54.1 Introduction

Knowledge of the adverse effects of tobacco products on the health of the adult has long gained acceptance. Scientists and clinicians are now unraveling the multifaceted relationship between tobacco smoke and human development starting from the intrauterine and possibly periconceptional phase. Evidence now correlates maternal smoke to derangement of organogenesis, decreased organ function and poorer neurodevelopmental performance. However, findings are not always unequivocal mainly because of methodological problems. In this chapter, we will critically address some of the current issues focusing on the available clinical evidence to give the reader a practical approach to the infant of the smoking mother.

54.2 Epidemiology

International authorities monitoring the smoking habits and their consequences consider tobacco as a "legalized health hazard" on a planetary scale. In 2007, the WHO classified 18.2% of European adult females as smokers [1]. Figures vary among individual countries but have remained substantially stable since the previous report in 2002. Separate data for smoking during pregnancy are not available on this scale and have to be deduced from epidemiological surveys. Reports from Sweden and the US estimate respectively that 13% and 10.4% of women smoke during their pregnancy, but more recent work from the UK has come up with a figure as high as 36% [2]. The percentage of women who smoke around the time of conception is higher as most women who stop smoking achieve this goal very early during the pregnancy. However, since many will attempt to quit smoking throughout their pregnancy, it is mandatory that they receive constant support and encouragement by healthcare professionals. This should continue after delivery, since many women who quit smoking during pregnancy will resume this habit shortly after giving birth. Moreover, Cnattingius et al have recently demonstrated that a previous adverse pregnancy outcome has only a modest influence on smoking habits in a successive pregnancy [3].

Besides direct smoking, a pregnant woman and her fetus may be exposed to environmental tobacco smoke (ETS). While the detrimental effects of this condition will be discussed below, it is difficult to gather good quality data on its prevalence. In 2007, Ward et al reported that in the UK as many as 13% of infants were born to non-smoking mothers who had had significant exposure to ETS [2]. Maternal smoking during pregnancy and ETS may have additive adverse effects on infantile health.

54.3 Pharmacology of Tobacco Smoke and its Detection in Biological Specimens

Tobacco smoke has many compounds, some of which might have effects on an infant's health that have not been yet investigated.

Carbon monoxide rapidly binds to both maternal and fetal hemoglobin with carboxyhemoglobin levels that eventually become higher in the fetus than in the mother because the former has a higher hemoglobin affinity for carbon monoxide and a longer elimination half-life than the latter. This leads to a potentially profound impairment of oxygen delivery to the tissues that can be aggravated by other smoke-derived chemicals (thiocyanates and other cyanides) that also bind hemoglobin.

Nicotine is the chemical that is primarily responsible of tobacco addiction and organ toxicity. In the brain, nicotine binds to nicotinic acetylcholine receptors eliciting the release of many neurotransmitters. Nicotine can also act peripherally

Federico II University of Naples, Naples, Italy

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

stimulating the release of epinephrine, ultimately increasing heart and respiratory rate and causing vasoconstriction. It also suppresses insulin release possibly affecting glucose blood levels and appetite. Nicotine passes into breast milk with concentrations that are in linear correlation with its levels in maternal serum [4].

Cotinine, the major nicotine metabolite, is currently used to objectively assess an infant's exposure to tobacco smoke both before and after birth. Cotinine may be dosed in plasma, urine, saliva, hair and meconium. This sampling is expensive, may be invasive (i.e., plasma) and depends on cotinine half-life (except for hair) but often reveals a greater exposure to tobacco smoke than maternal self-reports. In the study by Puig et al, infantile exposure to ETS was significantly higher when assessed by infant urinary cotinine compared to parental self-reported [5]. Similarly, 64.3% pregnant women who claimed to be non-smokers and not exposed to ETS had plasma cotinine levels above the limit of detection [6]. Despite the proven value of this biomarker, much of the research published to date still relies on self-reports.

54.4 Smoke, the Pregnancy and the Fetus

Nicotine is a powerful vasoconstrictor that can significantly reduce maternal blood supply to the fetus. The fetal blood supply is further impaired by placental alterations and high carboxyhemoglobin levels. These effects combined may explain why smoke during pregnancy has been associated with perinatal death, spontaneous abortion, stillbirth, abruptio placentae, placenta previa, fetal growth restriction, preterm birth and low birth weight. In a recent cohort study on 7098 pregnant women, the association with low birth weight was particularly true for active smoking during late pregnancy, while quitting smoking early in pregnancy was associated with a higher birth weight than continuing to smoke. A slight, non-significant trend to a beneficial effect on birth weight has been described for reducing the number of cigarettes without quitting completely [7]. Infant length and head circumference are also affected though probably to a lesser degree. Kannellopoulos reports that tobacco-related effects on fetal growth may be reversible during the first few years of life [8].

54.5 Neonatal Consequences of Smoke Exposure

The multifaceted damage of smoking during pregnancy on neonatal health starts with an increased rate of congenital malformations. Many questionnaire-based studies have reported a greater incidence of cleft lip and palate in infants of smoking mothers [9]. This piece of data has been recently confirmed by a biomarker-based study. Women with a serum cotinine above 2 ng/mL have a 2.4 odds ratio for delivery of a child affected by an orofacial cleft [10].

Congenital heart defects have also been associated to prenatal smoke exposure. Recently, a large questionnaire-based, case-control study conducted by Malik et al concluded that women who smoked around the periconceptional period were more likely to give birth to neonates with septal and right-sided obstructive defects [11].

Impaired development of the fetal femur and/or of its vasculature has been claimed to explain the increased risk of Legg-Calvè-Perthes disease in the offspring of mothers who smoked during pregnancy compared with matched controls [12]. More research is required to re-evaluate this topic using biomarkers as an objective measure of the infant's smoke exposure.

Besides organogenesis, neonatal organ function is impaired by direct maternal smoking during pregnancy or by ETS.

Studies of pulmonary mechanics in infants with prenatal exposure to tobacco smoke have shown an alteration in expiratory flow profile, a reduction in respiratory compliance and an increase in airways resistance [13].

Prenatal smoke exposure has a long lasting effect on expiratory flow rates as a significant reduction has been reported by Cunningham et al [14] in 8–12 year old children. The respiratory function deficit was larger for black children than for white and for boys than for girls [15]. The severity of wheezing may be further influenced by beta-2 adrenergic receptor variants in a complex gene-environment interaction [16].

Children of mothers who smoked during pregnancy have a higher risk of respiratory tract infections both during the neonatal period and during the first year of life. The same holds true, to a lesser degree, for ETS, which could directly damage the respiratory epithelial lining and also suppress the innate immune system [17].

A large, questionnaire-based, cohort study has recently evaluated the effects of maternal smoking in pregnancy on the cardiovascular function of the neonate [18]. Infants of smoking mothers had a 5.4 mmHg higher systolic pressure than offspring of non-smoking mothers but no significant association was found with diastolic pressure or heart rate. ETS alone (i.e., infants of non-smoking mothers but with smoke exposure in the household) did not have modified blood pressure or heart rate compared to controls.

54.6 Behavioral Aspects of the Offspring of the Smoking Mother

The profound impact of nicotine on neural cells suggests a possible effect on neonatal behavior. Questionnaire-based research results, however, have not been entirely clear. Most studies examined tobacco in the context of other factors such as illicit substance abuse or obstetric complications [19]. Our group has conducted a prospective analysis of neonatal behavior, assessed

by the Brazelton Neonatal Behavioral Assessment Scale, monitoring the infant's urine cotinine and administering a structured questionnaire to the parents [20]. Newborns of mothers who smoked during pregnancy had a higher urinary cotinine excretion. They were more irritable and less interactive with the environment when compared with controls. The same was true, although to a lesser extent, for offspring of non-smoking mothers but smoking fathers, used as a proxy of ETS. Using a different evaluation tool, Stroud et al came to similar conclusions [21]. Neonates of smoking mothers had an increased arousal and excitability throughout the first month of life, well past nicotine half-life. This has to be taken into account to prevent early disruption of a correct maternal-infant bonding.

The adverse behavioral effects of prenatal smoke exposure extend far beyond the neonatal period. Schmitz et al have documented an odds ratio of 3.44 for an increase of the inattentive form of attention deficit hyperactivity disorder (ADHD) and some studies show a higher rate of smokers among adolescents affected by ADHD as they were trying to self-medicate to alleviate cognitive or attentive disorders [22]. A prospective longitudinal study by Hook et al has linked prenatal smoke exposure to externalizing problems and aggression leading to a higher incidence of delinquent behavior both in males and females [23].

54.7 Smoke and SIDS

After the recognition that sleeping in the supine position is associated with a decreased incidence of sudden infant death syndrome, maternal smoke has become the main, preventable risk factor for SIDS. There is evidence that infants of smokers are less rousable both in REM and in non-REM phase of sleep [24] and have deficient hypoxic awakening response [25]. Work in lambs exposed in utero to nicotine shows delayed arousal and reduced ventilatory and heart rate responses to hypoxia. Infants who died of SIDS had increased apoptosis in their brainstem nuclei compared to babies who had suddenly died for other reasons; cigarette smoke exposure was especially associated with increased apoptosis in the dorsal motor nucleus of the vagus and the arcuate nucleus [26]. These pathology observations may provide the link between tobacco smoke, a defective cardiorespiratory control and SIDS.

54.8 Reducing Damages from Prenatal Smoke Exposure or ETS

It is intuitive that enforcing regulations on banning smoke from public places and taxing tobacco products should reduce smoking rates and ETS. More focused programs are in place in many developed countries where smoking cessation services are available before or during the pregnancy offering behavioral support. There is currently an open debate on the safety and efficacy of nicotine replacement therapy in pregnant women [27, 28].

54.9 Conclusions

Perinatal health professionals need to increase their awareness about the detrimental effects of smoking during pregnancy. Further research conducted with reliable biomarkers of smoke exposure will improve the quality of information both about the effects of direct maternal smoke and its role as an environmental pollutant. This information is much needed if we are to design successful interventions.

Infants of Diabetic Mothers

Jane E. Barthell and Michael K. Georgieff

55.1 Overview

While advances in maternal and neonatal medical care continue to improve the outcomes for infants born to mothers with glucose intolerance during pregnancy, the risks for spontaneous abortion, stillbirth, congenital malformations, and perinatal mortality and morbidity still exist. Abnormal maternal glycemic control caused by gestational diabetes mellitus or pregestational diabetes mellitus complicate up to 10% of pregnancies, and as the significantly overweight pediatric population develops into their child-bearing years, this number is likely to rise [1]. Pregnancies of mothers with diabetes are given increased surveillance, as the multifaceted metabolic changes that occur in the mother can place the infant at risk for periconceptional, fetal, neonatal, and long-term morbidities [1, 2]. Fortunately, appropriate periconceptional and prenatal care can improve the risks of perinatal complications by close monitoring of maternal glycemic control.

55.2 The Pederson Hypothesis and Diabetic Fetopathy

In general, maternal glycemic control remains the primary factor that determines the potential complications in the conceptus and the neonate. Some sequelae, such as failure of implantation, miscarriage and congential malformations are a function of pre and peri-conceptional maternal glucose control. Other sequelae, such as macrosomia, neonatal hypoglycemia, and fetal/neonatal iron deficiency result from worsening glycemic control in the last few weeks prior to delivery [3, 4]. Fetal hyperglycemia, hyperinsulinemia, or the combination of the two leads to the pathologic conditions seen in the late gestation fetus and neonate (Fig. 55.1).

55.3 Risks of Maternal Glucose Intolerance During the Periconceptional Period

Up to 40 known congenital malformations associated with maternal diabetes have been noted [5]. Indeed, a strong association between maternal glycemic control at the time of conception and early gestation and the incidence of congenital anomalies has been recognized in several epidemiological studies, with a significant decrease in congenital malformations reported in mothers with strict metabolic regulation during the periconceptional period [6, 7]. Anomalies of the heart, musculoskeletal system, and genitourinary system have been seen at a twofold to threefold higher incidence in infants of insulin-dependent diabetic mothers compared to the normal population [8]. The frequency of congenital anomalies is not increased in offspring of gestationally diabetic mothers [9].

The mechanisms by which these anomalies occur remain under investigation. Maternal hyperglycemia, the major teratogenic factor, may be involved in hyperglycemia-induced apoptosis that is associated with oxidative stress, lipid peroxidation, and decreased antioxidant defense capacity in the embryos [10, 11]. In studies of mouse embryos from diabetic mice, hyperglycemia appears to disturb cellular pathways specific for cardiac and neural tube development [12–14]. A three-to-fivefold increase in major malformations in infants as well as a fivefold increase in pregnancy loss rate in mothers with hemoglobin A1c levels (>7%) early in pregnancy has been demonstrated [15]. Latest recommendations include maintaining a hemoglobin A1c less than 5% in the first trimester of pregnancy and below 6% in the third trimester in healthy pregnant women with type 1 diabetes mellitus [16]. Routine screening for congenital anomalies of all infants of diabetic mothers (IDMs) is not cost-effective. The index of suspicion when evaluating a newborn IDM should clearly be very high.

55.4 Risks of Maternal Glucose Intolerance During the Fetal Period

Maternal hyperglycemia has effects on fetal growth, glucose metabolism, oxygenation, iron metabolism, cardiac anatomy and function, and transition to extrauterine life.

55.4.1 Growth Disorders

Neonatal macrosomia is the classic presentation of an IDM and results from biochemical changes along the maternal hyperglycemia – fetal hyperinsulinemia pathway [17]. Early in the second half of pregnancy, the pancreatic islet cells mature and insulin production escalates in response to hyperglycemia creating an environment of hyperinsulinemia, a key anabolic hormone, coupled with hyperglycemia, a key anabolic fuel. The combination produces a large increase in fetal fat stores and some mild increase in protein content [1]. Hepatomegaly, splenomegaly, and cardiomegaly resulting from septal hypertrophy are often seen in the context of a macrosomic infant, while the head circumference is usually not increased. A significantly increased fetal abdominal area growth rate in the third trimester has been associated with high maternal hemoglobin A1c levels early in pregnancy [18] and has been used to effectively reduce rates of macrosomia [19]. The risk of shoulder dystocia, perhaps the most feared birth complication, is greater for an infant of any weight born to a diabetic versus a nondiabetic mother [20]. Accordingly, it has been recommended that elective cesarean be strongly considered for diabetic mothers with fetal weight estimates greater than or equal to 4250 grams.

In contrast to the pathophysiology leading to the macrosomic infant, mothers with advanced diabetic vascular disease are at risk of having fetuses with significant growth deceleration, defined as birth weight less than the fifth percentile for gestational age.

55.4.2 Disorders of Glucose Metabolism

Glucose intolerance coupled with resistance to or absence of insulin characterizes maternal diabetes during pregnancy. Although glucose crosses the placenta to the fetus, insulin that is either maternal in origin or exogenously delivered does not reach the fetus. Therefore, fetal hyperglycemia leads to pancreatic islet cell stimulation and subsequent fetal insulin production. Additionally, hypoglycemic episodes may result from sudden reductions in maternal glucose in fetuses with islet cell hyperplasia.

Both hyper- and hypoglycemia have been identified as possible mechanisms for the increased fetal mortality rate seen in diabetic pregnancies [21].

55.4.3 Reduced Fetal Oxygenation

Abnormalities in fetal oxygenation during diabetic pregnancies were discovered in the 1980's and account for the high rate of polycythemia in offspring of poorly controlled diabetic mothers [1].

The fetal hypoxia is a consequence of an elevated fetal basal metabolic rate stimulated by chronic hyperglycemia and hyperinsulinemia. With increases in rate of substrate uptake and oxidation, the fetal environment becomes hypoxic, since the higher oxygen demand cannot be met by increased oxygen transfer by the placenta (human or ovine). Several studies have demonstrated the attempt of the fetus to increase oxygen-carrying capacity in the face of hypoxemia includes elevated erythropoietin concentrations and fetal polycythemia [22–27]. Fetal hypoxia constitutes a risk to the developing brain as does the potential for hyperviscosity and fetal stroke.

55.4.4 Disorders of Fetal Iron Metabolism

Chronic fetal hypoxemia and the subsequent compensatory erythropoiesis coupled with the larger blood volume of the macrosomic fetus places a large demand on fetal iron metabolism particularly in light of limitations on maternal-fetal iron transport to support this large demand.

IDMs are at greater risk for iron deficiency of multiple organs due to the inability of the placenta to upregulate iron transport sufficiently and subsequent iron prioritization and redistribution [28–35]. These deficiencies can affect neurodevelopment into infancy and beyond [28–32]. Decreased fetal hepatic iron stores, as indexed by abnormally low cord serum ferritin concentrations, occur in 65% of live-born IDMs [26].

55.4.5 Acute and Subacute Non-Structural Cardiac Abnormalities

Fetal cardiac septal hypertrophy and cardiomegaly as a result of glycogen loading from chronic hyperglycemia and hyperinsulinemia are specific phenotype findings associated with diabetic pregnancies. Despite good maternal metabolic control, serial evaluations of cardiac growth demonstrated cardiac hypertrophy in late gestation (34 to 40 weeks) in fetuses of diabetic mothers [36] making cardiomegaly a possible contribution to the increased risk of fetal death in diabetic pregnancies [37].

55.5 Risks of Maternal Glucose Intolerance During Pregnancy on the Neonate

The abnormal metabolic milieu of hyperglycemia and hyperinsulinemia during fetal life leads to multiple issues in the neonatal period, including abnormalities of neonatal body habitus, glucose, calcium and magnesium metabolism, hematologic status, cardiorespiratory function, bilirubin metabolism, and neurologic functioning (Table 55.1).

55.5.1 Growth Disorders

Newborn macrosomia is predicted by poor maternal glycemic control, particularly in the last few weeks of gestation. Occurring in 15-45% of diabetic pregnancies, macrosomia is generally defined as birth weight above the 90th percentile for gestational age or greater than 4000 grams [38].

Macrosomia at birth serves as a marker for identifying infants at risk for neonatal morbidities, including hypoglycemia,

Table 55.1 Risk, assessment and management of neonatal metabolic complications in infants of diabetic mothers

Condition	Assessment	Action value	Management
Hypoglycemia	Serum glucose	<40 mg/dL first 24 hours; <50 mg/dL after 72 hours	Early feedings; IV D10W 2 mL/kg body weight; repeat serum glucose in ½ hour
Hypocalcemia	Serum ionized calcium	<3.5 mg/dL	Calcium gluconate or calcium chloride if symptomatic; treat hypomagnesemia prior to calcium treatment
Hypomagnesemia	Serum magnesium	<1.5 mg/dL	Magnesium sulfate
Polycythemia	Hemoglobin Hematocrit (measured centrally)	>20–23 g/dL >65–70%	Partial exchange transfusion with target hematocrit of 55%
Iron deficiency	Serum ferritin	<35 mcg/L	Follow-up hemoglobin and ferritin at 6 months
Hyperbilirubinemia	Serum indirect (unconjugated) bilirubin	Dependent on age and infant size	Phototherapy, early feedings, hydration, rarely exchange transfusion

hyperbilirubinemia, and neonatal acidosis [38]. Complete anthropometric measurements, including weight, length, and head circumference should be assessed and plotted on population-specific appropriate growth curves for each infant soon after birth.

Appropriate for gestational age IDMs have been found to have significantly greater fat mass, percent of weight that was fat, and triceps, subscapular, abdominal, flank, and thigh skinfold measurements than infants of nondiabetic women [39]. Subsequently, macrosomic IDMs generally have higher weight than length and head circumference percentiles. Infants at risk for metabolic instability in the newborn period can be better identified by body proportion measurements, such as the mid-arm-circumference-to-head-circumference ratio [40].

55.5.2 Neonatal Hypoglycemia

Significant hypoglycemia, defined as a blood glucose level less than 45 mg/dL, is seen in up to 50% of IDMs following birth, with macrosomic or growth-restricted IDMs more likely to have hypoglycemia than IDMs of appropriate size for gestational age [1, 17]. The abrupt discontinuation of maternally derived glucose combined with neonatal hyperinsulinemia leads to hypoglycemia in the macrosomic infants. Normally, this interruption in glucose delivery is followed by a decrease in neonatal plasma glucose between 30 and 90 minutes followed by spontaneous recovery in most infants [8]. Hypoglycemia seen in infants with growth restriction due to diabetic vascular disease is more likely due to decreased hepatic glycogen stores and may not appear until 6-12 hours after delivery [17]. Hypoglycemia can persist and therefore require intervention consisting of a constant intravenous dextrose infusion.

Controversy exists concerning the threshold of what constitutes hypoglycemia, as little outcome data is available for symptomatic or asymptomatic hypoglycemia. A common recommendation is that IDMs be screened at ½, 1, 1 ½, 2, 4, 8, 12, 24, 36, and 48 hours of age [17], and be treated to maintain a glucose over 40 mg/dL [41].

Although most infants with hypoglycemia are asymptomatic, typical symptoms can include jitteriness, sweating, tachypnea or apnea, seizures, agitation, and respiratory distress. Newborn IDMs, especially those who are macrosomic or growth restricted, should be monitored closely with regularly scheduled serum glucose measurements.

Maternal history, with attention to glycemic control, and fetal anthropometric measurements and proportion studies can help to identify infants at highest risk [40].

Early initiation of feedings is highly recommended, as those infants who are asymptomatic, normoglycemic, and able to tolerate feedings do not need intravenous dextrose therapy.

55.5.3 Neonatal Hypocalcemia and Hypomagnesemia

Neonatal hypocalcemia and hypomagnesemia are two frequently encountered metabolic disturbances that occur in up to 50% of IDMs during the first three days of life and are related to lack of maternal glycemic control [8]. A physiological nadir of serum calcium is seen in healthy term infants by 24–48 hours of age during the transition from fetal to neonatal parathyroid and calcitonin regulation [42]. The nadir may be exaggerated to the point of hypocalcemia, generally accepted as an ionized calcium level less than 3.5 mg/dL [17]. Ionized calcium measurements, when available, are preferable to total serum calcium measurements. Hypocalcemia in the IDM may be caused by an inadequate neonatal parathyroid response to the abrupt interruption of maternally derived calcium as well as continual high levels of calcitonin, and possibly disturbances in vitamin D metabolism [8].

Neonatal hypomagnesemia is related to maternal hypomagnesemia and severity of maternal diabetes [17]. A serum magnesium level less than 1.5 mg/dL is considered pathologic [17], and may complicate the treatment of hypocalcemia.

Similar to hypoglycemia, neonatal hypocalcemia and hypomagnesemia may present with symptoms such as jitteriness, sweating, tachypnea, irritability, and seizures. They present later than hypoglycemia with nadirs seen at 24 to 72 hours following birth [1]. Because of this similarity of symptoms, the jittery IDMs should have serum glucose, calcium and magnesium levels measured. Symptomatic hypocalcemic IDMs can be treated with calcium chloride or calcium gluconate preferably via a central venous catheter to reduce the chance of peripheral vein damage from the medication. Hypomagnesemia needs to be corrected in order to enable normalization of calcium homeostasis.

55.5.4 Neonatal Polycythemia

Polycythemia is present in 20% to 30% of infants born to poorly-controlled diabetic mothers. The definition of polycythemia is a central venous hemoglobin concentration greater than 20 g/dL or hematocrit greater than 65% [1]. Blood hyperviscosity at levels higher than these leads to morbidities including vascular sludging, ischemia, and infarction of vital organ systems [38].

The cerebral microcirculation is one area at risk for hyperviscous blood sludging, resulting in neurologic irritability, jitteriness, and a high-pitched cry. Cerebral venous sinus thrombosis must be considered in these infants, and even though neuroimaging studies may not detect pathology, symptomatic, polycythemic IDMs should be treated with partial exchange transfusion to reduce blood viscosity and the predisposition to further clot formation [1].

Symptoms of vascular sludging in the renal, intestinal, and pulmonary systems may or may not be explicit. Hypertension, thrombocytopenia, hematuria, and abdominal mass are all possible signs of renal vein thrombosis. Feeding intolerance or necrotizing enterocolitis may indicate intestinal sludging. Finally, pulmonary vascular bed sludging may present as persistent pulmonary hypertension with worsening respiratory distress syndrome.

Assessment including an initial hematocrit and platelet count ought to be obtained soon after birth. Because of the physiologic diuresis that occurs in all newborns, an increasing hematocrit over the first three days of life is not uncommon. This phenomenon, however, prolongs the risk for microvascular sludging in the polycythemic IDM, making the importance of appropriate monitoring and hydration paramount. Sludging and thrombosis of the microvasculature of any of the aforementioned organ systems may first be indicated by a declining platelet count. Asymptomatic infants with hematocrit values from 65% to 70% ought to be hydrated with intravenous fluids at a rate of at least 100 mL/kg/day, and the hematocrit should be followed daily for the first three days. If the infant becomes symptomatic or the hematocrit continues to increase despite appropriate therapy, a partial volume exchange transfusion should be completed. An immediate partial exchange transfusion is indicated in any IDM who is symptomatic from blood hyperviscosity or those with a central hematocrit greater than 70% [1].

55.5.5 Neonatal Iron Deficiency

Abnormalities of iron metabolism at birth have been demonstrated in 65% of IDMs and 95% of macrosomic IDMs [26, 43, 44]. Of note, IDMs with the highest hematocrits at birth tend to also have the lowest ferritin concentrations. Iron deficiency presents a risk to the developing brain including effects on myelination [45], brain energy metabolism [46], and brain monoamine neurotransmitter metabolism [47]. Newborn IDMs have altered cognitive processing compared to healthy, term infants [48]. Treatment with supplemental iron (beyond normal recommendations) in the immediate newborn period has not been assessed with respect to improving the neurodevelopmental outcome and is currently not recommended.

55.5.6 Pulmonary and Cardiac Status

Respiratory distress syndrome (RDS) and transient tachypnea of the newborn (retained fetal lung fluid) are more commonly seen in IDMs than age-matched controls [1]. Fetal hyperinsulinemia may inhibit the normal maturational effect of cortisol on the lung leading to a decreased production of dipalmityl lecithin [38]. While the infant of a non-diabetic mother reaches pulmonary maturity at a mean of 34–35 weeks gestation, the IDM is not considered to be past the risk of pulmonary immaturity until 38.5 weeks gestational age [38]. Additionally, persistent pulmonary hypertension secondary to polycythemia associated vascular sludging may complicate RDS as both polycythemia and RDS are associated with fetal hyperinsulinemia.

Cardiopulmonary adaptation (e.g., transition) in IDMs has been shown to be significantly different than infants born to non-diabetic mothers. The classic findings of interventricular septal hypertrophy caused by glycogen loading of the septum and cardiomyopathy are seen in up to 30% of IDMs [38]. Hypertrophic subaortic stenosis physiology can be observed with severe septal hypertrophy rendering those infants in left ventricular outflow obstructive heart failure. In such a situation, inotropes and hypovolemia worsen the condition, whereas beta-blockers and volume help to alleviate the obstruction. Cardiomyopathy is usually seen in conjunction with septal hypertrophy, although it may appear exclusively [1].

55.5.7 Hyperbilirubinemia

Indirect hyperbilirubinemia is a common finding in IDMs as they have an increased red cell mass, ineffective erythropoiesis, and relative immaturity of hepatic bilirubin conjugation and excretion [1]. A 30% greater source of bilirubin is produced by the increased cell mass, and conjugation and excretion by the relatively immature glucoronosyltransferase enzyme system creates elevated serum unconjugated bilirubin levels. Bilirubin levels should be assessed within the first 24 hours of life and then followed until a peak has been reached. Phototherapy with appropriate hydration monitoring is the mainstay of treatment, but some infants will require exchange transfusion, using the same criteria as in hyperbilirubinemic infants born to mothers without diabetes.

55.5.8 Neuropathology

Central nervous system dysfunction can be seen immediately in the newborn period as well as manifested by neurodevelopmental and behavioral abnormalities not recognized until later infancy or childhood. The IDM is at risk for multiple morbidities that can result in neurologic injury and symptoms. Polycythemia with vascular sludging, glucose and electrolyte abnormalities, birth trauma and perinatal asphyxia due to macrosomia all pose possible etiologies for neurologic symptoms such as seizures, jitteriness, lethargy, tone abnormalities and movement disorders. Different neurologic symptoms typically present at specific time periods based on the etiology. Perinatal depression, birth trauma, and hypoglycemia

all generally present with symptomatology within the first 24 hours of life. Alternatively, symptoms due to hypocalcemia or hypomagnesemia typically present between 24 and 72 hours following birth, as this is the time period at which nadir levels are expected to be reached.

Initial hypotonia followed by increased tone, jitteriness, and seizures are signs and symptoms of brain injury secondary to perinatal asphyxia. The risk for seizures due to birth asphyxia generally peaks 24 hours following birth. Glucose, electrolyte or hematologic abnormalities must be identified and corrected prior to starting anticonvulsant therapy.

Brachial plexus nerve injuries secondary to neck stretching during delivery are more commonly seen in the macrosomic IDM than appropriately grown for gestational age infants. Erb's palsy (roots C5-7), Klumpke's paralysis (roots C-8), diaphragmatic nerve paralysis (roots C3-5), and recurrent laryngeal nerve damage (roots T1-2) have all been reported.

In humans, event-related potential (ERP) studies have indicated that while healthy, term infants born to nondiabetic mothers discriminate their own mother's voice from a stranger's voice, iron deficient IDMs do not show evidence of discrimination, suggesting abnormal cognitive processing [29, 49].

55.6 Long-Term Health Sequelae in IDMs

Periconceptional, fetal, and neonatal events all contribute to the long-term health issues of IDMs. The future risks for development include metabolic syndrome and iron status abnormalities in conjunction with neurodevelopmental problems.

55.6.1 Metabolic Syndrome

In light of the increasing obesity epidemic, concerns have been raised about the long-term health risks of IDMs given their fetal exposure to an abnormal metabolic milieu and macrosomic neonatal body habitus. Several studies have focused on the initial growth and ultimate likelihood of IDMs to go on to develop metabolic syndrome, characterized by increased insulin resistance often seen in the setting of obesity, hypertension, and dyslipidemia [50–54]. A longitudinal study focusing on growth of Pima Indian children showed significantly different patterns of growth of offspring of diabetic mothers compared to offspring of nondiabetic mothers. Offspring of diabetic mothers showed significant "catch-down" growth during their first 1 ½ years of life, but by age seven had greatly exceeded the weight of offspring of nondiabetic mothers [50]. Another longitudinal study identified a trend toward a higher incidence of insulin resistance (defined as a fasting glucose/insulin ratio of <7) in eleven-year-old children who were large for gestational age at birth compared to those who were appropriate despite no difference in obesity. The authors also demonstrated by multivariate logistic regression that childhood obesity and the combination of large for gestational age status and maternal gestational diabetes was associated with insulin resistance [51]. Finally, a review of studies examining the consequent development of metabolic syndrome in gestationally diabetic mothers and their offspring showed that metabolic syndrome in children with increasing age is related to maternal gestational diabetes, maternal glycemia in the third trimester, maternal obesity, neonatal macrosomia, and childhood obesity [52].

55.6.2 Neurodevelopment

Because of the many morbidities for which IDMs are at increased risk, the long-term motor and cognitive developmental trajectories of these children have been studied in comparison to infants born to nondiabetic mothers. Acute perinatal events as well as abnormal intrauterine environmental affects can contribute to the long-term risks to brain development. Both newborn studies and longitudinal research have demonstrated significant neurodevelopmental differences between these groups of offspring.

For infants that experience seizures in the newborn period, the etiology of the seizures is critical for determining prognosis. Seizures caused by metabolic abnormalities such as hypoglycemia or hypocalcemia have a 10% to 50% risk of later developmental delays. In contrast, infants who have seizures due to hypoxic-ischemic encephalopathy carry an 80% risk for developmental problems [55]. Transient hypoglycemia in the presence of large-for-gestational-age infants born to nondiabetic mothers has been shown to have no harmful impact on psychomotor development at four years [56]. Symptomatic, severe hypoglycemia (blood glucose <35 mg/dL), however, has been shown to be associated with neurodevelopmental abnormalities and white matter injury identified on MRI [57]. MRI is recommended for routine evaluation of a newborn infant with symptomatic hypoglycemia to elucidate any cerebral injury [58].

Specific areas of neurodevelopment of offspring born to diabetic mothers have been shown to correlate with the degree of maternal glycemic control [59–62]. Problems with attention span and motor functions appear to be present even in well-controlled mothers. Gross cognitive ability has appeared to be maintained unless pregnancies are associated with significant maternal nephropathy or hypertension or with neonatal iron deficiency [62] in which case the effects negatively correlate with the level of maternal glycemic control [59, 62]. Another longitudinal study that followed IDMs until 11 years of age showed that poorly controlled antepartum maternal glucose and lipid metabolism correlated with poorer child performance on standard measures of neuropsychological functioning [60].

55.7 Summary

Advances in medical care of pregnant women with diabetes have lead to improved outcomes for mothers and their offspring. Despite this trend, the rising obesity epidemic has the potential to alter the course of progress. Metabolic Syndrome characterized by insulin resistance and type II diabetes mellitus will likely continue to rise over the ensuing decade making glycemic control a more universal issue. Health care providers who care for pregnant women ought to stress the possible implications of poor glucose control, including fetal hypoxia and iron deficiency that can affect long-term neurodevelopmental trajectories of their infants. Women who first present with insulin resistance in pregnancy, particularly those who are overweight or obese, need to be followed for the possibility of developing type II diabetes later in life. Additionally, health care providers of infants and children ought to be aware of the possible sequelae for offspring of diabetic mothers both in the neonatal period as well as long-term. Atypical neurodevelopment and the propensity for a metabolic derangement are two arenas that warrant further research and attention as these infants are followed throughout childhood.

This work was sponsored in part by grants to MKG from the National Institutes of Health (HD-29421-14; NS-34458-14; HD-54490; and RR-00400-39).

Lung Development and Pulmonary Malformations

Corrado Moretti and Paola Papoff

56.1 Fetal Stage of Lung Development

56.1.1 Introduction

In the early weeks of gestation the human lung originates as a ventral endodermal pouch from the primitive foregut; it thereafter continues to grow through to adulthood until it reaches an exchange surface area of around 70–100 m^2; the air-blood barrier is some 0.2 microns thick, 1/50 of the thickness of a sheet of tissue paper.

From the structural standpoint the lung is made up of one part that serves to convey gas extending from the trachea to the terminal bronchioli, characterized by a series of 23 branchings of the respiratory tree, and of an alveolar zone where gas is exchanged, where the acinus is the functional unit. The acinus comprises the respiratory bronchioles, often with alveoli on the walls, the alveolar ducts and the alveoli themselves, which are characterized by a hexagonal structure (Fig. 56.1). The surface area of this structure is vast and maintains a constant relationship with body mass during postnatal growth (about 1 m^2/kg).

The development of the human lung begins when the lung bud appears in the embryo and ends in early childhood after relatively stable and progressive growth. Even though birth is an event that implies dramatic changes in the functions of this organ, it should not be considered as a precise point of transition from one stage of development to another. Nevertheless, since this is an important event, the artifact of dividing lung development into a prenatal and postnatal stage is justified, also to emphasize that at the end of gestation, this organ has not yet reached maturity. Indeed, at the time of writing we cannot define exactly when the lung reaches maturity [2]. Prenatal development of the respiratory system is in turn conventionally divided into five periods [3]; actually, a precise watershed between these periods does not exist, but their identification can however simplify the understanding of the morphogenesis of the lung.

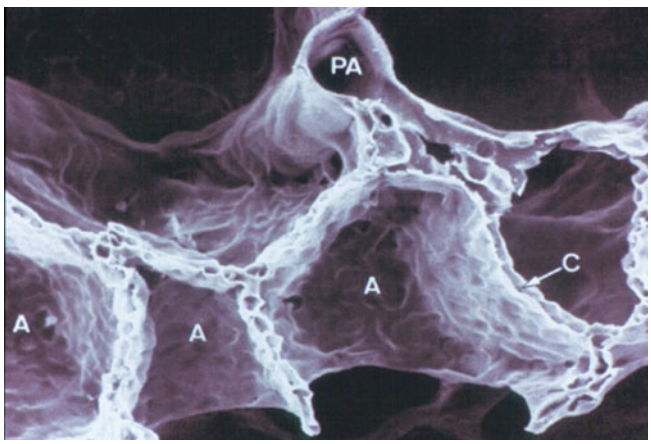

Fig. 56.1 The electron micrograph shows some alveoli (**A**) with a dense capillary network (**C**) between their walls. The capillaries stem from a branch of the pulmonary artery (**PA**). Reproduced from [1], with permission

56.1.2 Embryonic Phase (3rd–7th week)

The lung bud appears on the 26th day of gestation and is formed from relatively undifferentiated epithelial cells that expand into the surrounding embryonic connective tissue or mesenchyme (Fig. 56.2a,b). The bud begins to grow in length and to branch until, towards the 5th week, it forms five small saccular structures, two on the left and three on the right, which are the beginnings of the future secondary bronchi and

of the future lobes of the mature lung (Fig. 56.2c,d). The developing airways will undergo further branching and are accompanied by the pulmonary arteries that derive from the sixth aortic arches.

Interactions between the epithelial cells of endodermic origin that form the respiratory tree and the mesenchymal tissue of mesodermal origin covering it are of basic importance for the branching of the airways [5]; this process is often referred to as "cross-talk". The process is controlled through a multitude of molecular factors that include transcriptional regulators, growth factors, morphogens and extracellular matrix molecules, all of which must be carefully controlled in both space and time to form a properly functioning lung. If some of these developmental factors do not function at the right time and/or place, then lung defects may occur.

Towards the end of the 6th week of gestation, the main airways are complete, including the segmental and sub-segmental bronchi (Fig. 56.2e).

Developmental anomalies occurring in these first weeks of gestation may lead to many congenital malformations such as pulmonary agenesia, laryngeal or tracheal stenosis or athresia, tracheo-esophageal fistula, tracheo-malacia or broncho-malacia, bronchial malformations and ectopic lobes (Table 56.1).

Table 56.1 Stage of development of congenital pulmonary malformations

Embryonic
Pulmonary agenesis
Tracheal or laryngeal agenesis or stenosis
Tracheo- or bronchomalacia
Bronchial malformations
Ectopic lobes
Pseudoglandular
Cystic adenomatoid malformation
Pulmonary sequestration
Lung cysts
Congenital pulmonary lymphangiectasia
Congenital diaphragmatic hernia
Canalicular
Pulmonary hypoplasia
Saccular/Alveolar
Pulmonary hypoplasia
Alveolar capillary displasia

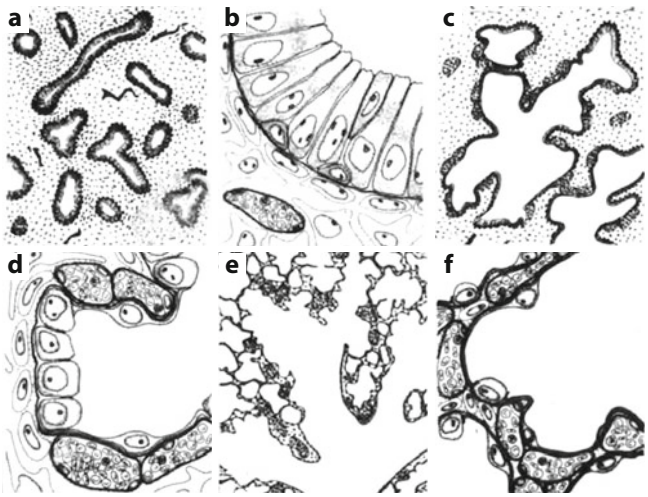

Fig. 56.3 Drawing that illustrates the light microscopic appearance of human lung during the glandular (**a**, **b**), canalicular (**c**, **d**) and saccular (**e**, **f**) stages of in utero development. Undifferentiated columnar cells of the early bronchi (**b**) rest upon a basal lamina, which has been emphasized. Mesenchymal cells and capillaries are present below the basal lamina. **d** shows that the epithelium overlying proliferating blood vessels thins to a squamous Type I morphology and that the most distal cells retain a cuboidal shape. At the saccular state (**f**), the septa are very thinned and the air spaces are lined by differentiated Type I and Type II cells. The low and high magnification drawings are shown at approximately the same magnification in each panel. Modified from [6]

56.1.3 Pseudoglandular Phase (6th-17th week)

During the pseudoglandular period the airways continue to divide until they form terminal bronchioles; by the end of this period the bronchial branching process is complete and the airways will continue to grow in proportion with the increase in pulmonary volume.

Since the newly formed epithelial tubules are surrounded by a considerable amount of mesenchyme, they make the lung look like a gland, hence the name of this phase (Fig. 56.3a,b). The proximal airways are covered by an epithelium that gradually becomes thinner towards the periphery, where the cells take on a cuboidal shape.

During this period the blood vessels develop in parallel to the airways so that, by the end of this phase, their hierarchical structure is already comparable to that of the adult [7]. Also, the development of the nerves in these structures is already fairly complete.

Alterations in the development of the lung during the pseudoglandular period may give rise to many congenital malformations such as pulmonary sequestration, cystic adenomatoid malformation, pulmonary cysts and congenital pulmonary lymphangectasia (Table 56.1). In the early stages of this period, the pleuro-peritoneal cavity starts dividing into the peritoneal and the pleural cavities due to the development of the diaphragm; when it does not divide correctly, the abdominal content in the chest becomes herniated (diaphragmatic hernia).

56.1.4 Canalicular Phase (16th-26th week)

The canalicular period is characterized by the appearance of vascular canals (capillaries), hence the name, and by further development of the distal airways where the primitive acinar structures appear, each made up of a respiratory bronchiole, an alveolar duct and rudimentary alveoli or saccules [8]. The development of the terminal airways and of the capillary network determines both the progressive thinning of the interlying mesenchyme and the formation of the alveolar-capillary membrane (Fig. 56.3c,d). This phase is also characterized by the differentiation from cuboidal type-II to squamous type-I cells in the distal epithelium. Differentiation of these cell types is an important step as the type-II cells will be required to produce and secrete surfactant and the type-I cells will form the thin cell layer to support future gas exchange.

In this period the presence of masses inside the chest and/or changes in the physical forces, essential for lung development, produced by the presence of the pulmonary liquid and by the breathing movements of the fetus, may interfere with the development of the respiratory system and give rise to pulmonary hypoplasia.

56.1.5 Saccular Phase (25th–38th week)

This phase is characterized by marked dilation of the terminal airways and resultant formation of saccules [3], with a considerable increase in lung volume and in the surface area for gas exchange together with a further thinning of the alveolar-capillary membrane (Fig. 56.3e,f). In this way also the microcirculation structure is modified because the capillary networks surrounding the saccules gradually come closer to each other and, at the end of the process, the interstitial septa, or primary septa, delimit a double network of capillaries necessary for the subsequent formation of the secondary septa [2].The formation of the final number of alveoli, around 200–300 million, happens during the alveolar phase, which begins towards the end of gestation and ends during early infancy. The alveoli are formed through the subdivision of the saccules into subunits, thus considerably increasing the exchange surface area. It must be pointed out that, given the great difficulty in carrying out histological measurements and in standardizing findings, there is still controversy over the beginning and the end of the alveolar phase and over the final number of alveoli.

The formation of alveoli is to be considered as mainly a postnatal event since most form during the first 24–36 months after birth with a subsequent slow increase in number up to around the 8th year of life [9].

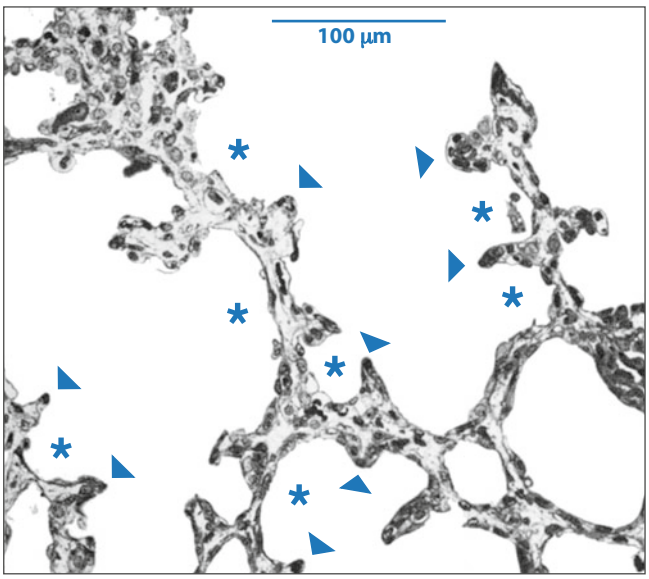

Fig. 56.4 Light micrograph of human lung. Air spaces are subdivided into small alveoli (*asterisks*) by secondary septa (*arrowheads*) projecting from the primary one

56.2 Postnatal Lung Development

56.2.1 Alveolar Phase and Development of the Pulmonary Vasculature (36th week of Gestation–24 months after birth)

Crests, or secondary septa, grow out from the intersaccular walls, or primary septa (Fig. 56.4), appearing as small ridges in epithelium [10]. Electron micrograph imaging shows the secondary septa to be formed by a thin layer of connective tissue flanked by capillaries on both sides and characterized by the presence of elastin at the tip. Elastin appears to have the function of supporting the outgrowth of the epithelium, and its presence is an essential prerequisite for the formation of the secondary septa, which takes place only after its deposition. Also, the capillary network gradually develops until maturity: in the first few weeks after birth, the interstitial layer of the septa gradually thins, drawing the two capillary networks closer until they finally merge. This transformation from a double to a single layer of the capillary network contained inside the septa is the last stage of pulmonary development [11].

56.3 Physical Determinants of Lung Development

Physical forces exerted on the lung during gestation are crucial to normal development. There are two main physical factors that aid lung development: lung fluid and fetal breathing movements (FBM).
