Mononuclear phagocyte migration has been examined in cord blood and neonatal peripheral blood. In most reports, random movement by cord blood monocytes appears to be equivalent to that of adult peripheral blood monocytes [21–23]. By contrast, several investigators have reported diminished directed movement by monocytes from cord and neonatal peripheral blood compared with those from adult peripheral blood. Yegin [24] reported that monocyte chemotaxis increased gradually during childhood and was equivalent to adult chemotactic activity at 5–6 years of age. These results are consistent with those of other investigators who reported similar chemotactic activity by cord blood and adult peripheral blood monocytes, but dramatically decreased chemotaxis by neonatal peripheral blood monocytes in the first few days of life [25]. Monocyte chemotaxis gradually increased but remained lower than adult peripheral blood monocyte activity during the first 6 months of life. Other groups of investigators reported slightly increased chemotaxis of cord blood monocytes in response to endotoxin-activated adult serum or activated adult lymphocytes [15, 26]. Differences in methods of measurements applied, patient populations examined and monocyte isolation used, likely account for the contradictory results reported by these investigators.

Neutrophils establish contact with microorgnisms through opsonins, including complement and IgG antibody. The phagocyte completely encircles the microorganisms with circumferential interactions between opsonins and receptors. Once the newly formed vacuole is internalized, the products of intracellular granules are discharged into the vacuole [27, 28]. Mobilization of granules appears to be normal in newborns compared to adults [29]. Neutrophilic granules from newborn infants possess equivalent content of myeloperoxidase and lysozyme, but diminished quantities of lactoferrin and gelatinase [29, 30].

In several experiments, neutrophils from healthy term infants provided with opsonins from adult serum exhibited normal phagocytosis of a variety of microorganisms including *Escherichia coli*, group B Streptococci, *Pseudomonas aeruginosa*, *Serratia marcescens*, *Staphylococcus aureus*, and *Candida albicans* [31–34]. Phagocytosis by neutrophils from preterm infants, while less well studied, appears to have competent phacocytic functions for bacteria and foreign particles. Ingestion of *Candida albicans* by neutrophils of preterm infants was reported to be normal in one study, but diminished in others [34–36].

The kinetics of phagocytosis by monocytes from cord blood and adult peripheral blood have been studied by Schuit and Powell [37]. These investigators found that monocytes isolated from adult peripheral blood ingested all polystyrene particles within 50 minutes. However, only 38% of cord

blood monocytes had initiated phagocytosis in the same time period. The cord blood monocytes were able to ingest the particles by 100 minutes. These studies were not influenced by the presence of serum or heat-inactivated serum. Other investigators have reported that opsonized (IgG) sheep erythrocytes, *Staphylococcus aureus*, *Escherichia coli*, *Streptococcus pyogenes*, *Toxoplasma gondii* and type II herpes simplex are ingested by cord blood monocytes as effectively as monocytes derived from adult peripheral blood [38]. Defective phagocytosis of *Streptococcus agalactiae* by cord blood monocytes has been reported by Marodi and colleagues [39]. Monocytes derived from term cord blood ingested fewer group B streptococci than monocytes isolated from adult blood. Other studies suggested that the phagocytic defect of group B *Streptococcus* by cord blood monocytes could be overcome by inclusion of adhesive glycoprotein fibronectin in the culture. Although fibronectin alone did not enhance phagocytosis, there was enhanced phagocytosis by cord blood monocytes of group B *Streptococcus* preopsonized with IgG preparation in combination with fibronectin.

The phagocytic activity of cord blood monocyte–derived macrophages has been compared with that of macrophages derived from adult blood monocytes. After a 10 day culture period, Speer and co-workers [40] determined that cord blood–derived macrophages ingested complement opsonized *S. aureus* to the same extent as macrophages from adult blood. Other investigations compared the phagocytic activity of alveolar macrophages from intubated newborns with alveolar macrophages from bronchoalveolar lavage of adult subjects. Phagocytosis of *C. albicans* by newborn and adult alveolar macrophages was determined to be equivalent with respect to rate and number of organisms ingested [41].

Table 105.1 Frequency of leukocyte abnormalities

Common
- Bacterial and fungal infection
- Maternal hypertension

Moderately common
- Twin-twin transfusion
- Isoimmune
- Rh hemolytic disease
- Drug induced
- Viral infection (rubella, cytomegalovirus)
- Leukaemoid reaction

Rare
- Severe congenital neutropenia (Kostmann syndrome)
- Cyclic neutropenia
- Shwachman-Diamond syndrome
- Reticular dysgenesis
- Autoimmune neutropenia
- Chediak-Higashi syndrome
- Dyskeratosis congenita
- Cartilage-hair hypoplasia syndrome
- Chronic granulomatous disease
- Leukocyte adhesion deficiency types I and II

105.2 Leukocyte Abnormalities

105.2.1 Etiology and Pathogenesis

The chief disorders of leukocytes observed in the newborn period include quantitative abnormalities such as neutropenia, neutrophilia, and a leukemoid reaction. Qualitative defects in phagocytic leukocytes also occur in conjunction with quantitative abnormalities and with rare hematopoietic disorders. Leukocyte disorders that occur in the neonatal period are categorized based on the frequency of the condition in Table 105.1.

105.2.2 Common Leukocyte Abnormalities

105.2.2.1 Infection

Animal studies comparing the hematopoietic response to infection between neonates and adults have demonstrated differences in the supply and release of neutrophils from the bone marrow [42]. These developmental differences increased the susceptibility of newborn animals to depletion of bone marrow reserves when subjected to experimental infection and ultimately limited their capability to survive such infections [43, 44]. Septic neonates who are neutropenic have a higher mortality than non-neutropenic neonates [45, 46]. Neonates also have an immaturity of neutrophil function and production. Immaturity of granulopoiesis in preterm neonates is manifest by a low neutrophil cell mass, a reduced capacity for increasing progenitor cell proliferation and frequent occurrence of neutropenia in response to sepsis [47]. Neonatal neutrophil function may be reduced in signal transduction, cell surface receptor upregulation, mobility, cytoskeletal rigidity, microfilament contraction, oxygen metabolism and intracellular oxidant mechanisms [48].

105.2.2.2 Associated with Maternal Hypertension

A high proportion of newborn infants delivered to women with hypertension have reduced circulating neutrophil concentrations [3, 4] because of decreased neutrophil production [49], particularly when there is fetal growth restriction. Studies have shown a decrease in neutrophil progenitor cells and decreased cycling of these cells, a relatively normal NSP, and absence of immature neutrophils in the circulation, termed a left shift. Although the precise cause of reduced neutrophil production is uncertain, it does not appear to be related to maternal medications [49, 50]. Non-specific innate host defenses may be impaired and there is a higher incidence of nosocomial infection among infants delivered to hypertensive mothers neutropenic infants compared to non-neutropenic infants [49, 51, 52].

105.2.3 Moderately Common Leukocyte Abnormalities

105.2.3.1 Leukemoid Reaction

Newborn infants may mount an exaggerated response to infection with an incease in neutrophil count and a left shift. There is a significant increase in neutrophil precursors in the peripheral blood as well as an increase in the WBC count exceeding 50,000 cells per microliter is considered a leukemoid reaction. A leukemoid reaction in response to a severe infection in the newborn is frequently accompanied by cytoplasmic vacuoles within the neutrophils and by the appearance of toxic granulations. Infants with Down syndrome may have a type of leukemoid reaction unrelated to infection.

105.2.3.2 Associated with Rh Hemolytic Disease

A well-documented complication of severe Rh erythroblastosis fetalis is a reduction in the concentration of neutrophils and platelets (35, 36). In one series of 20 infants with Rh sensitization, 11 infants had severe disease requiring multiple exchange transfusions (59). Before exchange transfusion all infants with severe disease had neutropenia. The neutrophil kinetic defect persisted between 3 and 5 days in these infants whereas none of the infants with mild disease exhibited neutophil depletion.

105.2.3.3 Isoimmune Neonatal Neutropenia

Isoimmune neonatal neutropenia results from maternal production of IgG directed against antigens on fetal neutrophils (2). This is analogous to Rh hemolytic disease in that maternal sensitization to fetal neutrophil antigens results in transplacentally acquired IgG antibody that destroys the infant's neutrophils (37). Maternal sensitization may occur during gestation and may even affect the fetus of a primagravida (38). The incidence of isoimmune neonatal neutropenia is estimated to be 0.5–2 per 1000 live births (39).

Affected infants frequently develop a fever in the first days of life and are particularly susceptible to cutaneous infections caused by *Stapylococcus aureus*. β-hemolytic *Streptococcus* and *E. coli* have also been linked to infections among susceptible infants with this disorder. The onset of infection is usually concurrent with severe neutropenia. In the circulation, the concentrations of other myeloid lineages particularly monocytes and eosinophils are typically increased. Characteristic findings on bone marrow examination are myeloid hyperplasia with a paucity of mature neutrophils and normal erythropoietic and megakaryocytic elements.

Neutrophil antibodies are detected in the sera of mother and infant. The antibodies react against neutrophils of the patient and of the father, but not against neutrophils from the mother. Several neutrophil-specific antibodies have been implicated including most commonly human neutrophil alloantigens (HNA)-1, HNA-2, and HNA-3. Other antingenic targets include NC1, SH, SAR, LAN, LEA, CN1, and certain HLA antigens. HNA-1 and NC1 have been identified as isotypes of the FcγIII receptor (2). HNA-2 is an antigen on glycoprotein (GP)50 and HNA-3 corresponds to an antigen on GP75-90. The infant's neutrophil counts typically normalize over the first 1–5 weeks of life as might be expected with the half-life of maternal antibodies.

Treatment for affected infants is supportive. Therapy also includes appropriate antibiotic administration for infections and close follow-up. The use of prophylactic antibiotics has been shown to be ineffective. Intravenous immunoglobulin (IVIG) administration and steroid therapy have not been shown to consistently improve circulating neutrophil counts. For infants with persistence of extremely low neutrophil counts (less than 500 cells per microliter), G-CSF administration might be undertaken. This therapy usually results in a prompt clinical response in circulating neutrophil concentrations.

105.2.3.4 Neonatal Autoimmune Neutropenia

Neonatal autoimmune neutropenia results from transplacental passage of maternal IgG autoantibodies directed against neutrophil antigens. Mothers of these infants can be asymptomatic or have autoimmune neutropenia from systemic lupus erythematosis or idiopathic thrombocytopenic purpura (40).

105.2.3.5 Drug-Induced Neutropenia

A significant number of medications have been implicated as causes of the development of neutropenia (Table 105.2). The mechanisms may involve bone marrow suppression or immune-mediated destruction. Marrow recovery generally begins several days after discontinuing the causative agent.

105.2.3.6 Late-Onset Neonatal Neutropenia

Most episodes of neonatal neutropenia occur during the first week of life and are related to low gestational age, low birth weight, infections, maternal hypertension, severe neonatal asphyxia, drug therapy or other perinatal events, or are of unknown cause. By contrast, late-onset neonatal neutropenia, defined as an absolute neutrophil count (ANC) $<1500/mm^3$, is observed in normally growing very-low birth-weight (VLBW) infants at a postnatal age of ≥3 weeks and is not associated to the typical complications that usually precede early-onset neonatal neutropenia (41).

Although less frequent than the early-onset type, late-onset neutropenia may be found in a significant proportion,

Table 105.2 Examples of drugs associated with neutropenia

Anti-inflammatory agents
- Indomethacin
- Pentazocine
- Para-aminophenol derivatives
  - Acetoaminophen
- Pyrozolone derivatives
  - Aminopyrine
  - Dipyrone
  - Oxyphenbutazone
  - Phenylbutazone

Antibiotics
- Cephalosporins
- Clindamycin
- Gentamicin
- Isoniazid
- Penicillins and semisynthetic penicillins
- Rifampin
- Streptomycin
- Trimethoprim-sulfamethoxazole
- Vancomycin

Anticonvulsants
- Carbamazepine
- Phenytoin
- Sodium valproate

Antidepressants
- Amitriptyline
- Amoxapine
- Doxepin
- Imipramine

Antihistamines (H-2 Inhibitors)
- Cimetidine
- Ranitidine

Antimalarials
- Amodiaquine
- Chloroquine
- Dapsone
- Pyrimethamine
- Quinine

Antithyroid
- Carbimazole
- Methimazole
- Propylthiouracil

Cardiovascular
- Captopril
- Dispopyramide
- Hydralizine
- Methyldopa
- Procainamide
- Propranolol
- Quinidine

Diuretics
- Acetazolamide
- Chlorthiadone
- Chlorothiazide
- Ethicrynic acid
- Hydroclorothiazide

Hypoglycemic agents
- Chlorpropamide
- Tolbutamide

Sedatives
- Benzodiezapines
- Meprobamate

Phenothiazines
- Chlorpromazine
- Phenothiazines

up to 22% of VLBW and in 5.5% of low birth-weight (LBW) infants, and is associated with anemia of prematurity and high reticulocyte counts, or the administration of erythropoietin at very high doses (42).

Mean age at onset of neutropenia is about 6 weeks, while the duration may range from 2–7 weeks.

An imbalance between hematopoietic growth factors (mainly erythropoietin and granulocyte colony-stimulating factor) with increased reticulocytopoiesis in response to anemia may explain the neutropenia.

Late onset neutropenia appears to be a benign condition that is not associated with any particular complication and does not require specific treatment. However, investigation should be performed to exclude other causes of neutropenia.

105.2.4 Rare Leukocyte Abnormalities

Hereditary neonatal neutropenia is covered elsewhere (see Chapter 106).

15.2.4.1 Cartilage-Hair Hypoplasia Syndrome

Cartilage-hair hypoplasia is an autosomal recessive disorder characterized by short-limbed dwarfism, fine hair, and moderate neutropenia [53]. Affected individuals have an increased susceptibility to infections, particularly varicella zoster viral infections. Immunologic defects are variable, but cellular immune functions are impaired.

105.2.4.2 Reticular Dysgenesis

Reticular dysgenesis, also called congenital aleukocytosis, is characterized by severe neutropenia associated with leukopenia, presence of rudimentary thymic lymphoid and splenic tissue, and agammaglobulinemia [54]. Histological examination of the bone marrow, spleen and lymphoid tissue reveals normal reticular structure with normal erythroid and megakaryocyte elements, but with absent or sparse myeloid cells. The mechanism of the disorder is unknown, but a defect in lymphohematopoietic progenitor cell development is suspected [55]. Bacterial and viral infections occur early in life and are severe. Aggressive antibiotic therapy and supportive care are necessary for survival. Treatment with G-CSF and GM-CSF have been ineffective. Bone marrow transplantation remains the only long-term treatment option available for infants with this disorder [54, 56].

105.2.4.3 Dyskeratosis Congenita

Dyskeratosis congenita (DC) is an inherited bone marrow failure syndrome clinically characterized by the triad of abnormal nails, reticular skin pigmentation, and oral leukoplakia, and is associated with high risk of developing aplastic anemia, myelodysplastic syndrome, leukemia, and solid tumors. Patients have very short germline telomeres, and approximately half have mutations in one of six genes encoding proteins that maintain telomere function. Accurate diagnosis of DC is critical to ensure proper clinical management, because patients who have DC and bone marrow failure do not respond to immunosuppressive therapy and may have increased morbidity and mortality associated with hematopoietic stem cell transplantation [57].

105.2.4.4 Leukocyte Adhesion Deficiency Type I

Leukocyte adhesion deficiency (LAD) encompasses a rare group of autosomal recessive disorders [58]. LAD type I is associated with defects in neutrophil adhesion and chemotaxis resulting in impaired clearance of complement-opsonized microorganisms. Infants present with delayed separation of the umbilical cord and recurrent infections despite a normal or increased neutrophil count. LAD should be suspected in any

infant with unusually severe bacterial infections accompanied by normal or increased circulating neutrophils and a striking absence of purulent material at the site of infections.

The clinical presentation varies depending on the relative deficiency of CD18. CD18 is the β_2-subunit of the cell surface leukocyte integrin. These molecules are involved in adherence, chemotaxis, C3bi-mediated ingestion, degranulation, and neutrophil respiratory burst. Diagnosis of LAD type I is made by demonstration of a severe deficiency of the β_2-subunit of neutrophil integrins. Carriers can be identified as having about 50% of the normal β_2-subunit levels in circulating neutrophils, whereas affected individuals express 0–10% levels. α/β-Integrins are common on the surface of all neutrophils and make up three distinct cell surface proteins: LFA-1 ($\alpha_1\beta_2$), MAC-1 ($\alpha_m\beta_2$) and P150, 95 ($\alpha_x\beta_2$). Each of these integrins are affected because they require a common β_2-subunit that is diminished in quantity or functionally defective. Several mutations have been identified in the gene coding for the β_2-subunit. These mutations fall into several categories in which there are absent, low or normal level of CD18 mRNA and in which the β_2-subunit protein precursor is absent, low in abundance or abnormal in size. There is a close genotype-phenotype correlation between the molecular defect and the clinical severity of disease.

Leukocyte trafficking from bloodstream to tissue is important for the continuous surveillance for foreign antigens as well as for rapid leukocyte accumulation at sites of inflammatory response or tissue injury. Leukocyte interaction with vascular endothelial cells is a pivotal event in the inflammatory response and is mediated by several families of adhesion molecules. The crucial role of the beta(2)-integrin subfamily in leukocyte emigration was established after LAD type I was discovered. Patients with this disorder suffer from life-threatening bacterial infections, and, in its severe form, death usually occurs in early childhood unless bone marrow transplantation is performed.

The LAD type II disorder (described in more detail below) clarifies the role of the selectin receptors and their fucosylated ligands and patients have a less severe form of infectious episodes (resembling the moderate phenotype of LAD type I) but also severe psychomotor and growth retardation. LAD type III emphasizes the importance of the integrin-activation phase in the adhesion cascade and all hematopoietic integrin activation processes are defective, leading to severe infection as observed in LAD type I and to an increased tendency for bleeding problems due to defective activation of beta(1), beta(2), and beta(3) integrins [58].

105.2.4.5 Leukocyte Adhesion Deficiency Type II

LAD type II is a rare autosomal recessive clinical syndrome involving recurrent bacterial infections, short stature, severe mental retardation, and the hh (Bombay) RBC phenotype. Neutrophils from patients affected with this disorder exhibit markedly diminished chemotaxis *in vitro*, although the neutrophils display normal levels of CD18 and are able to ingest serum-opsonized particles. The molecular defect in these patients is a defect in the fucosyltransferase gene responsible for the carbohydrate linkages associated with the AB blood groups, specifically the sialyl-Lewis X structure. Neutrophil function is defective in these individuals because sialyl-Lewis X is the neutrophil cell surface ligand recognized by endothelial cell surface E-selectin and P-selectin receptors [59].

105.2.4.6 Chediak-Higashi Syndrome

Chediak-Higashi syndrome is a rare, autosomal recessive disorder characterized by the presence of giant cytoplasmic granules in multiple cells throughout the body. The syndrome affects neutrophil and lymphocyte function [60]. Defects in the CHS1 gene family have been implicated in the causation of this disorder. These genes encode proteins involved in vesicular trafficking although the precise function of these proteins is uncertain. Neutrophils display abnormal adherence and chemotaxis, delayed degranulation, and impaired ingestion and killing of microorganisms. Patients with this syndrome are highly susceptible to bacterial infections. Most patients with Chediak-Higashi syndrome exhibit lymphohistiocytic infiltration of multiple organs that appears to result from a lack of natural killer cell function. Death often occurs in the first decade of life from infection, bleeding, or lymphohistiocytic infiltration. Bone marrow transplantation can be effective in treating the hematopoietic complications of Chediak-Higashi syndrome.

105.2.4.7 Chronic Granulomatous Disease

Chronic granulomatous disease (CGD) is an inherited immunodeficiency syndrome in which generation of superoxide by the respiratory burst oxidase of phagocytic leukocytes is markedly diminished or absent [61]. The disorder, which has an incidence of approximately one per 500,000 individuals, results from mutations in any one of four essential subunits of the respiratory burst complex. Superoxide generated during the respiratory burst is the precursor for a number of potent oxidants that are important in elimination of many microbial pathogens. Approximately two thirds of CGD cases are caused by defects in the X-linked gene encoding gp91-phox, the large subunit of the flavocytochrome b_{588}, a plasma membrane heterodimer that is the redox center of the phagocyte oxidase [61, 62]. A rare autosomal recessive form of CGD is caused by mutations in the gene encoding the small subunit of the p22-phox flavocytochrome b_{588}. Other cases of autosomal recessive CGD are caused by gene defects in two soluble proteins that interact with flavocytochrome b_{588}, p47-phox or p67-phox.

The clinical manifestations of CGD are apparent during infancy or early childhood [61–64]. Patients with CGD

experience recurrent purulent bacterial and fungal infections that are difficult to treat and often may be life threatening. Common sites of infection are skin, lymph nodes, lungs, bones, liver, and the gastrointestinal tract. Individuals with CGD are particularly susceptible to infections with *S. aureus*, a variety of gram-negative bacilli including *Pseudomonas*, *Salmonella*, and *Serratia* species and fungus such as *Aspergillus* species. Many of these microorganisms express catalase, which prevents phagocytes of CGD patients from scavenging microbe-generated hydrogen peroxide to promote microbial killing within the phagosome. The hallmark of CGD is the propensity to develop chronic inflammatory granulomas with wide spread tissue distribution [63, 65].

The prognosis for individuals with CGD has improved significantly since the disorder was first described in the 1950's. Current management includes aggressive treatment of acute infections in combination with the use of prophylactic antibiotics and interferon-γ (IFN-γ) [66, 67]. Allogenic bone marrow transplantation can be curative even in cases where transplantation results in mixed chimerism [68–70].

Because the genetic defect of CGD primarily affects cells of the hematopoietic system, this disorder has been considered a prime candidate for gene therapy targeted at hematopoietic stem cells [71]. Insertion of a functional copy of the involved gene into hematopoietic stem cells should reconstitute the respiratory burst oxidase activity in circulating and tissue phagocytes and thus could provide a life-long cure of the disease.

105.2.4.8 Autoimmune Neonatal Neutropenia

Autoimmune neutropenia (AIN) is a disorder caused by increased destruction of neutrophils as a result of autoantibodies to the patient's own neutrophils. The incidence is approximately one per 100,000 live births [72]. Primary AIN is not associated with other autoimmune disorders such as systemic lupus erythematosus. While this disorder was definitively identified in 1975, its cause has not been identified [73, 74]. Reports of associations with parvovirus B19 and beta-lactam antibiotics suggest mechanisms such as development of cross-reacting antibodies resulting from molecular mimicry, changes in endogenous antigens, enhanced HLA expression, or loss of suppression of self-reacting lymphocyte clones. HNA-1a (NA-1) autoimmunization has been linked to HLA-DR2, a finding implicating immune response genes [2]. Patients with this immune mediated neutropenia present in the first 3 years of life with a variety of infections. In approximately 80% of patients the infections are mild, consisting of abscesses, conjunctivitis, gastroenteritis, otitis media, pyoderma, and upper respiratory infections. In the remaining cases, AIN predisposes to serious infections such as meningitis, pneumonia, and sepsis [75]. Diagnosis of AIN is made by detection of neutrophil-specific antibodies. Although patients with AIN do not generally require specific treatment for neutropenia, to increase neutrophil counts in cases of severe infection or before elective surgery, some patients have been treated with corticosteroids, IVIG or G-CSF. Corticosteroids and IVIG increased neutrophil counts in about 50% of individuals, whereas G-CSF increased neutrophil counts in all patients treated. Infections are treated symptomatically with antibiotics. Infants with recurrent infections are often treated with prophylactic antibiotics.

105.2.5 Clinical Aspects

Classification of leukocyte abnormalities according to the underlying kinetic mechanism can provide useful clues for diagnosis and management of affected infants. The complete blood count and differential white count provides an estimate of the responsible kinetic mechanism by determining the degree of left shift, or the ratio of immature to total neutrophils in the blood. Neutropenia accompanied by a large left shift is likely to be on the kinetic basis of accelerated neutrophil destruction or usage [44, 76]. A large left shift is defined as a ratio of immature (band neutrophils or metamyelocytes) to total neutrophils of greater than 0.3. By contrast, neutropenias in which only mature neutrophils are observed in the blood are more likely to be on the kinetic basis of diminished neutrophil production or excessive margination [49, 77–79].

The variety of leukocyte abnormality is often suggested by associated findings (Table 105.3). For instance, neutropenia in an infant with intrauterine growth restriction delivered to a mother with hypertension, is likely to have neutropenia based on diminished neutrophil production, as commonly seen in that condition [49, 78]. The presence of neutropenia in the mother of an infant with neutropenia should prompt evaluation for maternal autoimmune antibodies causing immune-mediated neutrophil destruction. The presence of steatorrhea in a neutropenic neonate should prompt consideration of Shwachman-Diamond syndrome [80–82]. Severe and prolonged neutropenia, with counts typically less than 200 cells per microliter associated with monocytosis and eosinophilia

Table 105.3 Associated findings in newborn patients with leukocyte abnormalities that can suggest a specific disorder

Associated Finding	Variety of Leukocyte Abnormality
Albinism	Chediak-Higashi syndrome
Anemia and multiple gestation	Donor in twin-twin transfusion
Blueberry muffin rash	Congenital cytomegalovirus
Down syndrome	Leukemoid reaction
Hydrops	Rh hemolytic disease
Monocytosis and eosinophilia	Kostmann syndrome
Mother with hypertension	Neutropenia of PIH
Mother with neutropenia	Maternal autoimmune neutropenia
Pancytopenia	Reticular dysgenesis
Shock	Endotoxemia or sepsis
Steatorrhea	Shwachman-Diamond syndrome

on peripheral blood smear is seen in Kostmann syndrome where bone marrow examination is characterized by arrested neutrophil development at the promyelocyte or myelocyte stage [83, 84]. Neutrophilia with immature circulating myeloid elements in a stable infant with Down syndrome should prompt long-term follow-up because, although the neutrophilia is generally transient, up to 30% of these infants may develop leukemia later in childhood [85]. Neutrophilia or neutropenia with a left shift in conjunction with clinical signs of shock will prompt early and aggressive antibiotic treatment and supportive care in addition to investigation to identify the causative microbial agent. An association of neutrophilia and the presence of a "blueberry muffin rash", which is often indicative of extramedullary hematopoiesis, might prompt evaluation for congenital viral infections such as cytomegalovirus (CMV).

105.2.6 Differential Diagnosis

When evaluating a neonate with leukocyte abnormalities it can be helpful to maintain the perspective that some varieties of these abnormalities are common and others are exceedingly rare. The most common causes of leukocyte abnormalities among infants have an obvious underlying cause. One form of neutropenia, where there is a large left shift or an immature to total neutrophil ratio exceeding 0.3–0.5, accompanies overwhelming sepsis. However, another form of neutropenia (generally with no left shift or an immature to total neutrophil ratio of less than 0.2) occurs in infants with intrauterine growth restriction born to a woman with pregnancy-induced hypertension. In general these common varieties of neutropenia do not require additional investigations. Neutropenia accompanying sepsis resolves quickly if the patient survives. However, if neutropenia in the infant with sepsis persists for several days, additional investigations should be considered. Similarly, in most cases of neutropenia accompanying pregnancy-induced hypertension, neutropenia resolves within 5 days. If neutropenia persists for more than 5 days additional investigations may be considered, particularly if the neutrophil count is less than 500 cells per microliter.

Laboratory tests to be considered are those that provide a specific diagnosis, such as alloimmune or autoimmune neutropenia. These tests, while not diagnostic, are required to investigate rare forms of neutropenia such as congenital and cyclic neutropenia. Obtaining a complete blood count on the infant, including microscopic examination of neutrophil morphology, can be useful in identifying features such as left shift, monoytosis, eosinophilia, and the presence of cytoplasmic inclusions formed by fused lysosomes. Monocytosis and eosinophilia are commonly observed in patients with congenital neutropenia and cytoplasmic inclusions and are characteristic of Chediak-Higashi syndrome [60]. Also, a complete blood count on the mother to establish her neutrophil concentration can be useful to detect cases of autoimmune neutropenia in which mother has immune-mediated neutropenia, which is passively acquired by the fetus. Maternal and infant neutrophil antigen typing and anti-neutrophil antibody determination should identify most cases of immune-mediated neutropenia.

To evaluate neonatal immune mediated neutropenia, antibody testing is performed on both maternal and infant blood samples including two screening tests: 1) a neutrophil agglutination assay and 2) a granulocyte immunofluorescence assay. If either assay is positive, an HLA screen is performed because HLA antibodies can react with neutrophil assays and it cannot be determined whether the antibody is neutrophil specific or HLA related. When this occurs, an additional test with antigen capture assay is used. In this assay, monoclonal antibody immobilization of neutrophil antigens is done to differentiate between neutrophil antigen-specific antibodies from HLA antibodies [86, 87]. This assay can detect more than one neutrophil antigen-specific antibody.

A bone marrow study may be useful for patients with severe and prolonged neutropenia in whom isoimmune and maternal autoimmune neutropenia have been excluded. Bone marrow aspirate or biopsy may suggest the kinetic mechanism underlying the neutropenia by estimation of proliferative myeloid cells compared to postmitotic myeloid cells. For example, when neutropenia is caused by diminished neutrophil production, the proliferative compartment is decreased. In accelerated neutrophil usage or destruction, the proliferative compartment responds by expanding production. In addition, mature neutrophils are rapidly released into the peripheral blood, simulating a maturational arrest or decreased postmitotic pool. Despite its usefulness in narrowing the differential diagnosis, bone marrow studies almost never provide a precise diagnosis. For instance, no pathognomonic feature of bone marrow biopsy discriminates completely between hyporegenerative neutropenias in the neonatal period such as between neutropenia associated with maternal hypertension or Shwachman-Diamond syndrome. In a few instances, there are useful morphological clues in the bone marrow. For example, congenital neutropenia syndrome is suggested by enlargement and binucleation of promyelocytes and other myeloid precursors [84]. In autoimmune neutropenia, the bone marrow may contain macrophages with ingested antibody-coated neutrophils.

Neutrophil counts vary considerably early in the neonatal period with a mean of about 11,000 cells per microliter and a range between 6000 and 26,000 cells per microliter [3]. After the first 12 hours of life, neutrophil counts fall reaching a mean of 5000 cells per microliter (ranging from 1000 to 10,000 cells per microliter). Neutrophilia, defined as an elevation of the circulating absolute neutrophil count more than two standard deviations above the mean, may occur in response to both bacterial and viral infections, stress (post-operative or after seizures), or in conjunction with hemolytic anemia or immune thrombocytopenia. Occasionally, newborn infants exhibit an exaggerated response to infection with a significant increase in total WBC count (50,000 cells per

microliter) and increased early myeloid precursors in the peripheral blood, termed a leukemoid reaction [88]. The leukemoid reaction observed with a severe infection is often accompanied by cytoplasmic vacuoles within neutrophils and by the appearance of toxic granulations. The duration of the reaction ranges from days to weeks. Approximately 10% of infants with Down syndrome may have a transient leukemoid reaction that resembles congenital leukemia [85]. It is characterized by the presence of megakaryoblasts in the peripheral blood, hepatosplenomegaly, variable thrombocytopenia and infrequently hydrops fetalis and severe hepatic fibrosis. Abnormalities in all three hematopoietic lineages have been described. In most cases the leukemoid reaction is transient, although up to 30% of infants with Down syndrome infants who experience a neonatal leukemoid reaction develop acute megaloblastic leukemia later in childhood [85]. Leukaemoid reactions have also been reported in phenotypically normal infants who have trisomy 21 mosaicism associated with a clonal trisomy 21 in bone marrow cells [89, 90].

105.2.7 Prognosis

105.2.7.1 Infection

Infection remains a major cause of illness and death in the neonatal period [91, 92]. Newborn babies have an immature immune system and therefore may not show all signs of infection, and delayed treatment may lead to severe illness or death [93, 94]. Early treatment with antibiotics has been shown to reduce mortality due to sepsis in the neonatal period. Early treatment depends on a knowledge of risk factors and picking up early signs of infection [93, 94], which tend to be non-specific in this age group [95].

Although advances in neonatal intensive care have led to improved survival of very low birth weight (VLBW) and extremely premature infants, late onset sepsis (systemic infection after 48 hours of age) continues to be a significant cause of morbidity and mortality. The incidence of late onset sepsis increases with both decreasing birthweight and gestational age, and has been reported as occurring in approximately 25% of VLBW infants [96, 97]. Infants with the lowest birth weights are also more likely to have multiple episodes of sepsis [96]. In developing countries infection is estimated to cause 30–40% of neonatal deaths [98]. The spectrum of organisms responsible for early onset (vertically transmitted) sepsis differs from that associated with late onset (nosocomial) sepsis. This pattern becomes apparent from day two onwards [99]. Nosocomial infections are frequently associated with clinical deterioration including increased frequency of apnea or ventilatory requirements, temperature instability, abdominal distension, acidosis, lethargy, septic shock, necrotizing enterocolitis, meningitis and death [100]. The complications of necrotising enterocolitis and meningitis predispose an infant to an increased risk of future neurological impairment [101–103] and the mortality from late onset sepsis remains high, at 7–10% [96, 99]. This risk is secondary to immature immune responses, poorly developed skin and mucosal barriers to infection, numerous entry portals for organisms via cannulae, catheters and endotracheal tubes and continuing exposure to opportunistic organisms during a hospital stay, which is often prolonged.

105.2.7.2 Associated Abnormalities and Malignant Transformation

Congenital bone marrow disorders manifest by leukocyte defects are often associated with other congenital abnormalities. For instance, infants with Down syndrome may present with a variety of abnormalities in non-hematopoietic organ systems including cardiac and gastrointestinal malformations. Infants with Shwachman-Diamond syndrome exhibit exocrine pancreatic disorders and short stature. Barth syndrome is a mitochondrial disorder with associated development of cardiomyopathy and acidoisis. A predisposition to hematologic malignancy, in particular acute myelogenous leukemia (AML), is common among several of these disorders. It is postulated that the genetic disorder underlying these conditions provides a first hit expressed as variety of physical abnormalities, and a second hit later in life causes malignant transformation [104]. Downs syndrome, dyskeratosis congenita, Kostmann syndrome, and Shwachman-Diamond syndrome are among the syndromes associated with malignant transformation. Chronic granulomatous disease and cyclic neutropenia are not associated with malignant transformation.

105.2.8 Therapy and Treatment

105.2.8.1 Antibiotics

Early neonatal sepsis is mainly acquired from the mother. Vertical transmission of infection from mother to infant may take place before birth, during labor, or at the time of delivery. Most infants with peripartum acquired sepsis will develop clinical symptoms of sepsis within two days of life. After this period, nosocomial and community acquired infections start to play a bigger role.

The bacteria most commonly implicated in early neonatal sepsis are Group B *Streptococcus* and Gram-negative bacilli, and usually exclude coagulase negative *Staphylococcus*. Neonatal intensive care units or special care baby units tend to choose empirical first line antibiotic therapy that will cover both Gram-negative and Gram-positive bacteria. A combination of an aminoglycoside such as gentamicin and a beta-lactam such as penicillin has been the treatment of choice for early neonatal sepsis.

The range of organisms causing late onset sepsis includes gram positive and gram negative bacteria as well as fungal infection. As bacterial infections predominate, empiric antibiotic regimens focus on cover for both gram positive and negative bacterial infection. These antibiotics can be either narrow or broad spectrum in the range of organisms that they target. The epidemiology of late onset infection differs between developing and developed countries in the incidence of infection, the organisms responsible, and the subsequent mortality rates.

In general, prophylactic antibiotics are recommended for children with chemotherapy-induced neutropenia and children with chronic neutropenic conditions whose neutrophil count is less than 500 cells per microliter until recombinant G-CSF administration raises the neutrophil count to greater than 1000 cells per microliter [105, 106]. Broad use of prophylactic antibiotics for neutropenic neonates is not recommended because in most cases neutropenia is of limited duration and the general use of antibiotics may contribute to the emergence of bacteria with high antibiotic resistance. Individualization of care to include prophylactic antibiotics might be considered for an infant with severe neutropenia (500 cells per microliter) continuing for several days and requiring treatment with G-CSF to increase the neutrophil count above 1000 cells per microliter. Prophylactic antibiotics might also be considered for an infant with severe prolonged neutropenia who is unresponsive to G-CSF treatment. The precise antibiotics used in such cases should be selected based on the local nursery bacterial epidemiology.

105.2.8.2 Granulocyte Transfusions

The availability of new generations of effective antibiotics, recombinant hematopoietic growth factors to counter neutropenia, the risk of transmission of infection and the necessity for appropriate technology are some of the factors that have diminished the enthusiasm for use of granulocyte transfusions in neonates [107]. While there has been a resurgence of interest in enthusiasm for granulocyte transfusions in neutropenic patients, especially in patients with cancer, no recent studies have been conducted in newborn infants [108–112].

A recent systematic review evaluated the role of granulocyte transfusions as an adjunct to antibiotics in the treatment of neutropenic septic newborns [113]. This review included four eligible trials conducted on a small number of randomized infants [114–117].

There was no significant difference in mortality due to any cause during hospitalization in infants with sepsis and neutropenia who received granulocyte transfusions when compared with placebo or no granulocyte transfusion. In a single study by Cairo and coworkers, a reduction in all-cause mortality during hospital stay of borderline statistical significance, was observed when granulocyte transfusions were compared to intravenous immunoglobulin [117].

Granulocyte concentrates used for transfusion have potential adverse effects, including pulmonary complications, transmission of infections, fluid overload and graft versus host disease. Preparation of granulocytes for transfusion requires technical expertise and this is not universally available. Even among centers where it is available, there may be a delay in the procurement and transfusion of granulocytes after a decision to transfuse has been made. This delay may potentially render these transfusions of granulocytes less effective for neonates with neutropenia and sepsis.

105.2.8.3 IVIG

IVIG for Preventing Infection in Preterm and/or Low Birth Weight Infants

Administration of intravenous immunoglobulin provides IgG that can bind to cell surface receptors, provide opsonic activity, activate complement, and promote antibody dependent cytotoxicity. Intravenous immunoglobulin thus has the potential of preventing or altering the course of nosocomial infections. Ohlsson and Lacy conducted a systematic review to assess the effectiveness and safety of intravenous immunoglobulin (IVIG) administration compared to placebo or no intervention to preterm and/or low birth weight (LBW, less than 2500 gram birth weight) infants in preventing nosocomial infections [118]. Nineteen studies were included in this review, the most recent trial being in 2000. These included approximately 5000 preterm and/or LBW infants. Among qualifying studies the quantity of IVIG per dose varied widely from 120 mg/kg [119] to 1 g/kg [120]. Also, the number of doses varied from a single dose [119, 121–124] to seven doses [125]. Several different IVIG preparations were used. When all studies were combined the meta-analysis indicated that IVIG administration resulted in a 3% reduction in sepsis and a 4% reduction in any serious infection, one or more episodes, but was not associated with reductions in other important outcomes: sepsis, necrotizing enterocolitis, intraventricular hemorrhage, or length of hospital stay. Most importantly, IVIG administration did not have any significant effect on mortality from any cause or from infections. Prophylactic use of IVIG was not associated with any short-term serious side effects. From a clinical perspective the small reduction in nosocomial infections without a reduction in mortality or other important clinical outcomes is felt to be of marginal importance.

Antistaphylococcal Immunoglobulins to Prevent Staphylococcal Infection in Very Low Birth Weight Infants

Nosocomial infection continues to be a major problem affecting the immediate health and long-term outcome of preterm and very low birth weight neonates. More than half of these infections are caused by staphylococci. Various type specific

antibodies targeted at different antigenic markers of *Staphylococcus* have been developed and have shown promise in animal studies.

Shah and Kaufman conducted a systematic review to evaluate the efficacy and safety of anti-staphylococcal immunoglobulins in the prevention of Staphylococcal infection in very low birth weight infants [126]. Three eligible studies were included testing two different anti-staphylococcal immunoglobulin products. Two studies [127, 128] used pooled generic anti-staphylococcal immunoglobulin (INH-A21) and the third study [129] used antibody against type 5 and type 8 capsular polysaccharide antigen (Altastaph). These studies enrolled a total of 2,701 neonates. No significant differences were noted in the risk of staphylococcal infection or the risk of any infection between INH-A21 and placebo or Altastaph versus placebo. Furthermore, no significant differences were observed in the incidence of chronic lung disease, patent ductus arteriosus, necrotizing enterocolitis, intraventricular hemorrhage, retinopathy of prematurity or duration of antibiotic and vancomycin use. At the present time, anti-staphylococcal immunoglobulins (INH A-21 and Altastaph) are not recommended for prevention of staphylococcal infections in preterm or VLBW neonates. Further research to investigate the efficacy of other anti-staphylococcal products such as Pagibaximab under development may be forthcoming in the future.

IVIG for Treatment of Infections in Neonates

Ohlsson and Lacy conducted a systematic review to assess the effectiveness of intravenous immunoglobulin (IVIG) in reducing mortality and morbidity caused by suspected and proven infection in newborn infants [130]. Five hundred fifty three neonates with suspected infection were enrolled in randomized clinical trials in seven countries to evaluate the effect of IVIG on neonatal outcomes [131–138]. Six studies enrolling 318 infants reported on the outcome of mortality for randomized patients with clinically suspected infection. Results of the meta-analysis showed a reduction in mortality following IVIG treatment of borderline statistical significance. Treatment with IVIG (seven trials, n = 262) in cases of subsequently proven infection resulted in statistically significant reduction in mortality. There is insufficient evidence to support the routine administration of IVIG preparations investigated to prevent mortality in infants with suspected or subsequently proved neonatal infection. Moreover, well-designed trials will be required to confirm or refute the effectiveness of IVIG to reduce adverse outcomes in neonates with suspected infection.

105.2.8.4 G-CSF and GM-CSF

In the United States, G-CSF is approved for use by the Food and Drug Administration for use in patients with severe chronic neutropenia, cancer patients receiving myelo-suppresive chemotherapy, cancer patients receiving bone marrow transplantation and patients undergoing peripheral blood hematopoietic stem cell collection. Patients with severe chronic neutropenia generally derive considerable benefit from G-CSF administration. Varieties of neutropenia in neonates for which G-CSF treatment is effective are Kostmann syndrome, Shwachman-Diamond syndrome, cyclic neutropenia, and alloimmune neutropenia.

105.2.8.5 Bone Marrow and Hematopoietic Stem Cell Transplantation

Hematopoietic stem cell transplantation remains the only available treatment for patients with congenital neutropenia refractory to G-CSF treatment. Absence of response to G-CSF, G-CSF receptor mutation, and leukemic transformation are absolute indications for hematopoietic stem cell transplantation if a suitable donor is available. Pulmonary mycosis and pulmonary abscesses do not represent absolute contraindications to bone marrow transplantation, although a relapse rate of 30–50% for mycosis has been reported, despite adequate medical and surgical treatment [139, 140].

G-CSF has had a major impact on the management of severe congenital neutropenia, cyclic neutropenia, and Shwachman-Diamond syndrome. Almost all patients respond to G-CSF with increased neutrophils, reduced infections, and improved survival. Some responders with congenital neutropenia and Shwachman-Diamond syndrome have developed myelodysplastic syndrome and acute myeloid leukemia, which raises the question of the role of G-CSF in pathogenesis. The issue is complicated because both disorders have a propensity for myelodysplastic syndrome or acute myeloid leukemia as part of their natural history. To address this, the Severe Chronic Neutropenia International Registry used its large database of chronic neutropenia patients treated with G-CSF to determine the incidence of malignant myeloid transformation in the two disorders, and its relationship to treatment and to other patient characteristics. No statistically significant relationships were found between age at onset of myelodysplastic syndrome or acute myeloid leukaemia and patient gender, G-CSF dose, or duration of G-CSF therapy. What was observed, however, was the multistep acquisition of aberrant cellular genetic changes in marrow cells from patients who transformed, including activating ras oncogene mutations, clonal cytogenetic abnormalities, and G-CSF receptor mutations.

In murine models, G-CSF receptor mutation produces a hyperproliferative response to G-CSF, confers resistance to apoptosis, and enhances cell survival. Since congenital neutropenia and Shwachman-Diamond syndrome are inherited forms of bone marrow failure, G-CSF may accelerate the propensity for myelodysplastic syndrome and acute myeloid leukaemia in the genetically altered stem and progenitor cells,

especially in those with G-CSF receptor and ras mutations (82% and 50% of patients who transform, respectively). Alternatively, and equally plausible, G-CSF may simply correct neutropenia, prolong patient survival, and thus allows time for the malignant predisposition to declare itself. In patients who transform to overt myelodysplastic syndrome or acute myeloid leukemia, hematopoietic stem cell transplantation is the only chance for cure. In those with an isolated clonal cytogenetic change, but without other evidence of myelodysplastic syndrome, or with an isolated G-CSF receptor mutation, there is room for conservative management. One option is to reduce the G-CSF dosage as much as possible, and observe progression, if any, to more overt signs of malignancy [141].

Reticular dysgenesis is a very rare congenital immunodeficiency classified within the severe combined immunodeficiencies and characterized by impairment of both lymphoid and myeloid cell development. Bertrand and colleagues reported 10 patients with reticular dysgenesis, treated with HLA-haploidentical hematopoietic stem cell transplantation. All children but one were symptomatic within the first days of their lives. Five patients required two hematopoietic stem cell transplants. Five patients received conditioning therapy with busulfan and cyclophosphamide. Three of them survived with myeloid and T- and B-cell lymphoid reconstitution, whereas two patients died (one chronic graft-versus-host disease, one pneumonitis). Transplantation without or with other conditioning regimens in the other five cases led to absent or incomplete engraftment and none of these cases survived. These results demonstrated the importance of intensive conditioning before haploidentical hematopoietic stem cell transplantation in reticular dysgenesis to achieve full lymphoid and myeloid engraftment [54, 56].

Curently allogenic hemopoietic stem cell transplant is the only curative treatment available for severe congenital neutropenia, leukocyte adhesion deficiency, and chronic granulomatous disease [142].

105.2.8.6 Gene Therapy

Chronic granulomatous disease is a rare congenital disorder resulting from a failure of neutrophils to produce oxidases. Patients are therefore prone to recurrent infections from various organisms including fungi and atypical bacteria. The mortality in patients with the X-linked form of chronic granulomatous disease, the most common type, ranges from 3% to 5% per year and although management of infections has improved with advances in antimicrobial therapies, better methods are needed to cure these patients. Peripheral blood stem cell or bone marrow transplantation, while curative, is not widely used due to the episodic nature of the infections and the belief by many that conservative management is preferable to the risks of transplantation [143]. Still, as will be discussed, improvements in the field are making allogenic transplantation more desirable and tilting the risk benefit ratio in favor of this modality. Additionally, gene therapy, which has been considered a possible method to cure chronic granulomatous disease, has within the last 5–10 years become more and more of a reality and may be realized in the not to distant future [144, 145].

Neonatal Hereditary Neutropenia

Gaetano Chirico and Carmelita D'Ippolito

106.1 Introduction

Hereditary neutropenia includes many disorders of distinct origin and variable prognosis, characterized by a reduction of the absolute neutrophil count (ANC) that predisposes patients to bacterial infections, in particular pyogenic infections, such as cutaneous cellulitis, deep abscesses, pneumonia and sepsis [1, 2]. Susceptibility to bacterial infections, even in patients with severe neutropenia, can be quite variable, depending on the underlying etiology. Congenital neutropenia my be associated with extraematopoietic manifestations.

106.2 Severe Congenital Neutropenia (SCN)

In 1956 Kostmann described congenital neutropenia as an autosomal recessive disease in a large intermarried Swedish family. The incidence is estimated to be approximately 2 cases per million of the population [1]. Affected patients regularly have episodes of fever, skin infections, stomatitis, pneumonia and perirectal abscesses that usually begin in the first months of life and lead to death during infancy and childhood. The ANC is less than 0.2×10^9 cells/L. Eosinophylia, monocytosis and splenomegaly may be present.

The bone marrow examination reveals the typical arrest of the myeloid cell differentiation at the promyelocytic stage with a marked depletion of mature neutrophils [1, 3].

Recent studies on the genetic basis of SCN have detected mutation in the leucocyte elastase gene, *ELA2*, a gene defect that is inherited as an autosomal dominant trait in about 60–80% of patients [4], a gene defect that is inherited as an autosomal dominant trait. *ELA2* encodes a serine protease synthesized during the promyelocyte/myelocyte stage, which is stored in the primary granules [4]. Correct localization of the neutrophil elastase (NE) in the primary granules requires interaction of NE with the adaptor protein complex AP3 that shuttles transmembrane cargo proteins from the Golgi network to the lysosomes. Most mutations in *ELA2* remove the tyrosine-based recognition sequence for the AP3μ subunit, thereby favoring the misallocation of the enzyme to the membrane instead of inside the granules. It was proposed that mislocalized NE must drastically reduce the production of neutrophils from the myeloid progenitor cells in favor of monocytes.

The introduction of hematopoietic growth factors has greatly improved both life span and quality of life [5]. However, patients with SCN have a heterogeneous response to G-CSF therapy and often require a gradual increase of the dosage that generally ranges from 11 to 13 μg/kg/die. In addition 3–5% of SCN patients are refractory to G-CSF treatment.

Finally a significant number of children who are receiving G-CSF therapy are developing myelodysplastic syndrome (MDS) or acute myeloid leukemia (AML), the overall risk being between 9 and 13% [3]. The exact relationship between G-CSF treatment and the risk of leukemic transformation is still unclear [5]. A subset of SCN patients, namely those with more severe disease, are more prone to develop MDS, AML or both, probably because of exposure to other leukemogenic factors such as monosomy of chromosome 7, alterations of chromosome 21, activating mutations of the oncogene *ras*, and mutation in the G-CSF receptor (*CSF3R*) [5].

In the light of this finding G-CSF treatment seams a safe option for the vast majority of patients with neutropenia, while patients at risk for leukemic transformation would benefit from hematopoietic stem cell transplantation.

106.3 Cyclic Neutropenia

Cyclic neutropenia is an autosomal dominant or sporadic condition, characterized by periodic episodes of severe neutropenia with a nadir of less than 0.2×10^9 cells/L, that occur usually every 21 days [6].

G. Chirico (✉)
Neonatology and Neonatal Intensive Care Unit
Spedali Civili Hospital, Brescia, Italy

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

The neutropenic periods persist for 3–5 days and are accompanied by malaise, fever, gingivitis, oral ulcers and lymphoadenopathy. There are also regular oscillations of the other leukocyte subsets, reticulocytes and platelets. Symptoms begin during the first year of life, are often milder after puberty and are usually less severe than in SCN [3, 4, 6] even though fatal *Clostridium* bacteremia has been reported in untreated patients [3]. A variety of studies suggest that cyclic neutropenia occurs because of a periodic disruption in cell production in the bone marrow [3]. And it has recently been shown that a heterozygous mutation of *ELA2* is the genetic cause of the disease. The mutations reported in cyclic neutropenia are located in the same gene associated with SCN, but in different exons resulting in preferential accumulation of NE in granules – an example of genotype/phenotype correlation.

In the management of those patients the use of prophylactic G-CSF treatment is recommended, it has been very effective in improving peripheral blood neutrophil counts and avoids symptoms and infections [5]. The dose of G-CSF required is usually lower than in SNC: 2–3 μg/kg/die or on alternate days, the occurrence of MDS or leukemia has not been reported in patients with cyclic neutropenia [5].

106.4 Myelocathexis and WHIM Syndrome

Myelocathexis is a rare autosomal dominant disorder characterized by moderate to severe chronic neutropenia resulting from the retention of mature neutrophils in the bone marrow.

Myelocathexis is often associated with hypogammaglobulinemia, leucopenia and warts, a clinical picture recognized as WHIM syndrome (warts, hypogammaglobulinemia, infections, myelokathexis) [7], an autosomal dominant disease.

In WHIM syndrome ANCs are usually $<0.5\times10^9$/L, but during infectious episodes their number rises suddenly, allowing a more benign course with recurrent mild respiratory infections. Early death related to infections has not been reported. Recent studies showed that WHIM syndrome is caused by heterozygous mutations in the gene coding for the chemokine receptor CXCR4. Cells expressing the mutated CXCR4 have an increased responsiveness to chemokines and thus are not released from the bone marrow to the circulating blood pool [7]. The neutropenia associated with myelocathexis and WHIM is only partially corrected by administration of G-CSF [8].

106.5 Congenital Neutropenia with Extra Hematopoietic Manifestations

106.5.1 Hermansky-Pudlak Syndrome 2

This autosomal recessive disease is characterized by neutropenia, oculocutaneous albinism and moderate bleeding disorders [9]. It is caused by mutations of the gene encoding for the beta3 component of the AP3 complex, again preventing the transport of NE (and other proteins) from the Golgi network to the lysosomes in hematopoietic cells and in melanocytes [9].

The severe neutropenia is responsive to G-CSF treatment.

106.5.2 Shwachman-Diamond Syndrome

The Shwachman-Diamond syndrome (SDS) is a rare multiorgan disease inherited as an autosomal recessive trait that combines neutropenia, exocrine pancreatic insufficiency, skeletal abnormalities and short stature [10].

The symptoms begin early in infancy with bacterical infections (pneumonia, otitis media, osteomyelitis, skin infections, sepsis) and failure to thrive because of intestinal malabsorption.

Chronic neutropenia is constantly observed in all patients and two thirds of them have a neutrophil count less than 1×10^9 cells/L, so while the neutropenia can be intermittent it is never cyclic. Mild anemia and thrombocytopenia are described commonly [10].

Cytopenia reflects hematopoietic dysplasia, which, in association with cytogenetic abnormalities, may increase the risk of transformation in MDS/AML mainly in older children. For this reason annual bone marrow aspirates are recommended in patients with SDS. Indeed follow-up studies of SDS patients demonstrate that some cytogenetic changes my spontaneously regress.

The causative gene of the disease has recently been identified and was named *SDBS*. It is expressed in both hematopoietic and non hematopoietic tissues. Treatment of patients suffering from SDS includes pancreatic enzyme replacement and administration of G-CSF, which increases ANC to normal levels and should be started in case of severe infections [11].

106.5.3 Neutropenia Associated with Glucose-6-Phosphatase Complex Disorders

Glucose 6 phosphatase is a complex of three proteins bound to the endoplasmic reticulum responsible for glycogenolysis. Two of these three proteins are associated with congenital neutropenia: the translocase (SLC37A4), and G6PC3 that is a catalytic protein.

The association between these molecular changes and neutropenia is not clear because the glycogenolysis pathway is not the source of energy normally used by neutrophils, which mainly use the pentose pathway; this raises the hypothesis that this protein has another functions in neutrophils.

106.5.3.1 Glycogen Storage Disease Type Ib

It is a metabolic disorder characterized hepatic glycogen accumulation, intolerance of fasting, hypoglycemic events, and hyperlactacidemia, as well as susceptibility to infections [12] and colitis resembling Crohn's.

This susceptibility to infections is due to neutropenia and, sometimes, to neutrophil dysfunction (defective chemotactism). The origin of the neutropenia and neutrophil dysfunction is unknown.

106.5.3.2 G6PC3 Mutations

G6PC3 mutation prevailing in Armenia is caracterized by severe permanent neutropenia with granulocyte maturation arrest, susceptibility to infections, and several other clinical manifestations, (thin skin, urogenital malformations, and cardiac disorders). Mutations of the G6PC3 gene are generally homozygous, but a double heterozygote has been described [13].

106.5.4 Neutropenia Associated with Poikilodermia, Clericuzio Type

Clericuzio type neutropenia with genodermatosis that onset in the first year of life. Recurrent infections occur, and especially pneumonia. The neutropenia is often severe. The poikilodermia includes skin atrophy and popular erythematous rash. Composite mutations of the C16ORF57 gene are responsible of pathology [14].

Therapy with Recombinant Leukocyte Growth Factors

Robert D. Christensen

107.1 Discovering Neutropenia in a Neonate

The complete blood count (CBC) is one of the most commonly obtained laboratory tests in Neonatology. When a neonatologist finds a low blood concentration of neutrophils, it can be expected as in a neonate with septic shock, or it can be unanticipated and puzzling. A neonatologist finding neutropenia might wonder: What conditions should I consider in the differential diagnosis? Will the neutropenia be a significant clinical problem or will it be trivial and transient? Should I order rG-CSF? This chapter will focus on the last of these questions, reviewing the studies and the reasoning involved in this decision, and will include an algorithm as a guide to answering this question.

Preparatory to that discussion, it is imperative to first define neutropenia. Consider the number of neutrophils per microliter of blood, also known as the ANC (absolute neutrophil count) and not just the WBC (white blood cells or leukocytes per microliter). If the ANC is less than 1000/μL the neonate has neutropenia. If the ANC is < less than < 500/μL the patient can be said to have severe neutropenia [1–3]. Counts above 1000/μL can technically be neutropenic, if they fall below the 5th% reference range.

For instance, as shown in Fig. 107.1 an ANC of 3000/μL 12 hours after birth is indeed an abnormally low ANC [4, 5]. The fact that the ANC is below the reference range signals the presence of pathology. However, it is doubtful that an ANC as high as 3000/μL constitutes a host-defense deficiency, or renders the patient at high risk for acquiring an infection. Therefore we recommend using the diagnosis neutropenia, or placing neutropenia on the problem list, only if the ANC is less than 1000/μL.

107.2 The Importance of Neutrophils in Neonatal Host Defense

Neutrophils are pivotal to the process of antibacterial defense [6, 7], and patients lacking neutrophils can experience repeated local and systemic infections [8, 9]. Severe chronic neutropenia (SCN) is a cluster of diagnoses bearing the common feature of neutropenia, generally severe neutropenia, present from birth [10, 11].

The advent of recombinant granulocyte colony-stimulating factor (rG-CSF) dramatically improved the lives of patients with SCN, elevating their circulating neutrophil concentrations, markedly reducing infectious illnesses, and extending their life expectancy [8, 12].

SCN can be diagnosed in a neonate [13, 14]. However, the majority of patients with SCN are not diagnosed until they are several months old, following many infectious episodes that prompted evaluations into immunological deficiencies. When SCN is diagnosed in a neonate, that patient should receive the benefit of rG-CSF treatment [8, 12–15]. When a transient variety of neonatal neutropenia is diagnosed, distinct from SCN, the benefit of rG-CSF treatment is speculative and unproven [16–20]. This chapter will review the biological plausibility, the animal studies, and the clinical trials aimed at testing rG-CSF and rGM-CSF treatment for neonates with neutropenia.

107.3 Leukocyte Growth Factors in Severe Chronic Neonatal Neutropenia

107.3.1 Kostmann Syndrome

Table 107.1 lists varieties of neutropenia that are generally considered as part of the SCN syndrome. The condition is the result of mutations in the *ELA2* (neutrophil elastase) gene [24–27]. Although rG-CSF treatment is effective in increasing blood neutrophils and reducing febrile illnesses, it does not

Cartilage-hair hypoplasia
Cyclic neutropenia
Glycogen storage disease type 1b
Severe neonatal immune-mediated neutropenias

generally correct the gingivitis that is a prominent feature of this condition in some families. This is probably because rG-CSF does not increase the natural antimicrobial peptide (LL-37) deficiency in these patients [28, 29].

107.3.2 Shwachman-Diamond Syndrome

This variety of SCN is generally diagnosed after manifestations of exocrine pancreatic insufficiency, with diarrhea and failure to thrive. It is generally an autosomal recessive condition. Some children with this syndrome respond favorably to rG-CSF, yet some progress to bone marrow failure and require marrow transplantation [30, 31].

107.3.3 Barth Syndrome

These patients are generally males (X-linked) with dilated cardiomyopathy, organic aciduria, growth failure, muscle weakness, and neutropenia [32]. rG-CSF can be helpful in these patients as an adjunct to treating infections, or as a preventive measure if their neutropenia is sufficiently severe [33, 34].

107.3.4 Cartilage-Hair Hypoplasia

This is a form of short-limbed dwarfism associated with frequent infections. These patients have short pudgy hands, redundant skin, and hyperextensible joints in the hands and feet but flexor contractions at the elbow. Neutropenia occurs in some patients with cartilage-hair hypoplasia and these can benefit from rG-CSF administration [35].

107.3.5 Cyclic Neutropenia

This condition is caused by mutation in the *ELA2* (neutrophil elastase) gene, and results in periodic drops in blood neutrophil concentration, generally on a three to four-week cycle [36, 37]. Counts can drop to < 500/μL or lower, and infections can be a periodic problem. Because it generally takes several cycles before the diagnosis is considered, most cases are not diagnosed as neonates. rG-CSF administration is useful in preventing the very low nadir counts and thereby preventing infectious complications [36–38].

107.3.6 Glycogen Storage Disease Type 1b

Von Gierke disease is an autosomal recessive disorder caused by a deficiency of the enzyme glucose-6-phosphate translocase,

which transports glucose-6-phosphate into the endoplasmic reticulum for further metabolism. In GSD-1b, glucose-6-phosphate accumulates intracellularly. Affected neonates present with hypoglycemia, hepatomegaly, growth failure and neutropenia. Patients with GSD-1b have recurrent bacterial infections, oral ulcers, and inflammatory bowel disease. The gene causing GSD-1b is located on chromosome 11q23 [39]. rG-CSF can help these patients avoid the recurrent bacterial infections that are otherwise a problematic part of the condition.

107.3.7 Severe Immune-Mediated Neonatal Neutropenia

Most of the severe and prolonged immune mediated neonatal neutropenias are alloimmune [40–43]. However, a few severe and prolonged cases have been found to be autoimmune (maternal autoimmune disease) [43, 44], and a few have been found to be autoimmune neutropenia of infancy (a primary isolated autoimmune phenomenon in neonates) [43, 45].

Alloimmune neonatal neutropenia is a relatively common condition where the mother develops antibodies to antigens present on paternal and fetal neutrophils [40–44]. Antineutrophil antibodies have been found in the serum of as many as 20% of randomly surveyed pregnant and postpartum women [43, 44]. Mostly, such antibodies cause little problem to the fetus and neonate, but up to 2% of consecutively sampled neonates have neutropenia on this basis. This variety of neutropenia can be severe and prolonged, with a median duration of neutropenia of about seven weeks, but a range up to six months. Repeated infections can occur in these patients until their severe neutropenia remits. Delayed separation of the umbilical cord and skin infections are the most common infectious complications, but serious and life-threatening infections can occur. The mortality rate in this condition, due to overwhelming infection, is reported to be 5%. Severe cases have been successfully treated with rG-CSF. Unlike patients with other varieties of SCN, the neutropenia in this condition will remit spontaneously and the rG-CSF treatment can be stopped. Remission occurs when maternal antineutrophil antibody in the neonate has dropped significantly.

Neonatal autoimmune neutropenia occurs when mothers have autoimmune diseases, and their antineutrophil antibodies cross the placenta and bind to fetal neutrophils. Clinical features are generally milder than in alloimmune neonatal neutropenia and it is rare that a neonate with this variety of neutropenia needs rG-CSF treatment.

Autoimmune neutropenia of infancy is an unusual disorder where the fetus, and subsequently the neonate, has a primary isolated autoimmune phenomenon [46–50]. Neutrophil specific antibodies are found in the neonate's serum, reactive against his/her own neutrophils, but no antibodies are found in the mother's serum. Most cases occur in children between three and 30 months of age, with a reported incidence of 1:100,000 children. Affected children most often present with minor infections. Bux reported 240 cases and reported that 12% presented with severe infections, including pneumonia, sepsis, or meningitis [48]. The neutropenia in this condition generally persists much longer than in cases of alloimmune neutropenia, with a median duration of about 30 months and a range from 6–60 months [49, 50]. This variety of neutropenia can be severe, with blood neutrophil concentrations often < 500/μL. rG-CSF administration can increase the neutrophil count and reduce infections complications [48, 50].

107.4 Leukocyte Growth Factors in Neonatal Neutropenia not Categorized as SCN

107.4.1 Pregnancy Induced Hypertension

This is the most common variety of neutropenia seen in the NICU [51–58]. Perhaps 50% of neonates born to mothers with PIH have this variety of neutropenia. The ANC can be very low, frequently < 500/μL, but the count generally rises spontaneously within the first days, and is almost always > 1000/μL by day three. Usually no leukocyte left shift is seen, and no toxic granulation, Dohle bodies, or vacuolization are present in the neutrophils. It is not clear whether this variety of neutropenia predisposes neonates to acquire bacterial infection. Usually the condition is so transient that such a predisposition is unlikely. The condition is probably caused by an inhibitor of neutrophil production of placental origin that might function mechanistically by depressing natural G-CSF production [51–53].

107.4.2 Severe Intrauterine Growth Restriction

This variety of neonatal neutropenia seems to be identical to that associated with PIH. We observed no difference in the onset, duration, or severity of neutropenia in SGA neonates versus neonates born after PIH [59]. Obviously, some neonates born after PIH are also SGA, and it might be that the

Table 107.2 Varieties of neutropenia among neonates that are NOT classified as SCN

Pregnancy induced hypertension
Severe intrauterine growth restriction
The twin-twin transfusion syndrome
Rh hemolytic disease
Bacterial infection
Necrotizing enterocolitis
Chronic idiopathic neutropenia of prematurity

most severe neutropenias in this category are among those with both PIH and SGA. We assume that the neutropenia of PIH and SGA are mechanistically similar and that both are transient with few clinical consequences and no need for rG-CSF administration.

107.4.3 The Twin-Twin Transfusion Syndrome

The donor in a twin-twin transfusion is generally neutropenic, but the recipient can also have neutropenia, although usually not as severe [60]. As with the varieties of neutropenia accompanying PIH and SGA, there is generally no leukocyte left shift nor are there neutrophil morphological abnormalities. This condition is also transient, with the ANC generally spontaneously rising to >1000/μL by 2–3 days, and thus no rG-CSF administration is warranted.

107.4.4 Rh Hemolytic Disease

Neonates with anemia from Rh hemolytic disease are almost always neutropenic on the first day of life [61]. This variety of neutopenia is similar to that of PIH/SGA and donors in a twin-twin transfusion, and is likely due to reduced neutrophil production. The neutropenia is transient, generally resolving in a day or two, and thus no specific treatment is generally required for the neutropenia.

107.4.5 Bacterial Infection

Two strategies have been proposed for rG-CSF usage during neonatal infections.

Since neutropenia commonly accompanies overwhelming septic shock in neonates, perhaps rG-CSF might be a reasonable adjunct to antibiotics and intensive care treatment. Second, since neutrophil function, particularly chemotaxis, is immature among neonates, perhaps rG-CSF administration might be a reasonable way to prevent nosocomial infections among high-risk neonatal patients.

Animal models for both potential uses of rG-CSF were established and supported these hypotheses. In a Cochrane review, Carr et al examined both potential uses [62]. They located seven studies where infected neonates were treated with rG-CSF versus placebo [62–68] and three studies where rG-CSF versus placebo was used as prophylaxis against infections [69–70]. They found no evidence that the addition of rG-CSF or rGM-CSF to antibiotic therapy in preterm infants with suspected systemic infection reduces immediate all-cause mortality. No significant survival advantage was seen at 14 days from the start of therapy [typical RR 0.71 (95% CI 0.38, 1.33)]. They conducted a subgroup analysis of 97 infants from three of the studies who, in addition to systemic infection, had a low neutrophil count (<1700/μL) at trial entry. This subgroup did show a significant reduction in mortality by day 14 [RR 0.34 (95% CI 0.12, 0.92); RD –0.18 (95% CI –0.33, –0.03); NNT 6 (95% CI 3–33)].

The three prophylaxis studies [70–72] did not show a significant reduction in mortality in neonates receiving rGM-CSF [RR 0.59 (95% CI 0.24, 1.44); RD –0.03 (95% CI –0.08, 0.02)]. The identification of sepsis as the primary outcome of prophylaxis studies has been hampered by inadequately stringent definitions of systemic infection. However, data from one study suggest that prophylactic rGM-CSF might provide protection against infection when given to preterm infants who are neutropenic [72].

Carr et al concluded that there is currently insufficient evidence to support the introduction of either rG-CSF or rGM-CSF into neonatal practice, either as treatment of established systemic infection to reduce resulting mortality, or as prophylaxis to prevent systemic infection in high-risk neonates. This conclusion is consistent with other meta-analyses and reviews [71–83].

107.4.6 Necrotizing Enterocolitis

Neutropenia is relatively common among severe cases of NEC. In some cases the neutropenia is transient and resembles the neutropenia following endotoxin [84, 85]. No studies have focused on using rG-CSF among neutropenic neonates with NEC.

107.4.7 Chronic Idiopathic Neutropenia of Prematurity

Certain preterm neonates develop neutropenia when 4–10 weeks old. This variety of netropenia is often associated with a patient's spontaneous recovery from the anemia of prematurity. Neutrophil counts are generally <1000/μL but rarely <500/μL [86–89]. The condition is transient, lasting a few weeks to perhaps a month or more. It appears to be a hyporegenerative neutropenia, because it is not accompanied by a leukocyte left shift nor morphological abnormalities of the neutrophils.

Patients with this condition have an "rG-CSF mobalizable neutrophil reserve", meaning that if rG-CSF is given, their neutrophil count increases within hours. This has been taken as evidence that these patients do not have a significant host-defense deficiency and they can supply neutrophils to tissues when needed [87]. Thus, although these patients can be neutropenic for several weeks, this condition is likely benign and needs no treatment.

107.5 The Use of Leukocyte Growth Factors

G-CSF and GM-CSF are naturally occurring proteins involved in proliferation and differentiation of myeloid precursors into mature neutrophils [90]. The genes for both have been cloned, and the purified recombinant factors are commercially available in pharmacologic quantities [91]. These factors have been widely used in adult and pediatric medicine primarily to treat iatrogenic neutropenia and bone marrow failure syndromes [91, 92]. They can shorten the duration of neutropenia after chemotherapy for leukemia and solid tumors and after bone marrow transplantation. G-CSF is used in patients undergoing peripheral blood hematopoietic stem cell collection. Target cells for these factors differ. G-CSF is lineage specific for the committed progenitors of neutrophils [93, 94]. It stimulates proliferation and differentiation, expanding the available pool of neutrophil precursors and shortening their transit time through the marrow. It has been reported that G-CSF enhances several functions of mature neutrophils, but this has been questioned [95]. GM-CSF acts on multilineage progenitors and on those of monocyte and neutrophil lineage and enhances bactericidal activities of mature phagocytes [90, 91].

Patients with SCN generally derive considerable benefit from rG-CSF administration. Almost all respond to doses of 5–10 micrograms per kg administered at intervals ranging from every day to once per week in order to achieve neutrophil concentrations above 500–1000/μL [90–94].

Explanted blood monocytes and mononuclear cells from human neonates produce G-CSF and GM-CSF poorly, compared with cells from adults. Moreover, cells from preterm infants produce these proteins more poorly than do cells from term infants [95, 96]. Plasma concentrations of G-CSF are relatively low in newborn infants with neutropenia and in infants with presumed sepsis [97, 98]. Neonatal hematopoietic progenitor cells are equally responsive as adult bone marrow progenitors to the actions of G-CSF and GM-CSF in culture. The rapid neutrophil response to infection is impaired in the murine model of G-CSF gene disruption [98]. Animal studies demonstrated diminished production of G-CSF by neonates compared with adults during bacterial sepsis [100, 101]. rG-CSF and rGM-CSF administration in animal models of neonatal sepsis have documented improved survival [100–102].

The decision regarding whether to administer rG-CSF to a neutropenic infant must consider risks and benefits. Animal studies suggesting benefits administered the hematopoietic growth factor concurrently or within hours of inoculation with the bacterial agent. Under the best of circumstances treatment of clinical sepsis with rG-CSF or rGM-CSF within hours of bacterial invasion may not be feasible. In some infants with overwhelming sepsis bone marrow neutrophil storage pools may already be depleted, thus limiting the capability for response to rG-CSF or rGM-CSF treatment. Additionally, septic and neutropenic infants exhibit elevated circulating and urinary G-CSF concentrations suggesting that their G-CSF receptors are saturated with endogenous G-CSF [103].

The risk of developing nosocomial infection in preterm neonates with neutropenia due to maternal hypertension is controversial [104]. Some studies have demonstrated an increased incidence of nosocomial infections in these neonates, but others have not. Studies evaluating rG-CSF administration to correct the neutropenia caused by maternal hypertension have demonstrated a significant increase in circulating neutrophils compared with study entry, but have not demonstrated lower rates of infection [105, 106].

rGM-CSF has been studied in neonates using slightly different strategies than used in trials of rG-CSF administration. Three prophylaxis studies using rGM-CSF have been published. These studies adopted different treatment regimens and did not use comparable criteria for identifying episodes of systemic infection. rGM-CSF increased the circulating absolute neutrophil count and bone marrow neutrophil storage pool. Neutrophil function was enhanced as defined by up-regulation of surface C3bi expression [70, 71]. Circulating monocytes and platelet counts were increased among rGM-CSF recipients. A systematic review of these studies concluded that rGM-CSF prophylaxis did not lead to a significant reduction in mortality [62].

Similarly, a recent multicenter randomized controlled trial of prophylactic rGM-CSF for extremely preterm infants at high risk of sepsis did not demonstrate reductions in sepsis or improved survival [107].

107.6 A Consistent Approach to the Use of rG-CSF and rGM-CSF in the NICU

Fig. 107.2 is a simple algorithm for making the decision regarding rG-CSF administration in the NICU. It is intended as a guideline to serve until sufficient data accumulate for an evidence-based change in this approach. The algorithm is in

Table 107.3 Screening for severe chronic neutropenia

Inclusion questions:

1. Has a blood neutrophil count of <500/μL been documented on at least three occasions in the past three months?
2. Is there a history of recurrent infections? (specify)
3. Is the bone marrow evaluation consistent with severe chronic neutropenia? (date performed)
4. Has a cytogenetic evaluation been completed?
5. Is the patient now receiving Neupogen (rG-CSF)?

Exclusion criteria

1. The neutropenia is known to be drug-induced
2. Thrombocytopenia is present (<50,000/μL) except in the case of Shwachman-Diamond syndrome or glycogen storage disease type 1b
3. Anemia is present (hgb <8g/dL) except in the case of Shwachman-Diamond syndrome or glycogen storage disease type 1b
4. The patient has a myelodysplastic syndrome, aplastic anemia, is HIV positive, has some other hematological disease, has rheumatoid arthritis, or has had previous chemotherapy for cancer

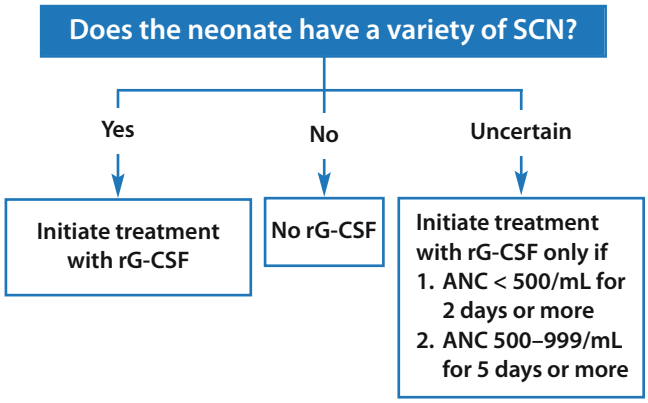

Fig. 107.2 The US FDA approved rG-CSF for use in children with severe chronic neutropenia, and for children receiving myelosuppressive chemotherapy of marrow transplantation. The rG-CSF used in the USA is produced by Amgen (Thousand Oaks, CA) and has a molecular weight slightly lower than natural G-CSF, because it is produced in *Eschericha coli* and is not glycosylated. It has an amino acid sequence identical to that of natural G-CSF except for the addition of an N-terminal methionine, which is necessary for its expression in *E. coli*. SCN includes Kostmann syndrome, Shwachman-Diamond syndrome, cyclic neutropenia, Bart syndrome, autoimmune or alloimmune neonatal neutropenia, or any syndrome or condition where severe and chronic neutropenia are a consistent finding. G-CSF administration is not recommended for neonates with neutropenia of a non-severe, or a non-chronic nature, such as the neutropenia associated with PIH, sepsis, or chronic idiopathic (mild) neutropenia

keeping with FDA approved approaches and avoids off-label uses. The principal question is whether the neutropenic neonate has a variety of SCN; a question to which there are three possible answers; 1) Yes, 2) No and 3) Uncertain. We propose that if the answer is yes, the patient should be afforded the benefit of rG-CSF treatment, and if the answer is no, rG-CSF should not be given. Cases where the answer is uncertain, might receive rG-CSF if the neutropenia is severe (ANC <500/μL for 2 days of more) or prolonged (<1000/μL for 5 days or more) while the question of SCN is being actively investigated.

An international registry for SCN cases can be accessed at the website http://depts.washington.edu/registry/, using the entry criteria and exclusion criteria given in Table 107.3. We propose beginning treatment with a dose of 10 μg/kg subcutaneously, once per day for three consecutive days. Thereafter doses are given as needed to titrate the ANC to around 1000/μL. We did not include criteria for administering rGM-CSF, as we found insufficient evidence for its use in the NICU. If one follows this schema (Fig. 107.2) it will result in little use of rG-CSF in the NICU. Any rG-CSF usage in Neonatology should be focused on patients with the most to gain and least to lose by its application. As additional pertinent investigative work is published, these guidelines shall be modified accordingly.

Fundamentals of Feto-Neonatal Immunology and Its Clinical Relevance

Akhil Maheshwari and Edmund F. La Gamma

108.1 Introduction

The transition from fetal to neonatal life at birth forms an important functional watershed in the developing immune system. In utero, the fetus is exposed to a steady stream of foreign antigens that are derived mainly from the mother, and must down-regulate its immune response to survive. After birth, however, the neonatal immune system is exposed to a new, more diverse set of antigens and must evolve dichotomous responses to contain the micro-organisms on various cutaneous and mucosal surfaces, and at the same time, develop tolerance to other commensal microbes and dietary macromolecules. During this remarkable transition, while some components of the immune system perform at par with adults, immaturity of the other arms results in a developmentally-regulated state of immunodeficiency. This chapter highlights major quantitative and qualitative differences in the innate and adaptive arms of the neonatal and adult immune systems and provides a brief review of the developing mucosal immune system.

108.2 Clinical Relevance

Preterm neonates have a high susceptibility to bacterial infections, especially of the Gram positive and Staphylococcal variety suggesting a preponderance of vulnerability due to neutrophil function. They are also remarkably deficient in circulating antibody after their trans-placental passage, yet preterm neonates can generate an amnesic response to produce antibodies. Nevertheless, this makes them vulnerable to impaired opsonization (a bacterial vulnerability) and viral dissemination (an uncommon but real biological threat). How these vulnerabilities arise and what opportunities remain to augment defenses can be understood best by an in depth grasp of how the mature capacities of function change over time. Our goal is to highlight those features.

108.3 Innate Immune System

This section will review the developmental issues relevant to the collection of defense mechanisms the human neonate is born with prior to exposure to environmental antigens and acquisition of adaptive immunity. Cell lines, their maturation and functional capacities or limitations will be defined.

108.3.1 Neutrophils

108.3.1.1 Development

The two major hematopoietic progenitors committed to the neutrophil lineage are the colony-forming units (CFU)-mix, which give rise to a mixture of various leukocyte populations, and the CFU-GEMM, which produce granulocytes, erythrocytes, megakaryocytes, and macrophages. The mechanisms underlying this process of lineage commitment are now beginning to be understood [1]. The effect of biomechanical forces as critical regulators of hematopoiesis is a new field of investigation [2], as is the prevention of apoptosis as a mechanism for hematopoietic progenitor cell growth and development [3]. In the bone marrow, the neutrophil cell lineage includes the early precursors with a capacity for 4–5 five cell divisions, and the later, post-mitotic stages that are in the process of differentiation (Fig. 108.1). In adults, the neutrophil proliferating pool (NPP) contains about 2×10^9 cells/kg body weight and the neutrophil storage pool (NSP) contains about 6×10^9 cells/kg body weight [4]. The NPP and NSP together contain nearly 90% of all neutrophils in the

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

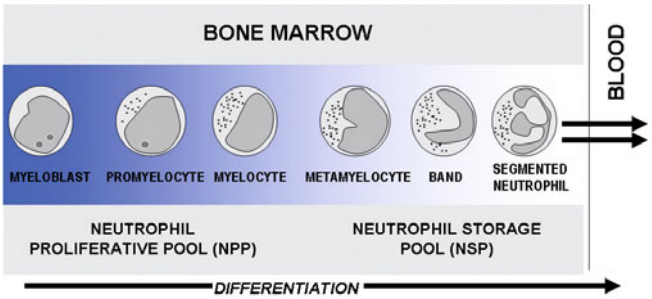

Fig. 108.1 Neutrophil differentiation process in bone marrow

body. The remaining 10% (0.6×10^9/kg) are equally distributed free in the circulation or attached to the microvascular endothelium.

Although umbilical cord blood and fetal blood have a 10–50 fold higher concentration of CFU-GM than does the blood of adults [5], the fetus has an overall much smaller pool of neutrophil progenitors [6]. In the mid-gestation fetus and preterm infant, the NSP is very small in size and can be readily exhausted during sepsis [4]. Studies in experimental animals show that the NSP is considerably smaller in animals delivered prematurely ($1.0–1.3\times10^9$ cells/kg) than at full-term ($1.3–2.5\times10^9$ cells/kg) and in adulthood ($4.5–7.5\times10^9$/kg). The NPP is also smaller, about one-tenth the size (per kg body weight) of adults. Indirect evidence for a small granulocytopoietic pool in the human fetus come from studies of soluble CD16, which is derived from apoptotic neutrophils, and its low concentrations in plasma of preterm neonates may reflect a low total body neutrophil mass. The low sCD16 levels of premature infants reach adult values only by the fourth postnatal week [7].

During acute inflammation, neutrophils are released from the NSP first, and once these stores are exhausted, progressively immature cells are mobilized (known as the left shift of sepsis). Circulating neutrophils persist in the bloodstream for 6–8 hrs and then for a few hrs to several days in tissues. In the fetus, as in the adult, mature neutrophils are stored within the bone marrow and also in the liver and spleen. These maturational relationships and short-half life frequently result in the presenting clinical sign of neutropenia rather than neutrophilia in newborns with bacterial sepsis.

108.3.1.2 Function

Transendothelial Migration

Circulating neutrophils leave the intravascular compartment to enter the tissues in three major steps: margination and rolling on vascular endothelium, attachment to the endothelial cells, and transendothelial migration [8]. Leukocyte traffic is preferentially directed to inflamed areas through regional changes in vascular flow and along concentration gradients of humoral chemoattractants such as chemokines, bacterial products (such as formyl-met-leu-phe or f-MLP), complement fragments (C5a), and leukotrienes (LTB_4). Among chemokines, members of the CXC subfamily with a glutamate-leucine-arginine (ELR) tripeptide sequence (such as interleukin-8 (IL-8/CXCL8)) have a neutrophil-specific chemotactic activity [9, 10].

In inflamed tissues, transient interruptions in the laminar flow of marginating neutrophils cause these cells to tumble and roll on the vascular endothelial surface. This process is mediated through a process of repetitive binding and release of selectins (L-selectin on neutrophils, E- and P-selectin on endothelium) from their sialomucin receptors called addressins. The term selectin is derived from a key lectin domain that interacts selectively with oligosaccharide receptors bearing sialylated carbohydrate moieties. L-selectin is constitutively expressed on neutrophils and is shed after cellular activation [11]. Rolling neutrophils slow down and attach to endothelium through the binding of β_2-integrins to cognate receptors on endothelial cells [12]. The β_2-integrins expressed on neutrophils include the leukocyte function-associated antigen-1 (LFA-1, $\alpha_L\beta_2$, CD11a/CD18), Mac-1 ($\alpha_M\beta_2$, CD11b/CD18), and the p150, 95 ($\alpha_X\beta_2$, CD11c/CD18), which bind endothelial receptors such as the intercellular adhesion molecule-1 (ICAM-1) and ICAM-2. LFA-1 binds to both ICAM-1 and ICAM-2, whereas Mac-1 and p150, 95 bind exclusively to ICAM-1. These neutrophils undergo activation on the endothelial surface and migrate through the capillary/venular wall, a process that involves the platelet-endothelial cell adhesion molecule (PECAM1, CD31), the integrin-associated protein (CD47), and a series of other junctional molecules [13].

Compared to neutrophils from adults, neutrophils from both term and preterm infants adhere poorly to the endothelium. Neonatal neutrophils have lower selectin expression than adults at birth [14], which might be further reduced by perinatal stress such as in birth asphyxia [15]. In addition, neonatal neutrophils display defective shedding of L-selectin [14]. This combination of decreased expression and impaired shedding of L-selectin impairs the ability of neutrophils to roll on the endothelial surface, thereby limiting the recruitment of circulating neutrophils into the tissues. Neutrophil-endothelial adherence and neutrophil transmigration is further limited in neonates due to a developmental deficiency of Mac-1 (CD18/CD11b), one of the β_2 integrins [16]. The transendothelial migration of neutrophils is also limited, at least in immature cells released from the NSP during sepsis, by reduced deformability of the neutrophil membrane and cytoplasm [17]. For these reasons, it is generally believed that the propensity of neonates to bacteremia is more typical than a proper localization and abscess formation.

Chemotaxis

Once outside the blood vessel, neutrophils migrate along concentration gradients of various chemoattractants such as IL-8 (and other ELR^+ CXC chemokines), f-MLP, and C5a [9].

These chemotactic stimuli bind to high-affinity G-protein-coupled receptors on the leukocyte surface, and minute spatial gradients in chemoattractant concentrations can cause the receptors to be distributed asymmetrically towards the migrating neutrophil pseudopodium. Cellular movement involves a number of intracellular signaling pathways and cytoskeletal proteins. A chemoattractant hierarchy has been reported wherein bacterial products are preferred over host chemokines [18].

Neutrophils from both term and preterm neonates have an impaired chemotactic response, migrating at only about half the speed traveled by adult cells [19, 20]. While neutrophils from term infants achieve normal chemotactic function by 2 wks after birth, such postnatal neutrophil maturation begins 2–3 weeks after birth in immature preterm infants and proceeds very slowly [21]. Neutrophils from preterm infants born at 34–36 wks gestation achieve normal chemotaxis by 40–42 weeks of post-conceptional age. In more immature preterm infants (<34 wks), neutrophil chemotaxis improves with time, but remains impaired in comparison to adults even at 42 wks PCA [22]. Although minor infections may enhance chemotaxis in neonates, the migratory responses of neonatal neutrophils may become further depressed during systemic Gram-negative sepsis [23].

Neonatal neutrophils bind various chemoattractants normally. However, chemoattractant-induced membrane depolarization, calcium transport, and sugar uptake are relatively less efficient. The chemotactic defect in neonatal neutrophils may be multi-factorial, affected by factors such as a larger, poorly motile neutrophil subpopulation, impaired calcium mobilization, and aberrations in intracellular signaling pathways such as NF-κB activation [24, 25]. Lower Mac-1 expression can also impede chemotaxis due to impaired neutrophil interaction with the extracellular matrix [24]. Inability to effectively direct neutrophils to the bacterial source contributes to the neonatal vulnerability to septicemia.

Phagocytosis

Phagocytosis is a specialized form of endocytosis directed at engulfing solid particles into an internal phagosome. This internalized phagosome "matures" through interactions with the endosomal compartment and eventually fuses with a lysosome for killing of internalized microorganisms and terminal degradation of the cargo [26]. Phagocytosis is more efficient when the target is opsonized by specific immunoglobulin G (IgG) or complement factors, which may act by neutralizing inhibitors of phagocytosis such as the capsular polysaccharide or by rendering the microbial surface more hydrophobic. Neutrophils express receptors for IgG ($F_c\gamma$ receptors I-III, or CD16, CD32, CD64), C3b (CR1), and iC3b (CR3). In some instances, microorganisms may be ingested without opsonization through lectin-carbohydrate (lectins on bacterial fimbriae interact with neutrophil glycoproteins), protein-protein (proteins such as filamentous hemagglutinin that express the arg-gly-asp or the RGD amino acid sequence bind to integrins), and hydrophobic-protein (bacterial glycolipids and neutrophil integrins) interactions [26].

The interaction of IgG or complement receptors on the neutrophil surface with the opsonized particle trigger cytoskeletal rearrangements to enclose the opsonized particle within a phagosome. Phagocytosis is most efficient when organisms are coated with both IgG and C_3, which allows cooperative interaction of cognate receptors for both the opsonins. As mentioned above, neutrophils express integrin receptors for matrix proteins with the RGD tripeptide motif (such as fibronectin, laminin, and collagen), and ingest C_3-coated particles more efficiently when adherent to surfaces coated with these RGD-bearing proteins [26, 27].

Preterm neutrophils have impaired phagocytosis, which corrects only in the late third trimester to become comparable to adults [19]. Preterm neutrophils ingest particles more slowly and ingest fewer bacteria (such as *E. coli*). The lack of opsonic activity is an important consideration, as preterm infants often have lower concentration of specific antibodies [28]. Compared to term neonates and adults, preterm neutrophils also have decreased expression of CD16 ($F_c\gamma$RIII) and CD32 ($F_c\gamma$RII), the two most abundant neutrophil IgG receptors [29]. Whereas CD16 expression normally increases to adult levels over the first three weeks of life, CD32 deficiency may or may not correct with time [30].

Intracellular Killing

The phagolysosome provides an enclosed space in which an ingested microbe is exposed to high concentrations of toxic substances, while limiting the exposure of the phagocyte and other cells to these potentially injurious agents [26]. The major killing mechanism in neutrophils involves the generation of reactive oxygen species (ROS) in a respiratory burst. An NADPH-dependent oxidase localized on the cell membrane (and therefore, the phagosome membrane) reduces molecular oxygen (O_2) to a superoxide anion ($O^{\bullet}_2^-$) [31]; subsequent generation of peroxide (H_2O_2) and the hydroxyl radical ($OH^{\bullet}$, formed in the presence of iron) also contributes to the microbicidal capacity of neutrophils [32]. These oxygen-dependent bactericidal mechanisms can be broadly divided into myeloperoxidase (MPO)-independent (such as hydrogen peroxide) and MPO-dependent (MPO catalyzes reactions between H_2O_2 and halides to form highly reactive products) [33]. H_2O_2 is a weak bactericidal agent per se, but the MPO-H_2O_2-halide system increases its efficacy by nearly 50-fold. The bactericidal effects of free oxygen radicals are due to oxidizing effects on various components of the bacterial cell wall [32].

Neutrophils also have elaborate non-oxidative killing mechanisms such as low pH (as low as 6.0), defensins, bactericidal/permeability-increasing protein (BPI), lactoferrin, lysozyme, and a variety of cationic proteins. Defensins are

broad-spectrum antimicrobial peptides with activity against gram-positive and gram-negative bacteria, fungi, and enveloped viruses and are also released in the gut by Paneth cells [34]. BPI binds lipopolysaccharide (LPS) and blocks its effects, can damage the outer membrane of gram-negative bacteria, and has some opsonic activity. Lactoferrin, an iron chelator, is bacteriostatic as it deprives bacteria of the iron required for growth. Lactoferrin is also involved in neutrophil degranulation, in oxygen radical production, and in granulocytopoiesis. Lysozyme hydrolyzes a glycoside bond in the bacterial cell wall peptidoglycan. Primary granules also contain other cationic antibacterial proteins such as azuricidin, indolicin and cathelicidins [26, 35].

The respiratory burst is depressed in preterm neutrophils, which explains the observed developmental defects in intracellular killing of bacterial pathogens such as *Staphylococcus aureus* or *E. coli* [36]. The killing capacity cannot be fully explained on the basis of low opsonic activity in preterm plasma and improves only as a function of gestational age [19, 37, 38]. The neutrophil respiratory burst in infants born at 24–28 wks is clearly less robust than in those born at 29–35 wks and takes about 2 months to correct. However, neutrophils from preterm infants continue to have an overall weaker oxidative burst than adults and may not show any improvement in critically-ill preterm infants [39]. Neonatal neutrophils are also less effective in killing group B streptococci, although the data on candidacidal activity are conflicting. The antiviral activity of neonatal neutrophils is also diminished compared with that of adults. Indeed, the most commonly recovered bacteria in extremely low birth weight/extremely low gestational age neonates (ELBW/ELGAN) is a commensal organism *Staphylococcus epidermidis*.

Degranulation

Neutrophils contain two major types of granules (Fig. 108.2): (1) the azurophilic granules (stain positive with the azure A dye) and (2) specific granules (do not stain with azure A). Azurophilic granules contain myeloperoxidase (MPO), proteolytic enzymes such as cathepsins, proteinase-3, and elastase, and antimicrobial proteins such as defensins and the bactericidal permeability-increasing protein (BPI). These granules release their contents into the phagolysosomes and are involved in intracellular killing. The specific granules contain antibacterial agents such as lactoferrin and lysozyme, receptors for complement components, and bacterial products such as f-MLP. Specific granules fuse with the cell membrane to release their contents by exocytosis, and also bring functionally important membrane proteins such as integrins, cytochrome-b_{558}, and receptors for chemotactic agents and opsonins to the cell surface. Specific granules play an important role in extracellular killing [40].

Neutrophils from term neonates have granule contents and degranulation responses similar to adults [41]. However, neutrophils from preterm infants have a lower capacity to release BPI, elastase, and lactoferrin than in adults and term infants [19, 42]. Collectively, neutrophil line immaturities and limited function accounts for a substantial component of neonatal susceptibility to invasive bacterial infections.

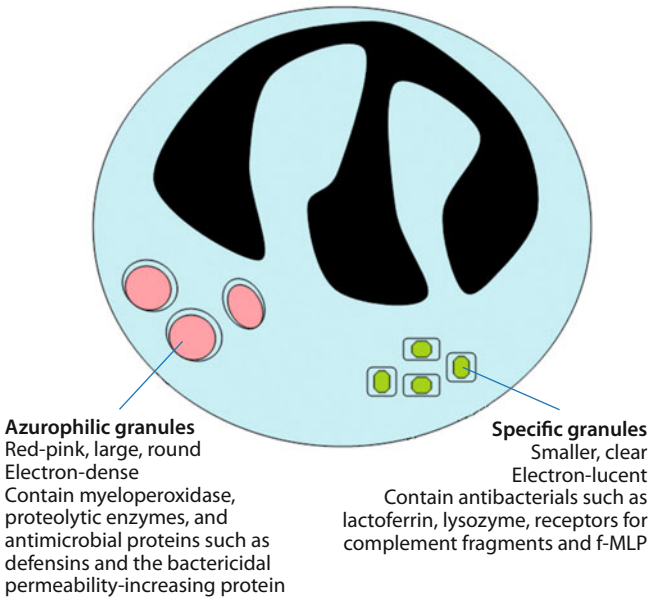

Fig. 108.2 Types of granules in neutrophils

108.3.2 Monocytes and Macrophages

108.3.2.1 Development

Embryonic macrophages are first seen in the yolk sac at 3–4 weeks of gestation. Unlike macrophages in the fetus and the adult, which are derived from circulating monocytes, these large-sized histiocytic cells develop in the early embryonic period from yolk sac progenitors prior to the first appearance of monocytes [43, 44]. At 5 weeks of gestation, two distinct cell lineages with a dendritic/macrophage structure can be identified in the yolk sac, mesenchyme and the fetal liver. The larger subgroup is MHC II-negative, and there is only a minor population that expresses these antigens. MHC II-negative cells also appear in the thymic cortex, in the marginal zones of lymph nodes, in the splenic red pulp, and in the bone marrow [45]. A few MHC II-positive cells are seen in the liver at 7–8 weeks of gestation, the lymph nodes at 11–13 weeks of gestation, and the T-cell areas of the developing thymic medulla by 16 weeks of gestation. Subsequently, the numbers increase gradually, and MHC class II-positive cells are also seen in the skin and gastrointestinal tract [45].

During the second month of gestation, as hematopoiesis becomes established in the fetal liver, monocytes are seen in

high proportions and constitute nearly 70 percent of all hematopoietic cells [46]. Over the next 6 weeks, as the erythroid cells predominate, this proportion falls to 1–2 percent [46]. The first monocytes in circulation are not seen until about the fifth month of gestation [46], and remain uncommon until the bone marrow becomes the predominant site of hematopoiesis [47]. At 30 weeks, monocytes comprise 3–7 percent of hematopoietic cells [48]. Term cord blood studies show a relative monocytosis, which persists during the neonatal period. The absolute monocyte counts tend to decline gradually from 1340–2200/μL in the first week to about 700 in the third week [49]. We are currently analyzing data from a large cohort of neonates with more than 100,000 blood counts to define the normal ranges of absolute monocyte counts.

Information on tissue macrophage kinetics in the neonatal period is mainly from autopsy studies. The size of the macrophage pool varies in different organ systems. In the gastrointestinal tract, macrophages appear in the lamina propria as early as 10 weeks of gestation and a sizable macrophage population can be seen during midgestation [44]. In contrast, the alveolar macrophage population remains small in the fetus and expands rapidly during the early neonatal period [50]. This increase may result both from an influx of monocytes from the circulation as well as from clonal expansion in situ.

Monocytes and macrophages can be identified using immunocytochemistry for the macrophage marker HAM56, cellular constituents such as nonspecific esterase and peroxidase, innate immune receptors such as CD11b, and the MHC complex [51–54]. A lower proportion of cord blood macrophages stain for esterase, although there are no discernible differences in peroxidase activity [52]. Neonatal monocytes have lower expression levels of the aforementioned surface markers, except for CD14 [53]. In certain tissues, such as in the gastrointestinal tract, resident macrophages are characteristically downregulated for the expression of innate immune receptors such as CD14 [55].

Due to the extraordinary importance in this particular lineage in epithelial surface barrier protection, the propensity of ELBW/ELGAN patients to pneumonias, necrotizing enterocolitis and invasive skin infections merits consideration.

108.3.2.2 Function

Transendothelial Migration, Chemotaxis, Phagocytosis, and Respiratory Burst

Unlike neutrophils, the major host defense functions of monocytes in cord blood of term infants are largely intact. Cord blood monocytes show adherence, random migration, chemotaxis, bactericidal activity, phagocytosis-associated chemiluminescence, production of superoxide anion (O-2) and generation of hydrogen peroxide at levels comparable to those of cells from healthy adult volunteers [56, 57]. The ability of fetal and neonatal monocytes to kill a variety of pathogens including *S. aureus*, *S. epidermidis*, *E. coli*, and *C. albicans* appears to be equivalent to that of adults [56, 58].

Resident macrophages are often the first phagocytic cells of the innate immune system to encounter invading pathogens breaching the various epithelial surfaces of the skin, gut and lung. These cells serve important host defense functions through phagocytosis, and also as sentinel cells that regulate local inflammatory responses by producing various cytokines and chemokines [59, 60]. Most studies on monocyte/macrophage cell function have been done on cord blood, and fetal cells have not been studied to the same extent so far. Term cord-blood monocytes produce IL-1, IFN-α and TNF-α in concentrations that are comparable to adults, but the levels of IFN-γ, IL-8, IL-10, and GM-CSF are lower. These cells also produce lower concentrations of extracellular proteins like fibronectin, and bioreactive lipids like leukotriene B_4 [61, 62]. Impaired monocyte secretory functions in neonates may be partially responsible for poorer cytokine responses of neonatal T-cells.

Emerging evidence indicates that macrophages are dynamic and heterogeneous cells, which are polarized into the classically-activated M1 macrophages that express various inflammatory signals, and the more-recently described M2 macrophages that function with an anti-inflammatory profile [63]. Although the effect of development on macrophage polarization is not known, the relative inability of cord blood monocytes (versus monocytes from adults) to mount a robust inflammatory cytokine response is intriguing [64].

108.4 Adaptive Immune System

108.4.1 Dendritic Cells

108.4.1.1 Development

Dendritic cells (DCs) are a discrete leukocyte population with a highly developed antigen-presenting function. DC populations have been grown from separated hematopoietic precursors, suggesting that there is a common granulocyte-monocyte-dendritic cell progenitor [65]. Cells with a dendritic/macrophage structure are present in the yolk sac, mesenchyme and the liver at 4–6 weeks of age. DCs are detectable in skin by 6–7 weeks of gestation.

DCs initially derived their name from their distinctive morphology, with numerous fine dendritic cytoplasmic processes commonly found penetrating epithelial bound organ surfaces. However, phenotype alone is not sufficient to define these cells in view of functional differences between the subpopulations. A working definition requires DCs to be able to stimulate T-cells, home to T-cell dependent lymph node areas, be able to pinocytose and have characteristic cell surface antigens.

Human peripheral blood DCs mainly include two subgroups [66]: (1) myeloid DCs (or mDCs) are $CD11c^+$ cells that express myeloid markers such as CD13, CD33, and CD11b; and (2) plasmacytoid DCs (or pDCs) are $CD11c^-$ and have a plasmacytoid morphology with well-developed rough endoplasmic reticulum and Golgi apparatus.

108.4.1.2 Function

Cord blood-DCs represent about 0.3% of all mononuclear cells. Most studies show an increased number and proportion of pDCs in cord blood compared to adult peripheral blood, with pDC:mDC ratios of 1–3:1 that contrast with the usual 1:2 ratio in adults [67].

Due to the low frequency of DCs in peripheral blood, most studies of neonatal DCs have been carried out using *in vitro* monocyte-derived dendritic cells (MDDCs). Compared to pDCs from adults, cord blood DCs exhibit low or no basal expression of co-stimulatory molecules CD40, CD80 or CD86, show an impaired maturational response following stimulation with agonists for various toll-like receptors (measured as an increase in the expression of co-stimulatory molecules and production of IFN-alpha, TNF-alpha, IL-1, IL-6 and IL-12), and perform poorly at accessory function [68]. Cord-blood dendritic cells have lower expression levels of ICAM-1 and MHC antigens than in adults. These cells are also poor stimulators of mixed lymphocyte reactions, regardless of whether cord or adult mononuclear or T-cells were used as the responders. How precisely these cells contribute to the susceptibility of neonates to maturation of adaptive immunity, prevention of invasive illness and barrier dysfunction is an area in need of further exploration.

108.4.2 T-Lymphocytes

108.4.2.1 Development

The thymus arises at about six weeks of gestation from the third branchial arch, with the cortex arising from its ectodermal layer and the medulla from the endoderm. Lymphoid cells migrate over the next 2–3 weeks, initially from the yolk sac and fetal liver, and then from the bone marrow to colonize the fetal thymus [69]. These prothymocytes interact with the stroma, proliferate actively, and are triggered to differentiate with expression of the first T-cell-specific surface molecules (e.g., CD2, and later CD4 and CD8) [70, 71]. A clear delineation of the thymic cortical and medullary regions occurs at 12 weeks of gestation; Hassall's corpuscles appear shortly thereafter [72, 73]. The most immature thymocytes are found in the subcapsular cortical region, and cells move into the deeper layers as they mature [72].

The early prothymocytes do not express CD3, the T-cell receptor (TCR), CD4, or CD8 and are often referred to as triple-negative thymocytes [74]. The progeny continue to divide and rearrange their TCR genes, and since these cells express both CD4 and CD8, they are now called double-positive [72, 74]. They undergo positive selection by self-major histocompatability complex (MHC) restriction, and more than 95 percent (about 50 million) cells die each day during this stage [74]. Negative selection occurs next, and is mediated by the bone marrow-derived antigen-presenting cells (APC) (e.g., dendritic cells and macrophages), which eliminate autoreactive cells either by clonal deletion or clonal anergy [75]. As these thymocytes mature and reach the medulla, they express only one of the CD4 or CD8 antigens. These single-positive T-cells migrate from the thymus to the peripheral lymphoid organs at about 14 weeks of gestation [72]. By 15 weeks, human thymocytes express a complete set of TCRs [72, 76].

During fetal life, thymus is the largest lymphoid tissue in terms of body proportions. It is about two thirds its mature weight at birth, and reaches its peak mass at around 10 years of age. Subsequently, it continues to involute and is replaced by adipose tissue [77].

108.4.2.2 T-Cell Receptor (TCR) Repertoire

The TCR is composed of two distinct functional subunits, each specialized for a different function [78]. The first, highly polymorphic, is uniquely structured for each T-cell for antigen recognition; it is composed of two polypeptide chains, α and β (except in a specific T-cell subset where it consists of γ and δ chains) [78]. The second, also known as CD3, is a trimolecular complex, involved in signal transduction and cellular activation. The extracellular region of the TCR resembles an immunoglobulin (Ig) Fab fragment, and derives its structural diversity from recombinatorial permutations involving a set each of Variable (V), Diversity (D), and Joining (J) gene segments [79, 80]. The variable domain is situated in the N-terminal end of the α/β (or γ/δ) chains, whereas the C terminal is the constant region [78]. The variable domains consist of V, D, and J elements in the β chain, and V and J in the α chain [81]. The antigen-binding sites are formed by three complementarity-determining regions (CDRs). CDR3, the most extensive of these segments, serves as a key site for antigen recognition [82].

By midgestation, all the TCR Vβ families (V here refers to the variable domain of the β chain, and should be recognized as different from the V gene segments mentioned above) are expressed, but they have shorter CDR3 regions. This is primarily due to limited expression of the enzyme terminal deoxynucleotidyl transferase (Tdt), which induces N-terminal diversity and, consequently, CDR3 heterogeneity. In term infants, the T-cell Vβ repertoire is similar to that seen in adults [82, 83]. Cord blood T-cells from term infants are also able to expand the TCR β repertoire on stimulation with bacterial toxins [83]. It is the central position of T-cell function in the maturing immune system that places the capacity to

adapt to a changing environment central to successful maturation of immune defenses. This is primarily a time and antigen experience-dependent process influenced by the maternal inoculation with flora during a normal birth as well as the subsequent clinical and home environments as influenced by clinicians and their use of antibiotics or other teleologically relevant experiences.

108.4.2.3 Circulating T-Cells

T-cell subpopulations gradually increase in number beyond 19 weeks' gestation, and continue to rise after birth to peak at about 6–9 months. The numbers subsequently decline, and adult levels are finally reached at 6–7 years of age [84]. In term neonates, CD4+ cells constitute a higher proportion of T-cells than adults. CD8+ cells, on the other hand, are fewer both in terms of their absolute number and as a percentage of total T-cells. The CD4/CD8 ratio, consequently, is as high as 4.9:1 during the perinatal period, and declines to adult values of approximately 2:1 only by 4 years of age [84]. Preterms have significantly higher numbers of CD4+ T-cells, but the number of CD8+ T-cells does not seem to change with gestational age [85]. These numbers decrease with perinatal distress, but normalize by 3 weeks of age except in some very-low-birth-weight infants [85].

Peripheral T-cells in the fetus and neonate may be in a relatively immature transitional state; in cord blood, nearly 85% of T-cells express CD38 (compared with less than 5% of adult cells), but lack other markers of activation. Cord blood T-cells also differ in being predominantly naïve (80–90% express the CD45RA phenotype, compared with only 40–60% of the adult cells) [86]. The percentage of memory T-cells (CD45RO) increases in healthy infants during the first few years of life, but reaches adult levels only by the second decade [86]. Neonatal T-cells also have lower expression of CDw29 and CD11b, providing further evidence to a lack of previous stimulation [86]. The ratios and relationships of T-cell subtypes and the clinical relevance to invasive disease is an area of perinatal immunology that is in need of further clarification.

108.4.2.4 Function

Proliferation

Cord blood T-cells from premature infants have a limited capacity for mitogen-induced proliferation but these defects are corrected by full-term [86, 87]. Similarly, proliferative responses to monoclonal antibodies against T-cell markers (e.g., CD3, CD2) are dramatically less than adult lymphocytes, and resemble adult naïve T-cells [88]. These responses improve as the numbers of peripheral blood memory T-cells increase. When tested with allogeneic cells (mixed lymphocyte reaction), however, cord blood lymphocytes respond better, though still somewhat less than cells from adult subjects [86, 87, 89, 90].

Cytokine Production

Neonatal concentrations of pro-inflammatory cytokines like IL-1, IL-6, TNF-α, IFN-α, and IFN-β are comparable to adults, and also increase similarly during sepsis [91, 92]. Premature infants, however, are known to produce lower amounts of TNF-α and IFN-α compared to those born at term [93, 94]. Among the cytokines involved in adaptive immunity, only IL-2 concentrations are comparable; others like IL-4, IL-5, IL-10, IL-15 and IFN-γ are known to be significantly lower than adults [93–96]. Transforming growth factor (TGF)-β_1 and macrophage inflammatory protein-1alpha (MIP)-1α, both of which play a negative role in hematopoiesis, are also present in much lower concentrations [97].

The concentrations of hematopoietic colony stimulating factors including IL-3, Granulocyte Macrophage-Colony Stimulating Factor (GM-CSF), Granulocyte-CSF and Monocyte-CSF are slightly lower to comparable to adults, but even full-term infants are known to be unable to mount adequate responses during stress [98]. Chemokines, which have emerged as important regulators of leukocyte trafficking, are currently an important area of study. The concentrations of some of these are known to be comparable to adults, including IL-8/CXCL8, epithelial neutrophil attractant (ENA)-78/CXCL5, growth-related oncoprotein (GRO)-α/CXCL1, eotaxin/CCL11, and RANTES (regulated upon activation, normal T-cell expressed and secreted)/CCL5 [99].

Most of these deficiencies are caused by altered regulation of post-transcriptional mRNA processing [97]. It is believed that lower concentrations of some of these cytokines are caused by a relative paucity of memory or primed T-cells. However, genetic and other individual traits such as atopy are also likely to be important determinants of the cytokine response [100].

During development, naïve T-cells differentiate into distinct effector T-helper (Th) subsets, a process in which cytokines play a critical role. These differentiated T-cells were originally categorically designated Th1 and Th2 cells based on distinct functional properties and the cytokines that drive their development [101]. Th1 type cytokines, such as IFN-γ and IL-2 play a key role in initiating early resistance to pathogens, and induction of cell-mediated immunity. Th2 cytokines drive the system toward immune tolerance rather than toward defense from microbial infections. Accumulating evidence suggests that Th1 responses in newborns are compromised at several steps including deficient production of Th1 type cytokines by neonatal CD4+ T-cells and hyporesponsiveness of neonatal macrophages to stimulation by IFN-γ. These deficiencies contribute to the apparently weak cellular immunity in newborns biased towards a Th2 type response [102].

Since the original Th1 and Th2 description, a differentiated T-cell population, Th17 cells, has been shown to have a pathogenic role in allergic, autoimmune and other chronic inflammatory diseases [103, 104]. Th17 cells have also been shown to play a protective role in immunity to infection, where they take on Th1-like effector functions to promote pathogen clearance by enhancing neutrophil recruitment to sites of infection and activating macrophages [103–105]. While the role of Th17 cells early in life remains unclear, cord blood mononuclear cells have a limited capacity to produce IL-17 [106]. In very premature infants with a history of serious bloodstream infections (BSI), we found lower serum IL-17 levels than their counterparts who never developed BSI.

The fetus occupies a unique immunologic position where the Th2 phenotype predominates in utero and transitions to a more Th1 functionality following birth. It is generally considered to be a core process of evolutionary significance where both mother and fetus maintain a high level of immunologic suppression to enable continuation of pregnancy.

Antigen-Specific Responses

The response of T-cells to specific antigens can also be assessed in terms of proliferation or cytokine production. These responses usually require previous exposure to the corresponding antigen, and are generally not detected at birth or from cord blood unless there was an intrauterine exposure. Neonatal T-cells do, however, respond well to certain antigens such as tetanus/diphtheria toxoids, influenza, and mycobacterial antigens [87]. In response to superantigens, cord blood T-cells produce lesser amounts of IL-2 [107]. However, after stimulation, the percentage of $V\beta_2$+ T-cells (which determine potential reactivity to superantigens) and the number of memory T-cells increase significantly just like adults [107]. But unlike adult T-cells, cord blood T-cells are unable to respond if restimulated with the superantigen. This tolerance induction in cord blood T-cells may again be due to the underlying immunologic naiveté [107, 108].

108.4.2.5 Other Subgroups

Cytotoxic T-Lymphocytes (CTLs)

CTLs are important in host defense against intracellular infections, in allograft rejection and tumor cell surveillance [109]. CTLs utilize two well-established mechanisms for cell lysis, one involving release of extracellular mediators (such as the pore-forming perforin/granzyme system), and a second fas/fas ligand dependent pathway that leads to target cell apoptosis [110].

CTL cytotoxicity is evident by 18 weeks of gestation, but is far less efficient that adult cells even at term (<20 percent of adult CTL activity) [111]. Perforin expression in neonatal CTLs is about 30 percent of adult levels. CD28, which is a T-cell activation marker, is also expressed to significantly lower levels [90]. Similar results are also observed in other assays; neonatal cells showed only 33 percent of lectin/mitogen-dependent cytotoxicity of adult cells [112]. Circulating inhibitors such as a-fetoprotein and prostaglandins may also lead to lower CTL activity in neonates [112].

γδT-Cells

The γδ T-cells represent a distinct functional subset, with a majority lacking surface expression of both CD4 and CD8 [113]. These cells are detectable in the fetal thymus and liver at 6–8 weeks of gestation, and comprise nearly 10% of the peripheral blood T-cells at 16 weeks [114]. Subsequently, the numbers decline gradually to reach about 3% at term [115]. These cells are present mainly on skin and mucosal surfaces [113]. Although the exact functions of these T-cells are not well understood, they can lyse target cells with the perforin/granzyme system like the cytotoxic T-cells, and can secrete cytokines like interferon (IFN)-γ and tumor necrosis factor (TNF)-α upon activation. The cytotoxicity of neonatal γδ T-cells is significantly less than adults [116].

Fetal γδ T-cells have a more diverse repertoire but a more limited junctional diversity than adults. This diversity is retained throughout the first year of life, and then decreases gradually over the first decade of life [116]. Overall, however, γδ T-cells have a relatively restricted repertoire in comparison to the αβ T- or B-cells [117].

T-Regulatory Cells

T-regulatory cells (Tregs) downregulate T-cell responses to both foreign and self antigens, thereby playing an important role in balancing Th1/Th2 effector lineages [118]. Treg cells, including both natural $CD4^+$ $CD25^+$ Tregs as well as the IL-10-producing Tregs, express the forkhead/winged-helix family transcriptional repressor-p3 (Foxp3) [119], a commonly-used but not entirely specific marker for Tregs [120]. Although Tregs have been detected in cord blood, current knowledge about Treg function early in life is limited and thus their relevance to immune defense of the newborn is uncertain.

108.4.3 B-Lymphocytes

108.4.3.1 Development

B-cell progenitors, pro-B-cells, are derived from pluripotent hematopoietic cells in the bone marrow [121]. The first

recognizable B-cell progenitor, the large pre-B-cell, is characterized by the presence of cytoplasmic μ heavy chains [121]. Immature B-cells undergo a selection process analogous to T-cells to eliminate self-identifying clones (clonal selection, clonal deletion), although there may also be other mechanisms to maintain self-tolerance [122]. Once B-cells begin to express surface IgM (sIgM), they are ready to leave the bone marrow to enter the peripheral circulation [123].

Pre-B-cells can be identified in the fetal liver as early as 7 weeks of gestation, and in the marrow by 12 weeks. sIgM+ B-cells are found in the fetal liver by 9 weeks and in the bone marrow, peripheral blood, and spleen by 12 weeks. B-cells with sIgA, sIgG, and sIgD isotypes appear between 10 and 12 weeks. There is also increased traffic to the lymphoid tissues, and by 22 weeks, the proportion of B-cells in the spleen, peripheral blood, and bone marrow is similar to that in adults. By 30 weeks, there are no detectable pre-B-cells in the fetal liver, and bone marrow becomes the exclusive site for B-cell maturation. Plasma cells are not generally found until 20 weeks' gestation. IgM/IgD+ B-cells populate the lymph nodes by 16–17 weeks' gestation and the spleen by 16–21 weeks. In fetal lymph nodes, primary nodules develop around the follicular dendritic cells by 17 weeks' gestation [124]. Considering the extreme degree of premature birth and survival in this era even below 24 weeks, it is perhaps no surprise that effective production of antibody for opsonization and enhanced cytotoxicity is limited.

108.4.3.2 Immunoglobulin Repertoire

Receptor diversity in the antigen binding site originates from DNA recombination involving various V, D, or J gene segments giving rise to a large number of V(D)J permutations [80]. Additional receptor diversity is generated by imprecise gene segment joins, additional nucleotides added to the splice junction of the VDJ joins by the enzyme terminal deoxynucleotidyl transferase (TdT), and somatic mutations (for B-cells only, not T-cells). Thereafter, these VDJ or VJ (light chains) units join to their respective constant region gene segments [125].

In the fetus and neonate, the Ig repertoire is relatively restricted. During early and mid-gestation, certain heavy chain V gene segments are preferentially expressed. Early in fetal life, the most J_H proximal V_H gene segments are preferentially utilized, and consequently, the CDR3 region of the rearranged VDJ gene segment is shorter than that in adults. This leads to relatively limited junctional diversity, but this altered architecture of the antigen-binding site may also allow greater polyspecificity of antigen binding (at a cost of lower antibody affinity) [126]. The utilization of V_H gene families spreads out more evenly with increasing gestation. However, even at term, cord blood B-cells have a higher usage of V_H genes of the V_H 1 and V_H 5 family with decreased V_H 3 use compared with adult B-cells [127]. In general, the antibody response in neonates is of low affinity, and restricted to the IgM isotype. The somatic mutation of the heavy and light Ig variable region genes and the selection of higher affinity antibody-producing B-cells is limited at birth but increases very slowly after 10 days of age [128]. It is significant that the maturation of antigen presenting cells and functional limitations of B-cells reduces the capacity of effective defense mechanisms during the period of novel exposure to nutrient derived antigens and gut flora yet eventually acquires the ability to accurately discern self from diet.

108.4.3.3 Circulating B-Cells

At birth, the proportion of B-cells is similar to that of adults, but the absolute number of B-cells is significantly higher [129]. The number peaks at about 3–4 months of age, and then declines to adult levels by 6–7 years of age [130]. Preterm infants have comparable B-cell numbers to the term infants [131]. However, the number is smaller in growth-retarded infants. Unlike adults, most B-cells in cord blood express activation markers (CD25, CD23, transferrin receptor) [132].

108.4.3.4 Function

Immunoglobulin Production

The fetus and the neonate are capable, although at a lower intensity than adults, of mounting antigen-specific antibody responses. The presence of allergen-specific IgEs in cord blood, anti-tetanus IgM in cord sera of newborns whose mothers were vaccinated during pregnancy, and reactivity to *Ascaris* antigens in the event of maternal infestation are some examples [133, 134].

However, this response remains immature [124]. They may be unable to respond to all the antigens in a vaccine, and often have delayed isotype switch [135]. It appears that the interval from birth is a more important determinant of antibody response than the gestational age. Both preterm and term infants immunized with diphtheria toxoid at 0–10 days of age had poorer responses than similarly immunized adults, but the response was better when vaccination was deferred until 1–2 months of age [135]. With certain antigens like hepatitis B, however, premature infants may show a relatively poorer early response than their term counterparts, although these deficiencies correct during later infancy [136]. Collectively, these observations suggest that many of the maturational signals needed to achieve a full capacity of host defenses arise from evolutionary appropriate cues received from the neonatal environment forcing the irrevocable expansion of a wide diversity of immune capacities. Thus, the newborn is effectively, not solely limited by its ontological immaturity of cellular and humoral capacities.

Serum Immunoglobulin Levels

Serum Ig levels remain very low until 18–20 weeks' gestation. Most of the newborn's serum immunoglobulins are derived from active transplacental transfer of maternal IgG (particularly IgG1 and IgG3) during the third trimester [137]. In the full-term neonate, serum IgG levels are equal or even higher than maternal serum IgG levels, but in the preterm, who missed these maternal antibodies, the levels are lower.

Hobbs and Davis found that nearly all infants born before 32 weeks' gestation had serum IgG levels less than 400 mg/dL at birth (compared with term infants who had serum levels around 1000 mg/dL) [138]. The levels fall after birth (through normal catabolism) to a nadir of 300–500 mg/dL between 3 and 5 months of age, when the infant starts producing increasing amounts of his/her own. Because of starting at a lower level, this nadir may be much lower, and earlier, in preterm infants [139]. Cord blood Ig levels also tend to be lower in growth retarded neonates [140].

The serum levels of IgA, IgM and IgE are very low even in term infants, since these do not cross the placenta. However, when faced with an intrauterine infection, the fetus is definitely capable of producing appreciable amounts of IgM [141]. For many years it was believed that augmenting the neonatal repertoire with exogenous pooled IgG could augment immune functions. Unfortunately, data proving efficacy of this approach for prevention or intervention for bacterial infections has not proven compelling; nevertheless, use of high titer Ig for mitigating perinatal transmission of hepatitis B is well established.

Taken together, it is clear that an improved understanding of these IgG relationships may some day be exploited to enhance bacterial opsonization.

108.4.3.5 Other Subgroups

CD5 Expressing B-cells

B-cells with surface expression of CD5, which is a T-cell antigen, may represent a functionally and ontogenically distinct subset. Some believe that CD5 positivity defines a so-called B-1 subset of cells, distinct from the conventional adult B2 population by virtue of their earlier appearance in ontogeny, capacity for bone marrow-independent self-renewal, and constitutively expressing signal transducer and activator of transcription-3 (STAT3) [142]. B-1 cells express the B-cell-lineage antigens CD19 and CD45R, although CD45R is present at lower levels on B-1 cells than on B-2 cells [143–145]. B-1 cells in the peritoneal and pleural cavities can be identified by their unusual CD11b+ sIgMhi sIgDlow phenotype and can be further subdivided on the basis of differential expression of the cell-surface antigen CD5, into CD5+ CD11b+ $sIgM^{hi}$ $sIgD^{low}$ B-1a cells and CD5- CD11b+ $sIgM^{hi}$ $sIgD^{low}$ B-1b cells [146].

These cells are the predominant B-cell type during fetal life, and have a distinctive anatomic localization in the fetal spleen and the peritoneal cavity. They appear in the spleen at 15 weeks, and are seen in the lymph node primary follicles at about 17 weeks of gestation [147]. In adults, CD5 expression can be found on about 25–35% of total B-cells and 1–7% of all the peripheral blood mononuclear cells. In contrast, CD5+ B-cells represent approximately 90% of the total cord blood B-cells. This number decreases to 75–80% during infancy, and reaches adult levels only by late adolescence [147].

The exact function of B-1 cells in the fetus is still unclear. The functional characteristics of B-1 cells such as the unique localization, broad polyspecificities, and a restricted Ig repertoire have been considered to indicate a role of these cells in the innate, rather than in adaptive immunity [148]. Unlike follicular B-2 cells that respond to protein antigens, and with T-cell help, undergo immunoglobulin heavy chain class-switching and affinity maturation, B-1 cells respond mainly to T-cell-independent immunogens that include carbohydrate antigens [143–145].

Recent observations indicate that the two types of B-1 cell, B-1a and B-1b, show functional differences during the immune response. B-1a cells spontaneously secrete IgM, which provides a first line of defense against certain encapsulated bacteria, such as *Streptococcus pneumoniae*, whereas antibody production by B-1b cells is induced and has a role in the ultimate clearance of the pathogen and in providing long-term protection [146, 149, 150].

108.4.4 T- and B-Cell Interaction

T-cell signals are crucial for the proliferation, differentiation, and survival of B-cells, and include both antigen presentation and humoral signals (cytokines like IL-2, IL-4, IL-5, IL-6, IL-10, IL-13, and IFN-γ) [151]. Several pairs of other receptor-ligand molecules are also involved, including the CD40-CD40 ligand (CD40L) in B-cell immunoglobulin isotype switching, and others like B7/CD28, CD11a (LFA-1)/CD54 (ICAM-1), and CD58 (LFA-3)/CD2 in T- and B-cell activation [151]. Only about 30% of naïve neonatal T-cells express CD40L, compared to 80% of the naïve T-cells from adults [152]. However, once primed with mitogen(s) and IL-2, which converts naïve T- cells to the memory phenotype, neonatal T-cell CD40L expression is upregulated to adult levels [153]. The capacity of neonatal B-cells to differentiate into plasma cells and undergo isotype switching can be variable (*vide infra*), but in general, neonatal T-cells are less efficient at providing humoral and CD40-dependent activation signals [154, 155].

108.4.5 Natural Killer Cells

108.4.5.1 Development

NK cells share some T-cell markers, but are not affected in many natural/experimental disruptions of the T-cell system [156–158]. It is conceivable that the two lineages derive from a common progenitor [159, 160]. Morphologically, NK cells are large granular lymphocytes, and have characteristic surface markers including the CD56/neural cell adhesion molecule and CD16/$F_c\gamma$ receptor IIIa ($F_c\gamma$RIIIa), a low affinity IgG receptor. They also express CD2, LFA-1 and cytokine receptors such as IL-2$R_{\beta\gamma c}$, IL-12R, IFN-γR and IL-15R_α [161].

NK cells can be detected as early as 6 weeks of gestation, and the number then increases progressively until birth. In cord blood, 10–15% of all lymphocytes are NK cells, which is comparable to adult peripheral blood [159]. The phenotype of fetal NK cells, however, is different from that of adults' cells. Fifty to 80% of fetal NK cells express CD3γ, ε, λ, and σ proteins, unlike a much smaller number in term infants, or in adults where only CD3σ is expressed [159]. On the other hand, only 30–50% of the fetal NK cells express CD16 (compared with more than 90% of neonatal and adult NK cells). Similarly, CD56 and CD57 are expressed poorly on fetal or neonatal NK cells, compared to nearly 50 percent positivity in adult NK cells [159, 162].

108.4.5.2 Function

NK cells recognize viral-infected and tumor cells by the absence or decreased expression of MHC class I molecules on the cell surface [163]. Their MHC-unrestricted killing is mediated by perforin/granzyme apoptotic pathways [164]. The other mechanism of cytolysis is antibody-dependent cell-mediated cytotoxicity (ADCC), where target cell-bound IgG1 or IgG3 triggers the $F_c\gamma$RIIIa receptor on the NK cell [163, 165]. NK cells are also believed to play a key role in maintaining immunological tolerance at the maternal-fetal interface [166].

Fetal NK cells have a significantly lower cytolytic activity (including ADCC) against tumor cell target cell lines than adults, but it increases with gestational age parallel to increasing expression of CD56 and CD16 [153, 159]. However, even at term, the cytolytic activity is only 50–80% of adult levels [160].

NK cells should not be confused with the natural killer T-cells, a heterogeneous group of T-cells that express an alpha beta T-cell receptor along with some of the NK cell markers. Many of these cells recognize the non-polymorphic CD1d molecule, an antigen-presenting molecule that binds self- and foreign lipids and glycolipids. NK T-cells constitute only 0.2% of all peripheral blood T-cells. These cells play an important role in mucosal immunity and in the pathogenesis of inflammatory/allergic conditions; the role during fetal life remains unclear [167]. Imbalances in this system produced by chronic inflammation may be involved in the presentation of the acquired forms of hemophagocytic lymphohistiocytosis in the neonatal period.

108.5 The Mucosal Immune System

108.5.1 Peyer's Patches and Other Organized Lymphoid Tissue

Peyer's patch anlagen become identifiable in fetal ileum at 11 weeks as aggregates of HLA-DR^+, $CD4^+$ lymphoid cells [168, 169]. Major events in Peyer's patch development have been summarized in Fig. 108.3 and Table 108.1 [169–171]. At birth, the organized lymphoid compartment is naïve but structurally complete, and the predominant activity involves proliferative expansion (rather than primary lymphopoiesis) [171]. The number of PP increases from about 60 at birth to over 200 by 12–14 years [172].

In the vermiform appendix, the development of lymphoid structures lags behind the Peyer's patches [173]. Appendiceal

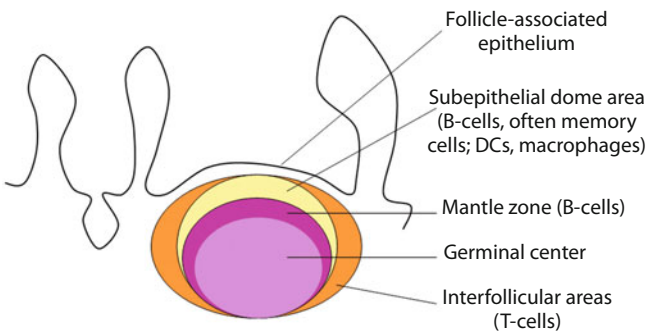

Fig. 108.3 Structure of Peyer's patch

Table 108.1 Development of Peyer's patches in the human fetus

11 wks gestation	PP anlagen with HLA-DR+ CD4+ lymphoid cells
16 wks gestation	Appearance of T- and B-cells First appearance of CD8+ cells* B-cell maturation with appearance of surface IgM and IgD
16–18 wks gestation	Appearance of CD5+ B-1 cells Surface IgA on B-cells
18–20 wks gestation	Appearance of PP zonation into B- and T-cell areas
24 wks gestation	PP are macroscopically identifiable
0–4 wks postnatal	Germinal center formation

* Fetal Peyer's patch T-cells are predominantly of the $CD4^+$ phenotype.

lymphoid follicles enlarge rapidly after birth following bacterial colonization and translocation [174]. The first IgA^+ plasma cells appear at 2 weeks after birth and then increase to adult levels at 4–5 months. To what extent full and appropriate capacity of this system contributes to the susceptibility of the preterm neonate to the development of necrotizing enterocolitis remains to be ascertained.

108.5.2 Lymphocytes in the Lamina Propria and Intra-Epithelial Compartments

Scattered B-cells are first observed in the lamina propria at 14 weeks gestation [169]. The fetal intestinal B-cell population consists of two distinct cell types. The first population of large, dividing, mature B-cells shares morphologic and phenotypic ($CD20^+IgM^+IgD^+$light $chain^+$) features with the thymic B-cells. These are large-sized cells with extensive cytoplasmic processes, which are in contact with adjacent T-cells. A second population of smaller pre-B-cells (IgM^+ light $chain^-$ $CD20^-$) has also been identified, suggesting the presence of local B-cell development [175]. As extrathymic T-cell development occurs in human fetal intestine (*vide infra*), it has been hypothesized that as in the thymus, the B-cells may play a role in the development and selection of the T-cells.

The B-cell population in the fetal intestine comprises IgM^+ and IgG^+ cells [176]. The fetal intestinal B-cell repertoire is similar to B-cells in circulation or other organs, but differs significantly from plasma cells in postnatal intestine [175]. After birth, the IgM^+ plasma cell population expands faster than IgG^+ cells, and at the same time microbial stimulation induces B-cells to undergo IgA class switch in both the lamina propria and organized lymphoid tissue [177]. IgA+ plasma cells are first seen in the lamina propria during the second postnatal week [178]. The number of IgA^+ cells in the mucosa reach adult levels at 2 years, although serum IgA concentrations reach adult levels only during the second decade [170].

Intestinal T-cells can be identified from 12–14 weeks of gestation [179]. Outside the organized lymphoid tissue, intestinal T-cells are distributed as intra-epithelial (IELs) and lamina propria lymphocytes (LPLs). The fetal gut has a small number of IELs (3–5 $CD3^+$ IEL/100 IECs compared to 6–27 cells/100 IECs in older children), which expand rapidly after birth (a 10-fold expansion of the αβ T-cells and a 2–3 fold increase in the γδ cells, vide infra) [170, 180]. In contrast, LPLs continue to expand during fetal period and have a density similar to the postnatal intestine by 19–27 weeks gestation [179].

Several early lineage T-cell populations can be seen in the fetal intestine, suggesting that T-cells may develop locally in an extrathymic pathway [169, 171, 179, 181]. These immature T-cell lineages are shown in Fig. 108.4. Whereas most immature LPLs differentiate rapidly after birth, the differentiation of IELs is slower and continues through infancy [182]. In addition to phenotypic changes, intestinal T-cells also continue to undergo functional maturation during infancy and childhood. The TCR β-chain repertoire is polyclonal during fetal period and infancy and only gradually becomes restricted to the oligoclonal pattern characteristic of adults. This restriction is likely due to expansion of a few dominant clones, which are specific for the commensal bacterial flora [182].

In the fetal intestine, about 10–30% of IELs express the γδ T-cell receptor [169]. Rodent studies suggest that γδ cells may regulate IEC function, display cytotoxic activity and may promote antimicrobial immunity [183, 184]. Similar to αβ T-cells, the fetal/neonatal γδ repertoire is also polyclonal [185].

108.5.3 Secretory Immunoglobulins

Secretory immunoglobulins, IgA and IgM, play an important role in mucosal defense. Secretory IgA (sIgA) can be detected in mucosal secretions as early as 1–8 weeks after birth [186–189]. sIgM, on the other hand, appears transiently during early infancy [188].

sIgA levels rise during the neonatal period to reach an initial peak (as measured in saliva) at 4–6 weeks. In premature infants, sIgA appears in secretions at a similar chronological age as in full-term infants, although sIgA concentrations may be lower. If chronological age is corrected for prematurity, sIgA concentrations then become similar to matched full-term infants [190, 191]. Salivary IgA levels continue to rise up to 18 months of age [191]. A transient nadir in sIgA has been inconsistently [189, 192] recorded at 3–6 months [188, 193].

Secreted immunoglobulins also change qualitatively during the first year. There is a switch from monomeric IgA to polymeric sIgA sometime during the first year, indicating maturation of the secretory immune system [194], or alternatively, increasing exposure to exogenous antigens [195]. The relative amounts of IgA subclasses in mucosal secretions also changes during infancy. At birth, sIgA1 is the dominant subclass but sIgA2 increases rapidly by 6 months of age [192].

Specific sIgA responses appear to be related more to the timing and quantum of the antigenic stimulus than to developmental factors during infancy. sIgA antibodies to *E. coli* somatic antigens appear in neonates within a few weeks after timed exposure and colonization [196]. The strength of the stimulus also has an effect: earlier, and stronger, specific sIgA responses are seen in neonates born in areas endemic for a pathogen compared to infants in the developed world [194, 197].

During the neonatal period, colostrum provides an important alternative source of sIgA [198]. Milk antibodies, amounting to about 0.5–1 g/day throughout lactation (comparable to the 2.5 g/day being produced by a 65 kg adult), are directed against antigens present in the environment shared by the mother-infant dyad [199]. The presence of enteromammary and bronchomammary pathways allow immune cells stimulated by antigens in the maternal intestine and bronchial mucosa to migrate to the mammary gland [198, 200]. Interestingly,

sIgA levels have been reported to be higher in colostrum and milk of mothers of preterm neonates [201].

Premature infants lack the intrinsic protective mechanisms of the adult intestinal mucosa that prevent sensitization against luminal constituents: a strong physical barrier, luminal enzymes that can alter ingested antigens, presence of regulatory T-cells, and the production of sIgA [202]. The risk of sensitization is further increased due to several developmental deficiencies within primary immune cells: (1) specific antibody responses in premature infants are abnormal due to reduced antigen affinity, increased polyreactivity, and autoreactivity [147, 203]; (2) the lengths of immunoglobulin heavy chain third complementarity determining regions (CDR3) are almost 3 amino acids shorter in the fetus/premature infant than adults [204]. This reduces the potential antibody diversity available to the fetus/preterm neonate by about 20^3 (= 8000) fold [204]. Moreover, antigen binding sites with short CDR3 regions, due to their tertiary structure, are more likely to bind to peptides such as allergens [205]; and (3) the short CDR3 regions of fetal $CD5^+$ B1 cells share characteristics with variable regions of IgE heavy chains [206, 207]. These observations have led to the hypothesis that B1 cells may contribute to the repertoire of allergen specific IgE^+ plasma cells, and that premature exposure of the immature intestinal B-cell repertoire to allergens may influence the risk of sensitization [207].

108.5.4 Intestinal Macrophages and Dendritic Cells

Macrophages first appear in the developing intestine at 11–12 weeks of gestation, increase rapidly during the 12–22 week period, and then continue to expand at a slower pace through early childhood [176, 208, 209]. These cells play a critical host defense role in being the first phagocytic cells of the innate immune system to encounter luminal bacteria that breach the epithelium and gain access to the lamina propria [60, 210]. Intestinal macrophages display avid phagocytic and bacteriocidal activity but are markedly attenuated in their inflammatory responses [60], a unique adaptive mechanism that prevents unnecessary inflammation in the gut mucosa despite the proximity to luminal bacteria. In sick and preterm neonates who are predisposed to bacterial translocation due to an abnormally permeable gut epithelial barrier, immaturity of the local adaptive immune system and low secretory IgA production [174, 211], intestinal macrophages assume even greater importance as a host defense system because of their ability to eliminate previously unknown bacteria through phagocytosis and intracellular killing. A breach of the gut mucosal barrier defense is met by tissue macrophages in the liver (Kupffer cells).

Intestinal macrophages are derived from circulating monocytes, which are recruited to the mucosa under the influence of various epithelial- and mesenchymal cell-derived chemoattractants [60, 210, 212]. Because neither intestinal macrophages nor their precursor monocytes have the ability to undergo clonal expansion [210], the only mechanism available for the development and maintenance of the gut macrophage pool is through the continuous recruitment and differentiation of blood monocytes. In adults, interleukin-8/CXC ligand 8 (IL-8/CXCL8) and transforming growth factor-beta (TGF-β) recruit macrophage precursors to the intestinal mucosa [210]. However, several lines of evidence indicate that IL-8 and TGF-β may not be important as macrophage chemoattractants in the fetal intestine. In the fetus, IL-8 is mainly comprised of a longer, less-potent 77-amino acid isoform (unlike the shorter 72-amino acid isomer in the adult) [213]. Similarly, TGF-β bioactivity is low in the early-/mid-gestation fetal intestine. Finally, macrophages appear in the fetal intestine at least a few weeks before lymphocytes or neutrophils [208, 209], suggesting that macrophage precursors are likely to be recruited to the early fetal intestine by chemoattractant(s) more specific for macrophage precursors than IL-8/CXCL8, which recruits both neutrophils and macrophage precursors [20, 210], or TGF-β, which mobilizes macrophage precursors as well as T lymphocytes [210, 214]. We have shown recently that epithelial cells in the fetal intestine produce chemerin (previously known as tazarotene-induced gene-2/TIG2 or retinoic acid receptor responder-2/RARRES2), to recruit macrophage precursors.

We have shown recently that unlike in the adult, intestinal macrophages in the midgestation fetus/premature infant are responsive to bacterial products and produce inflammatory cytokines. This inflammatory downregulation of fetal intestinal macrophages occurs under the influence of TGF-β, particularly the TGF-β_2 isoform. Further investigations are currently in progress to determine whether the incompletely-developed macrophage tolerance to bacterial products in the preterm intestine could predispose these infants to necrotizing enterocolitis.

There is very limited data on fetal/neonatal intestinal DCs [215]. $HLA\text{-}DR^+$ DC-like cells can be detected in both the lamina propria as well as the Peyer's patches after 14 weeks, but these cells may have some overlap with lamina propria macrophages. In rats and non-human primates, DCs have been noted in the fetal lamina propria as well in Peyer's patches [216]. The functional importance of these DCs is not clear.

108.6 Conclusions

It is apparent that the extraordinary complexity of the human immune system in general is amplified at the time of birth by the fetal stage of development, the postnatal age when examined, the ontological capacity of stem cells to respond to

maturational signals and each issue is compounded by the transition from a Th2 to a Th1 phenotype at the conclusion of pregnancy. All of these factors are occurring in tandem with a first inoculum of maternal bacteria as well as her repertoire of related antibodies followed by the acquisition of subsequent bacterial colonizers/modifiers of gut and skin flora (as influence by antibiotic exposure or ex utero environments) and nutrient-derived antigens that must all be distinguished from self to ensure an effective barrier defense and nutrient absorption. It is perhaps more surprising that this system works at all than the fact that there are limitations that increase vulnerability of neonates to infection. A fundamental and expanded understanding of these relationships will further the hope of identifying opportunities to augment immune defenses in ELGANs where bacterial invasiveness ranges from 30–50% of births.

Congenital Immunodeficiencies

Alessandro Plebani and Gaetano Chirico

109.1 Introduction

The primary immunodeficiency diseases (PIDs) are a heterogeneous group of inherited disorders with defects in one or more components of the immune system. PIDs are classified into T lymphocyte, B lymphocyte, phagocytic cell, and complement deficiencies. This classification is simple and practical because clinical symptoms, mainly susceptibility to infections, vary according to the affected arm of the immune system. The prognosis of these disorders and their treatment depends on their early recognition and initiation of appropriate management.

Evaluation of immune function should be considered for children with clinical symptoms of a distinct immune disorder or with unusual, chronic, or recurrent infections, such as: one or more systemic bacterial infections (sepsis, meningitis); two or more serious bacterial infections (cellulitis, suppurative otitis media, pneumonia, lymphoadenitis) during the first year; serious infections occurring at unusual sites (liver, brain abscess, omphalitis); infections with opportunistic pathogens (*Aspergillus*, *Serratia marcescens*, *Pneumocystis jiroveci* (formerly *P. carinii*), *Cryptosporidium*, *Nocardia*); infections with common childhood pathogen but with unusual severity.

Clinical suspicion of a primary immunodeficiency disease should be raised in case of a history of consanguinity or a positive family history for a congenital immunodeficiency. Physical signs include an absence of lymphoid tissue or the presence of syndromic features. Severe or recurrent infections caused by encapsulated bacteria suggest a primary B-cell or complement defect, and they occur after the first 6-12 months of age, in parallel with the decrease of the maternally acquired IgG. On the contrary, severe viral (adenovirus, cytomegalovirus, respiratory syncytial virus), fungal or opportunistic infections during the first few months of life, are indicative of a primary T-cell defect.

A. Plebani (✉)
Department of Pediatrics, Spedali Civili Hospital and University of Brescia, Brescia, Italy

A complete differential blood count and assessment of immunoglobulin serum levels are the most cost-effective diagnostic screening tests. A normal neutrophil count excludes neutropenia, and normal platelet size or counts exclude the Wiskott-Aldrich syndrome. If the absolute lymphocyte count is normal, the patient is unlikely to have a severe T-cell defect because T-cells normally represent 70% of circulating lymphocytes and their absence results in severe lymphopenia. This is not the case for T^-B^+ severe combined immunodeficiencies, in which the presence of circulating B-cells results in a normal absolute lymphocyte count and cytofluorimetric analysis of B- and T-cell subsets reveals that virtually all lymphocytes belong to the B-cell lineage. Low immunoglobulin serum levels with normal T-cell counts indicates a diagnosis of a primary B-cell defect. Normal neutrophil, T- and B-cell counts should point to a functional defect of phagocytes. The genes responsible for many PIDs are known, which may lead to successful neonatal screening programs. In this chapter we will focus on primary T- and B-cell defects and related disorders.

109.2 Defects of the B Cell Compartment

109.2.1 Agammaglobulinemia and Common Variable Immunodeficiency

Agammaglobulinemia, X linked (XLA or Bruton's Agammaglobulinemia) or autosomal recessive agammaglobulinemia (ARA) represent the prototype of disorders of the B-cell compartment. Both disorders are characterized by absent/low immunoglobulin serum levels, defective antibody response to antigens, and absence of circulating B-cells in the presence of normal T-cell counts and function. Both disorders result from an early block of B-cell development, caused in XLA by mutations in the gene encoding Bruton's tyrosine kinase (Btk), which has a crucial role in early B-cell differentiation. XLA accounts for 70–90% of agammaglobulinemic patients. Five

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

distinct autosomal recessive genetic defects have been found to cause ARA, including mutations in the genes encoding the following: the μ heavy chain; Igα and Igβ signalling molecules; B-cell linker adaptor protein (BLNK); the surrogate light chain, λ5/14.1; and in the gene leucine-rich repeat-containing 8 (*LRRC8*). With the exception of *BLNK* and *LRRC8*, the other genes encode for components of the B-cell receptor complex, which is responsible for transducing the signals necessary for early B-cell development [1]. The onset of symptoms in agammaglobulinemia usually occurs early in infancy between 6 and 12 months as maternally acquired IgG decrease. Infections may start sooner in extremely preterm infants. A positive family history of primary immunodeficiencies is an indication for immunological investigation even in the absence of clinical signs. Bacterial infections are the most common clinical manifestations of agammaglobulinemia, usually by *Streptococcus pneumoniae*, *Haemophylus influenzae*, *S. aureus* and *Pseudomonas* species. Infections include otitis media, sinusitis, pneumonia, sepsis and meningitis. Less common bacterial species, such as *Salmonella* and *Campylobacter* account for gastrointestinal infections. Viral infections are usually handled normally with the exception of hepatitis viruses and enteroviruses [1]. Live attenuated vaccines should not be administered. Physical examination often reveals lymphoid hypoplasia with minimal or no tonsillar tissue and no palpable lymph nodes. Patients found to have low/absent immunoglobulin serum levels should have their B-cells evaluated by flow cytometry using monoclonal antibodies against CD19 or CD20. Normally, approximately 10% of circulating lymphocytes are B-cells. B-cells are absent (or <1%) in both XLA and ARA. However, hypogammaglobulinemia in the presence of normal B-cell counts suggests a diagnosis of common variable immunodeficiency (CVID). This distinction is important because children with hypogammaglobulinemia due to XLA/ARA or CVID can have different clinical problems, and the two conditions clearly have different inheritance patterns. Although CVID is considered a disorder of adults, it may also occur in infancy.

Because of the transient hypogammaglobulinemia of infancy, a definite diagnosis of CVID cannot be made early in life unless a defective antibody response to antigens is documented. Gene sequence analysis of the genes causing CVID (*ICOS*, inducible co-stimulator; *TACI*, transmembrane activator, calcium modulator, and cyclophilin ligand interactor; *BAFF-R*, B-cell activating factor of the TNF family receptor, *CD19*, *CD20* and *CD81*), is useful for providing a definitive early diagnosis. However, mutations of these genes account only for 10% of CVID patients [1, 2].

Immunoglobulin replacement therapy is the treatment of choice in agammaglobulinemic patients. Current protocols are based on intravenous immunoglobulins (IVIG) or subcutaneous immunoglobulins (SCIG). Several international studies have shown that maintaining pre-infusion IgG levels > 500 mg/dL results in a notable reduction in the number of infections. This protective IgG level is usually achieved by administration of 400 mg/kg every 3–4 weeks.

109.3 The Hyper IgM Syndrome (HIGM)

HIGM is a heterogeneous group of genetic disorders characterized by normal/elevated IgM associated with low IgG and IgA serum levels because of a defect in the immunoglobulin class switch recombination process. There are X linked and autosomal recessive forms of the disorder [3, 4]. The X-linked forms are caused by mutations of the *CD40 Ligand* (HIGM1) or *NEMO* (nuclear factor κB essential modulator) genes. The autosomal recessive forms are due to mutations of the *AID* (activation-induced cytidine deaminase, HIGM2), *UNG* (uracil DNA glycosylase), or of the *CD40* gene (HIGM3). Distinct clinical features are associated with different genetic defects. HIGM1 and HIGM3 are the most severe forms and their clinical presentation is similar to that observed in immunodeficiencies characterized by T-cell defects. In fact, CD40L is expressed on activated CD4 T-cells and CD40 on B and dendritic cells and defective expression of these molecules ultimately leads to a defect of T-cell priming. Most patients present in infancy with bacterial infections of the upper and lower respiratory tract and have a unique predisposition to *Pneumocystis jiroveci* pneumonia (PCP). These patients are also susceptible to infection with opportunistic pathogens, such as Cytomegalovirus, *Histoplasma capsulatum*, *Cryptococcus*, and *Cryptosporidium parvum*, which is associated with chronic diarrhea. Infection of the biliary tree with Cryptosporidium parvum, may predispose patients to sclerosing colangitis and to tumor of the liver, pancreas or biliary tree. Neutropenia is a common finding in HIGM1. The HIGM caused by the *NEMO* gene is easily recognized because of the presence of anhydrotic ectodermal dysplasia with sparse scalp hair, conical teeth and absent sweat glands.

The HIGM syndromes due to mutations of AID and UNG genes are considered primary B-cell defects. There is typically an increased susceptibility to bacterial infections, similar to agammaglobulinemic patients often with lymphoid hyperplasia.

In the case of low/absent levels of serum IgG and IgA with normal/elevated IgM, the diagnosis of HIGM1 is usually made by demonstrating an inability of activated CD4+ T-cells to express functional CD40L. HIGM2 is diagnosed by demonstrating B-cells that are unable to express the CD40 molecule. Diagnosis of HIGM caused by mutation of AID or UNG genes requires gene sequence analysis.

Except for CD40L and CD40 deficiency, for which stem cell transplantation is recommended [3], appropriate use of antibiotics to treat infections and the regular administration of intravenous immunoglobulins are the only effective treatments for these disorders.

Patients with CD40L and CD40 deficiency should be given co-trimoxazole as prophylaxis for *Pneumocystis jiroveci* pneumonia, advised to drink boiled water, and azithromycin prophylaxis may lessen the risk of *Cryptosporidium parvum* infections.

109.4 Defects of the T Cell Compartment

109.4.1 Severe Combined Immunodeficiencies (SCIDs)

SCIDs are a heterogeneous group of congenital disorders characterized by block of T-cell differentiation, variably associated with abnormal development of other lymphocyte lineage, such as B or natural killer (NK) cells [5]. The overall frequency of these disorders is estimated to be 1: 50,000–1:100,000 live births. SCIDs include a large number of disorders with X-linked or AR-inheritance, most of which are now molecularly defined. The clinical presentation is quite uniform, among the various SCIDs. Affected patients present within the first few months of life with infections, mainly of the respiratory and gastrointestinal tract. Oral candidiasis, persistent diarrhea with growth impairment and/or interstitial pneumonitis are the most frequent manifestations. These patients have increased susceptibility to infections caused by opportunistic organisms including *Candida albicans*, *Pneumocystis jiroveci* and *Aspergillus* species or by viruses (adenovirus, cytomegalovirus, respiratory syncytial virus). Live attenuated vaccines are another cause of severe clinical manifestations. BCG vaccination may lead to disseminated, often lethal infection; progressive central nervous system poliovirus infection can occur secondary to oral polio vaccination or exposure to a recently vaccinated individual.

Non-infectious clinical manifestations consist mainly of graft-versus-host disease (GVHD), presenting with a severe skin rash, caused by maternal engraftment or following transfusion with non-irradiated blood derivatives.

A diagnosis is possible at birth, with most affected infants having lymphopenia (less than 2000 lymphocytes/mm^3). Lymphocyte phenotyping shows a low number of T lymphocytes. B lymphocytes and NK cells may be present or absent depending on the type of SCID. If a high T-cell count is against a diagnosis of SCID, but there are typical clinical symptoms, a systematic search for the maternal origin of the circulating T-cells should be performed. Serum immunoglobulin concentrations are diminished or absent and no antibody response can be elicited after immunization. Four lymphocyte phenotypes are possible on the basis of the influence of the defective gene on T-cell, B-cell, and NK cell development. The $T^-B^+NK^+$ immunophenotype is due to CD3δ–, or CD3ε–, or CD3ζ, or interleukin-7 receptor α-chain deficiency, the $T^-B^+NK^-$ form includes the X-linked SCID which is due to γc deficiency, and the autosomal recessive forms due to JAK3 (Janus kinase 3), or CD45 deficiency, the $T^-B^-NK^+$ form is caused by RAG1, RAG2 (recombination-activating gene), or Artemis deficiency, the $T^-B^-NK^-$ form is caused by ADA (adenosine-deaminase) deficiency. A total lack of both lymphocytes and granulocytes, is suggestive of reticular dysgenesis which is due to mutations of *AK2* (adenylate kinase 2).

The natural course of SCIDs is severe, with most patients dying within the first years of life, unless properly treated. Supportive therapy, which may at best prolong survival, consists of intravenous immunoglobulins, aggressive treatment of infectious episodes, prophylactic co-trimoxazole (to prevent *Pneumocystis jiroveci* pneumonia), and irradiated blood products. Bone marrow transplantation (BMT), or other stem cell transplantation, often results in permanent cure, with a survival rate of 90% if an HLA-identical family donor is available. Excellent results (80% survival) have been obtained with HLA-matched unrelated donor and with aploidentical donor (75% survival). ADA-deficient SCID and X-linked SCID have been treated with somatic gene therapy; although serious adverse events occurred in the case of X-SCID. ADA-deficient SCID is also managed with regular injections of polyethylene glycol conjugate to the bovine-derived adenosine deaminase (PEG-ADA).

109.4.2 Combined Immunodeficiencies (CID)

CID is distinguished from SCID by the presence of low but not absent T-cell function. Similar to SCID, CID is a syndrome of various genetic defects. Clinical presentation may overlap with that of SCID patients, although sometimes infections develop slightly later. CID is an heterogeneous group of immune disorders among which the following are included.

109.4.2.1 MHC Class II Antigen Deficiency

MHC class II antigen deficiency is an autosomal recessive primary immunodeficiency caused by the absence of MHC class II expression on cells normally expressing HLA class II molecules [6]. This disorder is caused by mutations in several different genes, which code for a complex of regulatory factors controlling transcription of MHC II genes. MHC class II-deficient patients have a very low number of CD4 T-cells but normal or elevated numbers of CD8 T-cells. Lymphopenia is only moderate. Patients are hypogammaglobulinemic due to impaired antigen-specific responses caused by the absence of antigen-presenting molecules. These patients present, from early infancy, with an increased susceptibility to viral, bacterial, fungal, and protozoan infections, primarily of the respiratory and gastrointestinal tract. Curative treatment is BMT, although it has limited success in comparison with other types of T-cell immunodeficiencies.

109.4.2.2 Wiskott-Aldrich Syndrome

The Wiskott-Aldrich syndrome (WAS) is an X-linked recessive disorder characterized by microplatelet thrombocytopenia, eczema, recurrent infections, and increased risk of autoimmunity and lymphoreticular neoplasia [7]. Thrombocytopenia and small platelet volume in a male should raise suspicion of the diagnosis. This disorder is caused by mutation of the *WASP* (WAS protein) gene. *WASP* is expressed in

all hematopoietic cells, including CD34+ stem cells. Mutation of this gene not only cause WAS, but also X-linked thrombocytopenia (XLT), a milder form of the disease characterized by microplatelet thrombocytopenia, but without the clinical findings associated with the classic WAS phenotype. The classic clinical symptoms (bleeding, infections and eczema) are usually not present simultaneously. The earliest manifestation, often present at birth, consists of petechiae and bruises. Additional early manifestations of thrombocytopenia include bloody diarrhea, and hemorrhage following circumcision. Eczema and recurrent bacterial infections usually develop during the first year of life; later, infections with microorganisms such as *P. jiroveci*, and the herpes viruses become more frequent. The severity of the immune deficiency can vary depending largely on the type of mutation and its effect on protein expression. Both T and B lymphocyte functions are affected. During infancy the number of circulating lymphocytes might be normal or moderately decreased. Consistent findings are low isohemagglutinins titers, and marked decreased response to polysaccharide antigens.

Intravenous immunoglobulin, appropriate treatment and control (use of killed vaccines) of infections and eczema, platelet transfusion for serious bleeding episodes are part of an appropriate supportive therapy. Bone marrow transplantation is the treatment of choice and may be curative.

109.5 Immunodeficiencies as Part of Complex Diseases

109.5.1 DiGeorge Syndrome (DGS)

DGS is one of the most common chromosomal disorders known (estimated prevalence of 1/4000–1/6000 persons). It is caused by developmental defects in the third pharyngeal pouch and fourth pharyngeal arch [8] and defects are found in the thymus, heart and parathyroid glands. Approximately 90% of patients with DGS are hemizygous for 22q11; in rare instances, patients are hemizygous for 10p13. DGS is characterized by the triad of clinical features: congenital heart defects, immunodeficiency secondary to thymic hypoplasia, and hypocalcemia secondary to parathyroid gland hypoplasia. However, it is now well recognized that the phenotypic features of DGS are much more variable and extensive than previously recognized and frequently overlapping with other disorders including velocardiofacial syndrome (VCFS) and conotruncal anomaly face syndrome (CTAFS), both of which are frequently associated with 22q deletions. The collective acronym CATCH22 syndrome (Cardiac defects, Abnormal facies, Thymic hypoplasia, Cleft palate, and Hypocalcemia resulting from 22q11 deletions) has been proposed for these differing presentations, but should probably be avoided when considering individual patients. Dysmorphic facial features of DGS include: hypertelorism, low-set, prominent ears, micrognathia, high arched palate, short philtrum of the upper lip. Cardiac defects, dysmorphic facial features and hypocalcemic seizures occurring during the neonatal period should raise the suspicion of DGS.

All children suspected of DGS should have an immunological work up. Most infant with DGS have a mild and transient immunodeficiency. Immunoglobulin serum levels are usually normal, T-cell production is usually moderately impaired and T-cell mitogen responses are often normal or near normal. These patients usually develop normal or near-normal immunologic function over time. Total thymic aplasia is present in less than 1% of cases. It occurs in complete DGS, when patients resemble SCID in their immunological phenotype and susceptibility to infections with low grade or opportunistic pathogens. Bone marrow and thymus transplantations have been performed in complete DGS.

109.5.2 Cartilage-Hair Hypoplasia (CHH)

CHH is a rare autosomal recessive disorder characterized by chondrodysplasia with growth failure, hypoplastic hair, defective immunity and erythrogenesis. CHH is caused by mutations in the *RMRP* (ribonuclease mitochondrial RNA-processing) [9]. The disease is prevalent among the Old Order Amish in the United States and in the Finnish population. Growth failure, has its onset prenatally, and is usually due to short limbs. All segments of the limbs are affected. The major radiological abnormalities are confined to the methaphyseal parts of the tubular bones, which are flared, scalloped, and irregularly sclerotic. The majority of the patients have sparse, fine, and silky hair. Hirschsprung's disease and predisposition to malignancies have been reported.

The defective cellular immunity is characterized by mild to moderate lymphopenia and impaired *in vitro* lymphocyte response to mitogens. Humoral immunity is usually intact. In a few patients a more severe immunological phenotype, similar to combined immunodeficiency (CID), has been reported. Deficient erythrocyte production presents usually as mild macrocytic anemia in early childhood, with spontaneous recovery before adulthood. Patients occasionally present with severe congenital hypoplastic anemia.

Hematopoietic cell transplantation has resulted in successful immune-reconstitution in CHH patients who present with CID, but will not affect the morphologic features or dwarfism.

109.5.3 Nijmegen Breakage Syndrome (NBS)

NBS is an autosomal recessive genetic disease belonging to a group of disorders often called chromosome instability syndromes, characterized by microcephaly, particular "bird-like" face, growth retardation, immunodeficiency and predisposition to cancer [10]. NBS is caused by mutation of the *NBS* gene, which encodes for a protein involved in the repair of DNA double-strand breaks. Suspicion of NBS should be

raised by intrauterine growth restriction, microcephaly and facial dysmorphism (sloping forehead, receding mandible, prominent mid face, upward slant of the palpebral fissures). Chromosomal rearrangements, typically involving chromosomes 7 and 14, and chromosomal hypersensitivity to X-irradiation are useful laboratory tests to support the clinical suspicion. The definitive diagnosis is through gene sequence analysis: the 657del5 mutation is present in approximately 90% of cases. Hypogammaglobulinemia is common. Mild to moderate lymphopenia is present with an impaired *in vitro* lymphocyte proliferative response to mitogens. The primary cause of death is cancer, with a median of age of cancer-related death of only 10 years. Patients also develop recurrent upper and lower respiratory tract infections and chronic lung disease is the second leading cause of death. Differential diagnosis should include ligase-4 deficiency, which shows overlapping clinical and laboratory findings with NBS. Ataxia telangiectasia (AT), overlaps NBS in a number of characteristics, including chromosomal instability, radiosensitivity, and cancer predisposition, but AT patients do not display the characteristic "bird-like" facial appearance, microcephaly and growth retardation of patients with NBS.

109.5.4 Immunodysregulation, Polyendocrinopathy, Enteropathy, X-linked (IPEX)

IPEX is a rare genetic disorder of immune regulation caused by mutations in the *FOXP3* gene located in the centromeric region of the X chromosome [11]. The product of this gene is required for the development of CD4+CD25+ T regulatory cells. In the absence of T regulatory cells, activated CD4+ T-cells produce multi-organ damage resulting in autoimmune manifestations such as type I diabetes mellitus, severe enteropathy, hypothyroidism, and autoimmune skin disease resembling eczema, psoriasis, or atopic dermatitis. These clinical manifestations, often fatal, usually occur in early infancy and often appear sequentially, rather than simultaneously. Immunologic testing reveals little beyond variably increased IgE levels, eosinophilia, mild increase in CD4:CD8 ratio and an increase in T-cell activation markers. Autoantibodies are often absent early but develop gradually or acutely. Immunosuppressive drugs have been used with some success. Unfortunately, these drugs do not maintain long-term remission of symptoms, may be toxic and facilitate opportunistic infections. Hematopoietic stem cell transplantation may be considered for the most severe forms.

109.5.5 Autoimme Polyendocrinopathy Candidiasis Ectodermal Dystrophy Syndrome (APECED)

APECED, also known as APS-1 (autoimmune polyglandular syndrome type 1), is an autosomal recessive disorder due to mutation of the *AIRE* (autoimmune regulator) gene [11]. The product of this gene is crucial for the induction of central tolerance through the regulation of self-antigen gene expression in the antigen presenting cells of the thymic medulla. Thus, defects of *AIRE* lead to a defective selection of organ-specific T-cells, which are responsible for autoimmune manifestations. APECED is characterized by a set of three abnormal features: chronic mucocutaneous candidiasis, hypothyroidisms and adrenal insufficiency. At least two of these major components need to be present for diagnosis. Usually the first sign of the syndrome is mucocutaneous candidiasis, which may occur soon after birth, while other signs appear later. High serum antibody titers to components of the affected endocrine organs are characteristic. Current management is supportive.

Inflammatory Mediators in Neonatal Asphyxia and Infection

Marietta Xanthou and Victoria Niklas

110.1 Introduction

Inflammatory mediators produced in response to hypoxic-ischemic (H-I) injury and infection in the newborn, include multi-potent cytokines and chemokines released by a variety of somatic and bone marrow-derived cells both locally, in the brain and systemically, in the circulation. Pro-inflammatory cytokines, such as interleukin (IL)-1, IL-6, IL-18, interferon (IFN)-γ and tumor necrosis factor (TNF)-α, are small polypeptides secreted in response to cellular injury and inflammation. Cytokines trigger somatic and immune cell activation, differentiation and death after signaling through their cognate receptors. Chemokines, such as CCL2 and CXCL8, are chemotactic cytokines that induce cells of the innate and adaptive immune system to leave the blood stream and migrate to sites of injury in the central nervous system (CNS) and in the periphery [1]. Cytokines and chemokines are considered critical mediators of brain damage and clinical indicators of overwhelming sepsis in the newborns. We review the cellular origin and role of cytokines and chemokines in these diseases. We also discuss treatment modalities that may interrupt these inflammatory cascades. A better understanding of the role of cytokines and chemokines in response to H-I injury and infection is likely to improve the outcome and long-term prognosis of these diseases in the newborn period.

110.2 Inflammatory Mediators and White Matter Injury in the Newborn

Hypoxia, ischemia and infection result in acute inflammatory responses and significant brain injury of the newborn. Moreover, preterm and low birth weight (LBW) infants may be at increased vulnerability due to cerebrovascular immaturity. White matter injury in the brain is a major cause of neurodevelopmental impairment and long-term disability in premature LBW infants [2]. Indeed, CNS injury following H-I injury and infection, as well as, their interplay with inherent vascular and oligodendroglial vulnerability of the immature white matter result in significant white matter injury and permanent neurodevelopmental impairment and disability [3]. Periventricular leukomalacia is one important correlate of the neurologic injury with significant morbidity in infants born at less than 1500 g. Approximately 10% of these infants exhibit cerebral palsy and 50% exhibit cognitive and behavioral deficits [4].

Cytokines and chemokines are known to be primary modulators of white matter injury in the brain of the newborn. Multiple cell types in the brain, such as microglia, astrocytes and neurons, as well as migratory cells of the innate and adaptive immune system, participate in injury via the secretion of pro-inflammatory cytokines and chemokines. Microglial cells, which also function as antigen presenting cells in the CNS, are triggered to release IL-1, IL-6 and IL-18, as well as neurotoxic substances, including excitatory amino acids [5]. Astrocytes release transforming growth factor (TGF)-β, IL-6 and the chemokines CCL3 and CCL5 [5], whereas glial cells directly enhance neuronal injury [4]. These cells also express receptors for inflammatory cytokines and chemokines allowing autocrine up-regulation of inflammatory responses to these mediators.

Increases in pro-inflammatory cytokines and chemokines in the CNS also function to recruit inflammatory cells, including granulocytes and lymphocytes, which are not normal inhabitants of the CNS. Recruitment occurs via cytokine-mediated activation of cell-type specific adhesion receptors on vascular endothelium and through the secretion of chemokines. Chemokines, such as CCL2 facilitate the accumulation of monocytes, which upon entry into the CNS, differentiate into macrophages at sites of injury. CXCL8 attracts neutrophils and CCL28, is a chemo-attractant for T- and

B-cells. Moreover, inflammatory mediators and cells of the innate and adaptive immune system also access the CNS more freely across a disrupted blood brain barrier (BBB) thereby minimizing the requirement for receptor-mediated migration of effector cells and soluble mediators.

Direct evidence that pro-inflammatory cytokines and chemokines damage the developing brain comes mainly from experimental studies in animal models where the type of injury and its duration can be controlled. Injection of IL-1 leads to neuronal death and delayed myelination in neonatal rats [6]. Blocking of chemokines or their receptors inhibits neutrophil-mediated damage to the BBB in experimental models. In addition, chemokine receptor inhibitors prevent CXCL8 responses and reverse the lethal sequelae of sepsis in mice [4]. Finally, TNF-α induces cell death in mature human oligodendrocytes and, in the developing ones, is associated with increased apoptosis and reduced myelination [6]. Today, there is increasing evidence that inherited cytokine or chemokine polymorphisms influence the risk for pre- and perinatal brain damage [6].

110.3 Inflammation and Injury Caused by Hypoxia-Ischemia

Birth asphyxia is an important cause of H-I injury, perinatal mortality and lifelong neurodevelopmental morbidity, including cerebral palsy, learning disabilities and mental retardation in the newborn. Perinatal asphyxia occurs in approximately 4/1000 term births and is more frequent in preterm newborns [7]. During H-I injury, glutamate excitotoxicity, free radical and pro-inflammatory cytokine release results in injury to the brain [4]. The inflammatory response to tissue injury occurs in response to the excitotoxic cascade during the reperfusion period and contributes to the evolution of injury. Free radicals produced by activated inflammatory cells activate NF-κB in brain cells leading to pro-inflammatory cytokine and chemokine release [4]. Furthermore, according to the "danger model" theory, signals from stressed or damaged cells in the CNS may initiate an immune response during which inflammatory cytokines and chemokines are also produced further contributing to injury [4].

Pro-inflammatory cytokine blood levels of IL-6, IL-1β, IL-12 and TNF-α are increased in infants with H-I encephalopathy and are associated with abnormal neurodevelopmental outcomes [4]. We have found that IL-6 and IL-1β serum levels are increased compared to controls, but these levels do not differ between asphyxiated and infected neonates [4]. However, TNF-α levels are similar between infants with H-I insults and controls. Furthermore, cytokine increases correlate with the severity of the perinatal insults [4]. In support, Okazaki et al demonstrated that serum IL-6, CXCL8 and IL-10 levels in asphyxiated terms are higher than those of the controls, while IFN-γ is lower [8]. Premature infants with MRI-defined cerebral white matter injury have higher levels of IL-6, IL-10 and TNF-α in the cerebrospinal fluid (CSF) than in the serum. There is no correlation between CSF and serum cytokine levels [6]. Finally, increased levels of activin-A, a cytokine hardly studied in term newborns, are observed in premature infants with perinatal hypoxia [9].

Elevated serum chemokines are also found in response to H-I injury. CXCL8, known to be chemotactic for neutrophils, basophils and lymphocytes, is elevated in term newborns with abnormalities on MRI and adverse neurologic outcome following H-I injury [4]. We have found increased levels of CXCL8 and CXCL10 in the blood of neonates with perinatal asphyxia during the first 24 hrs of life [4]. Our studies have also demonstrated a dichotomy of reactivity of activated peripheral blood lymphocytes according to the inflammatory insult; during perinatal infection these cells express increased levels of CXCL8 mRNA whereas during asphyxia, they express increased levels of CCL2 mRNA [10].

110.4 Inflammation and Injury Caused by Perinatal Infection

Perinatal infections are known to play an important role in the pathogenesis of white matter injury in the brain as well as in the pathogenesis of preterm labor and the later development of chronic lung disease. In fact, intrauterine infection and inflammation complicate up to 35% of preterm deliveries compared with 10–15% of those infants delivering at term [11]. Early onset sepsis occurs in 15–19/1000 live births in infants born as less than 1500 g, however, the overall risk of infection among preterm infants is greatest after the first week of life [11].

The primary barrier to infection in the fetus is the uterine-placental barrier, which has innate immune properties, in addition to innate and adaptive immune responses provided by circulating cells of the maternal immune system. In addition, passive immunity from the active transport of immunoglobulin G (IgG) across the placenta imparts additional protection to infants born at term although coverage is less complete in the premature infant as transfer is incomplete until the last trimester. The innate immune functions of uterine and placental tissues derive from the expression of toll-like receptors (TLR) [12]. TLR are pattern recognition receptors (PRR) that initiate inflammatory responses after binding a variety of viral nucleic acids and bacterial products [13]. TLR signaling further elicits anti-microbial and inflammatory responses through production of free radicals, proteases and inflammatory mediators. Ureaplasma species are implicated in inflammation induced at the feto-maternal interface [14]. Chorioamnionitis is associated with increased levels of CXCL8 and IL-6, while microbial invasion of amniotic fluid is associated with increased levels of IL-6, CXCL8 and IL-18 [14]. The fetal inflammatory response syndrome correlates

with elevated cord blood IL-6 [14]. More than 30 years ago, Dammann and Leviton showed that a strong inflammatory challenge, such as intrauterine infection, elicits a fetal inflammatory response and contributes to brain damage in preterm infants. Since then, studies have revealed that inflammatory mediators, such as cytokines and chemokines, are important links between infection and brain damage [15].

All aspects of innate and adaptive immune function after birth are immature and are further compromised in the prematurely born infant. Innate immune responses are initiated via the activation of complement, the release of anti-microbial peptides by neutrophils, paneth cells and macrophages and the engulfment of bacteria by phagocytes. Activation of the adaptive immune system occurs following antigen processing and presentation by antigen presenting cells, such as dendritic cells. Complement proteins, Ig and anti-microbial peptides promote direct cell killing following the release of anti-microbial peptides and enzymes, as well as phagocytosis through opsonization by Ig. Paneth cells, at the base of the crypts in the intestine and in other mucosal sites produce a variety of antibacterial substances including defensins and cathelicidins [16, 17]. These are small cationic peptides with broad-spectrum antimicrobial action, released in response to bacteria or to components of bacterial cell walls [18]. They are found at significantly lower levels in the intestine during fetal life when compared with the term newborn and adult [19]. Thus, the decreased production of defensins by paneth cells may predispose the fetus or infants born prematurely to bacterial overgrowth and overwhelming infection.

The production of granulocytes in the bone marrow and their progenitors is limited in the term and premature infant and their function is impaired potentially contributing to bacterial overgrowth and invasion. Likewise, the inflammatory cascade induced by bacteria may include a reduced oxidative burst in the premature infant due to low levels of NADPH, thereby reducing the function of the innate immune system [20]. Regarding adaptive immunity, although considerable development of T- and B-cells occurs during fetal life, complete maturation of the immune system occurs after birth. The production of antibodies by B-cells may be delayed and lower levels of Ig are detected despite the active transport of maternal IgG. Moreover, antigen uptake, degradation, and presentation by antigen presenting cells, a vital step in the initiation of an adaptive immune response, is less efficient in the newborn, hence, the ability of the adaptive immune system to detect and respond to pathogenic organisms is impaired. T-cells in the newborn are also less responsive to antigenic stimulation and have a decreased proliferative response to a variety of mitogenic stimuli [21]. Finally, circulating and epithelial-associated levels of IgA and IgG are also reduced resulting in greater susceptibility of the newborn to infections and across mucosal surfaces [22].

Regarding cytokines and chemokines in neonatal inflammation, increased levels of IL-6, CXCL8 and TNF-α are observed in newborns with early-onset sepsis [6]. Elevated levels of IL-6, IL-12p70, IL-10 and TNF-α levels are higher in LBW infants compared to controls, but these levels decrease after 24 hours with late-onset sepsis [23]. Premature newborns produce increased levels of pro-inflammatory cytokines, such as IL-2, IL-6, IFN-γ, TNF-α, and anti-inflammatory cytokines, such as IL-4 and IL-10 during infection compared to non-infected controls [23]. Yerkovich et al recently showed that IL-6, IL-10, TNF-α and IFN-γ release, following *in vitro* lipopolysaccharide (LPS) stimulation of cord blood cells, is equal or greater than that of adults [24]. The chemokine CXCL8 has been extensively studied and considered as a serum marker of neonatal sepsis, particularly in the early-phases of disease [4]. CXCL8, CXCL10, CCL9, CCL2, CXCL1 are all increased in neonates with sepsis, but their levels decrease after 24 hours whereas CCL5 is similar to non-infected controls [23]. Interestingly, Tatad et al proposed that the type of infectious agent leads either to increased inflammation or defective immunity. For example a lower level of IL-6 in response to *Staphylococcus epidermidis* infection may indicate a basis for vulnerability to infection whereas a high CXCL8 response to pathogenic *Escherichia coli* in preterm newborns is consistent with uncontrolled inflammation [25]. Taken together these results suggest that it is not only the absolute level of cytokines, but also the balance for pro-inflammatory cytokines and their counter-regulatory anti-inflammatory counterparts that may be important in disease pathogenesis.

The pathophysiology of an infectious disease in the fetus and newborn may be exacerbated by the inflammatory response to the pathogen rather than by virulence characteristics of the pathogen. In fact, excessive secretion of pro-inflammatory cytokines and chemokines may be more damaging to the host than the pathogen itself. Certain studies indicate that neonates have an increased inflammatory response compared to adults [24, 26]. Our findings also showed that LPS-induced TLR4, CD14 expression and CXCL8 release by neonatal peripheral blood leukocytes were significantly increased compared to adults [27]. Thus, quite often an overwhelming systemic inflammatory response may be generated during early or late -onset sepsis, meningitis or necrotizing enterocolitis, resulting in multi-organ failure, brain injury or death. Infants with infections are more likely to have brain damage [11].

Moreover, as the susceptibility of the newborn infant to infection is well-known, it is not unreasonable to propose that multiple defects in both innate and adaptive immunity contribute to further dysregulation of cytokine and chemokine secretion and account for significant "bystander injury" in organs such as the brain.

It is also important to note that physiologic responses to overwhelming bacteremia and sepsis may lead to microcirculatory dysfunction, shock and cerebral hypo-perfusion, resulting in pathways that overlap with primary H-I injury in the brain (Fig. 110.1). Hence, determining the primary root

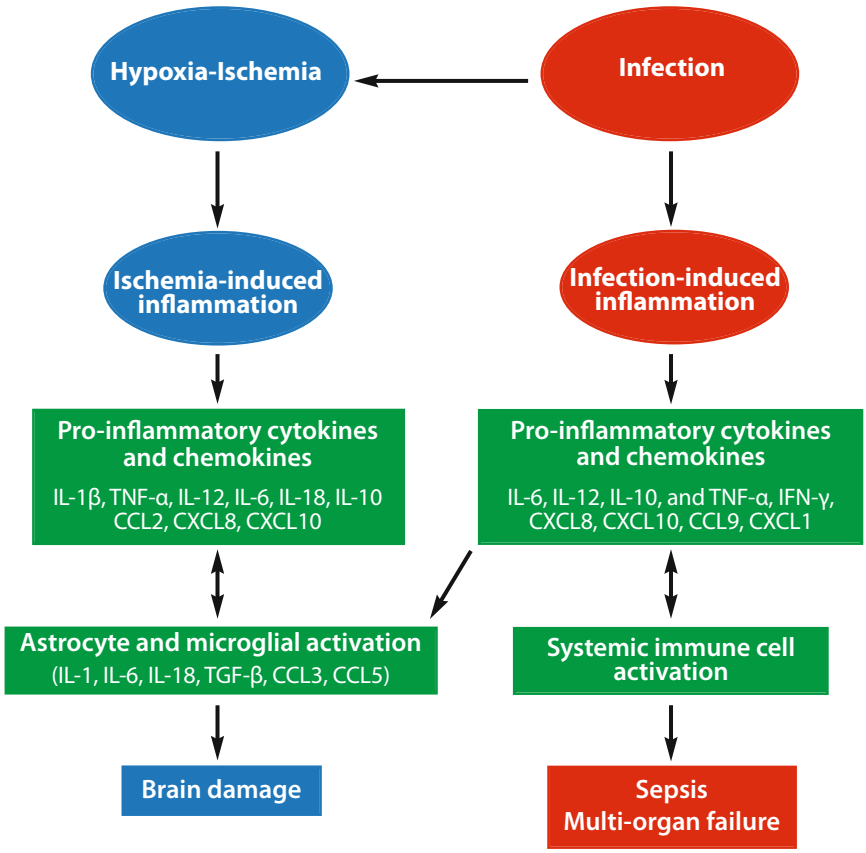

Fig. 110.1 H-I insults and infection lead to inflammation mediated by pro-inflammatory cytokines and chemokines produced by cells resident in the brain as well as by migratory bone marrow-derived immune cells. These mediators may either enter the brain and lead to white matter injury or cause systemic immune cell activation resulting in sepsis and multi-organ failure. Overwhelming infection can lead to H-I

of cause and effect of white matter injury in the brain during sepsis and shock may be difficult.

110.5 Cytokines and Chemokines as Therapeutic Targets in H-I Injury and Infection

Levels and ratios of pro-inflammatory cytokines and chemokines may provide the clinician with valuable diagnostic and prognostic information regarding inflammation induced by asphyxia and/or infection; however validation of these markers as prognostic indicators or as targets for treatment still needs to be documented. As yet, no definitive pattern or level of biomarker expression has been found to be predictive of disease severity or outcome, although certain cytokines and chemokines have been proposed [28].

Therapeutic interventions that either enhance the production or activity of anti-inflammatory cytokines or inhibit the production or activity of pro-inflammatory cytokines have been used quite successfully in a variety of animal disease models and in management of autoimmune and inflammatory diseases in humans such as in rheumatoid arthritis [29] and in inflammatory bowel disease [30]. However, clinical studies directed at modulating cytokine or chemokine function in newborn infants following H-I injury or infection with the goal of preventing overwhelming sepsis and minimizing white matter injury in the brain along with improving long-term outcome, are promising areas of research. Overall, targeting specific combinations of cytokines, chemokines and/or their receptors on brain and immune cells may inhibit excessive inflammation and injury, while sparing beneficial responses and protective immunity to infections.

110.6 Conclusions

Although neonates exhibit impaired expression of certain inflammatory cytokines and chemokines, such as IFN-γ, IL-12 and CCL5, the majority of inflammatory mediators are increased during infection and asphyxia to adult or more than adult levels. This could reflect the excessive inflammation often observed in neonates and, more so in premature infants, which can lead to septic shock and brain damage or the inability to mount an appropriate counter-regulatory anti-inflammatory response.

Understanding the mechanisms that contribute to the production of these pro-inflammatory cytokines and chemokines may lead to the identification of important therapeutic targets for brain damage and sepsis.

Neonatal Malignancies

Franca Fossati-Bellani

111.1 Introduction

Neoplastic or tumor-like conditions are rare in the fetus and newborn, but pose important diagnostic and therapeutic problems for pediatricians and oncologists, as well as imposing enormous emotional burdens on parents and caregivers. They also present significant medical and ethical dilemmas.

By definition, neonatal neoplasms are those diagnosed during the first month of life. Congenital neoplasms are those diagnosed at birth. It is essential to define and distinguish tumor-like conditions (such as hamartomas, hemangiomas, lymphangiomas and melanocytic nevi) from benign or malignant tumors. Tumors that are benign at histology can still grow aggressively, acquiring a malignant behavior due to their site of onset and local invasiveness. They can cause death, as in the case of extensive lymphangiomas and teratomas of the newborn in the head, neck or mediastinum. On the other hand, histologically malignant tumors of the newborn, such as neuroblastoma stage 4S and neonatal fibrosarcoma, can regress spontaneously and take a benign course even without therapy. Finally, there are non-neoplastic conditions (i.e., abdominal masses) that can simulate the presence of a tumor, and that have to be differentiated by appropriate diagnostic procedures (Table 111.1). The vast majority of neonatal neoplasms are solid tumors of mesenchymal and embryonic origin, and they can be diagnosed before birth. Because they are so rare, the management of these tumors represents a major challenge for neonatologists, surgeons and oncologists: the knowledge gained from infants cannot be applied to the newborn because of the physiological immaturity of the latter's metabolism, hemopoietic and immune systems. Furthermore, current therapeutic protocols used in cooperative studies on childhood tumors fail to consider the peculiarities of the newborn.

111.1.1 Incidence

Data on the incidence of neonatal malignancies are drawn from single-institution case studies or tumor registries, but there are no reliable general population based data available. Their incidence is estimated to be approximately 1 in every 12,500–27,500 live births. Neonatal malignancies account for 2% of all tumors affecting infants, children and adolescents. Half of neonatal tumors are found at birth, 20–30% during the first week and the remaining 20–30% within the first month of life. During the neonatal period, the incidence of a given tumor does not coincide with the related mortality rate because some tumors are rapidly lethal, while others cause death after the neonatal period, and yet others grow initially and then regress spontaneously, e.g., cystic neuroblastoma (NBL) and NBL in stage 4S. NBLs and teratomas (75% benign and 25% malignant) are the most frequent neonatal neoplastic conditions (accounting for 22% and 23%, respectively), followed by soft tissue sarcomas (8%), acute leukemias (6%), central nervous system (CNS) tumors (6%), benign and malignant liver tumors (6%), kidney tumors (7%), and retinoblastomas (5%). Males and females are generally affected equally, but retinoblastoma is more common in males, teratoma in females. Leukemias and CNS tumors are the most lethal in this age group.

111.1.2 Etiology

Neonatal congenital tumors constitute a unique model for studying the oncogenetics. The aging process and multiple environmental factors considered in adult studies are not applicable to the etiopathogenesis of tumors in children. Chemical and physical factors, and infections can influence the oncogenic processes involving the gametes, embryo and fetus. Genetic factors involved in the development of neoplasms, such as small mutations, the loss of heterozygosis and

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

Table 111.1 Malignant (a), non malignant (b), tumor like conditions (c) of the newborn by location

Brain	a. Teratoma, PNET (medulloblastoma, pinealoblastoma, cerebral neuroblastoma), choroid plexus carcinoma, ependymoma, astrocytoma, atipical teratoid rhabdoid tumor, sarcoma, melanoma b. Teratoma*, meningioma*, hamartoma*, craniopharyngioma* c. Vascular malformation, hemorrage, hydrocephalus
Head and neck	a. Rhabdomyosarcoma (orbit, nasopharynx, middle ear), neuroblastoma (neck), retinoblastoma, teratoma, melanotic progonoma, Langherans cell histiocytosis b. Trunk	a. Neuroblastoma, germ cell, soft tissue sarcoma, Langherans cell histiocytosis b. Lymphangioma*, hamartoma*, teratoma*, cardiac rhabdomyoma c. Pulmonary myofibroblastic tumor, massive mesenchymal malformation of lung
Abdomen pelvis	a. Neuroblastoma, renal tumors, hepatoblastoma, germ cell tumors, soft tissue sarcoma, acute leukemia b. Teratoma, hepatic hamartoma, hemangioma, hemangioendothelioma, congenital mesoblastic nephroma* c. Polycystic kidney, hydronephrosis, urinary retention, gastrointestinal duplication, storage disease ovarian cyst, congenital viral infections
Skin and superficial soft tissue	a. Soft tissue sarcoma, neuroblastoma, acute leukemia, Langherans cell histiocytosis, melanoma b. Hemangioma, fibromatosis, giant naevus c. Infections

* Benign tumors potentially life threatening because of size and location or tendency towards malignant transformation.

changes in genomic imprinting, are more prominent in children than in adults. The correlation between malformations, genetic syndromes (hemihypertrophy, aniridia, Beckwith-Wiedemann syndrome) and tumors of childhood points to the conclusion that genetic factors are more significant than environmental ones in neonatal neoplasms.

111.1.3 Clinical Features and Diagnosis

Most tumors are clinically manifest as an abnormal mass located in the abdomen or head and neck, or any soft tissue site. They may be detected before birth. Advances in diagnostic procedures, e.g., ultrasound (US) and magnetic resonance imaging (MR), have facilitated the prenatal diagnosis of congenital neoplasms such as teratomas, abdominal or intrathoracic masses, with consequent implications for prenatal therapy and the choice of vaginal versus cesarean deliveries, and for the outcome of the fetus.

MR provides details of the site and the anatomical extent of a lesion and, in selected cases, it has been instrumental in strategic prenatal therapeutic procedures, such as fetal surgery or fetal rescue at the time of delivery. Computerized tomography (CT) is a diagnostic tool commonly used to diagnose tumors postnatally, but MR performs better in evaluating CNS neoplasms and spinal cord compression. Positron emission tomography (PET) has yet to be validated for use in diagnosing childhood tumors. Imaging data, combined with clinical findings, provide the basis for the histopathological diagnosis of neoplastic lesions that have been totally resected or biopsied. To characterize a neoplasm precisely, the morphological features derived from classic histology must be combined with immunohistochemistry and cytogenetic assessment. For instance, the value of the N-myc oncogene (a molecular marker of NBL) is significant in terms of prognosis and treatment.

111.1.4 Principles of Therapy

Interdisciplinary cooperation between all specialists involved at the various stages of the diagnostic and therapeutic process is vital.

111.1.4.1 Surgery

Surgical ablation is the therapeutic procedure of choice for most solid tumors (such as teratomas, Wilms' tumor and neuroblastoma).

Pediatric surgeons do not have to undertake aggressive surgery. The timing and strategy of surgical procedures have to consider the newborn's metabolic and physiologic needs, as well as the local extent of the tumor to enable complete excision, and the feasibility of delaying surgery until after shrinking the tumor volume by chemotherapy to avoid mutilating surgery or operations that would interfere with the child's growth or impair any vital functions. In pediatric oncology, the purpose of a multidisciplinary approach is to limit the damage associated with invasive therapies, especially in younger patients, without affecting adversely survival prospects.

111.1.4.2 Chemotherapy (CHT)

There are not enough pharmacologic studies of drug metabolism, clearance and toxicity to organs and functions to support the use of antitumor drugs in the newborn. Data on the pharmacology of antitumor chemotherapy in infants and young children have revealed severe neurotoxicity of vincristine, hepatotoxicity of actinomycin D, myelotoxicity of adriamycin and ototoxicity of cisplatin. Traditional cytotoxic drugs, administered at doses adjusted to the infant's weight enable drug clearance from the patient with fewer global toxic effects and a good therapeutic index. Using a patient's weight to guide dosage has been empirically adopted for the newborn. Drug dosage must be modified in the event of major side effects.

111.1.4.3 Radiation Therapy

The adverse effects of radiation therapy on infants and young children are now well known. They include irreversible damage to growth, the musculoskeletal system, and endocrine and cognitive functions, depending on the site and volume of the radiation fields. Furthermore, the risk of second tumors limits the use of RT in pediatric oncology and makes it contraindicated for the newborn.

111.1.4.4 Supportive Care

In pediatric oncology, good therapeutic results have been achieved (now reaching a 5-year survival rate of 70%) because of improved supportive care. Hydration, antibiotics, blood products, growth factors, antiemetic agents, and nutritional support are all particularly important for the newborn because of their inability to withstand invasive treatments and because of the severe risk of infection and metabolic complications in the short term. Central venous access is important [1–6].

111.2 Tumors

111.2.1 Neuroblastoma

NBL originates from neural crest cells and can occur along the sympathetic chain and in the adrenal medulla. The link identified at autopsy between infants dying of other causes and a high incidence of NBL in situ might be explained by this tumor's tendency for spontaneous regression. Most NBLs are associated with chromosomal anomalies, some of the most frequent being amplification of the oncogene N-myc, deletion of chromosome 1p, and aneuploidy. An amplified N-myc carries a poor prognosis [5-9].

111.2.1.1 Clinical Findings

The most common finding is an abdominal mass originating from the adrenal gland, but the primary tumor may be located in the mediastinum and neck, retroperitoneum or pelvis. Abdominal distension with or without respiratory insufficiency is a clinical finding that correlates with massive liver involvement from a small adrenal tumor. Secondary subcutaneous nodules and bone marrow invasion are also observed in this stage, defined as 4S. Other symptoms are due to the mass effect of the tumor, according to its location (respiratory insufficiency, or Horner syndrome if it is in the neck or mediastinal region) and/or to any metastasis.

111.2.1.2 Prenatal Diagnosis

When prenatal US identifies an abdominal mass, MR can differentiate between NBL and other tumors. In the prenatal phase, adrenal cystic lesions are interpreted as persistent or late-regressing neuroblastic nodules. They tend to regress spontaneously and they do not alter catecholamine metabolite levels, which can cause hypertension or maternal pre-eclampsia when abnormal.

111.2.1.3 Postnatal Diagnosis

Both CT and MR can distinguish between adrenal hemorrhages, renal masses and intra-abdominal sequestration (Figs. 111.1 and 111.2). Methyl iodobenzylguanidine (MIBG) scintigraphy can be used both to identify a neuroblastic tumor and to detect metastases. Only 70% of neonatal NBLs are MIBG-avid.

Histology is the final diagnostic tool, together with the previously-mentioned prognostic markers (N-myc, 1p deletion). If the liver is extensively affected (stage 4S), liver needle biopsy has been used instead of open abdominal surgery to reduce the risk of respiratory impairment and complications related to abdominal healing.

111.2.1.4 Staging

The INSS (Intergroup Neuroblastoma Staging System) criteria are used.

111.2.1.5 Therapy and Prognosis

The treatment program depends on the stage of the tumor and its biological characteristics. Children under one year or infants have a significantly better prognosis than older children. Currently cooperative groups recommend monitoring cystic

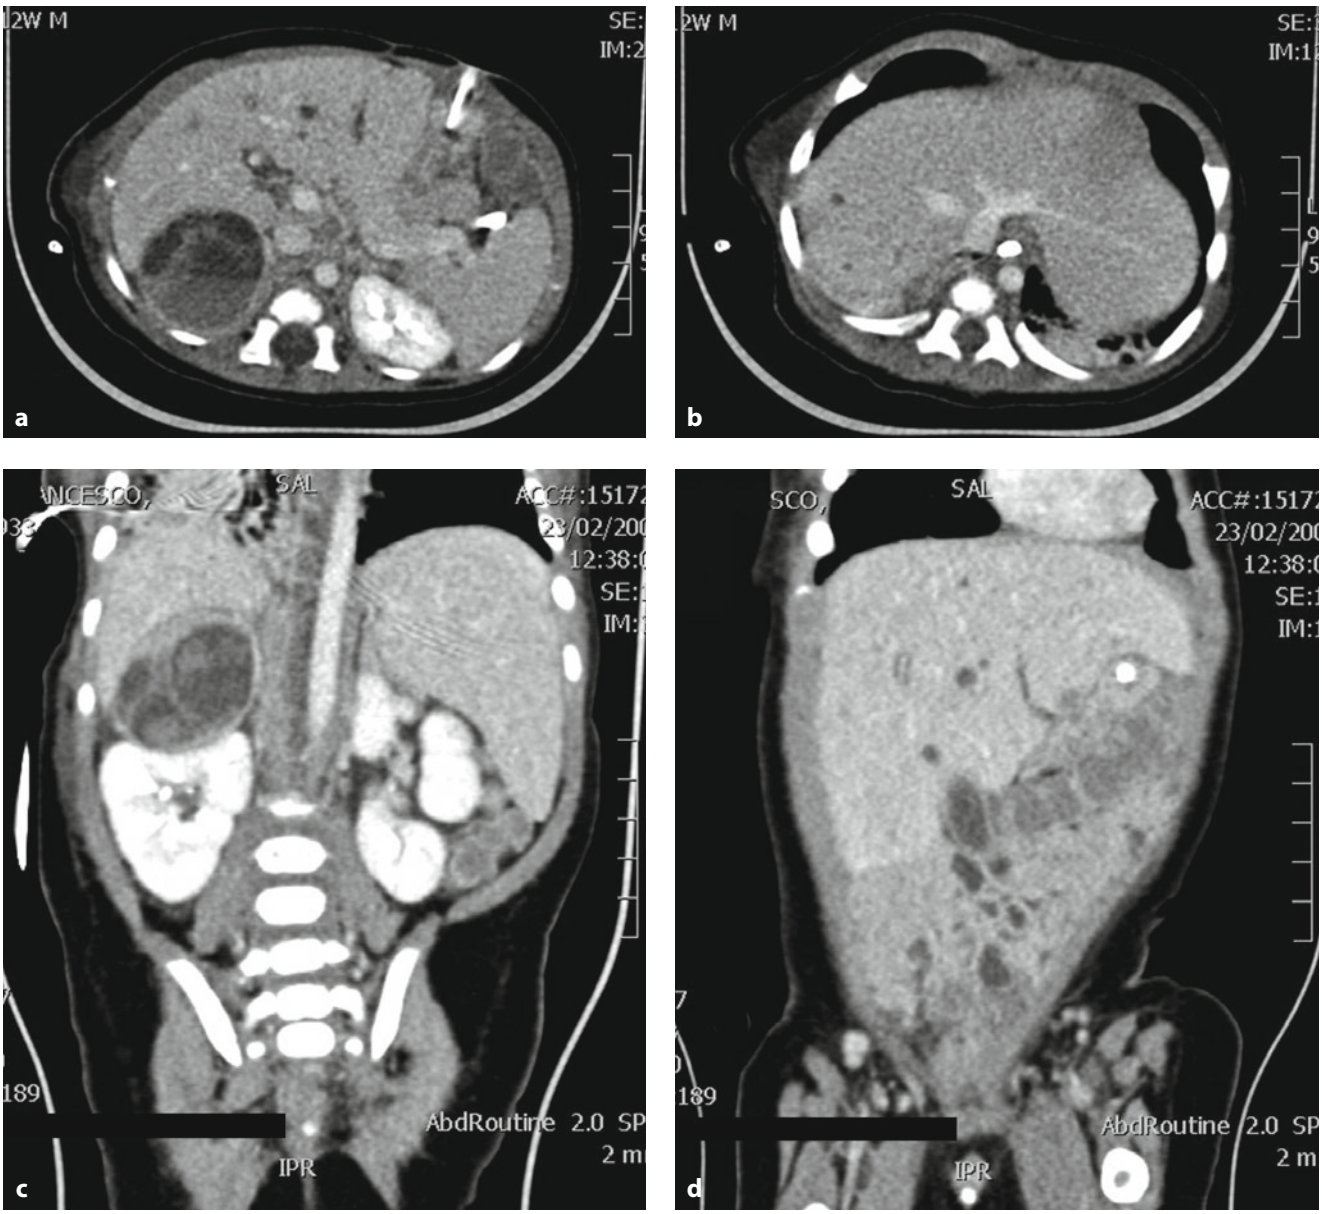

Fig. 111.1 Neuroblastoma 4S CT imaging. Right adrenal lesion, mostly cystic necrotic (**a**–**c**) with hematic level. Multiple metastatic little epatic lesions are present (**b**–**d**). (Courtesy Dr. Marcello Napolitano)

NBL during the first three months by US. Surgical resection is recommended when it neither regresses nor increases in size. Newborns in stages 1 and 2 have a good prognosis with surgery alone even when histology shows microscopic residues but no N-myc amplification in stage 2 cases. NBLs classified as stages 3 and 4 are prevalent in children over one year. Chemotherapy (CHT) is performed first to shrink the tumor, delaying surgery until later. For stage 3, the prognosis is excellent (about 90%), while for stage 4 it is 50%. If N-myc is amplified, high-dose intensive CHT with bone marrow rescue is recommended.

The prognosis is poor, however, especially when more than 10 pairs of the N-myc oncogene are identified. The drugs used are carboplatin, adriamycin, vincristine and topotecan. Newborns with stage 4S NBL have a good prognosis in 80% of cases without specific therapy. In cases with hepatic involvement and a risk of respiratory deficiency and/or vena cava compression, CHT can be implemented to accelerate tumor regression; surgery for the primary tumor is considered unnecessary. CHT and surgery are essential, however, in cases with biological markers indicating a poor prognosis [5–9].

111.2.2 Germinal Tumors (GT) and Teratomas (TRT)

These are the most frequent benign and malignant perinatal tumors. More common in females, they are embryonic tumors that originate from primordial germ cells or germ layers (the ectoderm, mesoderm and endoderm). The World Health Organization (WHO) classification divides GT into 7 categories, but only TRT, yolk sac tumor and, more rarely, gonadoblastoma have been described in the perinatal period. More than 50% of TRTs appear at birth in the sacrococcygeal region, but they can occasionally be found in the head and neck, mediastinum, brain, retroperitoneum, and liver. TRTs are classified into three different groups, depending on their histology: (a) mature, consisting mainly of adult tissue; (b) immature, consisting of embryonic tissue; or (c) malignant, consisting of malignant embryonic tissue, which is almost always a yolk sac tumor.

The germinal tumor marker alpha-fetoprotein (AFP) levels are significantly abnormal in the malignant form and must be measured and monitored over time (considering as normal the levels during its normal regression in the first year of life). Approximately 10% of neonatal TRTs contain malignant cells, while 20% have immature components. Neonatal TRTs are often found in association with multiple or combined malformations of the genitourinary tract, rectum, anus and sacrococcygeal region, or of the face in the head and neck. Sacrococcygeal TRT may be post-sacral (external), pre-sacral (internal), or both (dumbbell). They are solid, cystic, or mixed masses containing varying proportions of all tissues, i.e., fat, muscle, bone, teeth, hair, immature neuroepithelial glandular tissue and glia. Prenatal assessment of the volume and site of the tumor is used to manage the delivery and to decide on perinatal measures such as intubation for airway obstruction in the case of cervical and mediastinal involvement. Treatment is surgical: open fetal surgery is indicated for large sacrococcygeal tumors when cardiovascular complications

and hydrops are present in mother. After delivery, the sacrum and coccyx may be removed. There must be accurate histopathology to evaluate the quality of the surgical excision, the entity and characteristics of the various cytological components, and the presence of immature or malignant tissue. Local relapses may occur in 10% of mature/immature tumors, especially if the surgical resection was marginal, or if the coccyx was not removed. The introduction of CHT with cisplatin plus etoposide in metastatic disease or for initially inoperable tumors has achieved complete regression of metastatic deposits and enabled radical surgery by reducing the tumor's initial volume. This strategy allowed a spectacular improvement in survival in both locally advanced and metastatic disease (the prognosis is good in 90% of cases of localized disease and 80% of metastatic cases). Adverse prognostic factors are even minimal presence of yolk sac tumor cells in mature and immature TRT and an incomplete resection [5, 6, 10–12].

111.2.3 Soft Tissue Sarcoma (STS)

Benign and malignant soft tissue tumors are the neoplasms most commonly seen in newborns after teratomas. They include conditions that differ in histology, molecular characteristics, biological behavior and clinical evolution. They also differ from the STS seen in adults. Malignancies include rhabdomyosarcoma (RMS), congenital fibrosarcoma, and adult-type sarcomas. These have to be differentiated from benign tumors and tumor-like conditions such as vascular lesions and fibromatosis [5, 6, 13, 14].

111.2.3.1 Rhabdomyosarcoma (RMS)

This is the most common malignant sarcoma to be found in the newborn, but only 14 cases out of 3217 (4%) were reported in the study of the American IRS (Intergroup Rhabdomyosarcoma Study). The embryonal histotype is most common, while the alveolar one is rare. RMS can occur anywhere in the body, e.g. in the head, neck, genitourinary area, and limbs. Diagnostic procedures include CT, MR, bone marrow aspiration and radiographs of the skeleton. Metastases may already be present at diagnosis. Symptoms may vary, e.g., acute urine retention (when the RMS is located in the pelvis) or cranial nerve palsy (when it affects the head-neck region), due to swelling in the area affected by the tumor. The botryoid variety includes grape-like neoformations, especially in the vulvovaginal area or mouth. Treatment depends on the stage of the tumor and is the same as for children under one year (or infants), as established in cooperative international studies. A combination of CHT and surgery is used, depending on the location and extent of the tumor, and whether it is amenable to surgical resection. Surgery may be the first step for small lesions, since it may be both diagnostic and therapeutic. Where surgery fails to completely remove the tumor, a second-look surgery is recommended after CHT. A combination of vincristine, actinomycin D and cyclophosphamide is the first therapeutic choice for inoperable or metastatic disease. The prognosis is less favorable in the newborn than in older children, especially in cases with the alveolar histotype.

111.2.3.2 Congenital Fibrosarcoma

This tumor occurs in the newborn and up to six months of age. It mainly affects the limbs, but the trunk, the sacrococcygeal and retroperitoneal regions, and the head and neck may also be involved (Fig. 111.3). The characteristic chromosomal translocation t(12:15) involving genes ETV6 and NTRK3 in the newborn does not appear in older children. For cases of locally extensive disease, primary CHT can shrink the tumor and delay the need for surgery.

111.2.3.3 Other Soft Tissue Sarcomas

The atypical teratoid rhabdoid tumor (ATRT) of soft tissues has the same chromosomal abnormalities, or INI gene mutations, as those observed in the more common ATRTs of the kidney, liver and brain of children more than one year old. It is rare in soft tissues and carries a poor prognosis. There are reports in the literature of other types of STS in the newborn, including peripheral primitive neuroectodermal tumor (pPNET), vascular tumor and undifferentiated sarcomas.

111.2.3.4 Congenital Fibromatosis

This is a tumor-like condition that needs to be distinguished from the above-mentioned malignant mesenchymal tumors. A common feature of congenital fibromatosis is the proliferation of elongated fibroblastic cells that tend to invade the surrounding tissues, but do not give rise to metastases.

a. Solitary or multicentric congenital myofibromatosis is more common in males and affects the head and neck, trunk and skin. It may regress spontaneously.
b. A sternomastoid tumor is generally connected with birth trauma. It must be differentiated from cervical NBL and RMSA.
c. Infant desmoid-type fibromatosis is found in muscles, aponeuroses, shoulders, the head and neck, and the upper limbs.
d. Cranial fasciitis can grow rapidly and infiltrate the skull bone.
e. Fibrous hamartoma of infancy (which is congenital in 20% of cases) develops in the cutaneous tissue of the shoulders, arms, thighs, armpits and inguinal areas. It is composed of fibrous, adipose and immature mesenchymal cells, and is treated with surgery.

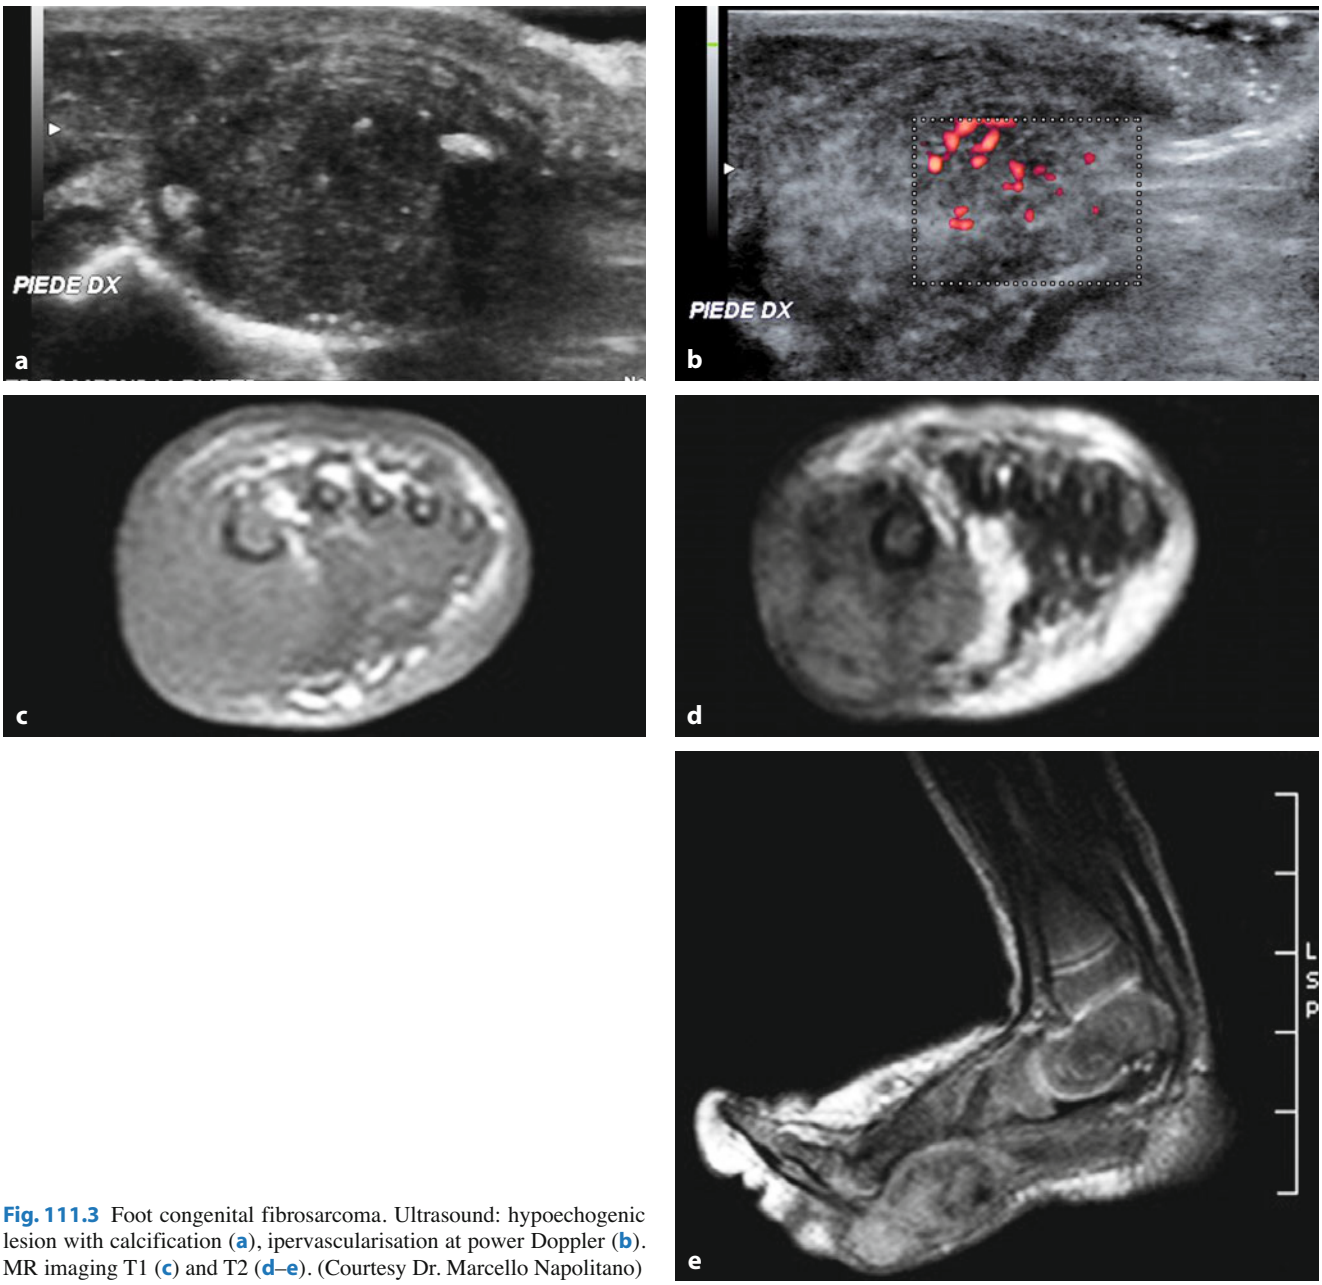

Fig. 111.3 Foot congenital fibrosarcoma. Ultrasound: hypoechogenic lesion with calcification (**a**), ipervascularisation at power Doppler (**b**). MR imaging T1 (**c**) and T2 (**d**–**e**). (Courtesy Dr. Marcello Napolitano)

111.2.4 Kidney Tumors

Neonatal kidney masses are benign in more than 40% of cases. Congenital mesoblastic nephroma, Wilms' tumor and RT are, in order of prevalence, the main perinatal renal neoplasms, but clear cell sarcoma of the kidney can also occur [5, 6, 15–17].

111.2.4.1 Congenital Mesoblastic Nephroma

These account for two thirds of all solid tumors in newborns. It is a mesenchymal tumor resembling infantile fibromatosis. It is generally benign and curable with surgery alone. It can be diagnosed before birth by US, and it has no imaging characteristics to distinguish it from Wilms' tumor, even in the postnatal phase. It is more common in males.

In addition to the abdominal mass, there may be symptoms such as hypertension, hematuria and vomiting. The tumor can grow beyond the renal capsule and invade the surrounding tissues. Local recurrences are observed if the tumor is ruptured during surgery. Distant metastases are rare, especially in the cellular type. The survival rate is better than 90%. Drugs are used for local recurrences or metastases, which however are seldom seen.

111.2.4.2 Wilms' Tumor (WT)

This occurs in nephrogenic residues persisting after the 36th week of gestation. There are no reports in the literature of WT being identified in the newborn carrying the correlated malformative syndrome, but babies with aniridia, hemihypertrophy or Beckwith-Wiedemann syndrome (organomegaly, macroglossia, hypoglycemia at birth) should be monitored to enable the tumor to be diagnosed before the onset of symptoms. The clinical sign of WT consists of an abdominal mass, which must be differentiated from other masses using US/CT/MR (Fig. 111.4). Surgery is the therapeutic procedure of choice. In addition to establishing the stage, histopathology should give information on the presence of anaplastic areas in tumor specimens, which suggest a poor prognosis.

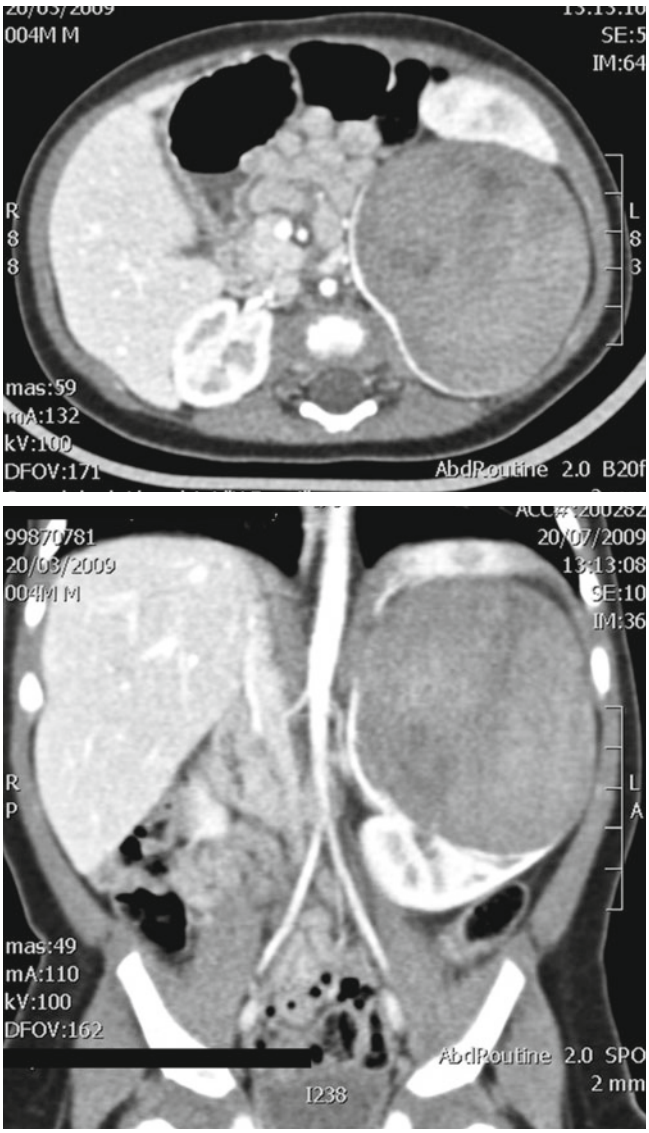

Fig. 111.4 CT imaging of Wilms' tumor with huge solid mass of left kidney

Staging methods have been based on the cooperative protocols of the COG (Children's Oncology Group) and SIOP (International Society of Pediatric Oncology). In the newborn, the tumor is generally detected in stages 1 or 2 and has a favorable histology (no anaplasia). The drugs used postoperatively include vincristine, actinomycin D and/or adriamycin, depending on the stage of disease. Ifosfamide and carboplatin are used in cases with metastases. The prognosis is extremely good (90%).

111.2.4.3 Atypical Teratoid Rhabdoid Tumor and Clear Cell Sarcoma of the Kidney

Both these diseases demand surgery whenever possible but metastases often occur. Chemotherapy has no influence on the prognosis, which is poor.

111.2.5 Brain Tumors

Congenital and neonatal CNS tumors represent 1% of all CNS tumors, and differ in terms of site, histology, clinical behavior and prognosis from those seen in older children. The most common site of onset is supratentorial. Benign cases (which are more common) may suggest malignancy due to their size, since they often cannot be removed. The most common brain tumor is a teratoma, followed by glioma, supratentorial PNET (primitive neuroectodermal tumors) (Fig. 111.5) and medulloblastoma; these last two may coincide with metastatic deposits along the spine.

All malignant CNS tumor types occurring in infants are seen in the newborn too (teratoma 50%, astrocytoma 16%, medulloblastoma 8%, choroid plexus papilloma 7%, ependymoma 3%, unclassified glioma 22%). Symptoms are unusual, macrocephaly (caused by hydrocephalus or the volume of the tumor) being the most significant clinical sign. The fontanel may pulsate. The tumor may displace normal brain without infiltrating it, which explains the absence of focal symptoms. Vomiting and papilledema are late signs, and are due to the increasing size of the neoplasm. Non-specific symptoms, such as lethargy, fever and gastrointestinal disorders, are often misinterpreted, causing delay in the correct diagnosis. MR of the brain and spine provide information on the tumor's size and its benign or malignant nature. Hemorrhagic episodes related to the neoplasm may simulate brain hemorrhage or even cause a massive brain hemorrhage. Treatment options must be discussed on a case by case basis and depend on the site and size of the lesion, imaging findings and the newborn's general conditions. Surgery may be curative in patients with benign teratoma and ependymoma. Cases of PNET and medulloblastoma require pharmacological treatment. Surgery is often only of diagnostic value. Given the poor prognosis (the survival rate is 28% in the

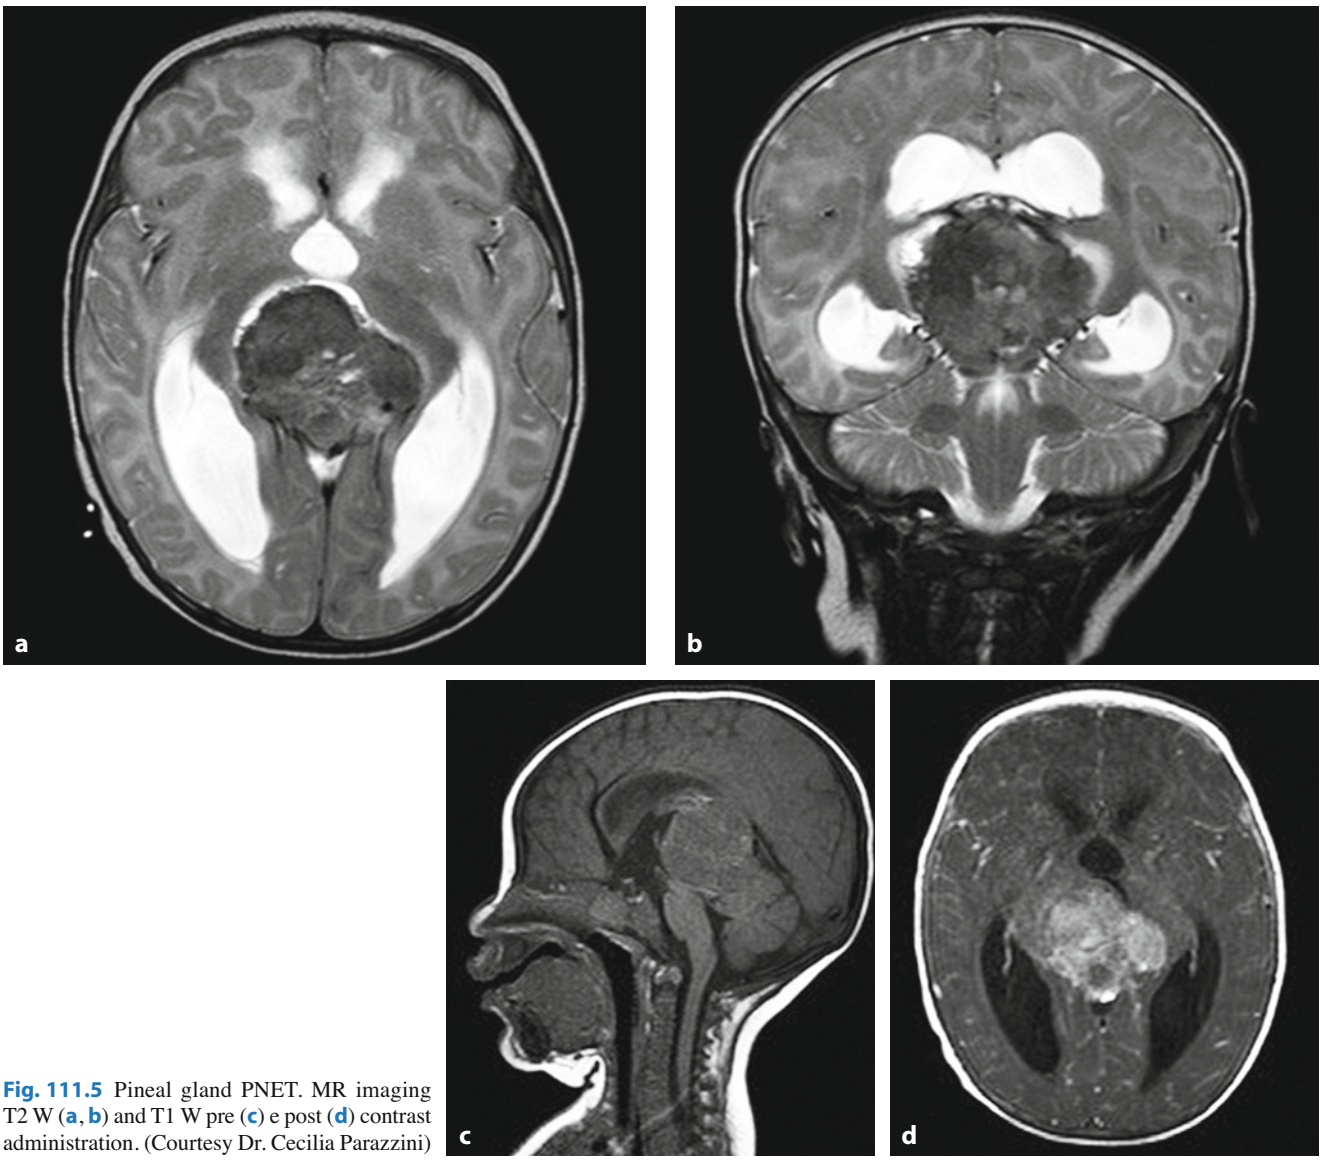

Fig. 111.5 Pineal gland PNET. MR imaging T2 W (**a**, **b**) and T1 W pre (**c**) e post (**d**) contrast administration. (Courtesy Dr. Cecilia Parazzini)

most comprehensive case studies in the literature, which include both benign and malignant lesions), non-intervention may often be the best option. An open and frank discussion between care-givers and relatives is essential before any treatment decisions are made [5, 18, 19].

111.2.6 Liver Tumors

Neonatal liver neoplasms are usually benign (hemangioma 60%, mesenchymal hamartoma 23%, hepatoblastoma 17%). Infant hemangioma is a benign vascular neoplasm, that is generally discovered incidentally during abdominal US for other reasons. There may be no clinical signs of its presence and it may not evolve, but extensive hepatic involvement may be a cause of severe and life-threatening cardiovascular complications [5, 20].

111.2.6.1 Hepatoblastoma (HB)

This is an embryonic neoplasm with variably differentiated epithelial and embryonic tissue with both embryonic and fetal components. It can be found prenatally and may be responsible for polyhydramnios and premature birth. While its association with malformative and genetic syndromes (hemihypertrophy, Beckwith-Wiedemann syndrome, familial polyposis)

is well known, hepatoblastoma has not been described during the prenatal period.

The clinical signs are abdominal distension and hepatomegaly. After imaging tests (MR/CT), the diagnosis is confirmed by a liver biopsy and abnormally high levels of alpha-fetoprotein, which represents a tumor marker. AFP is the major protein produced by fetal liver. AFP levels are markedly elevated in more than 90% of HB. One must relate the AFP values to the physiological AFP levels of premature newborns and infants. The SIOP protocol relies on primary cisplatin chemotherapy, followed by resection. Hepatoblastomas amenable to surgery have a more than 90% favorable prognosis. Liver transplantation should be considered in cases in which hepatic resection is unfeasible.

111.2.7 Leukemias

Leukemia is the most lethal disease of the newborn. It causes fetal hydrops and death, especially in Down syndrome patients. Leukemia in the newborn differs in clinical, hematological, molecular and biological aspects from the disease in older children.

Acute non-lymphoblastic leukemia (ANLL) is more common (65%) than acute lymphoblastic leukemia (ALL) and the former has a better prognosis in cases achieving remission (the survival rate is 24% for ANLL and 10% for ALL). The clinical findings include hepatosplenomegaly and skin lesions; the CNS is sometimes affected. Bone marrow cytomorphological, immunophenotypic and cytogenetic investigations are mandatory for diagnostic purposes. Congenital leukemia is CD10-negative and may be positive for markers in both the lymphoid and the myeloid lines. There is a rearrangement of the MLL (mixed linear leukemia) HRX gene on chromosome 11q23 in 50% of cases of congenital leukemia (both ANLL and ALL), and this is an unfavorable prognostic sign at all ages. Despite its unfavorable prognosis, ANLL may sometimes regress, though it may recur later on. It is important to distinguish congenital leukemia from florid neonatal leukemoid reactions, which are benign conditions defined as "transient abnormal myelopoieses", or "transient myeloproliferative disorders" (TMD), and characterized by hepatosplenomegaly and the presence of myeloid and lymphoid immature cells. The differential diagnosis must also consider fetal erythroblastosis and viral and bacterial infections. TMD differs from congenital leukemia in that the hemoglobin and platelet counts are normal, and blasts in the bone marrow are less than 15%, despite large numbers of white cells and myeloblasts in the peripheral blood. In these benign forms, the newborn's general condition is good and no specific therapy is required. In TMD, hematological indices return to normal over a period of time that may last from a few weeks to 1–2 months. Treatment guidelines for neonatal leukemia are the same as for older children, paying appropriate attention to the dosage of drugs involved, which must be administered in specialized hematological departments. Where feasible, high-dose therapeutic programs followed by hematopoietic cell transplants improve the remission and survival rates, which are currently about 20% [21–24].

111.2.8 Retinoblastoma (RB)

Newborn babies with retinoblastoma lack the normal "red reflex" when undergoing ophthalmoscopic examination, which is a part of routine newborn screening. A family history of retinoblastoma mandates a complete ophthalmic investigation because of the risk of bilateral disease. Familial cases (40%) are caused by a hereditary germinal mutation of the RB1 gene on chromosome 13q14. In such cases, DNA analysis identifies the individuals at risk. Hereditary cases are more common in the newborn, while non-hereditary, unilateral cases are seen more often in older children, who have a "de novo" RB gene mutation. Therapy is based on the outcome of a complete ophthalmic examination and MR can determine the extent of the lesion. The extent of retinal involvement is decribed as a percentage of the total retinal area. For localized forms, laser therapy and cryotherapy, combined with CHT using cisplatin and vepesid, are associated with the best prognosis for vision and survival. Surgery is limited to conditions affecting the extraocular areas, while radiotherapy (which was once used to prevent enucleation) has been abandoned because of the risk of secondary radio-induced tumors in adulthood. Therapy must be coordinated by oncologists and specialized ophthalmologists [2, 25].

111.2.9 Very Rare Congenital Tumors

111.2.9.1 Melanocytic Neuroectodermal Tumor (Melanotic Progonoma)

This tumor of neuroectodermal origin is characteristically located in the jaw, while other locations include the mediastinum and brain. It may be malignant and produce metastases. Surgery and chemotherapy are used, depending on the site of the lesion and the mitotic index.

111.2.9.2 Congenital Melanocytic Nevi

This condition is found in 1% of newborns. Giant forms are extremely rare and may contain nodular areas with a different mesenchymal cellular component. They sometimes resemble melanomas. Giant nevi undergo malignant transformation in

2–5% of cases. Fatal cases of congenital melanoma, with an intracranial involvement, can also occur.

111.2.9.3 Langerhans Cell Histiocytosis (LCH)

LCH comes half-way between malignant and histiocytic disorders. It affects one in a million newborns and 60% are cases of disseminated disease (with multiple organ involvement) while 40% are only cutaneous conditions. Gastrointestinal disease causes diarrhea, vomiting, and protein-losing enteropathy. The diagnosis of LCH requires a positive outcome of the CD1a immunohistochemical test. Depending on the extent of the disease, treatment may include steroids and vinblastine, with or without methotrexate.

The survival rate is 50% in cases of multiple-organ involvement, while it is more than 90% in patients with isolated disease [5, 26].

Fetal Infections: Cytomegalovirus, Herpes Simplex, and Varicella

Stuart P. Adler and Giovanni Nigro

112.1 Introduction

This chapter reviews three herpes viruses that cause infections of the fetus and/or newborn. These are herpes virus V, also called cytomegalovirus (CMV), herpes virus I and II, also called herpes simplex virus 1 and 2 (HSV), and herpes virus III, also called varicella-zoster virus (VZV). With the possible exception of HSV, CMV and VZV may produce severe fetal disease following a primary maternal infection during pregnancy when, in the absence of maternal immunity, these organisms are carried in the bloodstream to the placenta and then on to the fetus. With CMV and VZV, primary maternal infection during pregnancy does not always result in intrauterine infection of the fetus; and when intrauterine infection does occur, severe fetal disease does not always follow. Most commonly, infants infected in utero with CMV appear normal at birth. Chronic persistent infection with each of these herpes viruses causes progressive disease with significant developmental abnormalities which become apparent over the first several years of life. In general, infection of the mother with these viruses and the development of immunity prior to conception protects the fetus either from infection or from the severe disease both in utero and after birth for few months. With CMV, for example, women immune to the virus prior to pregnancy may deliver infants with intrauterine acquired infection but, with rare exceptions, congenital cytomegalic inclusion disease occurs only as the result of a primary infection during pregnancy.

Along with maternal immunity, another important factor that affects both the frequency of transplacental transmission and the severity of disease, is the gestational age of the fetus when the woman becomes infected. Infections with HSV 2 are for most part acquired during delivery from virus in the maternal cervical-vaginal tract. Maternal immunity to HSV 2 prior to delivery protects the newborn from severe or fatal disease due to HSV infection of the newborn. HSV 1 is a virus which is usually orally transmitted but may infect newborns and produce severe disease in the absence of maternal immunity.

Another influence on the severity and the manifestations of an intrauterine infection is the tissue tropism of each virus. Tissue tropism is the affinity of a particular microbe for specific cell types or tissues. Most of the microbes causing intrauterine infection replicate in all organs and tissues, hence causing disease in any or all organs or tissues. An example is VZV which is tropic for neural tissue, and many of the manifestations of severe intrauterine infection with VZV arise from effects upon the developing nervous system.

112.2 Cytomegalovirus

Human cytomegalovirus (CMV) contains within its capsid a double stranded DNA molecule of 150 million molecular weight. This DNA molecule contains at least several hundred genes and is the largest genome of any known virus. CMV viral particles are structurally similar to other human herpes viruses. The virus has a 65 nanometer inner core containing the viral DNA. The inner core is within an icosahedral protein capsid comprised of 162 capsomeres. This is in turn surrounded by a tegument layer and an outer enveloped membrane containing glycoproteins. The envelope glycoproteins are antigenic and are responsible for generating an immune response. The majority of the neutralizing antibodies induced by CMV antigens are directed against the major CMV glycoproteins. Cellular immune responses such as cytotoxic T-cells are directed primarily against the major tegument protein, pp65. There is only a single serotype of CMV. Thus antibodies induced by one viral isolate cross-react with most or all epidemiologically unrelated isolates. Genetically, however, there are probably thousands of different isolates. Each isolate of CMV differs genetically from all other epidemiologically unrelated isolates. CMV infects nearly all humans

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

but infrequently causes disease. CMV causes serious disease in those with impaired immunity associated with immunosuppression due to medical therapy, AIDS, or in the fetus with its immature immune system [1].

112.2.1 Epidemiology

In undeveloped areas or among those in lower socioeconomic groups, between 0.5 and 2% of all newborns are congenitally infected with CMV and by 5 years of age the majority of children have acquired the infection. Within the first year of life, for infants not congenitally infected, CMV is usually acquired perinatally by contact with maternal cervical-vaginal secretions or postnatally from seropositive mothers via breast milk. Approximately 30% of seropositive mothers shed CMV in breast milk and approximately 70% of infants of mothers excreting CMV in the milk will be infected perinatally. The infection is usually asymptomatic in term neonates, while that in preterm infants may be symptomatic. Heating the milk up to 62°C for 5 seconds inactivates the virus while saving its immunologic and nutritional properties.

Between 6 and 12% of seropositive mothers transmit CMV to their newborns via cervical-vaginal secretions. After a primary infection, CMV is shed for prolonged periods. Adults may shed the virus for several weeks or months and intermittently thereafter, but infants and young children shed CMV in saliva and urine for many months or years. Thus, those infants not acquiring CMV from maternal sources presumably acquire the infection from frequent contact with numerous other children shedding CMV. In developing areas with infection acquired early in life, CMV rarely causes acute or chronic disease [2–4].

In developed nations or among those in middle or upper socioeconomic groups, the epidemiology of CMV usually differs from that in undeveloped areas or among those in lower socioeconomic groups. In the United States, for example, although nearly all individuals eventually acquire a CMV infection, infection rates average between 1 and 2% per year. In the US, between 40 and 70% of women between 15 and 45 years of age have antibodies to CMV (seropositive), and seropositivity rates vary by race. Seroprevalence rates are significantly higher among African-Americans than Caucasians [5].

112.2.2 Pathogenesis

Worldwide, approximately 1% of newborns are infected with CMV in utero and excrete virus at birth, but approximately 10% of these infants have congenital CMV disease at birth or develop mental retardation or deafness. Of the 90% of congenitally infected infants who are without symptoms at birth, approximately 85% develop normally. Why do only 10% of infants congenitally infected with CMV have symptoms at birth, and why do approximately 15% of infants without disease at birth develop postnatal sequelae such as mental retardation and deafness? With occasional exceptions, the answer is that infants born of women acquiring a primary infection during pregnancy are those at highest risk for developing congenital disease.

Maternal-fetal CMV transmission as well as neonatal disease expression may be enhanced by transient cellular and humoral immunodepression occurring in the second and third trimesters of pregnancy. While the frequency of fetal infection by primary maternal infection increases with gestational age from about 30 to 60 %, early CMV transmission is correlated with poor outcome. If infection occurs in the 6 months before conception, transmission to the fetus and symptoms at birth will occur at a lower rate. The prevalence of infections following recurrent CMV infection in pregnancy is considered to be lower than 2%, but higher rates have been reported. Pre-existing humoral immunity completely protects seropositive women against reinfection or reactivation at a rate of 75–80%. Neutralizing titers and IgG avidity towards CMV are both inversely correlated with fetal transmission, while the role of cellular immunity is essential in modulating viral transmission and pathogenicity in pregnancy. A major pathogenic site of CMV is the placenta, which may be impaired in its capacity to provide oxygen and nutrients to the developing fetus [6–13].

Of congenitally infected newborns whose mothers acquired a primary CMV infection during pregnancy, approximately one-third will either have disease at birth or develop significant sequelae (Fig. 112.1). The risk for symptomatic infection appears to be greatest when primary maternal infection occurs in the first half of pregnancy, but congenital disease may also occur among infants born of mothers with a primary infection in the second half of pregnancy. If infection occurs in the 6 months before conception, transmission to the fetus and symptoms at birth will occur at a lower rate. Because primary maternal infection is responsible for the majority of congenital CMV disease, symptomatic infection is most frequent in areas with a high proportion of seronegative women frequently exposed to the virus. Primary maternal CMV infections during pregnancy are seldom recognized and many infants who develop neurologic sequelae following a primary maternal infection in early pregnancy are asymptomatic at birth. Thus, the precise number of affected infants born annually in any country is unknown. Estimates for the US are that between 1 and 4% of 4 million pregnant women acquire a primary CMV infection in the US annually and that up to 8000 newborns annually may develop significant handicaps caused by congenital CMV infection [3–5].

112.2.3 Clinical Manifestations

Cytomegalovirus infects the placenta and causes placental dysfunction manifested by an enlarged placenta and placental inflammation. Manifestions of placental dysfunction in the

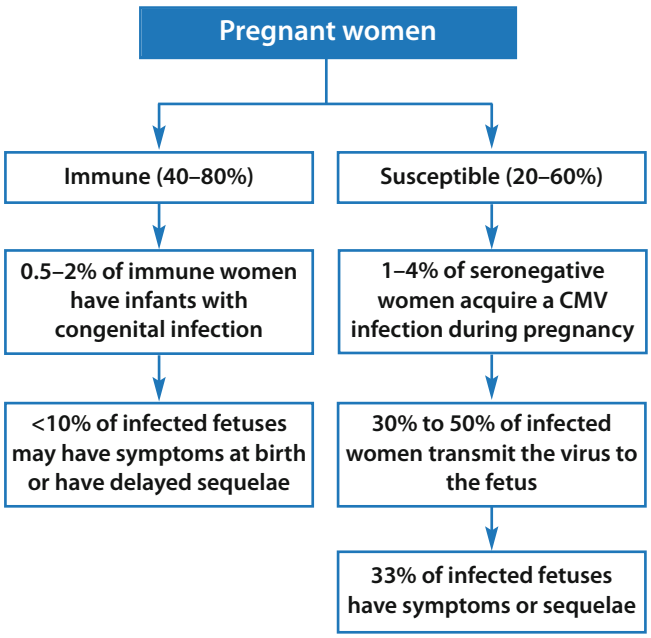

Fig. 112.1 Relationship of maternal immunity to disease caused by congenital CMV infection

newborn include growth restriction and problems with the reticuloendothelial and the central nervous system. Reticuloendothelial problems include hepatosplenomegaly and hepatitis, hemolytic anemia, thrombocytopenia, and direct hyperbilirubinemia. Central nervous system (CNS) involvement is often manifested by microcephaly and intracranial calcifications, typically periventricular. Alterations of neuronal migration, which occur between the third and fourth month of pregnancy, cause cerebral dysplasias (polymicrogyria, pachygyria, lissencencephaly, schizencephaly).

CMV is the only congenitally transmitted pathogen capable of causing alterated gyral development, the pathogenesis of which include both teratogenic and encephaloclastic mechanisms. Table 112.1 lists the more common features characteristic of infants who are symptomatic at birth. At birth chorioretinitis or intracranial calcifications or other abnormalities on a computerized axial tomography (CAT) scan or ultrasound of the head are associated with a poor neurologic prognosis, but none of the other manifestations of congenital infection accurately predict the severity of postnatal mental retardation or hearing deficit [5, 8, 13].

Approximately 15% of infants asymptomatic at birth will develop significant hearing deficits or mental retardation within the first 5 years of life. This may occur because CMV causes a chronic persistent infection. Symptomatic children are often viremic at birth and viremia may persist for the first few months of life. Both symptomatic and asymptomatic children will excrete CMV in urine and/or saliva for up to five years postnatally. At birth symptomatic children shed higher titers of virus (up to 10^6 PFU/mL of urine) than asymptomatic infants. Hearing deficit, either mild or absent at birth, may develop or progressively worsen over the first several years of life, perhaps as a result of the chronic CMV infection. Therefore, parents of congenitally infected children, including those without symptoms, should not be given a prognosis at birth. When hearing deficit is profound, however, it is not generally reversible. The severity of mental retardation and developmental delay, which are the most serious neurological sequelae of this infection, are difficult to predict at birth. Most children who are symptomatic at birth will have some degree of mental retardation or developmental delay; however, IQ scores may approach 100 or higher in these children. Thus, the level of impairment in these children may be relatively mild or inapparent. Congenital CMV infection should be suspected in any infant with one or more of the manifestations listed in Table 112.1 [3, 5, 12].

Transmission of CMV within the hospital occurs very infrequently. In numerous studies, CMV transmission from infected patients to hospital personnel has not been observed. Patient-to-patient transmission is rare and may occur when patients are hospitalized in close proximity for prolonged periods. Thus, CMV seronegative women caring for hospitalized young children or for other patients who may be excreting CMV can be reassured that there is minimal risk of acquiring CMV from patients. CMV may be transmitted by transfusion of whole blood and is located in the white cell fraction. For immunocompromised patients requiring transfusion the risk of CMV acquisition from a blood donor is eliminated either by selecting donors who are CMV seronegative or using blood products with white cells removed [3, 5].

Table 112.1 Common features in children with symptomatic congenital CMV infections

1. Unexplained hepatomegaly associated with abnormal liver function tests
2. Unexplained splenomegaly
3. Unexplained hyperbilirubinemia (usually direct > indirect)
4. Ocular findings, including chorioretinitis, strabismus, optic atrophy, microphthalmia, cataracts, or retinal necrosis
5. Microcephaly
6. Cerebral calcifications
7. Hemolytic anemia

112.2.4 Diagnosis

Without prospective serologic testing of pregnant women the diagnosis of a primary maternal infection during pregnancy is often difficult and is often only undertaken if signs and symptoms of either maternal infection or fetal disease become apparent. Symptoms of maternal CMV infection occur in about 25% of pregnant women infected during pregnancy. Maternal symptoms include a flu-like syndrome, myalgia, and asthenia with or without fever. There may also be a lymphocytosis

and/or elevated liver enzymes in about 50% of patients. Signs of fetal infection on maternal ultrasound include growth restriction, microcephaly, echodensities in solid organs or the intestines, or an enlarged placenta [13–17].

The best way to diagnosis of a maternal infection is by maternal seroconversion, however, this rarely occurs unless universal screening of pregnant women is standard practice in a particular country. Hence initial seronegative sera are rarely available. The detection of IgM antibodies in maternal sera may be helpful but although IgM antibodies to CMV occur in all primary infections they may also occur after reactivations or reinfections. After a primary infection IgM remains for many months. Thus IgM to CMV in a single serum of a pregnant woman does not alone establish a primary CMV infection during pregnancy. Antibody avidity, a measure of tightness of antibody binding to its target antigen, increases in the first weeks after a primary infection. Low avidity IgG antibodies to CMV persist for up to 20 weeks after a primary CMV infection. These low avidity antibodies are then replaced by high avidity antibodies (> 60% binding in presence of 5M urea). Thus the combination of IgM antibodies to CMV and low avidity IgG antibodies to CMV plus maternal or fetal symptoms argues for the diagnoses of a primary maternal infection [18–19].

Amniotic fluid may be a helpful adjunct in diagnosis. While viral culture of the amniotic fluid may yield false negative results, polymerase chain reaction (PCR), especially after 21 weeks gestation, is both sensitive and specific for fetal infection. A diagnosis of fetal CMV infection alone is insufficient to predict newborn disease, however, fetal abnormalities or placental enlargement by ultrasound predict newborn disease and long-term sequelae [7–13].

In the newborn the diagnosis for congenital CMV is established with a positive urine culture within the first 3 weeks of life. With the shell vial assay, which detects the immediate early protein of CMV expressed on cultured fibroblasts within 48 hours of inoculation, a diagnosis of congenital CMV infection can usually be obtained with 48–72 hours of life. Because congenital infection with CMV occurs in up to 2% of all newborns and because 85–90% of these babies will develop normally, a positive urine alone does not establish a diagnosis of symptomatic congenital CMV infection. One must also exclude congenital toxoplasmosis and syphilis [5].

112.2.5 Newborn Evaluation

If a congenital CMV infection is established or suspected, an evaluation should include measurement of transaminases and direct bilirubin. If liver function is abnormal, it should be monitored until near normal, which may take several months. A complete blood count should be obtained as some infants have a hemolytic anemia and almost all will have low platelets which may be mild or severe. Thrombocytopenia which is due to reduced platelet production in utero associated with CMV-induced megakaryocytic lysis and intrauterine hypoxia usually resolves in 1–2 weeks.

A lumbar puncture and head CT scan or head ultrasound should be obtained. The presence of cellular pleocytosis and elevated protein in the cerebral spinal fluid (CSF) or periventricular calcifications indicates CNS involvement. Other manifestations include ventriculomegaly and/or hydrocephalus. Cerebral dysplasias or atrophy may be seen by magnetic resonance imaging (MRI). An ophthalmologic exam should be obtained to evaluate for chorioretinitis.

Hearing deficit is an important consequence of congenital CMV infection and is the main cause of non-genetic sensorineural hearing loss accounting for about 23% of all hearing deficit that occurs before language development. Given this and the fact that hearing loss may be fluctuating and progressive, a complete audiologic exam should be performed soon after diagnosis with frequent subsequent exams over the first few years of life. Most infected infants will develop hearing loss in the first 2 years of life, although hearing deficit may develop as late as 4 years of age. Audioevoked potentials or brainstem evoked potential testing are the most accurate tests [20, 21].

112.2.6 Treatment

112.2.6.1 Prenatal Therapy

An effective therapy for fetal CMV disease is not yet available, in spite of relevant advances in the diagnostic procedures of maternal-fetal CMV infection. Pregnancy termination is offered as a management option when injured, or even only infected, fetuses are identified by ultrasonography or amniocentesis, respectively. A few case reports and one study have focused attention on the safe administration of oral ganciclovir or valacyclovir, respectively, to mothers of CMV-infected fetuses. The favorable use of CMV immunoglobulin intravenously to the mother and intramniotically to treat or prevent fetal CMV infection has been reported in a few case reports and in one study, which evidenced favorable clinical and immunological results. The placenta is probably the key site of activity of immunoglobulin, as shown by studies in guinea pigs and humans, in which placental enlargement due to CMV infection can be reduced by immunoglobulins [22–25].

112.2.6.2 Postnatal Therapy

CMV immunoglobulin was shown to be protective against CMV disease by studies on neonatal transfusions. Antiviral treatment of neonates or infants with congenital CMV infection is generally based on the use of ganciclovir, which has been given at different endpoints and regimens (both dosage and duration of therapy), and for different clinical manifestations. This drug is active only after phosphorylation to

ganciclovir-triphosphate, which substitutes guanosine-triphosphate in the viral DNA polymerase, with consequent inhibition of CMV replication. Since the first phosphorylation requires the presence of the CMV-encoded (UL 97 gene) phosphotransferase, ganciclovir can display its activity mostly in the CMV-infected cells. Besides being a possible consequence of CMV infection, neutropenia and increased aminotransferase levels may be associated with ganciclovir therapy, particularly in immunodepressed patients. A longer duration of antiviral therapy has been associated with favorable outcome more frequently than shorter courses, probably related to the longer inhibition of CMV. In fact, this virus reactivates soon after stopping therapy, and some of the favorable results obtained during ganciclovir therapy may be lost. Protracted and repeated courses of oral ganciclovir were useful for therapy of several CMV-related diseases, including neurologic and gastro-intestinal manifestations [21, 24–26].

112.2.7 Prevention

As CMV is a major cause of childhood deafness and neurological handicap, routine antepartum screening should be very useful, but appears to be impracticable. To avoid difficulties in differentiating recurrent from primary infections and problematic counseling when positive IgM antibodies are detected, serial examinations of CMV-specific IgG and IgM antibodies at least in the first two trimesters, particularly in women at high risk, such as daycare workers, may be suggested. In such a way, it is possible to reveal as soon as possible both primary (by seroconversion and high IgM levels) and recurrent (by significant IgG increase concomitantly or not with positive IgM antibodies) infections. To prevent possible viral transmission to the fetus, women with primary infection could receive hyperimmunoglobulin. Appropriate hygienic measures can prevent CMV transmission. The most aggressive preventive approach requires counseling of parents with seropositive children in daycare centers: seronegative parents should be instructed to frequently handwash after handling diapers and material contaminated with secretions and cautioned about the potential risk of intimate contact, especially mouth-to-mouth [20]. Seronegative women with multiple sexual partners and a history of sexually transmitted diseases should be counseled about the use of condoms. Since the detection of CMV DNA in CSF has been associated with developmental delay, this evaluation could be used in the future to identify infants who are at risk for neurodevelopmental problems and who may therefore benefit from antiviral therapy. A vaccine containing recombinant cytomegalovirus (CMV) glycoprotein B subunit antigen combined with MF59 adjuvant showed the potential to decrease of 50% incident cases of maternal and congenital CMV infection. Other vaccines, including live attenuated vaccines, other subunit vaccines, or vaccine candidates formulated with adjuvants other than MF59 are under evaluation [24, 27, 28].

112.3 Infection with Herpes Simplex Virus, Serotype 1 and 2

112.3.1 Epidemiology

HSV is another member of the Herpesviridae family, including two closely related virus types (1 and 2), which are transmitted through mucosal cells or cutaneous lesions and migrate to the nerve tissues, in which they persist in a latent state. HSV-1 predominates in the orofacial manifestations and is typically found in the trigeminal ganglia, whereas HSV-2 is most commonly detected in the lumbosacral ganglia. Nevertheless, these viruses can infect both orofacial areas and the genital tract, where they can reactivate either asymptomatically or with vesicular lesions [29, 30].

Vertical transmission is more likely to occur after primary maternal infection, but recurrent genital infections are more frequent and, consequently, they are the most common cause of neonatal herpes infections. The great majority of recurrent genital herpes are due to HSV-2 because this virus reactivates in the genital area more frequently than HSV-1 (7 versus 2%, respectively). In the asymptomatic period between clinical outbreaks of genital herpes, HSV can reactivate periodically in latently infected cells of sensory ganglia travelling via the neuronal axons back to the genital mucosa, without clinical signs or symptoms (“asymptomatic virus shedding”). The majority of sexual HSV transmission occurs during asymptomatic shedding because the patients are unaware of the viral presence [30–32].

Newborns may acquire infections with HSV in utero, peripartum at delivery, or postpartum. Approximately 5% of all newborn infections with HSV are acquired in utero, 85% are acquired at birth by contact with infected maternal lesions or asymptomatic cervical shedding of HSV, and 10% are acquired postpartum from environmental sources, such as scalp electrodes or individuals with oral HSV infections. Intrauterine infections with HSV occur with a frequency of from 1 in 200,000 to 1 in 300,000 live births as opposed to peripartum infections estimated at 1:5000. In utero infection during the first 20 weeks of gestation is associated with the highest infant morbidity and mortality, including stillbirths and spontaneous abortions [29, 31].

112.3.2 Intrauterine Infections: Pathogenesis

Although the exact route by which infants acquire intrauterine HSV infections is unknown, there is evidence that most infants are infected by virus ascending through the chorioamnionic membrane rather than from a maternal viremia and transplacental passage of HSV to the fetus. The first observation is that during both recurrent and primary maternal HSV infections, maternal viremia does not occur. The second is that HSV is commonly present in the cervical-vaginal tract,

and this is the usual site of primary or secondary HSV infection in women who deliver infants with intrauterine HSV infection. Although women with a primary HSV infection deliver infants with the most severe form of intrauterine infection, these primary infections are still in the cervical-vaginal tract and viremia does not occur. The third observation is that even when a woman with viremia develops disseminated HSV disease during pregnancy, the majority of fetuses born of these women die from maternal complications, but not as a consequence of intrauterine HSV. Surviving fetuses of women with widely disseminated maternal disease usually have no evidence of HSV disease at delivery. This suggests that the occurrence of maternal viremia is not necessary for intrauterine infection with HSV [29, 31].

The fourth fact is that most infants born with intrauterine HSV infection have cutaneous disease with scarring. The chronicity of the skin infection suggests that, as in postpartum and peripartum acquired infections, the skin or the mucous membranes are the first sites of HSV infection, followed by fetal viremia and subseqent central nervous system infection. Another fact suggesting an ascending route of infection is that when HSV is in the placenta, there is extensive fetal involvement, suggesting passage of virus was from fetus to placenta. In infants who survive placental infection there is usually evidence of disseminated organ dysfunction. The final fact suggesting an ascending route of infection is that nearly all infants with intrauterine infection are infected with HSV-2, the serotype commonly found in the maternal cervical-vaginal tract. If the route of fetal infection were via the maternal blood stream one would anticipate frequent fetal infection with HSV-1, since this serotype is common in pregnant women [31–33].

112.3.3 Intrauterine Infections: Clinical Manifestations

Diagnosis of intrauterine HSV infection requires clinical evidence of HSV infection within the first 48 hours of life and confirmation by recovery of the virus from the newborn. Symptoms are usually present at birth (Table 112.2). The classic symptom triad is skin scarring, hydranencephaly, and chorioretinitis. Skin vesicles and bullae are common. There may also be erythematous maculas that later become vesicles or areas of aplastic or denuded skins, or scars. These may occur at sites of trauma, for example fetal scalp electrode sites. Skin lesions often recur, but do not usually progress to other sites. Dissemination with multi-organ system involvement, if present, includes hepatic (i.e., liver failure), renal (i.e., anuria), and hematologic disorders (i.e., disseminated intravascular coagulopathy). Intrauterine growth restriction and subsequent postnatal growth retardation are also common [34].

When hydranencephaly is absent, microcephaly, intracranial calcifications, hydrocephalus, porencephalus, and subdural or epidural cysts may occur with subsequent blindness, deafness, and mental retardation. Involvement of the eye is common, particularly chorioretinitis with a strabismus. This occurs more frequently with intrauterine HSV infection than with HSV infection acquired peripartum or postpartum. Disseminated infection in infants with intrauterine disease is much less frequent than in infants with perinatally acquired infection because those infants who do develop disseminated disease usually die in utero [34, 35].

Table 112.2 Clinical manifestations of congenital or perinatal infection by herpes simplex virus (HSV)

Congenital HSV infection
Cutaneous lesions: scarring, vesicles, bullae, macular erythema, areas of aplastic or denuded skin
Cerebral: hydranencephaly, microcephaly
Ocular: chorioretinitis, microphtalmia
Perinatal HSV infection
Encephalitis
Pneumonia
Esophagitis
Muco-cutaneous manifestations
Systemic disease

112.3.4 Peri and Postnatal HSV Infections

112.3.4.1 Epidemiology

HSV transmission follows a direct contact with oral or genital secretions, even if asymptomatic. HSV-1 infection occurs early in the low economic level populations, while HSV-2 prevalence rapidly increases with sexual activity. Oral recurrences occur in 20 to 40% of the adult population. The prevalence of neonatal HSV infection is 1/2500–20,000 infants, being caused by HSV-2 in two thirds of the cases [29].

112.3.4.2 Pathogenesis

After entry at mucosal surfaces or abraded skin, HSV proteins bind to several cell receptors of epidermal and dermal cells, in which the virus replicates. In both clinical and subclinical infections, HSV reaches sensory or autonomic nerve endings and is transported intraaxonally to the nerve cell bodies in ganglia, in which initial viral replication takes place. Then, HSV spreads to other mucosal and skin cells by centrifugal migration along peripheral sensory nerves. After primary infection, viral DNA may be found in 10 to 50% of ganglion cells of the initially involved anatomic region. Ultraviolet light, immunodepression and trauma are associated with HSV reactivation but the pathogenic mechanism is unknown [31–33].

112.3.5 Clinical Manifestations

112.3.5.1 Neonatal Herpes

Neonatal herpes includes three major clinical features: oculo-mucocutaneous (50%), encephalic (33%) or systemic manifestations (17%) [9, 30]. Mucocutaneous and ocular signs can occur several days after delivery, and are generally slight: vesicles, which are often grouped, may be purulent and be considered as bacterial bullae. Encephalitis is shown, 2–3 weeks after birth, by fever and irritability or lethargy in the first 2 weeks, then by alterated muscular tone and partial or diffuse convulsions. The cerebro-spinal fluid shows 50–100 leukocytes, decreased glucose but increased protein content. Electroencephalography (EEG) reveals signs of disseminated cerebropathy, CT and MRI scans show focal alterations. The systemic infection is shown by fever, lethargy, hepatic dysfunction, pneumonia, disseminated intravascular coagulopathy and shock. Other signs include seizures, jaundice, and a vesicular exanthema which may be pathognomic. Encephalitis is a common manifestation (60–75%) of the disseminated HSV infection [36, 37].

The rate and severity of neonatal HSV infection depend on the type of maternal genital infection: the frequency is higher after primary than recurrent maternal infection (50 versus < 3%). However, 70% of neonatal HSV infections result from exposure to asymptomatic maternal HSV shedding during delivery. Prolonged rupture of membranes favors neonatal infection: a cesarean section should be chosen. Invasive obstetrical procedure and fetal scalp monitors can cause lesions which are sites of viral inoculation [31, 33, 34].

112.3.5.2 Gingivostomatitis

Gingivostomatitis is predominantly caused by HSV-1 and typically shown by vesiculo-ulcerative lesions on the tongue, lips, gingival, buccal mucosa and the hard and soft palate. Fever, painful oropharyngeal mucositis, cervical lymph-adenitis and fetid breath persist for several days and can cause dehydration because of the difficult feeding even with liquids [36].

112.3.5.3 Keratoconjunctivitis

Keratoconjunctivitis is commonly caused by HSV-1, presents as monolateral follicular conjunctivitis, localized lymph-adenomegaly, palpebral vesicles, photofoby, edema and corneal opacity [37].

112.3.5.4 Encephalitis

Encephalitis is one of the most common acute viral infections of the brain (1/250–500,000 people every year), caused by HSV-1 in > 90% of the cases, predominantly after recurrent infections. If untreated, it is lethal in 60–80% and followed by severe sequelae in > 90% of the surviving patients [32, 37].

112.3.5.5 Cutaneous Herpes

Primary cutaneous herpes infections can be localized in any part of the body, sometimes as an extensive zoster-like manifestation. Recurrences are generally localized on the lips, both mucosal and cutaneous parts. Because the immune system is still developing, then partially immature in early infancy, at this age herpetic recurrences may be more frequent and extensive than in adults. Occasionally, the children may present recurrent stomatitis or aphtosis with or without an erythema [35].

112.3.5.6 Herpes in Immunodepressed Children

Herpes in immunodepressed children occurs as an extensive mucocutaneous or multi-system infection, including Kaposi's varicella-like eruption or *eczema herpeticum*, pneumonia, meningoencephalitis. Children with AIDS may have a rapidly worsening and overwhelming herpetic infection shown by esophagitis, enterocolitis, pneumonia, hepatitis and neurological manifestations [35, 37].

112.3.6 Diagnosis

The HSV infection may be identified directly by detection of the virus or one of its components or indirectly by assaying for specific serum antibodies of the viruses. Direct site-specific methods, such as DNA detection by RT-PCR or viral isolation, are most relevant in patients with active, vesicular lesions at or near a genital site. When lesions have scabbed or are not evident, HSV-1 or HSV-2 infection can be diagnosed indirectly by detection of type-specific IgG against the glycoprotein G of HSV-1 (gG-1) or the glycoprotein G of HSV-2 (gG-2). Indirect (serological) testing can provide useful information in symptomatic patients when direct methods have yielded negative results. The detection of HSV-specific IgM antibodies may be negative or non-specific [32, 33].

Intrauterine HSV infections are diagnosed by virus detection from the infant's samples within the first 48 hours of life. Cultures should not be obtained for HSV early from asymptomatic infants or infants who have none of the signs or symptoms of intrauterine HSV infection because some infants may only be colonized with HSV at birth. Cultures should be obtained from skin lesions, perianally, mucous membranes, eyes, nose, oral pharynx, and ears. More sensitive than culture is the viral DNA detection by PCR from the liquid of vesicles and any other sample, particularly the CSF. A Tzank preparation

or Wright's stain of epithelial cells scrapped from cutaneous lesions may reveal multinucleated giant cells which are associated either with HSV or VZV lesions. After the first 48 hours of life, the isolation of HSV from an asymptomatic newborn means an active infection rather than colonization and requires antiviral therapy. Tissue HSV involvement may be also diagnosed using immuno-hystochemical methods or in situ hybridation. Cerebral imaging and auditory/ophthalmological examination should be performed [3, 32, 33, 37].

112.3.7 Treatment

Specific antiviral therapy with acyclovir is appropriate for infants with either intrauterine or postnatal HSV infections. To treat encephalitis or systemic HSV infection, intravenous acyclovir (10–15 mg/kg three times daily) should be started soon after collection of the samples for virologic confirmation. If acyclovir-resistance develops, ganciclovir or, preferably, foscarnet should be given.

For gingivo-stomatitis or muco-cutaneous lesions, oral acyclovir should be given at the dosage of 200 mg five times daily. The starting time of treatment is crucial for prognosis, especially in case of disseminated infections. HSV infections localized to skin, eyes and mucous membranes are treated for 14 days, whereas CNS or disseminated infections required 21 days of therapy. For recurrent skin lesions, which are frequent after neonatal HSV infection, acyclovir treatment is indicated for weeks to months, at doses of 300 mg/m^2 2–3 times daily [35, 38].

112.3.8 Prognosis

For both intrauterine and postnatal HSV encephalitis and systemic infections, if untreated, the mortality is about 70%. Treatment with acyclovir reduces mortality until to about 30% and to only 5% for neonates with encephalitis. The effect of antiviral therapy on morbidity is unknown; and some treated infants, particularly those with manifestations of central nervous involvement, will be blind, deaf, or profoundly retarded. The outcome is correlated with the virus type and disease classification. Moreover, after a neonatal herpes infection, cutaneous recurrences may occur [39].

112.3.9 Prevention

Numerous approaches, including subunit or peptide vaccines, live virus vectors and DNA vaccines, have been used in developing both prophylactic and therapeutic vaccines, since several antiviral therapies are available to control disease and spread, but these are not completely effective and do not affect latent virus. Currently, neither active nor passive immunization is available for prevention of HSV infections in pregnant women and neonates. However, the developing vaccine strategy should take in account the most important features of herpesvirus family: viral latency, immune escape and high seroprevalence [33, 40].

All pregnant women with genital herpes should be treated with acyclovir or valacyclovir, which were shown not to be associated with teratogenic effects. However, since these drugs are not officially approved for treating pregnant women, patients should give consent about the limited information before the drug is used. The high rate of undiagnosed or asymptomatic HSV infections complicate prevention. Identification of the serostatus of pregnant women during early pregnancy is the first and most important step, to establish their susceptibility to the infection. A history of HSV infection in all pregnant women and their partners should be obtained at the first prenatal visit. Women with a negative personal history of HSV and especially those with a positive history in the male partner, should be strongly advised to have no oral and sexual intercourse at the time of recurrence in order to avoid infection, particularly in the third trimester of pregnancy. The use of condoms throughout pregnancy should be recommended to minimize the risk of viral acquisition, although they are not considered to be a complete barrier for the genital region.

Prophylactic administration of acyclovir or valacyclovir in the third trimester of pregnancy should be provided to all pregnant women with frequent genital herpes outbreaks and with active genital HSV infection near term or at the time of delivery. A careful examination of the vulva, vagina and cervix should be performed on any woman who presents signs or symptoms of HSV infection at the onset of labour. Artificial rupture of membranes should be avoided. All pregnant women who have suspected active genital HSV infection should undergo cesarean section, although membranes are intact. Neonates, born to women with active genital lesions, with a confirmed or suspected HSV infection should be isolated, managed with precautions to avoid direct contact with skin and mucosal lesions, excretions, body fluids and immediately treated with intravenous acyclovir. Since neonatal herpes can also be acquired postnatally, postpartum women, family members and nursery personnel with active herpetic lesions of the mouth, skin or breast should take necessary precautionary measures to prevent direct contact with the neonate and/or should be excluded from the neonatal unit until the lesions are fully healed [29, 31, 34, 35].

112.4 Varicella

112.4.1 Epidemiology

Varicella zoster virus (VZV) is a herpesvirus, which causes chicken pox and shingles. About 5% of women have not had

chicken pox before pregnancy. Women who have had chicken pox before pregnancy are immune and their fetuses are not at risk. The average incidence of varicella in pregnancy ranges 0.7–3%. If a woman becomes infected with VZV during pregnancy, infection of the fetus with the development of a varicella syndrome occurs up to the 26th week of gestation. However, the risk for intrauterine disease after a primary maternal VZV chicken pox is low, about 4%, mostly in the first two trimesters. This is much lower than when a woman acquires primary varicella within a few days of delivery, when the risk for the newborn of acquiring postnatal varicella approaches 20%. The rate of spontaneous abortion by varicella does not exceed that of women without varicella. Pregnant women who contract varicella are at risk of severe pneumonia associated with life-threatening ventilatory compromise and death, apparently more often in the third trimester. If a woman develops zoster, also called shingles, during pregnancy there is no risk to the fetus [3, 41, 42].

112.4.2 Pathogenesis

The VZV virus causes both primary chicken pox and recurrence within an initially infected dermatome. Recurrence which occurs months to decades after a primary infection is called shingles or zoster. VZV infection in a normal person consists of two episodes of viremia. The first episode of viremia follows the replication of the virus at a regional lymph node in the head or neck. This primary viremia results in the seeding and replication of VZV at multiple body sites. After the second stage of viral replication, secondary viremia leads to infection of epithelial cells in the entire body and produces the skin lesions of chicken pox.

Transmission to the fetus occurs with either the primary or secondary viremia. Infection after a primary maternal viremia can cause fetal disease within a day or two of the appearance of skin lesions in the mother. If, however, fetal infection occurs after the secondary maternal viremia, fetal skin lesions do not appear until 10–14 days following the appearance of lesions in the mother.

In the first 20 weeks of gestation, since the fetal organs are embryonic, VZV may cause teratogenic abnormalities. Maternal chicken pox late in gestation may lead high fetal mortality but not structural abnormalities. Spontaneous abortion, fetal demise, and premature delivery can occur at an indetermined but low frequency [43, 44].

112.4.3 Clinical Manifestations

112.4.3.1 Congenital Varicella Syndrome (CVS)

Since VZV has a tropism for peripheral and central neural tissue, the major manifestations of intrauterine varicella infections are those related to the nervous system. The characteristic clinical signs and symptoms (Table 112.3), which also include skin lesions in dermatomal distribution, eye diseases and limb hypoplasia are: zigzag skin lesions and hypopigmented areas, damage to the eye including microphthalmia, cataracts, chorioretinitis and optic atrophy, damage to the cervical-lumbar spinal cord with hypoplasia of the upper and lower extremities with decreased motor and sensory deficits, absent dependent reflexes, anal dysfunction, and Horner's syndrome. Based on the segmental distribution of some clinical features, some lesions might be not consequent to immediate intrauterine varicella but zoster-like VZV reactivations. Cortical damage includes encephalitis with microcephaly, hydrocephaly, intracranial calcifications, and aplasia of the brain. In spite of the initial poor prognosis, a favorable outcome can occur in children with CVS. In addition to the developing disease, prenatally infected infants may develop VZV infection without symptoms: intrauterine infection is more common than fetal disease. The developmental effects of asymptomatic intrauterine VZV infection are unknown [43, 44].

Table 112.3 Congenital Varicella syndrome: principal clinical manifestations

Skin lesions
Microphtalmia, chorioretinitis, cataract, atrophy of the optical nerve
Neurosensorial deafness or hypoacusia
Microcephaly, calcifications, cerebral atrophy, hydrocephalus, mental retardation
Limb hypoplasia or paresis

112.4.3.2 Neonatal Varicella

Maternal varicella between 4–5 days before and 2 days after delivery may be followed by a generalized and severe neonatal varicella, since protective antibodies are not transferred to the infant. The attack rate for the infant ranges 20%. A fatal outcome is more likely if neonatal disease occurs between 5 and 10 days after delivery. Chickenpox occurring after the first 10 days of life is most likely acquired postnatally, and is associated with a low morbidity, since most neonates are protected by maternal antibodies. However, premature infants younger than 28 weeks' gestation or weighing below 1000 g are at increased risk for severe varicella during the first 6 weeks of life [43, 44].

112.4.3.3 Complications of Postnatal Varicella

Otherwise healthy children may have secondary bacterial infections, usually caused by *S. aureus* and *S. pyogenes*, meningoencephalitis, which is prevalent under 5 years or over 20 years of age, acute cerebellar ataxia, Reye syndrome, which is significantly reduced by avoidance of salicylates, transverse

myelitis, hepatitis, thrombocytopenia, arthritis. These clinical manifestations may have a vasculitic or immune-mediated pathogenesis. Immunocompromised children, pregnant women and adults are at high risk of developing a severe and progressive varicella. Varicella pneumonia is the major cause of maternal morbidity and mortality. The risk of progressive disease, including prolonged cutaneous lesions, pneumonia, hepatitis, encephalitis, and disseminated intravascular coagulopathy is up to 50% for children with lymphoproliferative malignancies or solid tumors, particularly if chemotherapy is given during the incubation of varicella. In children with cancer, disseminated VZV infection may also be associated with esophagitis, enterocolitis, pancreatitis, and necrotizing splenitis. Thrombocytopenia and hepatitis are the major clinical complications in kidney transplanted patients. Children receiving high doses of corticosteroids, especially during the incubation period, may develop a severe, even fatal varicella [42–44].

112.4.3.4 Diagnosis

Maternal varicella may be confirmed by detection of specific IgM and IgG antibodies. Fetal ultrasound and MRI at 16–22 weeks' gestation or 5 weeks after infection can show possible signs of CVS. Fetal infection should be confirmed by detection of VZV DNA in the amniotic fluid. Termination of pregnancy may be suggested if serious fetal abnormalities are shown. The causal relationship between maternal varicella and congenital abnormalities can be verified by detection of viral DNA or antigens in the infant. Contrary to congenital rubella or CMV infection, VZV has not been isolated in cell cultures from any infant with CVS. Serologic diagnosis is mostly based on the detection of VZV-specific IgG beyond 7 months of age, since IgM antibodies are present in about 25% of infants with CVS. Neonatal varicella is easily diagnosed on the basis of the typical clinical picture but PCR should be used for laboratory diagnosis from skin swabs or biopsies, CSF and tissue samples [42, 45].

112.4.3.5 Treatment

Antiviral therapy with acyclovir or valacylovir for intrauterine varicella should be started as soon as possible, preferably after contact with infected children. If a woman develops chicken pox at or within a few days of delivery, prophylactic treatment of infants with acyclovir may be appropriate. Neonates exposed to VZV should receive varicella-zoster immune globulin (VZIG). If neonates show signs of either infection, immediate treatment with acyclovir must be initiated. These newborns are at high risk for death due to chicken pox since they do not have maternally acquired antibodies to VZV [38, 45].

112.4.3.6 Prevention

A pregnant woman who does not recall having chicken pox or the vaccine and who is exposed in her household should promptly receive VZIG and tested for immunity, to prevent maternal infection or subsequent complications. Although no controlled studies show that VZIG prevents CVS, the biologic plausibility of this treatment comes from favorable results in improving or preventing clinical varicella in immunocompromised or otherwise healthy patients. However, the effectiveness of VZIG has not been evaluated later than 96 h [44].

Varicella pneumonia must be regarded as a medical emergency, since pregnant women are at risk of life-threatening ventilatory compromise and death. Neonatal varicella is more severe if maternal rash appears 5 days prior to or 2 days after delivery. The newborn should be given VZIG immediately. Intravenous acyclovir is recommended for maternal pneumonia and the severely affected neonate. No controlled study has yet evaluated the effectiveness of acyclovir or valacyclovir for postexposure prophylaxis to pregnant women or neonates. Most women who do not recall having had chicken pox are in fact immune, but delaying the administration of VZIG while awaiting a test result is inappropriate. Whereas VZIG is very effective in either preventing or reducing the severity of maternal disease, its effectiveness in preventing intrauterine infection is unknown; nonetheless VZIG is recommended for administration to women during pregnancy [43, 46].

Varicella vaccine, which is a live attenuated strain of varicella virus, is recommended for all adults who have not had chickenpox. Pregnant women should not be immunized because of the potential risk for fetal infection. Women inadvertently immunized 3 months before pregnancy or during pregnancy can be reassured about the low risk and the incident should be reported to the public health authorities and the vaccine manufacturer. If a pregnant woman, for whatever reason, received varicella vaccine in the first half of pregnancy, VZIG may be given [47, 48].

Fetal infections: Rubella, HIV, HCV, HBV, and Human Parvovirus B19

Pier-Angelo Tovo, Stefania Bezzio and Clara Gabiano

113.1 Rubella Virus

Rubella: Salient Points

- Congenital rubella (CR) infection leads to damage in over 80% of fetuses during the first trimester of pregnancy, in 25–34% of cases in the second trimester, while no malformations occur in the third trimester.
- CR syndrome (CRS) is characterized by the combination of cardiac, ocular, and hearing defects, although any organ may be affected leading to long-term disabilities.
- To prevent CRS it is essential to verify before or during pregnancy, that all women have natural or vaccine-induced immunity to the rubella virus.

113.1.1 Etiology and Pathogenesis

The importance of congenital rubella (CR) was recognized in the 1940s and the etiological agent was discovered in the 1960s. Rubella epidemics occur at 6- to 9-year intervals, and major pandemics every 10–30 years. Theoretically, universal immunization programs should eradicate rubella, but at least 100,000 cases of CRS still occur annually worldwide [1].

The rubella virus, a member of the togavirus family, is composed of an icosahedral nucleocapsid containing a single-stranded RNA genome, surrounded by a lipid envelope. The mechanism by which the virus causes fetal damage is poorly understood. The virus spreads through the bloodstream, it can infect and replicate in the placenta, it then reaches the fetus, where it persistently infects cells, inducing a decreased growth rate. In the first trimester of gestation the fetus is unable to mount an adequate immune response and the passive transfer of maternal antibodies is inefficient, thus the viral replication leads to altered organogenesis. From the second trimester of gestation, the risk of congenital rubella syndrome (CRS) decreases, in fact changes in the placenta, the appearance of the immune response, and the passive transfer of maternal IgG result in a higher protection from viral damage. The virus can persist for over a year in target organs, where it can undergo recurrent replications. Late onset CRS manifestations are due to persistent virus-driven tissue damage and scarring.

113.1.2 Transmission

Miscarriage, stillbirth and a series of birth defects (low birth weight, failure to thrive, congenital heart disease and central nervous system damage) are possible sequelae of CRS. Fetal infection may occur at any stage of pregnancy. The outcome of infection depends on the gestational age. Primary maternal infection causes damage in more than 80% of the fetuses during the first trimester of pregnancy, in 25–34% in the second trimester, while no malformations occur in the third trimester. Rubella reinfection may also occur both in vaccine-immune and, to a lesser extent, in naturally immune subjects. In these cases, the risk of CRS is estimated to be around 5% in the first trimester of pregnancy.

113.1.3 Clinical Aspects

Rubella infection spreads by droplets and it is usually subclinical or paucisymptomatic in infants and children. Clinical manifestations (fever, non-confluent maculopapular rash, headache, malaise, lymphoadenopathy, usually involving sub-occipital, post-auricolar and cervical nodes) develop after 14–21 days incubation.

CRS is typically characterized by the combination of cardiac, ocular, and hearing defects, although the virus can infect virtually any organ (Table 113.1) [2].

P.-A. Tovo (✉)
Department of Pediatrics, University of Turin, Turin, Italy

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

Table 113.1 Congenital rubella syndrome main defects (listed in order of decreasing frequency)

Early onset manifestations
- Deafness
- Mental retardation
- Cardiovascular defects affecting primarily the left atrium and the heart septa
- Ocular defects (nuclear cataracts, microphthalmia, pigmentary retinopathy, glaucoma)
- Thrombocytopenia
- Hepatitis
- Bone lesions
- Dental defects
- Hypospadias
- Cryptorchidism
- Inguinal hernia
- Interstitial pneumonitis
- Meningo-encephalitis
- Cerebral calcification
- Splenic fibrosis
- Nephrosclerosis
- Nephrocalcinosis

Late onset manifestations
The reported delayed manifestations (due to the altered immune system of CRS patients) underscores the importance of careful follow-up of these patients
- Insulin-dependent diabetes
- Thyroid dysfunction
- Neurodegenerative disorder (panencephalitis)
- Slower growth rate during preschool years
- Smaller head circumference
- Ocular defects (secondary glaucoma, strabismus)
- Congenital defects in the immune system (transitory hypogammaglobulinemia, especially ipoIgA, defects in cell-mediated immunity)

113.1.4 Diagnosis

Amniotic fluid and fetal blood samples have been used to detect fetal rubella infection by means of nested reverse-transcriptase polymerase chain reaction (RT-PCR). Fetal blood, obtained by cordonocentesis, can also be tested for Rubella IgM. Amniocentesis is less invasive than fetal blood sampling. Both tests should be performed 6–8 weeks after maternal infection; the best reliability is when the fetus is 22 weeks old.

Postnatally, CRS is diagnosed by detection of rubella-specific IgM, though both false negative and false positive results have been described, or by stable or increased titers of specific IgG over several months. IgG avidity testing may help to differentiate between recent and past infection [3]. Identification of the virus in urine, blood or nasopharyngeal secretions by cultures or by RT-PCR may also confirm the diagnosis.

113.1.5 Prognosis

Children affected by CRS may require medical, surgical, educational and rehabilitative management. CRS must be managed as a dynamic rather than a static disease, requiring a multidisciplinary approach: for instance, early treatment is critical for hearing defects and psychomotor difficulties.

113.1.6 Therapy and Treatments

The prime strategy for the prevention of CRS is to ensure that all pregnant women are immune to rubella. In developed countries, vaccination programs are based on the universal immunization of infants at 12–15 months of age, plus a second vaccination in adolescents to achieve immunity in patients with primary vaccine failure. Furthermore, all women at childbearing age should be tested and targeted vaccinated, if still susceptible. The RA 27/3 strain is used as a rubella vaccine. This is remarkably safe, has high efficacy (over 90%), and induces long-lasting protection. It is used as a component of the measles-mumps-rubella (MMR) vaccine or of the recent tetravalent vaccine (MMR plus Varicella).

Vaccination programs have led to a significant reduction in morbidity and mortality associated with CRS. Benefits of the vaccine far outweigh the costs of treatment and rehabilitation of affected children and adults.

113.2 Human Immunodeficiency Virus (HIV)

HIV: Salient Points
- Mother-to-child transmission (MTCT) is the most common route of HIV infection in children.
- MTCT may occur in utero and at the time of delivery. Breast-feeding is another route of transmission.
- The MTCT rate is estimated to be 15–20% in bottle-fed infants, but the implementation of preventive strategies has reduced the risk to approximately 1–2%.
- Effective preventive interventions include the administration of prenatal antiretroviral (ARV) prophylaxis, elective cesarean section, administration of ARV during delivery and for the infant, avoidance of breastfeeding.
- The early diagnosis of infection in exposed infants is based on detection of HIV-RNA by PCR assays in two separate determinations.
- An early combined ARV therapy in HIV infected infants offers the great benefits of a longer asymptomatic period and of a prolonged survival.

113.2.1 Etiology and Pathogenesis

More than 2.5 million children are estimated to be living with human immunodeficiency virus type 1 (HIV-1) infection worldwide, mostly following mother-to-child transmission (MTCT).

HIV is a retrovirus belonging to the subgroup of lentiviruses. The first step of its life cycle is characterized by the integration of the virion envelope glycoproteins (gp120 and gp41) with the cell surface CD4 molecule. After entering the cell, the virus is rapidly uncoated. Then, through reverse transcriptase its viral RNA is transformed into linear DNA. This is circularized and transferred into the nucleus where it is inserted at random sites as a provirus. The provirus is activated by host cell responses to antigens, cytokines or products of other viruses. Thousands of infectious particles can originate from a single infected cell, either chronically, over weeks, or as a single burst resulting in cell death. HIV infection leads to a profound qualitative and quantitative attrition of the immune system, particularly of cell-mediated immunity with a decrease in CD4+ cell count. Immune mediated damage presumably plays a key role in AIDS pathogenesis.

Two genetically distinct HIV types have been identified: HIV-1 and HIV-2; the latter is localized mainly in Western Africa and causes a less aggressive disease.

HIV infection results in a minimal risk of adverse pregnancy outcomes, such as spontaneous abortion, intrauterine growth restriction, and premature delivery [4].

113.2.2 Transmission

HIV is a sexually transmitted infection that also spreads by contact with infected blood. After the screening of blood donors, MTCT has become the most common route of infection in children. MTCT ranges between 15–23% in bottle-fed infants. Prolonged breastfeeding may account for an additional 10–15% of infections. With the implementation of effective, cost saving preventive measures, MTCT rate can be reduced to 1–2% in non breast-fed infants.

Viral, maternal, obstetrical, fetal and infant factors influence the risk of MTCT (Table 113.2). Most children are infected perinatally, though intrauterine transmission may occur. An infant is considered to have been infected in utero when HIV-1 can be detected from peripheral blood within 48 hours from birth. In contrast, a non breast-fed child is taken to have had intrapartum infection if he/she becomes viremic subsequently. Transmission due to household contacts is not documented.

113.2.3 Clinical Manifestations

According to the infection status, an infant born to a seropositive mother is classified as exposed (E), infected (I) or seroreverted (SR) (see below). A breastfed infant is at risk of infection in the 6 months after interruption of maternal lactation.

HIV+ children are classified into mutually exclusive, progressive categories according to their clinical and immunological status (Table 113.3) [5]. Once classified in a more severe category a child cannot be reclassified in a less severe one, even if the clinical or immunologic situation improves.

HIV disease progression is more accelerated in children than in adults. HIV-infected newborns are usually asymptomatic, but they can become seriously ill within the first weeks to months of life. Growth delay is an early finding in untreated perinatally infected infants. Children are more likely than adults to have serious bacterial infections and lymphoid interstitial pneumonia is almost entirely restricted to the pediatric age. *Pneumocystis jirovecii* pneumonia (PCP) is the most common serious opportunistic infections (OI) in infected infants, with the highest incidence at 3–6 months of age.

113.2.4 Diagnosis

Diagnosis of HIV infection in exposed infants is based on the detection of viremia in two separate determinations. Most uninfected children lose passively acquired maternal antibodies by 12-15 months of age, though these may persist in 2% up to 18 months. Criteria for diagnosis or exclusion of infection [6] through detection of viremia are detailed in Table 113.4.

Table 113.2 Maternal, obstetrical, and neonatal factors associated with increased HIV transmission rate

Pregnancy	Labour and delivery	Breastfeeding
• High maternal viral load (new infection or advanced AIDS) and/or CD4 cell count < 200/mm^3 • Viral, bacterial, or parasitic placental infections, such as malaria • Sexually transmitted infections	• High maternal viral load (new infection or advanced AIDS) and/or CD4 cell count < 200/mm^3 at delivery • Rupture of membranes (> 4 hours) • Invasive delivery procedures that increase contact with the mother's infected blood or body fluids (e.g., episiotomy, artificial rupture of membranes) • Chorioamnionitis (from untreated STI or other infections) • Preterm delivery	• High maternal viral load (new infection or advanced AIDS) and/or CD4 cell count < 200/mm^3 • Duration of breastfeeding • Breast abscesses, mastitis, nipple fissures • Oral disease in the baby (e.g., thrush or sores)

Table 113.3 Classification system for HIV infection in children younger than 13 years of age

	Clinical categories			
Immune categories (Based on age-specific CD4+ cell count or percentage)	No symptoms (N)	Mild symptoms (A)	Moderate symptoms (B)	Severe symptoms (C)
1 - No suppression 0–11 months → > 1500 cells/μL (≥25%) 1–5 years → > 1000 cells/μL (≥25%) > 6 years → >500 cells/μL (≥25%)	N1	A1	B1	C1
2 - Moderate suppression 0–11 months → > 750-1499 cells/μL (15-24%) 1–5 years → 500-999 cells/μL (15-24%) > 6 years → 200-499 cells/μL (15-24%)	N2	A2	B2	C2
3 - Severe suppression 0–11 months → > < 750 cells/μL (<15%) 1–5 years → > < 500 cells/μL (<15%) > 6 years → < 200 cells/μL (<15%)	N3	A3	B3	C3

Modified from [5].

Table 113.4 Diagnosis of HIV infection in exposed children less than 18 months of age [6]

Diagnosis of HIV Infection (I)	Exclusion of HIV-1 infection (SR)
1. Positive results on two separate specimens (not including cord blood) from one or more of the following tests: – HIV nucleic acid detection and/or – HIV p24 antigen (for a child > 1 month) and/or – HIV isolation (viral culture) 2. Severe clinical conditions resulting from HIV-1 infection	1. At least two negative HIV-1 RNA or DNA virologic test results from separate specimens, both of which obtained at > 1 month of age (1 of them after 4 months of age) 2. At least two negative HIV-1 antibody test results from separate specimens obtained at > 6 months of age and no other laboratory or clinical evidence of HIV-1 infection

HIV nucleic acid detection is the method of choice for the diagnosis or exclusion of infection in children < 18 months of age. Although HIV culture can be used, it is less standardized and less sensitive than nucleic acid detection tests. The use of p24 antigen testing to exclude infection in children <18 months is not recommended because of poor sensitivity, especially in presence of HIV antibody. Quantitative RNA tests have been approved for monitoring HIV infection and qualitative RNA tests have been approved to aid diagnosis. HIV-2 can be diagnosed with HIV-2 DNA PCR.

113.2.5 Prevention of MTCT

All pregnant women should be tested routinely for HIV during an early prenatal visit (first trimester) in order to adopt effective preventive strategies. These include

- administration of maternal antiretroviral (ARV) prophylaxis during pregnancy and at delivery
- elective cesarean section
- ARV treatment of the infant
- avoidance of breastfeeding.

113.2.5.1 Prenatal ARV Prophylaxis

Prenatal ARV regimens with highly active antiretroviral therapy (HAART) from 28 gestational weeks, regardless of viral load and CD4 cell count, are recommended to prevent MTCT [7]. In particular, women undergoing ARV treatment should continue their therapy during pregnancy, while those who do not require treatment for their own health should receive a three-drug combination to prevent HIV transmission to their offspring. Zidovudine (ZDV) prophylaxis alone is controversial, but it may be considered when maternal HIV RNA level is < 1000 copies/mL. After the onset of labor or rupture of membranes (or approximately 3 hours before an elective cesarean section) intravenous ZVD (2 mg/kg over the first hour, then 1 mg/kg per hour until delivery is complete) should be administered to all infected women, even if they are under HAART and their viral load is undetectable.

Although animal studies suggest possible congenital abnormalities with some antiretroviral drugs, results from registries and cohort studies do not confirm this association in human beings.

Mitochondrial toxicity of clinical relevance has been described, albeit anecdotically, in Europe after in utero exposure to nucleoside analogues, but these findings are still a matter of debate. There is no evidence that exposure to antiretroviral drugs in utero or neonatally is associated with an increased risk of childhood cancer.

Table 113.5 Zidovudine prophylaxis in HIV exposed infants [8]

Gestational age at birth	Oral dose (mg/kg per dose)	Intravenous dose (mg/kg per dose)	Frequency	Weeks
≥ 35 weeks	2	1.5	Every 6 hours	6
30 > weeks < 35	2	1.5	Every 12 hours advancing to every 8 hours at 2 weeks of age	6
< 30 weeks	2	1.5	Every 12 hours advancing to every 8 hours at 4 weeks of age	6

113.2.5.2 Elective Cesarean Section

The MTCT rate is lower in women who delivered by elective cesarean section than in those who delivered by emergency cesarean section or vaginal delivery [7]. There is general agreement that elective C-section should be recommended at 38 weeks' gestation to all pregnant women with a viral load > 1000 RNA copies per mL near the time of delivery [8]. The benefit of elective C-section in women with low or undetectable viral loads and/or under HAART therapy remains questionable, though it is widely adopted in some countries.

113.2.5.3 Infant ARV Prophylaxis

A 6 week course of ZDV prophylaxis is recommended for all exposed neonates and should be initiated as soon as possible after birth (Table 113.5). In certain situations (e.g., treated women with suboptimal viral suppression, or only intrapartum ARV therapy or known ZDV-resistant virus) some experts suggest adding other ARV drugs [9].

113.2.5.4 Breast-feeding

Although the risk of postnatal HIV transmission through maternal milk is well documented, the WHO recommends breastfeeding in the first 6 months of life in some developing countries, because such a risk is lower than that of death from diarrheal diseases and malnutrition. Conversely, in countries where replacement formula feeding is acceptable, feasible and safe, breastfeeding should be discouraged [10].

113.2.6 Prognosis

The prognosis of perinatally acquired HIV infection was initially poor, particularly for infants with in utero infection or early clinical manifestations. Opportunistic infections (OIs), such as PCP, progressive neurological disorders, malignancies, severe bacterial infections, and wasting syndrome were the main causes of death. Morbidity and mortality have significantly decreased since the introduction of HAART in

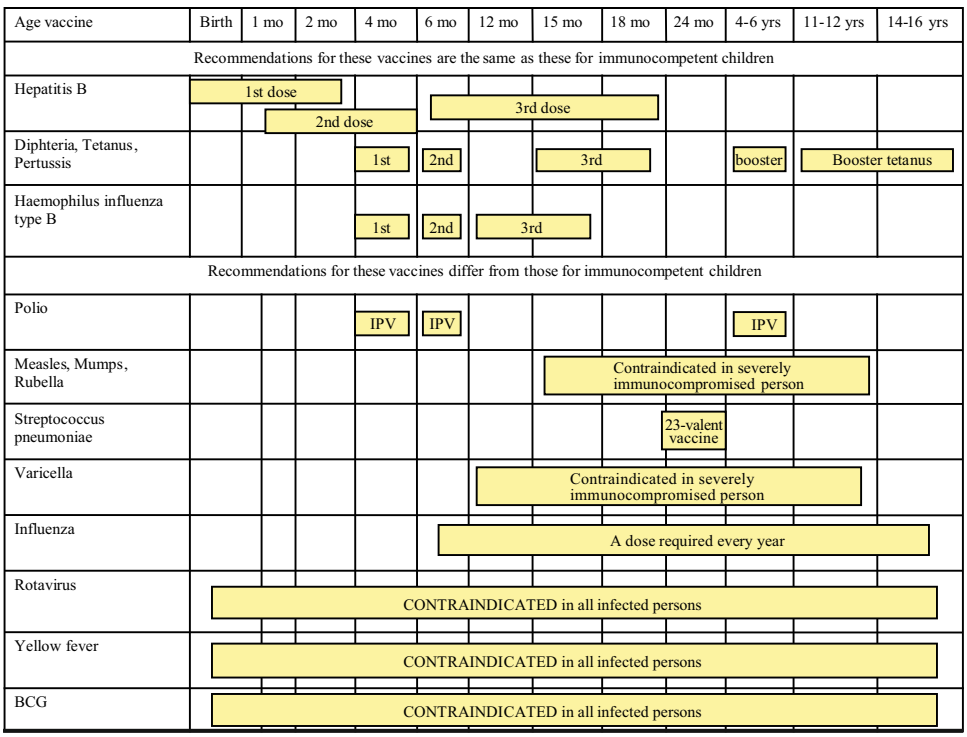

Fig. 113.1 Recommendations for routine immunizations in HIV infected children. Modified from [12]

Table 113.6 Prophylaxis to prevent *Pneumocystis jirovecii* pneumonia in HIV-exposed infants or HIV-infected children

Pathogen	Indication	First choice	Alternative
Pneumocystis jirovecii	Exposed children: – from 6 weeks until exclusion of infection Infected children: – from 6 weeks until 1 year – from 1-5 yrs if CD4 < 500 cells/mm^3 – from 6-12 yrs if CD4 < 200 cells/mm^3 or percentage < 15%	TMP-SMX 150/750 mg/m^2/die orally divided in 2 doses daily and administered 3 times weekly on consecutive days	– Dapsone (>1 mos of age) 2 mg/kg orally daily or 4 mg/kg weekly – Atovaquone: children aged 1–3 mos and >24 mos, 30 mg/kg orally daily; children aged 4–24 mos, 45 mg/kg orally daily – Aerosolized pentamidine: >5 yrs, 300 mg every months

MTCT mother to child transmission, *TMP* trimethoprim, *SMX* sulfamethoxazole, *TST* tubercolin skin test, *mos* months, *yrs* years. Modified from [12].

children with good treatment adherence. Most of these children remain in good health for many years.

113.2.7 Therapy and Treatments

113.2.7.1 Antiretroviral Therapy

Initiation of ARV therapy is recommended for all infected infants < 12 months at the time of diagnosis, regardless of clinical condition and immunological parameters. Subsequently, the therapeutic options should be based on clinical, immunologic and virologic findings. The initial regimen should include two nucleoside reverse transcriptase inhibitors (NRTIs) plus a highly active protease inhibitor (PI) or a non-nucleoside reverse transcriptase inhibitor (NNRTI) as the initial regimen [11]

113.2.7.2 Supportive Care

All HIV-infected children should be protected from vaccine-preventable diseases (Fig. 113.1). In general, all inactivated vaccines can be administered safely, and usual doses and schedules are recommended. Children with HIV infection are at a high risk for complications of varicellazoster and measles. Bearing in mind the limited safety, immunogenity and efficacy of varicella and MMR vaccines in HIV infected children, these should be considered for subjects who are not severely immunosuppressed (CD4+ cell percentage > 15%).

Prophylactic measurements to prevent PCP pneumonia are detailed in Table 113.6 [12].

113.3 Hepatitis C Virus (HCV)

HCV: Salient Points

- Mother to child transmission (MTCT) is the most common route of HCV infection in the pediatric population.
- Maternal HCV infection does not impair the course of pregnancy or increase the risk of spontaneous abortion or fetal death.
- No interventions are currently available to prevent MTCT of HCV.
- Early diagnosis of infection in exposed infants relies on the detection of HCV-RNA by PCR.
- The natural history of vertically acquired HCV infection in infancy and childhood is relatively benign.

113.3.1 Etiology and Pathogenesis

The hepatitis C virus (HCV) is the most common cause of chronic liver disease, with 130 million infected individuals worldwide and about 3 million new infections each year. The prevalence of the infection varies from 0.5–2% in Western World to 5–15% in some endemic African areas. After the screening of blood donors with consequent disappearance of post-transfusional hepatitis C, MTCT has become the most common route of infection in the pediatric population.

HCV is a small (50 nm in size), enveloped, single-stranded RNA virus. Six major genotypes exist; each genotype responds differently to antiviral therapies and comprises hundreds to thousands of subtypes, referred to as quasi-species, resulting from the high viral mutation rates and reflecting the unique ability of the virus to continually alter its immunologically recognizable epitopes. HCV primarily enters hepatocytes, although other cell types, such as dendritic cells and B-cells, can also be infected. The virus is non-cytopathic by itself.

113.3.2 Transmission

Because of the absence of effective preventive strategies, routine screening for HCV in pregnant women is not recommended. However, screening is suggested in special circumstances (women positive for HIV or hepatitis B virus, a history of intravenous drug use, transplantation, hemodialysis, blood, or blood products transfusion prior to 1992, tattooing or unexplained elevated liver enzymes). In this setting,

antenatal screening might be useful to identify infected children before the onset of symptoms and to offer post-pregnancy therapy to their mothers.

HCV infection does not seem to impair the course of pregnancy or increase the risk of spontaneous abortion or fetal death. The time of transmission remains unclear. The largest studies consistently estimate that 30–50% of HCV infections are acquired in utero while the remainder occur in the late intrauterine/intrapartum period [13].

Several risk factors for MTCT have been identified (Table 113.7) [14]. However, none are modifiable and no preventive interventions can be adopted.

High viral load is associated with MTCT. Thus, infected women with undetectable HCV-RNA during pregnancy can be reassured that the risk of transmission to their infants is very low, though it cannot be excluded. Anti-viral drugs, such as interferon-alpha plus ribavirin cannot be used in pregnancy to reduce viremia due to their teratogenic effects. Viral clearance prior to pregnancy would increase the likelihood that a woman remains non-viremic in pregnancy. In this context, women should be advised not to conceive until at least 6 months after cessation of therapy.

Although the evidence is inconclusive, it is prudent to avoid amniocentesis, instrumental vaginal delivery and a prolonged rupture of membranes. These procedures should only be used when indicated to avoid maternal or infant morbidity. Elective cesarean section should not be offered to HCV infected women to prevent transmission and breastfeeding should not be discouraged.

Table 113.7 Potential risk factors for HCV mother-to-child transmission

Variable	Risk factor	Strength of the evidence
Maternal HCV/HIV coinfection	Yes	Strong
High maternal viral load	Yes	Sufficient
Cesarean section	No	Sufficient
Vaginal delivery	No	Sufficient
Breast feeding	No	Sufficient
Girls gender	Yes	Sufficient
Amniocentesis	?	Insufficient
IV drug users	?	Insufficient
ALT levels during pregnancy	Yes	Insufficient
Internal fetal monitoring	Yes	Insufficient
Forceps deliveries	Yes	Insufficient
Perineal or vaginal lacerations	Yes	Insufficient
Episiotomy	No	Insufficient
Prolonged membrane rupture	Yes	Insufficient
Cigarette smoking	No	Insufficient
Alcohol intake	No	Insufficient
Maternal age	No	Insufficient
HCV genotype	No	Insufficient
Numbers of pregnancies	No	Insufficient
Prematurity	No	Insufficient
Genetic background	Yes	Insufficient

113.3.3 Clinical Aspects

The natural history of vertically acquired HCV infection remains to be elucidated.

Infected children are asymptomatic at birth and their general condition usually remains good in the first decade of life with regular growth. Only a fraction develop minor abnormalities, such as hepatomegaly, or non specific symptoms and signs.

Alanine aminotransferase (ALT) activity is highest in the first two years of life, after which it declines, often assuming a fluctuating pattern. Viremia also fluctuates in a large proportion of infected children.

Liver function tests are of little help in assessing the development of aggressive hepatitis and cirrhosis. Necrotic inflammation and fibrosis are usually milder in children than in adults. Progression of liver damage is not linear and cirrhosis or HCC are rare in childhood. Routine liver biopsy in children with HCV is not recommended.

Extrahepatic manifestations, such as mixed cryoglobulinemia and autoimmune disorders, are rare in childhood. However, autoantibodies are frequently detected in infected children [15].

113.3.3.1 Diagnosis

Persistence of anti-HCV antibody beyond 18 months of age represents the "gold standard" for the diagnosis of vertically acquired HCV infection. Earlier diagnosis in an exposed child relies on the detection of HCV-RNA by PCR. Children are taken to be infected if PCR positive in at least two separate determinations. The test is highly specific, but its sensitivity is low at birth (22–33%), whereas it increases up to 85% after the first month of life [16].

It must be underlined that a negative PCR might also reflect fluctuations in viremia. Thus, both antibody testing and the detection of serum HCV RNA are recommended [17] for definition of the infection status in exposed children (Fig. 113.2).

113.3.4 Therapy and Treatments

Limited data are available for the management of children and adolescents with chronic HCV infection [18]. Treatment algorithms often are based on adult trials. Treatment is offered to selected patients (Table 113.8). Since histological progression is rare within the first three years of life and treatment may give rise to significant side effects, such as the interferon-induced growth impairment, this should be delayed to older children [19].

Children with HCV should be immunized against hepatitis A and B.

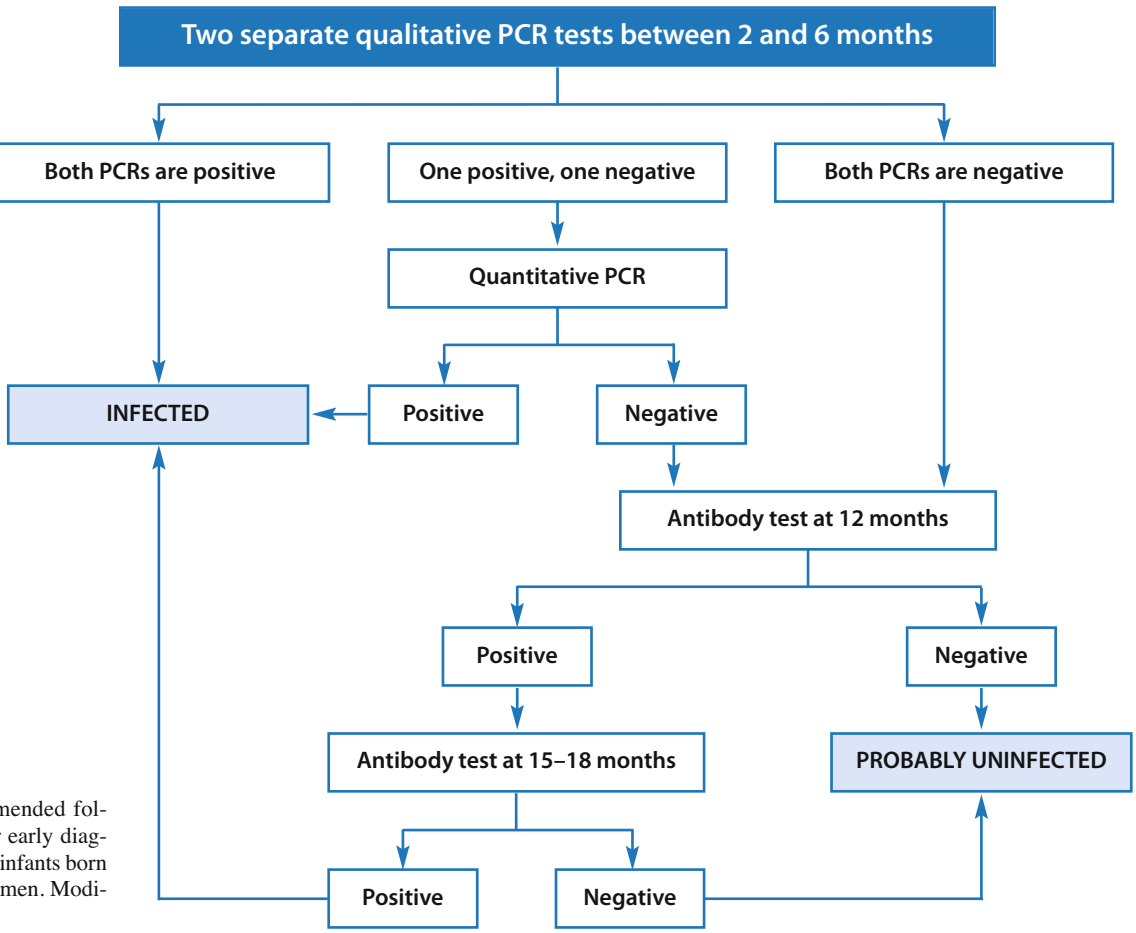

Fig. 113.2 Recommended follow-up schedule for early diagnosis of infection in infants born to HCV infected women. Modified from [13]

Table 113.8 Treatment for chronic HCV infection

Drugs	Dosage	Duration of therapy
IFN-α*	3-5 million units per square meter of body surface, intramusculary or subcutaneously, three times a week for 6-12 months	• 48 weeks for genotype 1 • 24 weeks for genotype 2 or 3
PEG-IFN-2αb**	60 mcg/m^2/week injected subcutaneously once a week	
Ribavirin	15 mg/kg/day orally in two divided doses (capsule and oral solution)	

* Recombinant IFN-alpha.
** Pegylated interferon alpha-2b recently approved by the U.S. Food and Drug Administration for the treatment of chronic hepatitis C virus infection in previously untreated children and adolescents 3 years or older [25].

113.4 Hepatitis B Virus (HBV)

HBV: Salient Points

- Mother to child transmission (MTCT) is the main route of HBV infection in children.
- More than 90% of perinatally exposed children develop chronic infection.
- All term infants born to HbsAg-positive women should receive HBV vaccine and specific immunoglobulins at birth, followed by completion of three-dose vaccine series.
- Universal infant immunization has reduced the MTCT rate by 85–90%.

113.4.1 Etiology and Pathogenesis

Two billion people worldwide are estimated to have acquired hepatitis B virus (HBV), and more than 350 million to be chronically infected [20]. In low prevalence areas (chronic infection < 2%), such as the USA and Western Europe, most

new infections occur in young adults and are acquired sexually or through intravenous drug use, while in moderate or high prevalence areas (chronic infection 2–7% or > 8%, respectively) perinatal and horizontal transmission are the prevalent routes of infection.

HBV is a member of the Hepadnavirus family. The virus is divided into four major serotypes (adr, adw, ayr, ayw) and into eight genotypes (A-H). Differences between genotypes affect the disease progression and the response to treatment.

Hepatocytes are the primary target of HBV, but the kidney, pancreas and mononuclear cells can also be infected. HBV is non-cytopathic by itself. The host's immune response causes both viral clearance and hepatocellular injury. The cytotoxic T-cell-mediated lysis of infected hepatocytes is the predominant mechanism of liver damage. Intrauterine exposure to HBV antigens may induce tolerance, accounting for the high rate of carriers among perinatally infected children.

113.4.2 Transmission

Possible routes of HBV transmission include unprotected sexual contact, blood transfusions, re-use of contaminated needles or syringes, and MTCT. The vertical transmission rate is 70–90% in untreated infants of HB surface antigen (HbsAg) and HBe antigen (HbeAg) positive viremic women, while it decreases to 10–30% in the HBsAg carrier mothers who have anti-e antibody (anti HBe) and are PCR negative. In utero infection is uncommon and mainly takes place during acute maternal infection. Transmission to the offspring mostly occurs at delivery by microtransfusion or contact with contaminated body fluid. The mode of delivery (cesarean *vs* vaginal) does not affect transmission, and breastfeeding is not an additional risk factor in infants treated with proper immunoprophylaxis.

Acute HBV hepatitis or exacerbation of chronic disease may occur during pregnancy. However, these conditions increase neither maternal morbidity or mortality nor the risk of fetal complications, though a high number of preterm labors have been reported in women with acute hepatitis B.

113.4.3 Clinical Aspects

The age of HBV acquisition is roughly inversely correlated with the likelihood of developing a persistent infection. Neonates have > 90% risk of developing chronic infection, as compared to 25–50% of older children and adolescents and 5% of adult subjects.

113.4.3.1 Acute Infection

HBV infected infants and children are usually asymptomatic. However, disease onset may be insidious. Symptoms and signs include anorexia, malaise, nausea, vomiting, abdominal pain and jaundice.

Extrahepatic manifestations encompass skin rashes, membranous glomerulonephritis, arthralgias, and arthritis. MTCT is the most important route of transmission for acute or fulminating hepatitis in infancy. The incubation period ranges from 6 weeks to 6 months and the mortality rate of fulminating hepatitis is high (around 67%) and may often require liver transplantation.

113.4.3.2 Chronic Infection

Chronic infection is defined as a persistence of HBsAg for > 6 months. Affected children are usually asymptomatic with normal growth. In vertically infected children, the spontaneous clearance of HBV (i.e., loss of HBsAg and development of anti-HBs Antibody) occurs at a rate of 0.6% per year over the first decade of life.

Most children who remain infected develop immune tolerance and have normal levels of hepatic transaminases, which usually mirror less active hepatic inflammation. Chronic hepatitis B may exhibit various degrees of liver inflammation and fibrosis on biopsy. The extent of inflammation and fibrosis or cirrhosis correlates with a worse prognosis. Less then 4% of infected children have persistent viral replication (HBeAg+) and elevated HBV DNA levels with ongoing inflammatory hepatitis and persistently or intermittently elevated transaminase levels (active hepatitis). Most concerns are focused on the latter patients, because they could develop cirrhosis and hepatocarcinoma (HCC) over a 20–30 year period.

113.4.3.3 Diagnosis

All pregnant women should be tested routinely for HBsAg during an early prenatal visit (first trimester) at each pregnancy, including women previously vaccinated or tested.

Antigens and antibodies to be tested include: HBsAg and specific antibody (anti-HBs), hepatitis B core antigen (HBcAg) and specific antibody (anti-HBc), HBeAg and anti-HBe, bearing in mind that at least one serologic marker is present during the various phases of infection (Table 113.9). The presence of a confirmed HBsAg is indicative of ongoing infection. The detection of HBeAg and HBV DNA-positive PCR document viral replication. In general, these markers correlate with high infectivity. The appearance of anti-HBe means a loss of replicating virus, although reversion to HBeAg positivity may occur.

In exposed infants who undergo proper immunoprophylaxis, HBsAg and anti-HBs should be checked at 9–15 months of age or 1–3 months following completion of the primary immunization series to assess whether they are immune or infected.

Table 113.9 Interpretation of serologic tests result for hepatitis B virus infection

Serologic markers				Interpretation
HBsAg	Total anti-HBc	IgM anti-HBc	Anti HBs	
–	–	–	–	Never infected
+	–	–	–	Early acute infection; transient (up to 18 days) after vaccination
+	+	+	–	Acute infection
–	+	+	–	Acute resolving infection
–	+	–	+	Recovered from past infection and immune
+	+	–	–	Chronic infection
–	+	–	–	False positive (i.e., susceptible); past infection; "low-level" chronic infection; passive transfer to infants born to HBsAg-positive mothers
-	-	-	+	Immune if concentration is > 10 mIU/mL; passive transfer after hepatitis B immune globulin administration

HBsAg hepatitis B surface antigen, *anti-HBc* antibody to HBV core antigen, *anti HBs* antibody to surface antigen.

113.4.4 Prevention

All term infants born to HBsAg+ women should receive hepatitis B vaccine and hepatitis B immunoglobulin (HBIG) 12–24 hours after birth, administered at different injection sites, followed by completion of the three-dose vaccine series. This schedule prevents infection by 85–95%. Transplacental transmission cannot be interrupted by immunoprophylaxis and may account for the small percentage of unprotected infants.

Hepatitis B immunoprophylaxis for preterm infants differs slightly (Table 113.10).

113.4.5 Therapy and Treatments

Therapy for HBV infection has not been studied in neonates. Antiviral treatment is contraindicated in children under 3 years of age, given the adverse effects of interferon administered early in life. In general, children with normal ALT levels are not candidates for antiviral treatment.

113.4.5.1 Acute HBV Infection

There is no treatment of proven efficacy for children with acute HBV infection.

113.4.5.2 Chronic HBV Infection

General management of children with chronic infection includes [21]:

- education and counseling of family members (including vaccination with hepatitis B vaccine)
- periodic clinical checks and laboratory investigations for liver disease

Table 113.10 Hepatitis B immunization of term and preterm (< 2000 g) infants by maternal hepatitis B surface (HBsAg) status

Newborn	Maternal HBsAg status	Management		
		Drugs	Dose	Age
Mature infants and preterm infants weighing > 2000 g	Positive	Vaccine	1	Birth (< 12 hours)
		Vaccine	2	1-2 months
		Vaccine	3	6 months
		HBIG	0.5 mL intramusculary	Birth (< 12 hrs)
	Unknown	Vaccine	1	Birth (< 12 hrs)
		Vaccine	2	1-2 months
		Vaccine	3	6 months
		HBIG*	0.5 mL intramuscularly	< 1 week of age**
Preterm infants weighing ≤ 2000 g	Positive	Vaccine	1	Birth (< 12 hrs)
		Vaccine	2	1 month
		Vaccine	3	2-3 months
		Vaccine	4	6-7 months
		HBIG	0.5 mL intramuscularly	
	Unknown	As infants born to HbsAg positive mother		
	Negative	Delay first dose of vaccine until 1 month of age or hospital discharge. Complete the vaccine series		

* If mother tested as soon as possible after admission for delivery is found to be HBsAg positive.
** As soon as possible if HBsAg positive status is confirmed.

- vaccination with hepatitis A vaccine
- antiviral therapy, if appropriate

No limitations in terms of school or other activities should be placed in children with chronic HBV infection.

The goals of chronic hepatitis B treatment are the cessation or reduction of viral replication, normalization of aminotransferase levels, and the prevention of cirrhosis, hepatic failure, and HCC.

Treatment with two antiviral drugs, i.e., interferon (IFN)-α and lamivudine are recommended for children over 3 years of age with evidence of chronic infection (i.e., detectable HBsAg for at least 6 months), active viral replication (i.e., the presence of HBeAg and/or elevated HBV DNA levels), and elevated ALT levels (Table 113.11). HBV DNA is also essential to monitor response to antiviral therapy. Elevated levels (> 20,000 IU/mL or > 10^5 copies/mL) after 24 weeks of therapy raise the highest concerns for liver health [22].

113.5 Human Parvovirus B19

Human Parvovirus B19: Salient Points

- 50% pregnant women are susceptible to B19 infection. The vertical transmission rate, in the first or second trimester, is around 30%.
- Primary maternal infection with parvovirus B19 is associated with asymptomatic fetal infection, nonimmune hydrops fetalis, intrauterine fetal death, and birth defects.
- There is no specific therapy against B19 infection; in case of hydrops and/or signs of fetal anemia, intrauterine erythrocyte transfusions are recommended.

113.5.1 Etiology and Pathogenesis

Parvovirus B19 (B19) is the only member of the family *Parvoviridae* to be pathogenic in humans. It may cause a wide spectrum of clinical manifestations; its seroprevalence increases with age and infection confers lifelong immunity.

B19 is a single-stranded non-enveloped DNA virus, genetically stable, resistant to heat and detergent inactivation, which can survive in blood products despite elimination procedures. It requires a mitotically active host cell for replication, such as erythroid precursors, fetal liver cells, or cord blood mononuclear cells. B19 infects these cells lytically. It uses at least three cellular receptors for cell attachment and entry. One of these, the glycolipid globoside (P-ag), is present on the hematopoietic precursors, endothelial cells, fetal myocytes, and placental trophoblasts. The presence of P-ag on these tissues may explain the hematological disorders, the myocardial disease, the congenital infection and the vasculitis syndromes.

113.5.2 Transmission

Parvovirus B19 is transmitted by respiratory route, blood products and vertically, from the mother to the offspring. About 50% of pregnant women are susceptible to B19 infection. In the first and second trimester of pregnancy the vertical transmission rate reaches 30%. Among vertically infected children, 5–10% presents an abnormal outcome. This risk is higher when maternal infection occurs in the first 20 weeks of pregnancy.

113.5.3 Clinical Aspects

Human parvovirus B19 infection may give rise to a large array of clinical manifestations, depending on the patient's immunologic and hematologic status. In the normal host, the infection may be asymptomatic or give rise to erythema infectiosum (EI) and/or arthropathy. EI, also referred to as Fifth disease or Slapped cheek syndrome, usually affects

Table 113.11 Treatment for chronic HBV infection

Drugs	Advantage	Disadvantage	Response in children
IFN-α [a]	No drug resistance Short duration of treatment	Parenteral administration Adverse effects common	20–58% HBV DNA or HBeAg loss [b]
PEG-IFN-2αa [c]	Administration once a week	Parenteral administration Adverse effects common	HBV DNA disappearance in 6 out of 13 children without any side effect [c]
Lamivudine [d]	Minimal adverse effects Oral administration Liquid formulation available	Drug resistance common (20%/years)	23–35% HBV DNA and HBeAg loss [e]

[a] Dosage in children > 3 years of age: 5-10 MU/m^2 three times a week for 24 weeks.
[b] From [27].
[c] In children there is only one preliminary report evaluating the rapid viral response of PEG-INF (100 μg/m^2/week) [26]. Not currently approved in chronic HBV infection in children.
[d] Dosage in children > 3 years of age: 3 mg/kg/day up to 100 mg/day for 52 weeks.
[e] From [28].

Table 113.12 Disorders associated with Parvovirus B19 infection

Autoimmune disorders
- Systemic lupus erythematosus
- Systemic vasculitides
- Rheumatoid arthritis
- Production of auto-antibodies to double-strained DNA, anti-nuclear soluble antigens, cardiolipin and rheumatoid factor

Increased bone marrow cell turnover
- Transient aplastic crisis (TAC) with severe anemia, resulting in congestive heart failure, cerebrovascular events and acute splenic sequestration
- Thrombocytopenia
- Neutropenia
- Pancytopenia

B19 persistence in immunocompetent patients
- Persistent infection with potentially severe and chronic anemia, with various long-lasting symptoms such as fatigue, fever, arthralgia and myalgia

Other associated disorders
- Myocarditis and heart failure
- Hepatitis
- Kawasaki disease
- Gloves-and-socks syndrome
- Neurological disease
- Fibromyalgia

Infection in immunocompromised individuals
- Persistent BM suppression with chronic anemia (predisposing conditions are congenital immunodeficiencies, leukemia, lymphoma, myelodysplastic syndrome, BM and solid organ transplantation, chemotherapy and infection with human immunodeficiency virus)
- Infection-associated hemophagocytosis

Vertical transmission, fetal hydrops and intrauterine fetal death (IUFD)
- Nonimmune fetal hydrops
- Congenital anemia

school-aged children with low-grade fever, malaise and the characteristic facial rash, involving the cheeks with relative circumoral pallor, that subsequently spreads to the trunk, back and extremities. Arthralgia is more frequent in adults.

Patients with underlying hematological or immunological disorders are at risk for transient aplastic crisis (TAC), due to the block of erythropoiesis with a profound reticulocytopenia. Other manifestations associated with B19 infection are illustrated in Table 113.12.

Primary maternal infection has been associated with:
- asymptomatic fetal infection;
- birth defects, particularly ocular and central nervous system abnormalities (long-term neurologic sequelae in infants with no signs at birth have been described);
- intrauterine fetal death, more common in the first and second trimester, often unassociated to hydrops;
- fetal hydrops, occurring in 1 out of 3000 births, with a mean interval of 6 weeks between the onset of maternal infection and fetal symptoms.

Maternal clinical manifestations do not influence the pregnancy outcome.

113.5.3.1 Diagnosis

Diagnosis of B19 infection is based on detecting specific IgG and IgM or viral DNA in blood or tissue samples by PCR [23].

Specific IgM are present 10–12 days after infection; IgG appear shortly afterwards and mediate lifelong immunity. Caution is needed in interpreting serology in immunodeficient individuals or in pregnant women, because they are not always able to mount an adequate antibody response.

PCR analysis of B19 DNA in serum, bone marrow (BM) and other tissues may integrate serology. In immunocompromised patients, a positive PCR test in blood indicates ongoing acute or persistent infection, in BM it may indicate either acute or previous infection. In cases of fetal complications, PCR analysis of amniotic fluid or cord blood may have a high priority for possible therapeutic interventions. Quantitative PCR allows the viral load concentration in different tissues to be quantified. However, further studies are needed to correlate the viral load with disease progression.

113.5.4 Prognosis

After intrauterine exposure to B19, the risk of fetal death is 0.1–0.3%. Information on long-term outcomes of congenital infections is limited. No studies report significant developmental delay in live-born children infected in utero, including those treated with intrauterine transfusion for B19 anemia and hydrops.

113.5.5 Therapy and Treatments

There is no specific therapy against B19 infection; some alternative interventions are however recommended, such as transfusion therapy to recover from aplastic crisis or intravenous IgG ($0.4\ g\ kg^{-1} \times 5$ days or $1\ g\ kg^{-1} \times 3$ days) to facilitate the clearance of the virus in immunocompromised patients.

If maternal B19 infection is confirmed, weekly ultrasound examinations are appropriate to monitor the fetus: if hydrops and/or signs of anemia appear, intrauterine erythrocyte transfusions can reduce the mortality rate [24].

Fetal Infections: Congenital Syphilis, and Tuberculosis

Pier-Angelo Tovo, Carlo Scolfaro, Federica Mignone and Silvia Garazzino

114.1 Syphilis

Significant progress has been made in the diagnosis and treatment of syphilis since the identification of the causative agent, *Treponema pallidum*, in 1905. However, syphilis remains a major public health problem in many developing countries and there has been a recrudescence in developed countries during the last two decades [1].

The prevention of congenital syphilis is based on good antenatal care and routine serological screening to detect infection in pregnant women.

The newborn can be infected in utero by the transplacental passage of *T. pallidum* from an infected, untreated or inadequately treated mother, or at delivery by contact with an active genital lesion. Breastfeeding does not cause transmission. *T. pallidum* may cross the placenta from about 14 weeks of gestation. The risk of transmission increases with gestation and is inversely related to the duration of maternal infection. The vertical transmission rate in an untreated mother ranges from 70–100% during primary syphilis, 40% during early latent syphilis, and decreasing to 10% during late latent infection [2, 3].

Syphilis is classified as early and late. It is early when it is diagnosed within the first or second year after infection. Late syphilis is diagnosed one or two years after infection [3].

114.1.1 Epidemiology

The World Health Organization (WHO) estimates that 12 million people are infected with syphilis each year [4]. Untreated early syphilis during pregnancy results in perinatal death in up to 40% of cases. If acquired during the 4 years preceding pregnancy, it can cause infection of the fetus in 80% of cases.

In sub-Saharan Africa, an estimated two million women with active syphilis become pregnant each year and the infection remains mostly undetected during pregnancy. In Latin America and in the Caribbean the prevalence of syphilis in pregnant women ranges from 5 to 10%, while in Asia it is generally below 5% [2]. The rates of primary and secondary syphilis declined in the United States in the 1990s, but in the new millennium it has increased annually with 1.1/100,000 women being infected in 2007 with a peak in the 25- to 29-year-old age group (8.9/100,000). As a consequence, the rate of congenital syphilis has increased after 14 years of decline. Recently, there has also been a resurgence of syphilis in Europe [3, 4].

114.1.2 Etiology and Pathogenesis

T. pallidum is a member of the order Spirochaetales, family Spirochaetaceae and genus *Treponema*. If untreated, the infection persists despite evidence of an immune response. *T. pallidum* interacts with vascular endothelium. Its membrane 47 kDa lipoprotein activates vascular endothelial cells to upregulate the expression of intercellular adhesion molecule-1 (ICAM-1) and stimulate procoagulant activity, resulting in fibrin deposition and perivasculitis. Delayed-type hypersensivity to treponemal antigens appears later and may be related to the onset of latency [5].

114.1.3 Clinical Manifestations

Symptoms and signs of congenital syphilis within the first 2 years of age are considered as early congenital syphilis, and later clinical manifestations as late congenital syphilis.

In pregnant women, untreated or inadequately treated syphilis is associated with spontaneous abortion during the second and early third trimester, perinatal death, premature

Turin, Italy

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

delivery, low birth weight, and non immune hydrops. Most affected infants are asymptomatic at birth, but two-thirds develop manifestations by 3–8 weeks. Persistent rhinitis (snuffles) is an early feature, with an infectious discharge that is sometimes blood-tinged. Other signs include a non-tender generalized lymphadenopathy, hepatosplenomegaly, anemia, leukopenia or leukocytosis, thrombocytopenia and conjugated hyperbilirubinemia. The most common skin lesion is a maculopapular rash or a vescicolo-bullous eruption, affecting the palms and soles and associated with desquamation. Glomerulonephritis followed by nephrotic syndrome with generalised edema may develop between 2 and 3 months of age. Bone lesions are not unusual, with involvement of the metaphyses and diaphyses of long bones; radiographic abnormalities can be detected in about 20% of infants with asymptomatic infection. Osteochondritis or Parrot's pseudo-paralysis is a most common and early manifestation characterised by an asymmetric, painful, flaccid paralysis of the limbs and knees.

Late congenital syphilis may involve many organs, most frequently the bones, teeth and nervous system. The stigmata of late infection include Hutchinson's triad (notched upper incisors, interstitial keratitis and eight nerve deafness), saddle nose, palatal erosions, frontal bossing, sabre tibia, rhagades, nodules and gummata.

114.1.4 Diagnosis

Syphilis can be diagnosed by direct and indirect tests (Table 114.1). Direct methods can be used for symptomatic patients with primary or secondary syphilis and include:

- the detection of *T. pallidum* by direct examination of fluid or exudation from lesions immediately after sample collection through dark-field microscopy. The sensitivity of the method (74–86%) is limited by the fact that 10^5 organism/mL are necessary for visualization. However, this method cannot be used for oral lesions because non-pathogenic oral spirochaetes can be confused with *T. pallidum* and systemic antibiotics may result in a false-negative test. Specificity is 77–100% and depends on the experience of the observer;
- direct fluorescent antibody *T. pallidum* test (DFA-TP) in smear or tissue section. This does not require motile organisms and is more sensitive and specific than dark-field microscopy, though more expensive;
- polymerase chain reaction (PCR) for the identification of treponemal DNA has been developed but not yet standardized. Can detect as few as 10 organisms in lesions or tissues [5, 6].

Indirect diagnosis is based on serological tests to detect antibodies. These tests include non-treponemal tests for screening and treponemal ones for confirmation.

- Non-treponemal tests (e.g., Venereal Disease Research Laboratory [VDRL] and Rapid Plasma Reagin [RPR]) measure both IgG and IgM antiphospholipid antibodies against lipoidal material released by damaged host cells and the treponemal cell surface. These tests become positive 6 weeks after exposure and 1–4 weeks after the appearance of the primary lesion. They usually correlate with disease activity. Results are reported quantitatively and a four-fold titer change is considered significant. Sequential serology should be performed using the same test, preferably by the same laboratory. Non-treponemal tests usually become non-reactive over time after treatment, though they may persist at low titer (serofast reaction, which occurs when a nontreponemal test reaction is overwhelmed by antigen-antibody excess) in some patients [7]. False-positive results may occur because of cross-reactivity during acute viral infections, auto-immune conditions or pregnancy. False-negative results may be due to prozone reactions.
- Treponemal tests (e.g., fluorescent treponemal antibody adsorbed [FTA-ABS], *T. pallidum* particle agglutination [TP-PA]) do not correlate with disease activity and can remain positive regardless of treatment.

Treponemal enzyme immunoassay [EIA] can be useful because it identifies IgG and IgM against *T. pallidum* [2, 3, 5, 6].

Effective prevention and detection of congenital syphilis depends on identifying the infection by routine serological screening at the first antenatal visit and at delivery. Serology should be repeated at the beginning of the third trimester in populations with a high risk of congenital syphilis (e.g., multiple sexual partners, presence of a sexually transmitted disease, drug addiction, lack of antenatal care) or in areas with a high prevalence of syphilis (Table 114.2). Information about the treatment of the sex partner should be obtained to assess the risk of re-infection. Pregnant women with syphilis should also be tested for HIV infection. No infant should be discharged from the hospital without determining the maternal serological status for syphilis.

Every infant born to a mother with reactive non-treponemal and treponemal test results should be carefully examined for signs and symptoms of congenital syphilis. A quantitative non-treponemal serological test and EIA IgM should be done on infant serum, using the same test as that for the mother to compare titre results. If the EIA IgM test is negative and other tests have titers less than four-fold higher than the mother's,

Table 114.1 Diagnostic tests for syphilis

Direct tests
• Direct examination through dark-field microscopy
• Direct fluorescent antibody *T. pallidum* test (DFA-TP)
• Polymerase chain reaction (PCR) assay
Indirect tests
• Non-treponemal tests
– Venereal Disease Research Laboratory (VDRL)
– Rapid Plasma Reagin (RPR)
• Treponemal tests
– Fluorescent treponemal antibody adsorbed (FTA-ABS)
– *T. pallidum* particle agglutination (TP-PA)
– Treponemal enzyme immunoassay (EIA)

Table 114.2 High risk of congenital syphilis

- Symptomatic newborn
- Untreated, inadequately treated or non-documented treated maternal syphilis
- Non-penicillin treatment of syphilis during pregnancy
- Treatment of maternal syphilis for less than 4 weeks before delivery
- Absence of at least a four-fold decrease in non-treponemal maternal titres after therapy
- Four-fold increase of maternal titres or infant titres at least four-fold greater than maternal titres

an asymptomatic infant should have repeat serology at 3, 6 and 15 months of age or until seroreversion.

Congenital syphilis is diagnosed if the EIA IgM test is positive and/or the non-treponemal or treponemal titres are four-fold higher than in the mother. Further investigations are mandatory: cerebrospinal fluid (CSF) examination (protein, cell count and VDRL test), hematology and liver function tests, skeletal X-rays and ophthalmological assessment. A definitive diagnosis of congenital syphilis is made if PCR and/or dark field microscopy detects *T. pallidum* in a sample from a lesion, the placenta or body fluids [5, 6–9].

114.1.5 Treatment

Several guidelines define the criteria for the correct management of infants born to mothers with syphilis. Treatments for infants with suspected congenital syphilis are listed in Table 114.3. In infants at low risk of congenital syphilis, some specialists recommend a single intramuscular dose of benzyl penicillin G (50,000 U/kg) with follow-up serology.

114.1.6 Follow-up

Treated infants should be followed-up at 3, 6 and 12 months of age until non-treponemal serology becomes non-reactive or the titer has decreased four-fold. In adequately treated children, non-treponemal titres usually decrease by 3 months and become negative by 6 months. If they persist or increase at 6–12 months of age, the infant should be investigated and treated with a further 10 day course of parenteral penicillin G.

If the mother was adequately treated, no further investigations are required for untreated asymptomatic infants. If the newborn's or the mother's status is unclear, the non-treponemal test should be repeated at 3 and 6 months and a treponemal test should be performed at 15 months [4, 7–9].

114.2 Tuberculosis

Tuberculosis (TB) is the leading cause of death from a single infectious agent and a worldwide primary health problem. In the last decades, TB has remained a major disease in developing countries, and has also become an emerging infection in industrialized areas because of sustained migration and the spread of multidrug-resistant strains. The resurgence of TB has raised particular concerns for pregnant women and their children with a dramatic increase in the incidence of TB among women of child-bearing age [10].

114.2.1 Etiology and Pathogenesis

TB infection in infants is most commonly acquired postnatally through exposure to family members with bacillary pulmonary disease. Congenital TB is rare and is caused by maternal transmission of *Mycobacterium tuberculosis* to the fetus. Fetal infection can occur by hematogenous spread of mycobacteria through the placenta, by in utero aspiration or ingestion of infected amniotic fluid, or by direct contact with maternal genital lesions at delivery. Placental involvement may result from the dissemination phase of either a primary maternal infection or reactivation of a previous infection. Disseminated disease very often complicates acute infection rather than being due to reactivation. Primary infection during pregnancy therefore implies a higher risk of congenital transmission. The latter is unusual if maternal antituberculous treatment is adequate. HIV-infected women are at greater risk of congenitally transmitting mycobacteria, as they are more frequently affected by miliary or extrapulmonary forms of TB [11].

In hematogenous congenital TB, mycobacteria reach the fetus through the umbilical vein, causing a primary lesion within the liver and the periportal lymph nodes followed by spread into the systemic circulation and the lungs. The bacilli

Table 114.3 Recommended regimens for infants with suspected congenital syphilis

Drug	Route	Dosage	Total duration	Notes
Benzyl penicillin	IV	*Infants < 4 weeks*: 50,000 U/kg/dose every 12 hours for the first 7 days of life and every 8 hours thereafter *Infants > 4 weeks*: 200,000–300,000 U/kg/day, administered as 50,000 U/kg every 4–6 hours	10–14 days	If more than one day of therapy is missed, the entire course should be restarted
Procaine penicillin G	IM	50,000 U/kg/dose once daily	10–14 days	

generally remain dormant until the pulmonary circulation and oxygenation increases after birth, when they can cause active pulmonary disease and further systemic dissemination. When congenital TB is caused by aspiration or ingestion of infected amniotic fluid, primary complexes develop in the gastrointestinal and/or respiratory tract.

114.2.2 Clinical Patterns

Symptoms and signs of congenital TB are non-specific, often mimicking common neonatal diseases, such as sepsis or other congenital or perinatal infections. Clinical manifestations may be evident at birth, but usually appear within 2–3 weeks (see Table 114.4). Typically, infected infants are born prematurely. Virtually any organ system may be involved, although the lungs, liver and gut are the most common primary infection sites. A chest X-ray is usually abnormal and there is often a miliary pattern. TB in the newborn often results in disseminated and fatal disease [12].

114.2.3 Diagnosis

The diagnosis of congenital TB is often difficult. It should be suspected in a newborn with negative tests for other congenital infections, and whose mother has risk factors for, or has been diagnosed with, TB.

The tuberculin skin reaction is unreliable in neonates, since it may be initially negative, becoming positive after a few months. However, neonates often yield positive acid-fast bacilli smears and cultures (up to 75%), as disseminated and rapidly progressive diseases lead to high bacillary loads.

Diagnosis relies on the demonstration of *M. tuberculosis* in tissues or fluids. An early morning gastric aspirate is more easily collected than sputum from infants. In the case of pulmonary TB, mycobacteria may also be demonstrated in the tracheal aspirate because of high bacillary loads in the lungs. Three consecutive samples should be obtained, but a single positive pulmonary smear should be considered indicative of TB. Data on the accuracy of polymerase chain reaction (PCR) techniques in neonates with congenital TB are limited [11, 13]. The development of interferon gamma assays has offered new possibilities for the diagnosis of latent TB infection and active disease in adults, but little is known about their performance in children, especially in those exposed perinatally. Some concerns have been expressed about the reliability of these assays in newborns and infants, given their depressed IFN-γ production.

Due to high co-infection rates, all newborns and mothers diagnosed with TB should also be tested for HIV infection.

The diagnostic criteria for distinguishing congenital TB from TB acquired postnatally requires the documentation of tuberculous lesions, plus at least one of the following: (1) onset of lesions during the first week, (2) a primary hepatic complex or caseating granulomas, (3) infection of the placenta or maternal genital tract, (4) exclusion of TB acquired after birth from the mother or other sources.

114.2.4 Therapy and Treatments

Because of its high mortality rate, the early treatment of congenital TB is mandatory. The optimal treatment regimen and its duration have yet to be established. High mycobacterial loads support using a combination of drugs (Table 114.5). One regimen starts with a combination of four antituberculosis drugs (isoniazid, rifampin, pyrazinamide and streptomycin or ethambutol) for 2 months, followed by isoniazid (INH) and rifampin (RFP) for 4 to 6-months. For sensitive strains, an alternative 9-month-regimen using only INH and RFP has been suggested. Extrapulmonary disease requires longer treatment for 12 months and some experts recommend a total treatment duration of 9–12 months, regardless of the site of infection because of the impaired immunologic defences of neonates and infants.

When there are drug-resistant strains and/or intolerance to first-line treatment, second-line drugs include fluoroquinolones (i.e., moxifloxacin, levofloxacin and ciprofloxacin), ethionamide, PAS, cycloserin, aminoglycosides (amykacin, capreomycin, kanamycin) and linezolid.

During treatment, liver function tests and serum uric acid levels should be monitored and hearing tests done when streptomycin and aminoglycosides are used. Vitamin B6 is recommended to prevent INH-induced peripheral neuropathy.

Table 114.4 Signs and symptoms of congenital tuberculosis

Common	Rare
– Hepatosplenomegaly	– Vomiting
– Respiratory distress	– Jaundice
– Fever	– Cyanosis
– Lymphadenopathy	– Apnea
– Abdominal distension	– Seizures
– Poor feeding/low weight gain	– Petechiae
– Lethargy/irritability	
– Ear discharge	
– Papular skin lesions	

Table 114.5 First-line antituberculosis drugs

Drug (generic name)	Daily dose (mg/kg)	Maximal daily dosage	Route
Isoniazid	10–15	300 mg	Oral
Rifampin	10–20	600 mg	Oral
Pyrazinamide	20–40	2 g	Oral
Streptomycin	20–40	1 g	Intramuscular
Ethambutol	15–25	2.5 g	Oral

Ethambutol administered in young infants at > 15mg/kg/day can cause optic neuritis and red-green color blindness.

A gastric aspirate should be repeated after 2 months of therapy to establish the response to specific treatment. Chest X-rays should be obtained 1–2 months after the start of therapy to estimate the extent of the disease [11, 12, 14].

114.2.5 Prevention

Key to the prevention of congenital TB is the prevention and treatment of active infection in pregnant women [12]. The treatment of active disease during pregnancy includes the standard regimen of four active drugs for the first 2 months followed by a consolidation regimen with INH and RFP for a further 4 months. No teratogenic effects have been demonstrated with first line antituberculosis drugs. Careful monitoring for clinical features of hepatitis and other side effects is recommended. Recent guidelines advocate treating latent infection during pregnancy at any gestational age with INH for 9 months, aiming at preventing the development of active disease and spread to other people.

The Bacille Calmette-Guérin vaccine is ineffective in preventing congenital tuberculosis. New vaccine development may become a key future strategy for the prevention of TB.

114.2.6 Prognosis

The early diagnosis and the institution of appropriate therapy have markedly decreased the mortality of congenital TB.

Toxoplasmosis in the Fetus and Newborn

Wilma Buffolano

115.1 Introduction

In the developed world, human toxoplasmosis is considered a benign self-limiting disease mostly detectable by specific antibody *Toxoplasma gondii*-immunoglobulin (*Tg*-Ig) testing. Patent and sometimes devastating disease may be appreciated in immune-compromised hosts and congenitally infected infants [1]. Congenital toxoplasmosis (CT) occurs almost exclusively when primary maternal infection occurs during gestation. As more than half of mothers giving birth to infected offspring could not recall an infection-related illness and no test reliably marks off infection time, there is pressure for screening. Alternative strategies include prenatal surveillance in *Tg*-Ig negative pregnant women and prophylaxis of fetal infection/damage in seroconverters, and newborn *Tg*-IgM testing on filter paper blood spots and sequelae prophylaxis in the *Tg*-IgM positive infant. Monthly or quarterly re-testing of unprotected pregnant women has been widely practised in the EU since the '70s, whereas newborn testing has been included in the New England Neonatal Screening Program (NENSP) since 1986, and feasibility confirmed across the globe.

New assays and combined multi-test strategies have dramatically improved prenatal diagnosis, while treatment relies on few out-dated poorly understood pharmaco-kinetics/dynamics drugs which showed unable to eradicate tissue cysts.

Weak proof of treatment benefits, concerns about infrastructure costs and adverse effects, differences in test and medicine local availability on markets and interpretation of study results cause wide variability in practice. Equipoise considerations are blocking randomized-placebo controlled trial realization in screening countries [2].

W. Buffolano (✉)
Department of Paediatrics, Regional Register for Perinatal Infection and Special Unit for Perinatal Infection, Federico II University of Naples Naples, Italy

Toxoplasmosis in adult is emerging as a potential serious food/water-borne disease requiring hospitalization [3], and as a major cause of retinal infection, with overall 24% of affected eyes becoming legally blind [4]. News inside host and parasite might open new opportunity of health intervention. For example the association of positive *Tg*-Ig with changes in reaction time and personality profile, the inhibitory effect on parasite replication of some antipsychotics and mood stabilizers [5, 6], parasite and host genetics, such as non-archetypal highly virulent strains in severe acute course [7], kinase polymorphism virulence linkage [8], and association of ocular disease with parental polymorphisms in COL2A1 on EU and USA [9].

115.2 Epidemiology

Nearly one-third of humans shows serological markers of acquired toxoplasmosis with variation in local prevalence according to sanitation, dietetic habits, and latitude. In the Northern hemisphere, gestational toxoplasmosis and CT prevalence range from 0.5 to 8 per 1000 susceptible pregnancies and 1 to 10 per 10,000 live newborns, respectively [1]. Unexpectedly, a ten times higher than expected CT incidence with a burden of 2300 disability-adjusted life years (DALYs) has been recently calculated in the Netherlands [10]. Incidence updating is needed in the EU as an increasing number of women is facing gestation while unprotected. In fact, depending on improved conditions on farming and food storage, and on prenatal standards of care, a progressive decrease in age-specific *Tg*-IgG prevalence has been found.

115.3 Etiology and Pathogenesis

Humans usually become infected by ingesting the tissue cyst stage of *Toxoplasma gondii* (*Tg*) in meat or the oocyst stage

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

released by acutely-infected felidae in water and ground. A seronegative recipient could become infected by organ transplantation from a *Tg*-Ig positive donor. If primary infection occurs during gestation the fetus might be transplacentally contaminated. Gestational toxoplasmosis is mostly under-diagnosed. In fact, only on a few cases lymphadenopathy and/or flu-like illness, without remarkable prenatal ultrasounds (US) findings, were complained. A severe TORCH syndrome should be investigated if fetal intracranial calcification, ventricular dilatation, hepatomegaly, ascites, and/or placental thickening are detected.

In a minority of women, ocular toxoplasmosis might occur in the acute and latent phase.

With rare exceptions, highlighting the inability of the host immune response to eradicate *Tg* tissue cysts, reactivation of latent toxoplasmosis poses no threat [11, 12]. The potential for overt disease and fetal transmission during the chronic phase has been reported in severely immune-compromised pregnant women (CD4 count < 200 cells/mm^3) and on a few anedoctic cases.

The major determinant for fetal infection is the gestational age week (AW) of maternal infection [13]. Acute disease

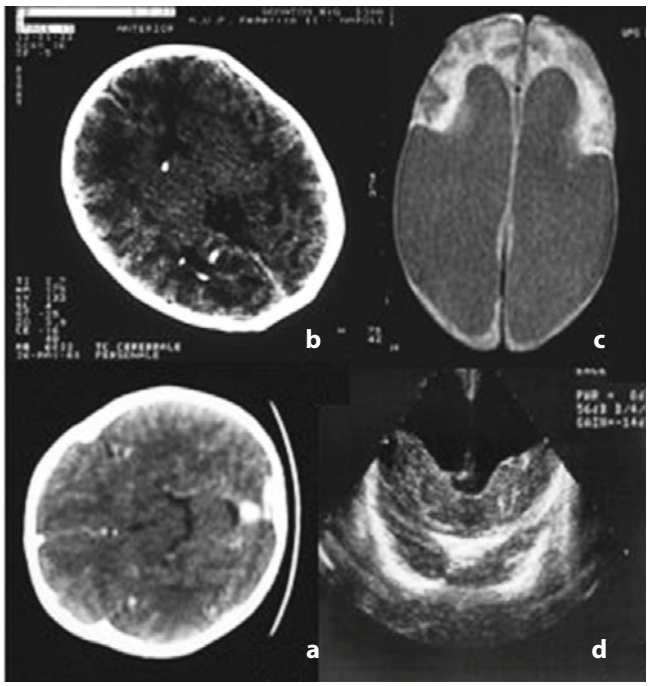

Fig. 115.1 Intracranial lesions in congenital toxoplasmosis. (**a**) Cranial CT scan showing multiple nodular calcifications near ventricular borders in a 2 month old boy with moderate onset congenital toxoplasmosis, including microcalcifications and peripheral retinochorioiditis scars on the left eye. (**b**) Cranial CT scan showing multiple sparse microcalcifications in a 43 day-old girl with asymptomatic congenital toxoplasmosis. Both children were treated for 1-year. (**c**) Massive tetra-ventricular dilation as a consequence of obstructive hydrocephalus and intracerebral calcifications in a 1 month-old infant with severe onset congenital toxoplasmosis, including bilateral chorioretinitis, and microftalmia and cataract on the right eye (CT scan on **c**, and ultrasonography on **d**). P-S regimen was applied on the mother starting from 22 AW until delivery because of positive *Tg*-PCR on amniotic fluid from a II trimester proven gestational contamination. Despite shunt placement and 1-year treatment, the child remained developmentally and neurologically severely compromised, and bilaterally blind. (Courtesy of Prof. A. Brunetti and Dr. A. D'Amico)

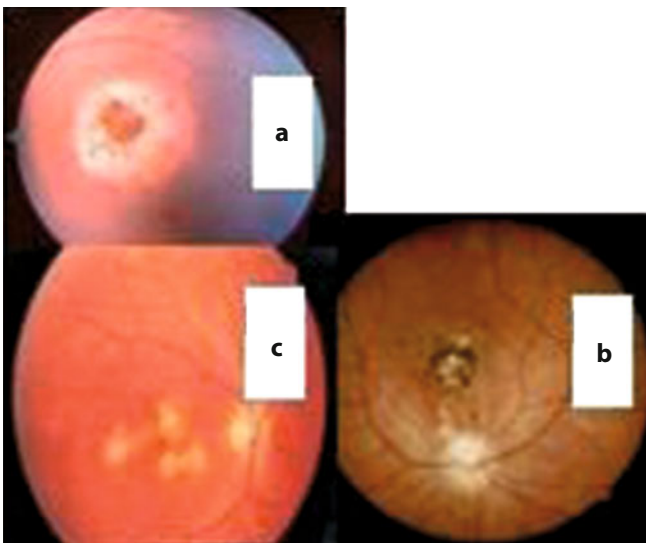

Fig. 115.2 Fundoscopic images of retinochorioiditis on patient with congenital toxoplasmosis. (**a**) Large macular lesion with a central hyperpigmented area and a semi-quiescent border on which pigmentation started developing in a 3-year old boy with presumed severe onset congenital toxoplasmosis (multiple cranial calcifications and macular retinochorioiditis were detected when he was 14 months old and referred because of "lazy eye"). (**b**) Large old chorioretinal scar with sharply demarcated and pigmented edge, and many satellite lesions on different resolution phases in a 13-year old boy with untreated severe onset congenital toxoplasmosis (misdiagnosis of sepsis at birth on a child with systemic signs, cranial calcifications and slight ventricular enlargement). Adjacent to the scar, two lesions; on the lower-temporal lesion pigmentation with sharply demarcated edges accompanied the absence of inflammation, while on the upper nasal lesion active inflammation is revealed by a yellow blurred edge. Two new inflammatory lesions on the mid- inferior. (**c**) Many small yellow-white soft blurred edges displayed acute peripheral lesions in a 11-year old girl with recently treated congenital toxoplasmosis. She was born prematurely and treated with O_2 therapy soon after birth. The diagnosis of congenital toxoplasmosis was suspected when she was 9 months old, based on the detection on the other eye of a peri-papillary scar during ophthalmologic follow-up. (Courtesy of Prof. A. Magli)

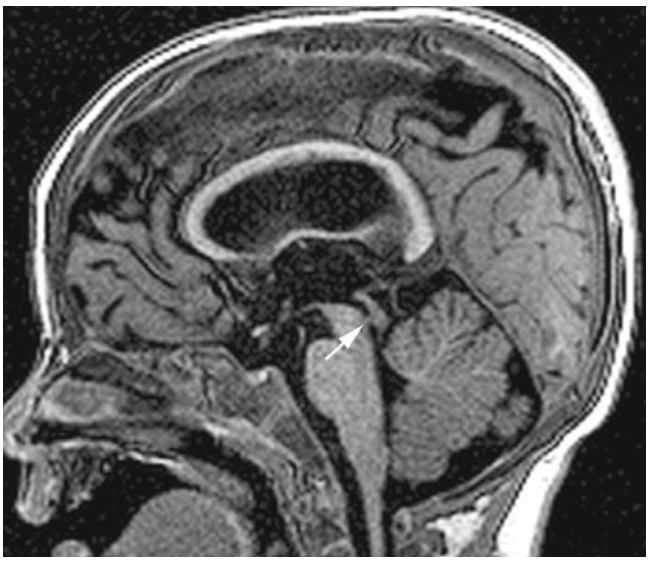

Fig. 115.3 Midline sagittal T1-3D (MPRAGE) scan (thickness = 1 mm) showing obstructed aqueduct (*white arrow*), with dilated supratentorial ventricles and normal IV ventricle. (Courtesy of Prof. A. Brunetti and Dr. A. D'Amico)

acquired ≥ 6 months before gestation shows a transmission risk approaching zero. Overall transmission rate is about 30%, with 15% at 13 AW, 44% at 26 AW, and 71% at 36 AW (Fig. 115.1). The odds of transmission increase by 12% per AW after seroconversion time. The odds of intracranial lesions markedly decrease with higher AW at maternal infection whereas the risk of ocular lesions declines less significantly (Fig. 115.2). Given the relationship, the risk of giving birth to a child with clinical signs is greatest (10%) for women acquiring toxoplasmosis between 24 and 30 AW.

In the fetus, tachyzoites show the ability to cross non-permissive biological barriers transported in antigen-presenting cells. Brain microcalcifications and ventricular dilation on neuroimaging (Figs. 115.1 and 115.3) and retinochorioiditis foci or scars on fundoscopic examination (Fig. 115.2) or on optical coherence tomography (OCT) reveal tissue damage generated by local Th1-mediated immune responses. Periaqueductal vasculitis with necrosis gradually sloughing into the ventricles might cause obstructive idrocephalus (Fig. 115.3). Long-term ocular damage is the consequence of bradyzoite to tachyzoite reconversion with at times invasion of adjacent cells (recrudescence) and secondary autoimmunity for retinal soluble antigen.

115.4 Clinical Aspects

Brain and eye damage are the hallmarks of CT, including retinochoroiditis, intracranial calcifications, and hydrocephalus. A wide clinical spectrum, including microcephaly, hypotonia, epilepsy, intracranial calcifications, electroencephalographic and/or cerebrospinal fluid abnormalities, retinochoroiditis, strasbismus, nystagmus, blindness, microftalmia, cataracts, glaucoma, optic atrophy, prematurity, intrauterine growth restriction (IUGR), hepato-splenomegaly, anemia, thrombocytopenia, fever, and lymphoadenopathy was featured in untreated cohorts [13]. Milder disease is more prevalent in the EU where overt signs were reported in a minority of congenitally infected infants enrolled in EU centers performing prenatal or neonatal screening, and attributed to differences on *Tg* genetics [14]. Of 691 infected infants, 105 (19%) presented with at least one type of clinical manifestation, 79 (14%) had ocular lesions and 49 (9%) had intracranial lesions, and only one infant died at 7 days with disseminated disease.

The diagnosis of toxoplasmosis mostly relies on serological tests. A negative post-delivery and a positive pre-conceptional *Tg*-Ig test reasonably rule out offspring risk. Conversion from a negative postconceptional test to a *Tg*-Ig M/G positive result forms a solid basis for proven gestational toxoplasmosis, and marks off maternal infection time when the between test time interval is short. Clinical usefulness of delayed treatment in order to detect high or markedly increasing *Tg*-IgG titer is reduced by the short "therapeutic window", as a recent meta-analysis reported that ≥ 3 weeks of delay in starting maternal treatment increases the odds of transmission.

On *Tg*-IgG/M positive women at their first prenatal test (≤12 weeks AW), a sequential multi-test strategy using highly sensitive IgM assays and methods examining IgG avidity or stage specificity might reasonably exclude acute infection and fetal risk on the residual IgM carrier [15]. Treatment impact on maturation of *Tg*-IgG avidity is unpredictable.

Appropriate definition of infant infection status might instead be problematic, as most of cases are normal on routine clinical examination, cranial findings are not pathognomonic and might go undetected, and serological test sensitivity is poor.

High *Tg*-IgG titer at birth might reflect transplacental transportation. Beyond the age of 12 months, *Tg*-IgG persistence or disappearance definitely confirms or rules out CT, respectively. Sequential *Tg*-IgG titer compared to the expected decay on transplacentally transported *Tg*-IgG (one half per month) or better to trend on total antibodies (IgGs) (then computing antibody load) could show between the ages of 4 to 6 months and before *Tg*-IgG level starts rising the infant is infected, thus treatment could be indicated.

Demonstration of positive *Tg*-IgM/A on newborn whole blood or sera samples is highly specific if maternal antibody leak can be ruled out. Overall IgM and IgA sensitivity was shown 52% and 55%, respectively [16]. According to maternal infection AW, IgM sensitivity increases by 29% in the first to 71% in the third trimester, and IgA sensitivity increases by 40% in the first to 64% in the third trimester. A multitest strategy including two tests (*Tg*-IgM and A) or three tests (*Tg*-IgM, A and Western blot) increases sensitivity up to 73% and 78%, respectively [17, 18]. The most informative results is a

Table 115.1 Guidelines for diagnosis of congenital toxoplasmosis

Criteria for diagnostic suspicion		
Toxoplasmosis on gestation	Maternal diagnosis precision	Proven Unproven Unlikely
	Gestational time of infection (AW)	< 13 13–35 ≥ 36
	PCR on amniotic fluid	Positive Negative
Clinical findings on newborn infant (isolated or in combination)	Ocular	Nystagmus or strabismus Posterior segment abnormalities (retinochoroiditis, optic nerve atrophy) external eye abnormalities (microphthalmos, cataract)
	Intracranial	Microcalcifications (spotty distribution, particularly) Ventricular dilatation Obstructive hydrocephalus
	Neurological	Seizures; EEG and/ or CSF abnormalities Microcephaly, macrocephaly Tone or motor dysfunction
	Systemic (TORCH syndrome)	Rash Hepatosplenomegaly Anemia, thrombocytopenia
Newborn screening	Toxo-IgM and/or IgA positivity	

Onset severity definition
– Careful pediatric examination
– Neurologic evaluation[a]
– Expert ophthalmologic examination[abc]
– Brain CT scan[de]
– Brain ultrasound (follow-up)[f]
– Auditory brain-stem response[g]

Infection status definition	
Indirect criteria	– Toxo-IgM[h] and IgA[i] ± comparative IgG WB – Toxo-IgG increase or antibody load – Toxo-IgG persistence beyond age 12 months
Direct criteria (not routinely)	– Parasite isolation or positive inoculation on mice or tissue culture (placenta) – Parasite DNA demonstration (PCR on amniotic or cerebrospinal fluid)

[a] Data sheets and narrative evaluations for each child at each examination.
[b] Appropriate examination includes cycloplegia, and under-sedation indirect fundoscopy to detect both central and peripheral lesions.
[c] Fundus photographs and optical coherence tomography (OCT), whenever the patient cooperation allowed.
[d] Without contrast medium enhancement.
[e] Higher inter-observer agreement than US and higher (five times) sensitivity.
[f] US is widely practiced to monitor short–term treatment effect.
[g] Only on infected infant.
[h] EIA and ISAGA-IgM.
[i] ELISA-IgA.

positive *Tg*-IgM result on second trimester maternal seroconversion (with a pre-test probability of 27% and a post- test probability of 79%), and a negative *Tg*-IgM result on third trimester maternal infection (with a pre-test probability of 59% and a post-test probability of 32%).

The diagnosis can be carried out prenatally at ≥18 AW and at least 4 weeks after the estimated infection time by performing PCR assay on amniotic fluid. Despite poor standardization, PCR has become standard of practice to channel prenatal management on France. The assay is highly specific, but a negative PCR result does not rule out fetal infection [19].

Ideally, suspected CT infection should be confirmed in an experienced reference laboratory, and management carried out in (or with the formal support of) a specialized center where a multidisciplinary expert team working in high quality standardized conditions and performing valid and reliable measures reported on standard format, and including retinal photographs and neuroimage report in a large database, might minimize potentials for differential misclassification [20, 21]. Particularly, on prenatal screening settings, parents and physicians felt there was less risk in prompt treatment than in deferring initiation of treatment in infants who are often undistinguishable from healthy uninfected babies. The more clinical onset definition is appropriate based on correct estimation of maternal infection time and interpretation of fetal diagnosis results, and post-test probabilities measures, the less the misdiagnosis rate, i.e., the number of treated among healthy infants and untreated among congenitally infected ones.

115.5 Differential Diagnosis

Other causes of TORCH syndrome, including Cytomegalovirus, Herpes simplex virus, Rubella and Syphilis, should be ruled out in symptomatic newborn infants by a combination of diagnostic tools. Systematic exclusion of congenital cytomegalovirus (CMV) coinfection by urine culture or PCR within 2 weeks of birth should channel appropriate onset severity definition/management, and outcome measures. A negative post-partal CMV-IgG test rules out congenital CMV, whereas a positive CMV-PCR of Guthrie card might allow differentiation between congenital and perinatal infection on case with testing delay. Exclusion of pseudo-TORCH syndrome might be indicated in multisystemic disease simulating TORCH syndrome upon which extensive screening for congenital infectious disease is negative [22].

115.6 Prognosis

In outdated studies, only 11% of asymptomatic untreated patients remained sequelae-free. Favorable cognitive, neurological, and auditory outcomes were shown in the group without substantial neurological disease at birth, and in over 72% of

moderate or severe neurological disease groups after 1-year (1-y) long postnatal treatment in the National Collaborative Chicago-Based Congenital Toxoplasmosis Study (NCCCTS) recruiting referrals all over USA [23]. New eye lesions remained undetectable in 91% of the children without neurological disease and in 64% of those with moderate or severe neurological disease. Reactivations are reported in as many as 34% of cases with early ocular involvement. More than 70% of patients in the untreated group developed new eye lesion after the first decade of life, whereas new central lesions were uncommon in 1-y treated children [24, 25].

In the EU-treated cohorts recruited through screening, outcomes were found milder than anticipated based on historical data, as 5% of patients showed serious neurological sequelae that would be apparent in the first two years of life [13]. In the European Multicentre Study on Congenital Toxoplasmosis (EMSCOT), comparable development and behavior were reported at the age of 4 years in treated infected children compared to uninfected controls [26]. Moreover, in 281 infected children, 18% had ≥1 retinochoroidal lesions, and 6% had recurrent retinochoroiditis during a median follow-up of 4.1 years, which is near to the ocular lesion prevalence reported in

Table 115.2 Treatment of *Tg* infection in pregnant women and congenital toxoplasmosis (CT) assessment

	Treatment	Dosage	Indication	Comment
Mother	Spiramycin	1 g (3 million U) every 8 h (for a total of 3 g or 9 million U per day)	a. pregnant women suspected of having acquired the infection < 16 AW b. Unproven maternal diagnosis (any AW) c. negative amniotic fluid PCR and negative US at follow-up	Until delivery not teratogenic
	Pyrimethamine (P), sulfadiazine, and folinic acid	(P) Loading dose: 50 mg every 12 h for 2 days; then 50 mg daily Sulfadiazine. Loading dose: 75 mg/ kg, followed by 50 mg/kg every 12 h (maximum, 4 g daily) Folinic acid: 10–20 mg daily (during and 1 week after (P) therapy completion)	a. women with proven infection acquired ≥ 17 AW b. women with suspected infection acquired ≥ 30 AW c. documented fetal infection (positive result of amniotic fluid PCR or abnormal US)	(P) is teratogenic half-life is 100 h Complete blood count twice a week (reversible neutropenia) (a) (b)
	Pyrimethamine (P) - sulfadoxine, and folinic acid	2 tablet (50 mg (P) 500 mg sulphadoxine each tablet) each 10 days Folinic acid: 50 mg weekly		Sulfadoxine half-life is 200 h. Potential for lethal hepatotoxicity (a) (b)
Infected infant	Pyrimethamine (P) - sulfadiazine, and folinic acid	(P) Loading dose: 2 mg/kg every 12 h for 2 days; then 1 mg/kg daily for 2 or 6 months; then same dose each alternate day or half dose daily Sulfadiazine: 50 mg/kg every 12 h Folinic acid: 20 mg each alternate day (during and 1 week after completion of (P) therapy)	Two months high dose regimen on subclinical onset; 6 months high dose regimen on symptomatic onset	1-y treatment; (P) half-life on infant is 60 h. CSF level are 10-20% of concomitant serum levels (a) (b) (c)
	Pyrimethamine (P) - sulfadoxine, and folinic acid	(P) 1.25 mg/kg – sulfadoxine 25 mg/kg each 10 days; folinic acid: 50 mg weekly	A pre-regimen with (P) and sulphadiazine for 2 months has been recently introduced. Loading dose: 1 mg/kg every 12 h for 2 days; then 1 mg/kg daily; Sulfadiazine: 50 mg/kg every 12 h for 2 months; then	For 10–24 months treatment duration; Sulfadoxine half-life on infant is 60 h (a) (b) (c)
	Prednisone	0.5 mg/kg each 12 h	a. CSF protein ≥1g/dL b. active chorioretinitis vision-threatening	Until inflammatory markers subsides (1–2 weeks apart)

Notes: Before starting sulphonamids, check for G6PDH deficit. (a) Sulphonamide discontinuation if hypersensitivity signs, including rash, Stevens-Johnson, and asthma, or micro-hematuria with urolithiasis occur; continue with pyrimethamine alone. (b) Urine alkalinisation and diuresis maintenance. (c) On absolute neutrophil count (N) < 1500/mm^3, double folinate dosage and repeat count after 3-4 days; on N count < 1000/mm^3 double folinate (20 mg/day) and stop Pyrimethamine until N >1000/mm^3; on N count < 500/mm^3, triple folinate (30 mg/day) and stop pyrimethamine until N > 1000/mm^3, repeat N count each 3–4 days. Seizure can occur on (P) regimen as overdosage consequence. (P) half-life is reduced while fenobarbital is administrated.

* None manufactured as pediatric formulation.

the National Enteric Surveillance Program NESP (20%) [27]. Nearly half of the children who eventually developed retinochoroiditis had already had their first lesion detected before age 4 months. The main retinochoroiditis determinants were US intracranial lesions and presence of clinical findings. The highest risk (80%) was found in cases with serious neurologic sequelae with the lower risk (12%) in subclinical cases. Only 2.7% of infected children developed bilateral visual impairment severe enough to affect eligibility for a driving license.

Sensorineural hearing defect is still a CT-associated sequela in untreated children. More severe ocular disease (frequency, size and multiplicity of retinochoroidal lesions) was shown in congenitally infected children in Brazil compared with EU, which might be a consequence of more virulent *Tg* genotypes predominating in Brazil, but rare in Europe [28].

In conclusion, CT is mostly a sight-threatening chronic eye disease in which occurrence of lesions during postnatal treatment contrasts with the regression or even disappearance of cranial lesions, and in which long-term follow-up to adolescence is necessary. Ophthalmologic surveillance should be more active in cases with cranial findings. Little is known about the consequence of visual impairment on life quality and comprehension subscale upon which impaired vision might impact. Further follow-up in recruited cohorts could allow better knowledge of long-term learning disabilities and behavioral problems in congenitally infected patients with and without intracranial lesions.

115.7 Therapy and Treatments

Despite the uncertainty of treatment benefits, prompt antibiotic prophylaxis in gestational toxoplasmosis to reduce vertical transmission and clinical severity, and in infected infants to reduce duration and severity and avoid permanent visual impairment is advocated. On unproven maternal infection, an expert and exhaustive discussion with parents could channel appropriate treatment choices based on presumed AW of infection and offer relief to parental anxiety.

A synergistic combination of folate inhibitors, pyrimethamine and sulfonamides, given with folinic acid is the standard regimen for gestational, fetal and congenital toxoplasmosis, with the following exceptions: 1) <16 AW treatment of early on gestation maternal infection to avoid teratogenic effects of pyrimethamine; 2) unlikely maternal diagnosis (any AW) to avoid side effects; 3) maternal infection <30 AW with negative fetal diagnosis and without US findings.

The potential for life-threatening arrhythmias exclude spiramycin from use in newborn infants [29].

Differences in treatment regimens among centers include type of sulfonamide, pyrimethamine dosage, and duration of postnatal treatment. One-year long regimen is the standard, whereas 3 months high dose continuous and 2 years low dose discontinuous were the shortest and longest regimens, respectively. On low dose discontinuous regimens, the potential for early and more severe sulphonamide side effects such as Lyell syndrome are counter-balanced by improved adherence to treatment. Dosage adjustment according to weekly complete blood count might be necessary on as much as 14–58% of cases because of neutropenia. Precautionally, glucose-6-phosphate dehydrogenase (G6PD) deficiency screening should be performed before sulfonamide administration.

Adjunctive steroids (1 mg/kg daily) might be introduced to shorten the course of vision-threatening retinochorioiditis such as that localized in the proximity of the optic nerve or the macula, and when cerebrospinal fluid (CSF) protein concentration is ≥ 1 g/dL suggesting encephalytis. Treatment reinstitution after a serological rebound is not indicated. If new eye lesions are detected, treatment reinstitution is contraindicated in the presence of healed lesions, whereas standard treatment should be given for 1–2 weeks after the resolution of acute phase in active lesions.

Guidelines for prenatal and postnatal treatment are summarized in Table 115.2.

Ventriculoperitoneal shunt placement might be necessary with frequent controls of adequate drainage suitability as patients usually require repeated shunting procedures. Compensatory strategies such as large print and "talking" books, camera magnification of materials, and spectacles to maintain best corrected visual acuity can help children compensate for the impact of the disease on cognitive function and quality of life.

Neonatal Bacterial and Fungal Infections

Mauro Stronati and Alessandro Borghesi

116.1 Introduction

Neonatal infection is the invasion of tissue by an infective organism. This may be considered early-onset when occurring during the first 72 hours of life (very early-onset if starting during the first 12 hours), and late-onset when occurring after the first 72 hours. Infections represent a major cause of mortality and morbidity in the neonatal intensive care units (NICUs), where reported incidences range from 6% to 33% [1], and up to 40% in neonates born before 28 weeks' gestational age or with birth weight < 1000 g (extremely low birth weight, ELBW) [2]. Septicemia accounts for 45–55% of all infections, followed by lower respiratory tract infections (16–30%) and urinary tract infections (UTIs, 8–18%) [1, 3].

In NICUs, Gram-positive bacteria and particularly coagulase negative staphylococci (CONS) are the most frequent pathogens associated with nosocomial infections (55–75%), followed by Gram-negative bacteria (18–31%) and fungi (9–13%) [1, 4].

The National Institute of Child Health and Human Development (NICHD) Neonatal Research Network reported that 61% of sepsis of very low birth weight (VLBW) infants was caused by Gram-negative organisms (*E. coli* in 44% of cases) and 37% by Gram-positive organisms (*S. agalactiae* [GBS] in 11% of cases), while 70% of late-onset infections were caused by Gram-positive bacteria, 18% by Gram-negative bacteria and 12% by fungal organisms [5, 6]. CONS were the most frequently isolated late-onset pathogens, accounting for 68% of infections caused by Gram-positive organisms, and for 48% of all infections. Other Gram-positive organisms included *S. aureus* (8% of all infections), *Enterococcus* spp. and group B *Streptococcus* (GBS). *Escherichia coli*, *Klebsiella*, *Pseudomonas*, *Enterobacter* and *Serratia* spp. were the most frequently isolated Gram-negative bacteria. *Candida albicans*, accounting for 6% all infections, was the third most frequently isolated organism.

116.2 Bacterial Infections

116.2.1 Etiology

116.2.1.1 Gram-positive Bacteria

Coagulase Negative *Staphylococcus* (CONS)

Colonization and infection by CONS usually occur nosocomially, particularly in VLBW infants [7] with an indwelling intravascular catheter (with higher risk for central venous catheters in place for prolonged times); an additional risk factor for CONS sepsis occurs with the use of lipid emulsions in solutions for parenteral nutrition [8, 9].

Staphylococcus aureus

Infections caused by *S. aureus* are most frequently nosocomial and may be superficial, involving skin (*impetigo bullosa*, staphylococcal scalded skin syndrome, breast abscess) and conjunctivae. Deep tissues may be involved (osteomyelitis and septic arthritis, pneumonia, meningitis, infection of ventricular cerebral shunts in neonates with post-hemorrhagic hydrocephalus and endocarditis) with or without associated septicemia [10] and may induce local pus (cerebral abscesses, empyema, pneumatoceles).

Infants with an indwelling central venous catheter or who have undergone surgical procedures are at increased risk of invasive *S. aureus* infections [11].

Enterococci

Account for a small proportion of nosocomial neonatal sepsis, but in the last two decades an increase in enterococcal

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

infections has been reported, as well as an alarming emergence of vancomycin-resistant Enterococci.

Group B *Streptococcus* (GBS)

GBS (*Streptococcus agalactiae*), the only species belonging to Group B of the Lancefield classification, is a Gram-positive diplococcus colonizing the enteric, genital and urinary tracts of 15–40% of pregnant women [12]. In the neonate streptococcal sepsis may be early-onset (onset during the first 6 days of life) or late-onset (onset at ≥ 7 days of life) [13].

Approximately 40–70% of infants born to GBS-colonized mothers acquire surface colonization at delivery, and, without intrapartum antibiotic prophylaxis, about 1% of colonized full-term infants develop early-onset streptococcal sepsis [13]. Maternal vaginal colonization by GBS usually precedes the development of early-onset sepsis. Other risk factors for early-onset streptococcal sepsis include maternal fever at delivery (> 38°C), premature rupture of membranes (PROM) if prolonged for more than 18 h before delivery, preterm birth, GBS urinary tract infection during pregnancy or at delivery [14]. Prematurity is the only identified risk factor for late-onset invasive streptococcal disease.

116.2.1.2 Gram-negative Bacteria

Gram-negative sepsis is less frequent than Gram-positive sepsis, but with higher mortality (36% in VLBW neonates) [6]. Gram-negative pathogens are mainly *Enterobacteriaceae* (*E. coli*, *Klebsiella*, *Serratia* spp.) and *Pseudomonas* (*P. aeruginosa*, *P. mallei*).

Enterobacteriaceae

Enterobacteriaceae colonize the enteric tract soon after birth. Invasion of the immature and/or injured mucosa and translocation of organisms to the bloodstream may cause late-onset sepsis, sometimes associated with necrotizing enterocolitis (NEC). Among Gram-negative bacteria, *E. coli* is the most frequently isolated organism in term and preterm neonates. In a survey of the Pediatric Prevention Network by Sohn et al, *E. coli* was responsible for 8.5% of all NICU infections [15]. Powdered infant formula milk has been implicated as a possible source of Gram-negative pathogens, e.g., a reported association between contamination of powdered milk by *Enterobacter sakazakii* and the occurrence of sepsis and NEC [16, 17].

Citrobacter

Citrobacter koseri, occasionally causing chorioamnionitis and urinary tract infections (UTIs) in pregnant women, may be vertically transmitted to the neonate causing sepsis and meningitis. Epidemic outbreaks in NICUs and nurseries have been described.

Pseudomonas

Organisms belonging to the *Pseudomonas* genus are preferentially transmitted through nosocomial routes of infection in NICUs. *P. aeruginosa* grows in wet environments such as humidified incubators [18] and ventilator circuits [19]. Patient-to-patient transmission through hands of healthcare workers is an important route of transmission [20]. *P. aeruginosa* may cause focal infections, e.g., pneumonia and severe conjunctivitis. In VLBW infants *P. aeruginosa* is highly virulent: Shah and Gallagher [21] reported a high incidence (39%) of systemic complications (bacteremia, meningitis, cerebral abscess, death) following *Pseudomonas* conjunctivitis. Sepsis by *P. aeruginosa* are associated with a high mortality rate (50-75%) [22].

116.2.1.3 Anaerobic Bacteria

Anaerobic bacteria account for less than 5% of all neonatal sepsis, with premature infants representing a substantial proportion of these cases. Sepsis caused by anaerobic bacteria is almost always associated with preterm maternal chorioamnionitis [23]; *Clostridium perfringens* and *Peptostreptococcus* spp. are responsible for the majority of cases of early-onset sepsis caused by anaerobic bacteria. Late onset sepsis caused by Gram-negative anaerobic bacteria (*Bacteroides fragilis*) has been associated with NEC or focal intestinal perforation. Particular virulence factors, such as pili, fimbriae and capsular polysaccharide, have been reported [24].

116.2.2 Diagnosis

Diagnosis of infection should be established soon after the onset of clinical signs of infection in order to start effective therapy as soon as possible. Signs are non-specific, but delaying antibiotic treatment may be lethal. Empirical antibiotics therapy (see below) should therefore be started before the results of investigations are available. The definitive diagnosis of infection is made by appropriate microbiological investigations, but hematological and biochemical investigations (Table 116.1) are also informative and will determine therapy.

116.2.2.1 Microbiological Tests

Isolation of a microorganism from a swab or from body fluid (blood, cerebrospinal fluid [CSF], urine) constitutes the gold standard for the diagnosis of infection and allows for adjustment of antibiotic therapy based on the antibiogram. However,

Table 116.1 Diagnostic tests in infants with suspected infection. Modified from [14]

Microbiological tests	Cultures (blood, cerebrospinal fluid, urines, swabs) Direct identification (*buffy coat*; Gram stain) Detection of bacterial antigens (electroimmunophoresis, agglutination, ELISA)
Laboratory tests	Total and differential blood count Neutrophils: immature/total C reactive protein Fibrinogen, platelet count Procalcitonin Serum A amyloid Citokines and soluble receptors (IL-6, IL-8, sCD-14, s-TREM)
Molecular diagnostics	Detection and amplification of bacterial DNA (gene coding for 16S RNA) or fungal DNA (gene coding for 18S RNA) by PCR

cultures may be falsely negative or positive, making the definitive diagnosis difficult,

False Negative

Blood cultures may be negative despite symptoms and signs of septicemia and even when disseminated bacterial or fungal infection is proven at autopsy. Sensitivity of blood cultures in neonates ranges from 8 to 73% in different studies [25].

Negative blood cultures in infants with sepsis may be due to the administration of antibiotics to the neonate or to the mother during labor, insufficient sample volume, or to a systemic inflammatory response due to non-infectious causes.

Diagnosis of sepsis has become more accurate after the introduction of sensitive and reliable culture tests as "BacTec" or "BacT Alert", that retain high sensitivity even with a small sample size (< 0.5 mL) [26].

False Positive

A single positive blood culture from a neonate with clinical signs of infection is considered evidence of sepsis. It has been suggested that two positive cultures may be required to confirm the diagnosis of CONS sepsis because of frequent contamination of samples [13]. Careful disinfection of the skin before taking blood and taking two blood cultures have been effective in reducing the contamination of cultures [27].

116.2.2.2 Laboratory Tests

Several laboratory tests can make the diagnosis of infection more accurate and timely, including hematologic tests (total and differential blood count) interleukin-6 (IL-6), IL-8, C-reactive protein (CRP), procalcitonin (PCT), serum A amyloid.

Total white blood cell count (abnormal if < 5000/μL or > 20,000/μL) and differential white blood cell count have highly variable degrees of sensitivity (17–90%) and specificity (31–100%) [28]. Thrombocytopenia (< 100,000/μL), white blood cell morphology, total neutrophil count, and the immature/total neutrophil ratio have a poor predictive value.

Blood IL-6 and IL-8 concentrations rise 12–24 hours before the onset of clinical symptoms and strongly predict infection. However, they are not routinely used by all laboratories because of the rapid fall in blood concentrations after the onset of sepsis and because of expense [29].

CRP has a 1000-fold increase in blood during an acute-phase response [25], and is not influenced by gestational age [30]. Serial measures of CRP seem to have the best predictive value during screening for sepsis, i.e., the sensitivity of a single CRP measurement is about 48–63%, increasing to 90% when the test is repeated 24–48 hours after onset of symptoms [13]. Normal serial measurements may be useful for excluding infection in a neonate with nonspecific symptoms and negative cultures [31] and in guiding the duration of antibiotic therapy.

Procalcitonin, a polypeptide precursor of calcitonin, is produced by hepatocytes and monocytes [25], has high sensitivity and specificity (87–100%) and increases during early and late onset sepsis. However, it is not generally available as an emergency diagnostic test, and is considered more accurate for late than for early onset sepsis [29, 32].

The diagnostic accuracy of the serum amyloid A has been recently evaluated. It is an acute-phase protein induced by IL-6 and IL-8 [29], and its diagnostic accuracy has been reported as higher than that of CRP in the diagnosis of both early and late onset sepsis [33, 34].

116.2.2.3 Molecular Diagnostics

The use of molecular techniques (polymerase chain reaction [PCR]) for the diagnosis of neonatal infections is still uncertain. The identification of bacterial nucleic acids in blood relies on PCR amplification of the gene for the 16S rRNA, which is present in bacteria but not in humans.

In a study of 548 samples from neonates with suspected sepsis that compared high sensitivity cultural tests (BacTec) with PCR amplification of the gene coding for the 16S rRNA, sensitivity, specificity, positive and negative predictive values were 96.0%, 99.4%, 88.9% and 99.8%, respectively. The time to obtain results was 9 hours and only 200 μL were required [35]. The high negative predictive value makes this test an important tool for limiting the excessive use of antibiotics in neonates with nonspecific symptoms.

116.2.3 Bacterial Sepsis

Sepsis is defined as the clinical syndrome characterized by a host systemic inflammatory response to invading pathogens.

For neonates, "microbiological sepsis" refers to the isolation of a microorganism from a blood culture of a baby with signs of infection and/or abnormal laboratory tests. "Clinical sepsis" is used when a neonate with evidence of infection has negative cultures [13].

116.2.3.1 Pathogenesis and Routes of Transmission

About 33–66% of neonates admitted to NICUs develop an infection (sepsis in 50%). Early onset sepsis (during the first 72–96 hours) is associated with maternal complications during pregnancy (preterm birth, premature rupture of membranes, chorioamnionitis). Pathogens associated with early onset sepsis are usually organisms of the maternal genito-urinary tract. Mortality rates range from 15 to 50% [14].

Late onset sepsis (after the first 72–96 hours of life) is usually caused by nosocomially transmitted or environmental organisms. Less commonly, maternal urinary tract organisms colonize the neonate causing later infection. Mortality rates range from 10–20% [14].

Neonates may become infected via several routes of transmission. An ascending amniotic infection is thought to be the main route of transmission for early onset sepsis. Maternal genital tract organisms (GBS, *E. coli*) ascend through the birth canal and infect the amniotic fluid either through intact amniotic membranes or, more commonly, after the rupture of membranes. Thus, vertically acquired organisms may be aspirated or swallowed by the fetus, penetrate immature mucosae into the bloodstream, and cause sepsis, often with pneumonia.

Late onset sepsis is generally acquired through horizontal or nosocomial routes of transmission (hands of healthcare workers or parents, water of ventilator circuits and incubators, biomedical instruments such as contaminated stethoscopes). Less commonly, a vertically acquired organism may colonize the neonate and cause infection.

Microorganisms pass into the bloodstream through loss of integrity of the skin and mucosae, and their translocation into deep tissues and bloodstream is increased by repeated trauma due to biomedical devices (endotracheal tubes, nasogastric tubes); alternatively, they may enter the circulation directly through a central venous catheter. Healthcare workers represent the main route of patient-to-patient transmission of microorganisms in the NICU.

Several risk factors predispose the neonate to infection and sepsis: maternal, extrinsic (nosocomial), and intrinsic (the individual susceptibility of the neonate to infection) [36].

Maternal risk factors include prolonged PROM (>18 hours before delivery), intra-amniotic infections, colonization of the maternal genital tract by GBS, maternal infections (UTI, listeriosis), obstetric invasive procedures (amniocentesis, intrauterine transfusions) and low socio-economic status.

Extrinsic risk factors include:

- Colonization. The likelihood of colonization of deep mucosal tissues (respiratory and gastrointestinal tracts) by hospital-acquired organisms is increased by the presence of biomedical devices (endotracheal tubes, nasogastric tubes). Invasive procedures that facilitate the translocation of colonizing organisms into the bloodstream include central venous catheters, total parenteral nutrition, exchange transfusion, chest drainage, prolonged intubation, frequent tracheal aspirations.
- Central venous catheters and total parenteral nutrition. The use of central venous catheters increases the risk of infection by 3.81–7-fold [4]. Freeman et al in the early 1990s reported that 14.9% of CONS neonatal infections were associated with the use of central venous catheters [9], and several subsequent studies have demonstrated a direct correlation between the duration of central venous catheter placement and the incidence of infection [1]. In a point prevalence survey by the Pediatric Prevention Network, neonates with a central venous catheter had a relative risk of infection of 3.8 (CI 2.3–6.3; $P < 0.001$) compared to infants without catheters, and the risk was 5.7 (CI 3.5–9.5; $P < 0.001$) for patients receiving total parenteral nutrition [15].
- Drugs. An association between systemic postnatal steroids for chronic lung disease and sepsis has been observed in several studies. Stoll et al [37] in a study on 371 VLBW neonates treated with dexamethasone at 14 days of life, showed that the incidence of infection was significantly higher in the treated than in the control group (22 *vs* 14%).

  The use of antagonists of the histamine type 2 receptor (H2-antagonists) for stress gastritis and gastroesophageal reflux increases the risk of both sepsis and NEC in preterm neonates [37, 38].

  Prolonged antibiotic therapy selects resistant bacteria and increases the risk of fungal infections [39]. Ampicillin, third generation cephalosporins and carbapenems select extended spectrum β-lactamase producing strains of Gram-negative bacteria that are resistant to several antibiotics, not only β-lactams. Similarly, vancomycin selects vancomycin-resistant enterococci and methicillin selects methicillin-resistant staphylococci [39].
- Formula milk. Breast milk is protective for sepsis in both term and preterm neonates. Hylander et al [40], in a study of 212 VLBW neonates, showed that the incidence of sepsis was significantly lower in those who were breast fed compared to those who were formula-fed (19.5% *vs* 32.6%; $P = 0.04$).
- Other risk factors include overcrowding, prolonged hospital stay, poor attention to good hygiene, low compliance to hand hygiene [41].

Intrinsic risk factors include:

- Birth weight and gestational age. The risk of sepsis increases with decreasing birth weight and gestational age at birth. In a survey conducted by the Neonatal Research Network, the incidence of sepsis was 43% in neonates with birth weight 401–750 g, 28% for 751–1000 g neonates, 15% for 1001–1250 g neonates, and 7% for

1251–1500 g neonates. Similarly, the incidence of sepsis was 46% for neonates < 25 weeks at birth, 29% for babies born at 25–28 weeks, 10% for babies at 29–32 weeks, and 2% for neonates > 32 weeks [6].

- Underlying diseases. Perinatal asphyxia, hyperbilirubinemia, galactosemia, malformations, patent ductus arteriosus, meconium aspiration syndrome and low Apgar scores increase the risk of infection [14].
- Immaturity of the immune system. Neonates have lower IgA levels and lower serum levels of complement factors. Several studies have demonstrated an immaturity in chemotaxis, phagocytosis, and cytotoxicity. Furthermore, maternal-to-fetal transplacental transfer of IgG occurs mainly during the third trimester of pregnancy and neonates with gestational age < 32 weeks have lower IgG levels and an immature humoral immune response [36]. For further details see Chapter 108.
- Gender. Although many studies have shown that male infants are more likely to develop neonatal infections, particularly by Gram-negative bacteria [42], studies by the NICHD Neonatal Research Network on early- [5] and late- onset sepsis [6] in VLBW infants failed to confirm this association.
- Bacteremia can be considered to be central venous catheter-related if a catheter has been in place for at least 24 hours or if it was removed less than 48 hours before the infection [3]

116.2.3.2 Clinical Features

The clinical features of neonatal sepsis are highly variable and depend on the causative organism, the site of the primary infection, neonatal age and gestation. The lower the gestational age, the more nonspecific the clinical features of sepsis. Thus, clinical features attributable to infection are nonspecific and may also be shown by non-infected neonates. Respiratory distress, disseminated intravascular coagulation, necrotizing enterocolitis, persistent pulmonary hypertension, diminished peripheral perfusion and septic shock, are frequently associated with sepsis [14]. Fanaroff et al [43] reported the following clinical signs of sepsis : apnea (55%), gastrointestinal symptoms (43%), dyspnea (29%), lethargy/hypotonia (23%), disturbances in white blood cell count (46%), metabolic acidosis (11%) hyperglycemia (10%). Bizzarro et al reported the following signs in neonates with late-onset sepsis: hypothermia (< 36.5°C; 41%), hyperglycemia (>140 mg/dL; 38%), apnea (38%), bradycardia (30%), hyperthermia (>38°C; 22%) and hypoglycemia (< 40 mg/dL; 7%) [44]. Organ-specific and systemic signs have been described (Table 116.2).

Table 116.2 Clinical signs of neonatal sepsis. Modified from [14]

General	Hypothermia, fever, poor feeding
Gastrointestinal tract	Anorexia, vomiting, diarrhea, abdominal distension, hepatomegaly
Respiratory tract	Cyanosis, tachypnea, dyspnea, apnea, respiratory distress
Cardiovascular	Pallor, cold skin, tachycardia, bradycardia, hypotension
Central nervous system	Irritability, lethargy, trembling, seizures, hyporeflexia, hypotonia, bulging fontanella, irregular breathing, acute crying
Blood	Petechiae, purpura, splenomegaly, pallor, jaundice, bleeding
Urinary tract	Oliguria

116.2.3.3 Prognosis

Both early and late onset sepsis increase hospital length stay [6], mortality and morbidity. Mortality increases with decreasing gestational age and depends on the causative microorganism, ranging between 26 and 42% for Gram-negative sepsis, 8.7 to 10.1% for Gram-positive sepsis, and 27 to 28% for fungi [1].

The Neonatal Research Network [6] reported that the overall mortality in VLBW neonates was 10%. Mortality in neonates with late onset sepsis was significantly higher than in neonates without late onset sepsis (18% *vs* 7%, $P < 0.001$). In that study, mortality was 11% in neonates with Gram-positive late onset sepsis, 36% with Gram-negative late onset sepsis, and 32% with fungal sepsis. *Pseudomonas* and *C. albicans* were associated with the highest mortality (44% and 74%, respectively).

The clinical course is usually less severe in Gram-positive compared with Gram-negative sepsis and fungi. In the Neonatal Research Network study [6], 76% of deaths due to Gram-negative late onset sepsis occurred during the first 7 days, and 24% after day 7. By contrast, only 25% of deaths due to CONS sepsis occurred during the first 7 days, and 75% after day 7. Seventy-three percent of deaths due to fungal sepsis occurred during the first 7 days and 27% after day 7 [6].

116.2.3.4 Therapy

Empirical antibiotic treatment should be started in every neonate (especially preterm neonates) with suspected infection. Antibiotics should be stopped after 48–72 h if laboratory and microbiological tests exclude initial symptoms being due to an infection [39, 42, 45].

A flow-chart for the management of the neonate with suspected sepsis is in Fig. 116.1. Antibiotic combinations should be used for empirical treatment. Ampicillin plus gentamicin is still the best antibiotic combination for early onset sepsis [39, 42]. Ampicillin is effective against enterococci, some Gram-negative bacteria (*E. coli*, *Proteus*, *Klebsiella*), GBS and *L. monocytogenes*. Aminoglycosides widen the antimicrobial spectrum, being effective against some ampicillin-resistant Enterobacteriaceae (some strains of *E. coli*, *Proteus*,

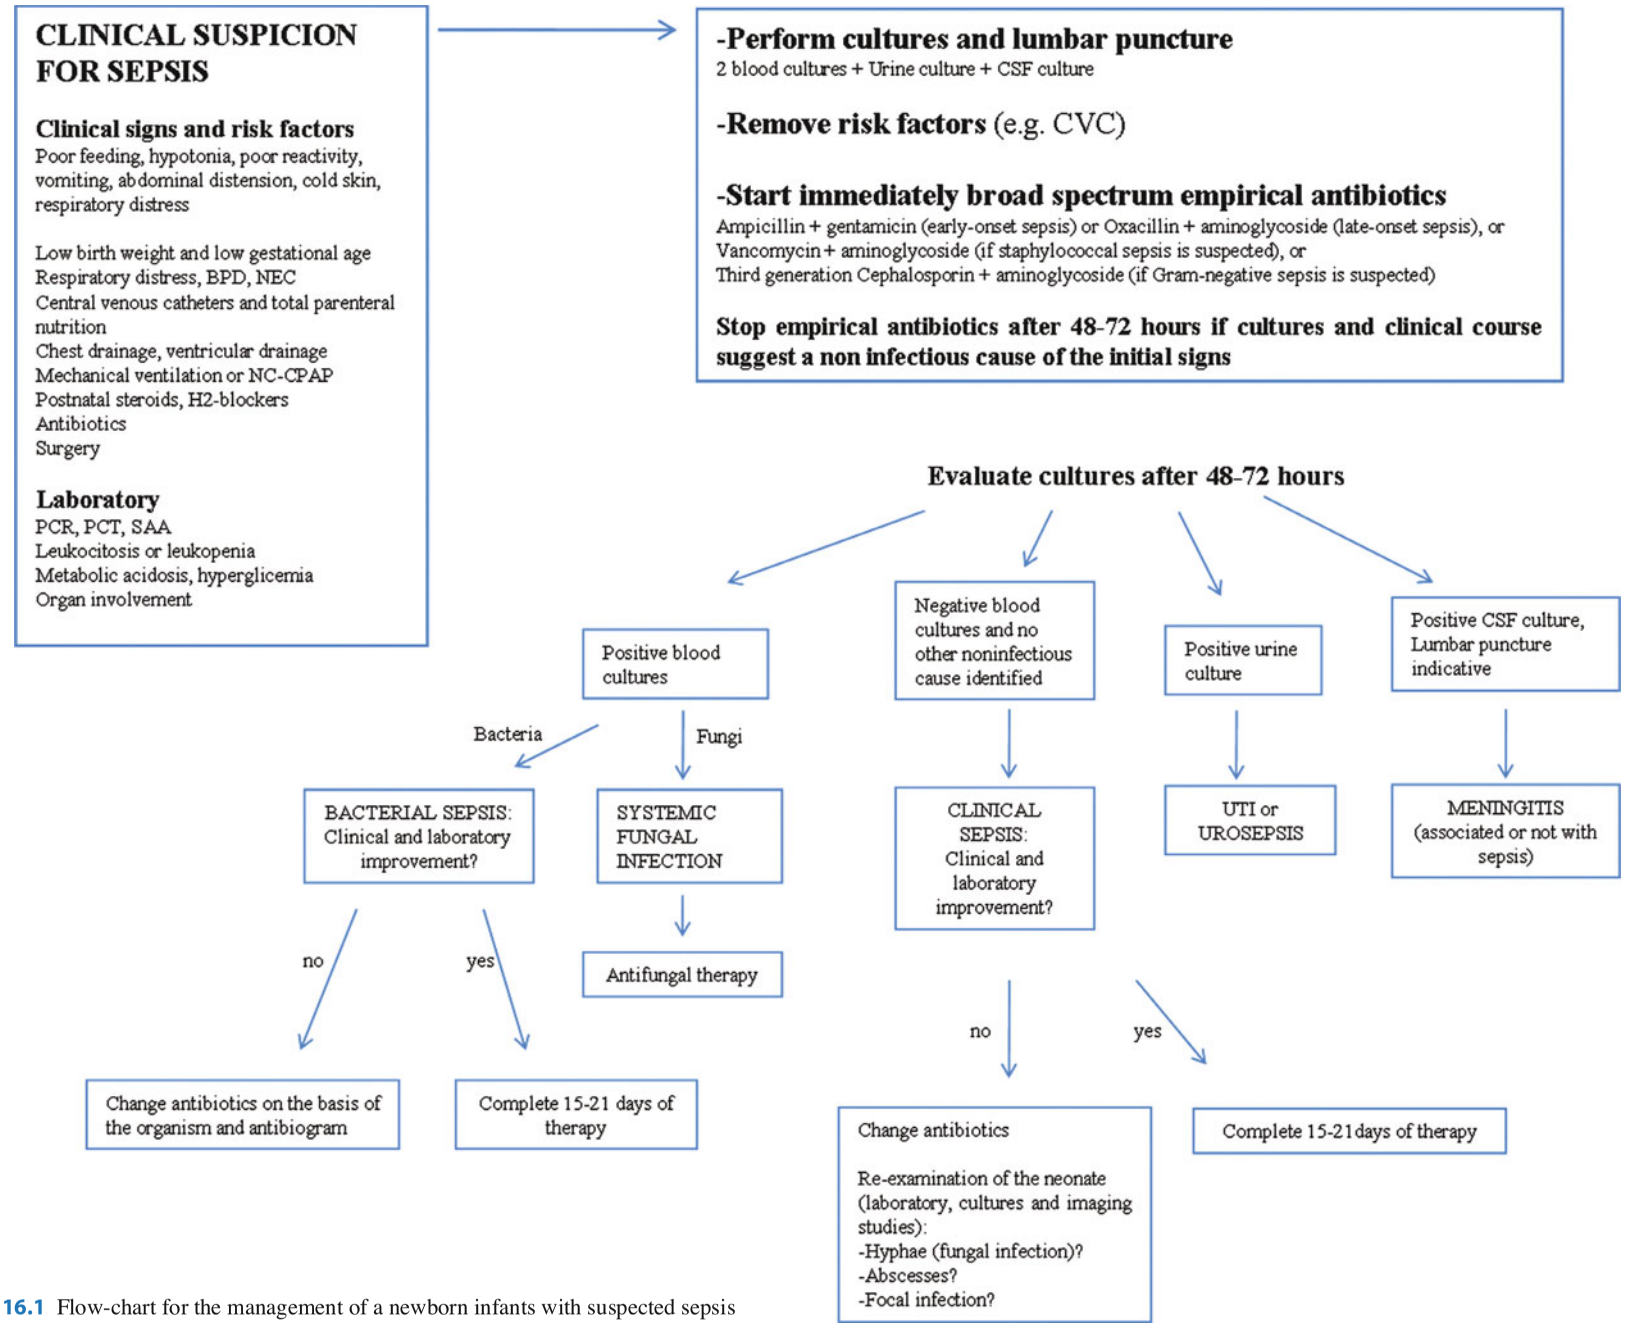

Fig. 116.1 Flow-chart for the management of a newborn infants with suspected sepsis

Klebsiella) and some ampicillin-resistant enterococci. Gentamicin is the most frequently used aminoglycoside in term and preterm neonates, and may be administered in a single daily dose. It is important to note the synergistic effect of ampicillin and gentamicin on several organisms.

Third generation cephalosporins are effective against the majority of bacterial pathogens and achieve high bactericidal concentrations in the CSF, but they should not be should not be used in the absence of proven bacterial sepsis to reduce the emergence of resistant organisms and fungal infections.

An antistaphylococcal penicillin (oxacillin or nafcillin or flucloxacillin) plus an aminoglycoside is an effective combination for late-onset sepsis [39].

When a staphylococcal infection by a methicillin-resistant *staphylococcus* is suspected or proven, vancomycin or teicoplanin should be used in combination with an aminoglycoside. Teicoplanin has fewer side effects (oto- and nephrotoxicity) and a longer half life than vancomycin, but the emergence of resistant organisms has been described less frequently with vancomycin administration.

Carbapenems may be an option for severe infections by multi-resistant organisms. Carbapenems have a very large antimicrobial spectrum (almost all Gram-negative and Gram-positive pathogens) and are resistant to known beta-lactamases. Meropenem is used because of a greater effectiveness against *Haemophilus influenzae*, Enterobacteriaceae and *Pseudomonas*. The incidence of seizures is lower than with imipenem and cilastatin.

The duration of therapy differs for Gram-positive and Gram-negative sepsis. A ten day antibiotic course seems to be reasonable for Gram-positive sepsis; longer courses may be necessary for Gram-negative sepsis and sepsis with organ involvement (2–6 weeks).

Antibiotic dosages are reported in Table 116.3.

Intravenous immunoglobulin may be useful in reducing the duration and severity of sepsis, especially in extremely low birth weight neonates. A dose of 500 mg/kg/day for 1–5 days to a maximum total dose of 2–2.5 g/kg has been suggested [46, 47].

Exchange transfusion may reduce the severity of sepsis. The volume to be transfused is 160–180 mL/kg, i.e., about twice the neonatal blood volume. Benefits depend on the removal of endotoxins, cytokines, and molecules that increase the permeability of vascular endothelium. Other advantages are attributed to the presence in the transfused blood of complement factors, antibodies and coagulation factors, and on improved lung and tissue perfusion and oxygen delivery because of the shift in the oxygen dissociation curve with the transfusion of adult hemoglobin. However, there is still little evidence of its effectiveness in reducing morbidity and mortality in patients with sepsis, and its use should be limited to patients with severe sepsis with septic shock and disseminated intravascular coagulation.

Fresh frozen plasma (10–20 mL/kg/day) may supply septic neonates with complement and coagulation factors. However there is no evidence that it benefits infants with sepsis and it is not recommended in the treatment of neonatal sepsis.

Recombinant human C activated protein modulates the clotting system and has been effectively used in adult patients with a reduction in sepsis- associated mortality. Clinical trials demonstrating safety and effectiveness of recombinant human C activated protein are lacking. Septic neonates are at high risk of bleeding, and preterm neonates are at risk of intraventricular hemorrhage. Recombinant human C activated protein increases the risk of bleeding and should be used only in the context of clinical trials [48].

Granulocyte-Colony Stimulating Factor (G-CSF) is important for differentiation, mobilization, and proliferation of bone marrow white cell precursors. A dose of 5–10 μg/kg/day subcutaneously or intravenously for 3–10 days may improve neutrophil counts in neutropenic neonates and reduce mortality in neonates with sepsis associated with severe neutropenia. Administration should be stopped for neutrophil counts greater than 20000/μL.

116.2.4 Meningitis

Isolation of a microorganism from a CSF culture is considered evidence of meningitis.

A national survey by the British Paediatric Surveillance Unit (BPSU) reported an annual incidence of viral and bacterial neonatal meningitis of 0.39/1000 births [49]. Etiology, risk factors, and pathogenesis of neonatal meningitis are similar to those for neonatal sepsis.

Early-onset meningitis (onset before the first 7 days of life) is usually caused by vaginal microorganisms transmitted vertically to the fetus (GBS, *E. coli*, *L. monocytogenes*). Late-onset meningitis (onset after the first 7 days of life) is caused by community or nosocomially acquired organisms (mainly Gram-negative bacteria and staphylococci) [13].

In a survey by the British Pediatric Surveillance Unit of 274 neonates (age < 28 days) treated for meningitis during the years 1996–1997, the most frequently isolated organism was GBS (25%), followed by *E. coli* (10%), *L. monocytogenes* (3%), other Gram-positive bacilli (6%), other Gram-negative bacilli (4%), *S. pneumoniae* (3%), and *C. albicans* (2%) [49]. There was a viral etiology in 7% of cases, and no organism was isolated in 35% of cases.

Stoll et al [50] reported on 9,641 VLBW newborn infants born at centers of the NICHD Neonatal Research Network. Gram-positive bacteria (63%) were most frequently associated with the first episode of late-onset meningitis and CONS accounted for 29% of cases. *Enterococcus* spp. accounted for 13%, *S. aureus* for 8%, and GBS for 7% of cases. Gram-negative bacteria were associated with 19% of cases of late-onset meningitis (*E. coli* accounting for 7%). Fungal organisms were associated with 18% of cases and *C. albicans* accounted for 13% of cases.

Table 116.3 Suggested dosage schedules for antibiotics used in newborns[a]

		Dosage (mg/kg) and interval of administration				
		Weight <1200 g[f] Age	Weight 1200–2000 g Age		Weight >2000 Age

i.m. intramuscular, *i.v.* intravenous, *ODD* once-daily dosing, *p.o.* oral, *SDD* standard daily dosing.

Frequently, meningitis is associated with, or is a complication of, neonatal sepsis, but there may be meningitis without bacteremia [51, 52]. In the study of the NICHD Neonatal Research Network, meningitis occurred in 7% VLBW neonates with positive blood cultures compared with 1.5% with negative blood cultures (P <0,001), about one third of neonates with meningitis (45/134) had negative blood cultures [50].

Microorganisms may reach the central nervous system and the meninges through breaks in the skin and consequent invasion of soft tissues and cranial sutures, but in many cases organisms reach the choroid plexus by a hematogenous route [42].

The clinical diagnosis of meningitis in the neonate is often difficult (especially in the preterm neonate) because clinical signs are often nonspecific and subtle. Meningitis can occur without systemic spread of the microorganism, and sometimes it is suspected late during the course of the disease when antibiotic treatment has already been started. Thus, the risk of underestimating the incidence of meningitis and of undertreating an infant with meningitis is very high [53].

Clinical signs of neonatal meningitis are similar to those of neonatal sepsis: fever, lethargy, vomiting, anorexia, respiratory distress, apnea, seizures, irritability, jaundice, bulging fontanelle, and neck stiffness. Perlman et al [54] reported 10 cases of late onset meningitis where the age at onset was 20 ± 14 days. Clinical signs were nonspecific: apnea and bradycardia in eight neonates, abdominal distension in 5, hyponatremia (< 130 mEq/L), oliguria and weight gain (syndrome of inappropriate secretion of antidiuretic hormone) in three. Specific signs were observed in three neonates: seizures in two and 3rd cranial nerve palsy in one. Cranial US abnormalities were found in seven out of 10 neonates (70%) and included: progressive enlargement of cerebral ventricles (six cases), thalamic echolucency (three cases), ventriculitis (four cases) and cystic leukomalacia (one case). Placement of a ventricular shunt was necessary in all six cases with enlargement of cerebral ventricles.

The diagnosis of meningitis depends on lumbar puncture for examination of the cerebrospinal fluid (cell count, chemistry and cultures). Imaging techniques (ultrasonography, magnetic resonance imaging) are mainly useful for prognosis or to establish whether there are complications.

There is debate about whether a lumbar puncture should be always performed in the investigation of an infant with suspected sepsis. Although cardiovascular and respiratory instability may often preclude the immediate performance of the procedure, the risk of undertreatment is very high. Several authors recommend examination of the cerebrospinal fluid as routine during the investigation of suspected sepsis and not only when meningitis is suspected [52].

Garges et al [51] evaluated the diagnostic accuracy of cell count and chemistry of the cerebrospinal fluid in 9,111 neonates ≥ 34 weeks: 95 had a microbiological diagnosis of meningitis. In their study, neither white blood cells nor protein or glucose levels in cerebrospinal fluid were accurate predictors of neonatal meningitis. Infants with culture proven meningitis had a mean of 477 white blood cells/mm^3 (0–15,900; interquartile range 38–1950) in the cerebrospinal fluid, higher than infants without meningitis. However, the authors observed that about 5% of infants with bacterial meningitis had 0–1 white blood cells/mm^3 in the cerebrospinal fluid, and about 10% of infants with bacterial meningitis had a white blood cell count in the cerebrospinal fluid ≤ 3/mm^3. The sensitivity and specificity for bacterial meningitis of a white blood cell count in the cerebrospinal fluid > 0/ mm^3 were 97% and 11%, respectively. If a cut-off value of > 21/mm^3 was used, sensitivity and specificity were 79% and 81% respectively. Glucose and protein levels are also very variable and poor predictors of culture-proven meningitis. However, the cell content and biochemical examination of the cerebrospinal fluid remains invaluable in the management of an infant with suspected meningitis while culture results are awaited. Suspected bacterial or fungal meningitis should always be confirmed by a positive cerebrospinal fluid culture.

The choice of antibiotics is the main tool for the treatment of meningitis, and should take account of potential pathogens (maternal or nosocomial) and their spectrum of sensitivity, based on patterns of sensitivity of previous isolates). To treat all potential pathogens, a combination of three antibiotics should be considered for initial empirical antibiotic therapy (usually ampicillin with a third generation cephalosporin and an aminoglycoside). Once culture results are available, antibiotic therapy can be modified and one antibiotic can be withdrawn on the basis of the isolated organism and its sensitivity pattern.

Ampicillin is effective against GBS and *L. monocytogenes*, which is resistant to third generation cephalosporins. In GBS meningitis, suggested by Gram stain of the cerebrospinal fluid or confirmed by culture, high doses of ampicillin (up to 300–400 mg/kg/day) or penicillin (up to 450,000 U/kg/day) should be used in combination with an aminoglycoside (usually gentamicin) [55].

Third generation cephalosporins are effective against several Gram-negative bacteria and rapidly achieve therapeutic concentrations in the cerebrospinal fluid (50–100-fold the MIC). This is in contrast to other antibiotics, such as aminoglycosides (which reach concentrations 2.5-fold the MIC) [13]. Cefotaxime is effective against the great majority of Gram-negative pathogens but not against *P. aeruginosa* (which is sensitive to ceftazidime).

For multiresistant organisms, meropenem together with an aminoglycoside may be a reasonable choice.

Antibiotic therapy should be started as soon as possible and continued for at least 21 days. The effectiveness of the initial empirical antibiotic therapy should be proven by a negative cerebrospinal fluid culture, performed 24–48 h after the onset of symptoms and a lumbar puncture for cerebrospinal fluid culture before the withdrawal of the antibiotic treatment. If the cerebrospinal fluid is not sterile at 24–48 hours, a focal infection of the brain (cerebral abscess, subdural empyema,

obstructive ventriculitis) should be suspected and excluded by imaging techniques [55].

An herpetic encephalitis should be always considered in a neonate with suspected meningitis. Aciclovir (20–30 mg/kg every 8 hours) should be started when Gram staining of the cerebrospinal fluid is negative and should be withdrawn when the herpetic infection has been excluded [55].

No consensus has yet been reached on the effectiveness of corticosteroid therapy with dexamethasone to improve the prognosis of infants with meningitis, and no randomized clinical trials have been performed.

Neonatal meningitis has a high mortality and morbidity. In the BPSU survey [49], the mortality rate for neonates with meningitis during 1996–7 was 6.6%, although the figure was high, it was less than the 19.8% reported by a previous study in 1985–1987.

The neurologic prognosis following neonatal meningitis is generally poor. In a study of 274 babies, who developed meiningitis at ≤ 28 days, there were mild-to-moderate neurologic disabilities in 12% of babies with birth weight > 2500 g, 31% for babies with birth weight 1500–2499 g and 44% for babies with birth weight < 1500 g [49]; 7.3% had severe disability, 18.2% moderate disability, and 24.1% mild disability [56]. Neurologic sequelae following neonatal meningitis include learning and language defects, motor disorders, seizures, hearing and visual defects, and behavioral disturbances.

116.2.5 Pneumonia

Neonatal pneumonia may be of early or late onset. Some authors define early-onset pneumonia as pneumonia during the first 48 hours of life, and late-onset pneumonia after the first 48 hours of life. Other reports define pneumonia as early-onset when arising during the first 7 days of life and late-onset when onset as occurring after the first week of life.

Early-onset neonatal pneumonia is caused by pathogens that colonize the birth canal or infect the amniotic fluid (especially after prolonged rupture of membranes or in the presence of chorioamnionitis) and that are inhaled by the fetus during labor. Symptoms may present at birth as neonatal respiratory distress or appear during the first days of life. Neonatal pneumonia is often associated with fetal asphyxia; the mechanism for this association is not certain but some authors hypothesize that organisms are inhaled during gasping movements caused by asphyxia [57, 58].

Pathogens may be acquired in utero and localize to the fetal lung causing congenital pneumonia. Congenital pneumonia is rarely a focal infection. It presents most often as a part of a systemic congenital infection, acquired transplacentally because of a systemic maternal infection associated with chorioamnionitis or, less frequently, in association with asymptomatic maternal infections, e.g., human immunodeficiency virus, cytomegalovirus, *L. monocytogenes*, *M. tuberculosis*, *T. pallidum* may cause congenital pneumonia) [57].

The term intrauterine pneumonia defines an inflammatory disease of the lungs, which is frequently associated with low Apgar scores, respiratory distress syndrome, or even intrauterine death of the fetus. It is usually diagnosed at autopsy in stillbirths or in babies dying during the first days of life. The etiology may be infectious (amniotic infection) or non-infectious (fetal asphyxia) [59].

Late-onset neonatal pneumonia may be acquired or may represent the clinical evolution of an infection acquired in utero.

Pathogens that cause pneumonia in the neonate are similar to those responsible for sepsis and meningitis [57, 58]. In one study of 261 neonates admitted during the first 4 days of life with respiratory distress, cultures of tracheal aspirates, blood and cerebrospinal-fluid demonstrated a prevalence of Gram-positive bacteria (71%) compared with Gram-negative bacteria (29%). GBS (19%) was the most frequently isolated Gram-positive organism, followed by *S. Epidermidis* (13%), *S. aureus* (10%), and *S. Pneumoniae* (10%). Among Gram-negative bacteria, *E. coli* was the most frequently isolated (13%), followed by *H. influenzae* (6.5%), and *Proteus mirabilis* (6.5%) [60]. The WHO young infant study (studying neonates aged 7–29 days) reported *S. pneumoniae* as the most frequent etiologic agent of late-onset community-acquired neonatal pneumonia, followed by *S. aureus*, *Klebsiella*, and *S. epidermidis* [61].

Other causes of neonatal pneumonia are:

- *Treponema pallidum*, frequently associated with a poor clinical condition and severe hypoxemia.
- *Chlamydia trachomatis*, causing a characteristic form of pneumonia with hyperinflation and diffuse bilateral infiltrates of the lungs on chest X-ray, sometimes with a peripheral blood eosinophilia and the diagnosis is confirmed by an increase in anti-*Chlamydia* IgM.
- *Mycobacterium tuberculosis*, acquired transplacentally or following inhalation of amniotic fluid, and causing pneumonia with a nonspecific, clinical course, which may be chronic or acute and which is characterized by multiorgan involvement.
- *L. monocytogenes*, responsible for fulminant sepsis, sometimes associated with pneumonia [58].

The differential diagnosis of neonatal respiratory distress should include viral pneumonia as possible etiology. Viruses causing pneumonia in the neonate include respiratory syncytial virus, metapneumovirus, influenzavirus, parainfluenzavirus and adenovirus.

Clinical manifestations of neonatal pneumonia include focal signs of infection (e.g., respiratory distress) and general signs of infection (poor feeding, lethargy, hypothermia or hyperthermia) [62]. In three studies of neonates with radiologically confirmed pneumonia, signs included tachypnea (60–89%) and increased respiratory effort (in more than 80%) [63–65].

The differential diagnosis of neonatal pneumonia includes diseases associated with respiratory distress (e.g., hyaline

membrane disease, transient tachypnea of the newborn, meconium aspiration syndrome, and asphyxia). Nonspecific signs of infection are similar to those of other neonatal infections.

Difficulties in the diagnosis of neonatal infections depend on the poor specificity of clinical signs, imaging techniques, and laboratory tests. Guidelines from the Centers for Disease Control and Prevention-National Nosocomial Infections Surveillance System included criteria for the diagnosis of pneumonia for infants aged <1 year [66]. The diagnosis of pneumonia is made on the basis of a progressive infiltrate on chest radiography associated with the isolation of a pathogen. However, pulmonary infiltrates on chest radiography may be due to other disease processes: meconium aspiration syndrome, atelectasis and bronchopulmonary dysplasia [66].

In ventilated patients, ventilator-associated pneumonia (VAP) is an extremely difficult diagnosis, particularly in preterm infants. Stolfi et al [3] defined VAP as a pneumonia in a ventilated infant in the presence of the following: a) onset after at least 24 h of mechanical ventilation; and/or b) onset not later than 48 hours after withdrawal of mechanical ventilation. Apisarnthanarak et al [67] reported 211 newborns ventilated for more than 48 h: signs of VAP included hypothermia (77%), tachypnea >75/min (65%), increase in bronchial secretions (50%), bradycardia <100/min (35%), fever (23%) and apnea (15%). Laboratory findings included purulent tracheal aspirate (> 25 leukocytes per high power field) (46%) and thrombocytopenia (15%).

Mechanical ventilation is the greatest risk factor for nosocomial pneumonia [59]. Humidification systems and ventilator circuits represent a source of organisms, mainly *P. aeruginosa*. In a study on 170 newborn infants ventilated for more than 48 h, Petdachai [68] found that an umbilical catheter (P = 0.007), respiratory distress syndrome (P = 0.03) and an orogastric tube (P = 0.01) were all independent risk factors for VAP.

Empiric treatment is based on the combination of two antibiotics, ampicillin with an aminoglycoside (usually gentamicin). If a staphylococcal infection is suspected (pneumatoceles, empyema, skin abscesses or pustules, or associated omphalitis) an antistaphylococcal penicillin (cloxacillin, flucloxacillin) or vancomycin should be used instead of ampicillin. Before antibiotic treatment, blood and urine cultures should always be performed to guide treatment in case first line empiric antibiotic therapy is ineffective. Duration of the antibiotic course depends on the microorganism: Gram-negative or GBS pneumonia should be treated for at least 10 days, but longer courses are needed for staphylococcal pneumonia (3–6 weeks). *C. trachomatis* pneumonia should be treated with a macrolide (erythromycin 50 mg/kg/day in 4 doses) for 2 weeks.

Treatment of pneumonia should include the treatment of hypoxemia (supplemental oxygen and, if necessary, mechanical ventilation), drainage of pleural purulent effusions, and the maintenance of hydration status and ion balance.

116.2.6 Urinary Tract Infections (UTI)

UTI is generally defined as the presence of an organism in the urinary tract, which is usually sterile. Urosepsis is the isolation of the same microorganism from urines and blood.

In the neonate, the incidence of UTIs is 0.1–1% increasing to 14% in febrile neonates [69]. During the first months of life, the incidence is higher in males than in females, and this ratio is reversed after the third month [70].

Kanellopoulos et al [69] studied 62 term neonates with UTI (51 males and 11 females). The pathogen most frequently isolated was *E. coli* (73%) followed by *Proteus mirabilis*, *Klebsiella pneumoniae*, *Klebsiella oxytoca*, *Proteus vulgaris*, *Pseudomonas aeruginosa*, *Enterobacter aerogenes* and *Morganella morganii*. Other potential pathogens for UTIs include GBS, *S. aureus*, *Enterococcus* spp. [71]. *E. coli* is most frequently isolated in infants without vesico-ureteral reflux, while in the neonates with vesico-ureteral reflux other Gram-negative bacteria are most frequently isolated.

During the first 48–72 h, the urine is usually sterile. In a retrospective study of 369 neonates with signs of infection by Tamim et al, blood and urine samples were cultured during the first 24 h: no urine cultures were positive, while blood culture was positive in eight neonates (2%) [72].

Lower urinary tract colonization after birth is the first step in the pathogenesis of a UTI in a neonate with risk factors for UTIs. Such risk factors include obstructive uropathies (malformations and functional abnormalities of the urinary tract, including urethral valves and phimosis, reported in up to 4% of cases) and vesico-ureteral reflux, reported in 25–40% of cases [69, 70]. A UTI is often the first clinical sign of a urinary tract malformation.

During the neonatal period, UTIs are characterized by an increased incidence of ascending infection and associated sepsis [71]; organisms that enter the lower urinary tract may easily reach the upper urinary tract and infect the kidney, leading to a systemic infection (urosepsis), or, less frequently, the kidney may represent the secondary localization of a sepsis [73].

Clinical signs of UTIs overlap with those of sepsis; therefore, every neonate with age > 3 days with suspected sepsis should undergo diagnostic evaluation for UTIs [74]. The presence of fever has been always considered in clinical practice as an indirect sign of upper urinary tract involvement [71].

Kanellopoulos et al [69] reported the most common signs of UTI during the neonatal age as fever (77% of cases), poor feeding (48%), lethargy (26%), jaundice (18%), diarrhea (13%), vomiting (8%) and failure to thrive (7%). In their study, the mean age at onset was 20 days for males and 18 days for females. 24% of neonates (14/51 males, 1/11 female) had vesico-ureteral reflux; there was pyelonephritis in 39% , and urinary tract malformations in 8% (including hydronephrosis and uretero-hydronephrosis, pyelectasis, double collecting system, posterior urethral valves).

UTI should be excluded for every neonate with nonspecific clinical signs, such as poor feeding and failure to thrive.

The diagnosis of UTI should be confirmed by positive urine culture. As urines may be easily contaminated, UTI is defined as the isolation of at least 100 colony forming units/mL (CFU/mL) from a specimen obtained by suprapubic bladder aspiration, or at least 10,000 CFU/mL from a sterile bladder catheterization [74]. In preterm infants, lower colony counts may indicate a UTI, especially in the case of Gram-negative bacteria or *Candida* spp. [13]. However, Hoberman et al [75] found that 65% of cultures with bacterial counts of 10,000–49,000 CFU/mL yielded Gram-positive bacteria or mixed flora, both suggestive of contamination rather than infection. Specificity of microbiological diagnosis may be improved by indirect signs of UTI (pyuria, bacteriuria).The false positive rate is further increased by using bags for urine specimens [71]. Urinary leukocyte esterase, nitrites, and leukocyte count and an increase in blood inflammatory markers suggest upper UTI. Sepsis and meningitis are frequently associated with UTI in the neonate, and a blood culture should be always performed before starting antibiotic. A lumbar puncture should be considered for febrile babies [73].

Treatment should be started immediately after taking blood for culture. Sepsis cannot be excluded until blood cultures results are available and the initial empirical antibiotic therapy for UTIs is identical to that for sepsis [73]. A penicillin (ampicillin) and an aminoglycoside are the first choice antibiotics; culture results and antibiograms should guide subsequent changes of treatment. Therapy should last for 10–14 days, but longer courses may be needed for relapses or malformations. A second urine culture should be taken 48 h after starting therapy to assess the effectiveness of treatment [73].

About 25–40% of infants with UTI suffer from vesico-ureteric reflux, defined as retrograde flow of urine in the ureters and/or the collecting system of the kidney. This is associated with a high risk of pyelonephritis, which, especially when relapsing, is associated with renal scarring, hypertension, and chronic renal insufficiency [76, 77]. The American Academy of Pediatrics recommended a renal ultrasound (US) and voiding cystourethrogram in all infants with a febrile UTI during the first 24 months of life [76].

A renal US should be performed in all neonates with UTI. Although its ability to detect scars in the renal parenchyma is limited, it allows for detection of dilation of the renal collecting system and the exclusion of renal abscesses or obstructive diseases [78].

A voiding cystourethrogram will detect vesico-ureteral reflux and assessment of its severity (grades I to V, from mildest to severe). It should be performed within the first 3–6 weeks in all neonates with a febrile UTI. As the risk for relapse is high in the presence of a vesico-ureteral reflux, antibiotic prophylaxis should be started after antibiotic treatment until completion of imaging studies to assess reflux [76, 79]. Prophylaxis should be continued in neonates with vesico-ureteral reflux. Prophylaxis should be performed with a single daily oral antibiotic dose given at night at half of the normal dosage. Cephalosporins and amoxicillin are the most used antibiotics.

Antibiotic prophylaxis may be appropriate for low grade reflux (grades I-II) which frequently resolves spontaneously during the first year of life, but grade V reflux that should be treated surgically. Treatment for grade III, IV or V reflux should be decided with the involvement of a pediatric urologist and should take account of the probability of spontaneous resolution, the presence of renal scars, and the failure of medical treatment (poor compliance, appearing of resistance to antibiotics, side effects of antibiotics).

Renal scintigraphy (with dimercaptosuccinic acid, DMSA) is indicated in all infants with grade III, IV or V reflux or in the presence of renal injury at US.

The follow-up of a UTI includes urine culture and urinalysis for every unexplained febrile episode. The presence of vesico-ureteral reflux should be monitored (annually or less frequently) until resolution or surgical correction.

116.2.7 Osteomyelitis and Septic Arthritis

Osteomyelitis is the infection of the bone and/or the bone marrow. It may be acute or chronic, but in the neonates the course is usually acute. Septic arthritis is the infection of a joint and may present in isolation or as a complication of osteomyelitis [80]. Osteomyelitis is infrequent during the neonatal period with a reported incidence of 1–3/1000 admissions in NICU [81].

The pathogen most frequently isolated from infants with osteomyelitis or osteoarthritis is *S. aureus*. Other organisms include *C. albicans*, *E. coli*, GBS and CONS [80, 81]. Wong et al [81] studied 94 infants aged 0–3 months and investigated for osteomyelitis: in 28 out of 94 a microorganism was isolated, including methicillin-sensitive *S. aureus* in 16 cases, methicillin-resistant *S. aureus* in seven cases, *E. coli* in three cases, and GBS in two cases.

Organisms may reach the bones by hematogenous spread, which seems to be the most frequent route of infection in neonates, particularly those with vascular catheters. Less often, infection of the skin and tissues surrounding the bones are the source of infection [80].

During the neonatal period, osteomyelitis is frequently associated with arthritis. This association is explained by the vascular supply to the epiphysis and metaphysis in the newborn. In adults and older children, the blood supply for each structure is provided by separate vascular networks, while in the neonate before ossification, epiphyseal cartilage growth depends on metaphyseal vessels. Through these vessels, infection reaches the epiphysis and the joint causing septic arthritis [80].

Risk factors for osteomyelitis include preterm birth, the coexistence of a UTI or neonatal respiratory distress, and presence of vascular catheters [80, 82]. Wong et al [81] reported 30 infants with osteomyelitis, of whom 17 were mechanically ventilated preterm neonates, and four were term neonates undergoing intensive care.

Clinical suspicion of osteomyelitis must be confirmed by laboratory and radiological tests. During the early stages, clinical signs may be non-specific but swelling or immobility of the limb are common. Physical examination is often characterized by functional limitation of the involved limb, pain during passive movements, joint immobility, swelling, edema and soft tissue inflammation. General signs of infection include poor feeding and/or irritability; fever and abnormal inflammatory markers are not always present in the early stages. In a study of 25 newborn infants, Narang et al [83] reported functional limitation of the involved limb (64%) and local swelling (60%) as the most frequent clinical findings at the time of onset of ostemyelitis; multi articular involvement was reported in eight cases (32%). Hip (48%) and knee (48%) were most frequently involved. Wong et al [81] reported that osteomyelitis was multifocal in 40% of cases and associated with septic arthritis in 47%. In their cohort, fever was present in about 10% of cases.

Septic arthritis is a medical emergency. The destruction of the epiphysis by the infectious process and avascular necrosis caused by compression of the joint by the inflammatory exudate may result in a long-term, severe, functional limitation of the involved joint. The prognosis depends on the rapidity of the diagnosis and institution of appropriate treatment. Osteomyelitis should be suspected in every neonate with local pain, functional limb limitation, or systemic clinical signs without a known source of infection [80].

Microbiological confirmation to guide the choice of antibiotics or to change treatment in the case of lack of therapeutic response is desirable but only available in no more than 50–80% of cases [84]. Deshpande et al [85] reported 15 newborns with positive blood culture in only seven cases (47%) and synovial fluid culture in nine cases (60%). The isolation of a microorganism should be attempted by culture of blood, tip of the central venous catheter, and, if available, synovial fluid, including Gram staining.

X-rays of the involved limb may show nonspecific signs of osteomyelitis and septic arthritis such as edema of soft tissues and an increase of the articular space caused by the presence of a purulent exudates. Cortical osteolysis, a sign of bone necrosis, is seen only in the late stages of the disease. The ability of X-rays to detect lesions characteristic of osteomyelitis is limited in neonates because soft tissue edema and enlargement of the articular space are not always evident, and areas of osteolysis are rarely visible in the early phases, appearing as late as 10–21 days after the onset of symptoms [80, 84]. Despite these limitations, X-rays remain a relevant technique for the confirmation of osteomyelitis [86].

Ultrasound is a highly variable technique that depends on the experience of the physician; a negative result does not exclude osteomyelitis. However, it may be useful during the diagnostic workup of suspected osteomyelitis, showing soft tissue edema, subperiosteal abscesses or joint effusions [80, 87].

Bone scintigraphy with 99m-technetium enables diagnosis in 80–100% of cases. It has high sensitivity in detecting single or multiple foci of infection during the first 48–72 h after the onset of signs. These are seen as hyperperfused areas (expression of inflammation) or as "cold spots" (in areas where edema has reduced vascularization) [84]. However, in the neonatal period this technique has a lower diagnostic value than in older children and its use should be limited to neonates with a negative radiograph and clinical evidence of osteomyelitis.

Computerised tomography enables early detection of necrosis and periosteal reaction and may be useful in the diagnosis of osteomyelitis of the bones of the skull (e.g., after infection of a cephaloematoma). MRI may show abscesses and periosteal involvement, but may require sedation of the infant [86].

If a purulent synovial effusion is suspected, puncture should be always performed to reduce pressure within the joint and enable appropriate microbiological investigations.

Success of treatment depends on the appropriateness of antibiotics and the removal of the purulent effusion. The empirical antibiotic combination should take account of known likely etiologic agents: *S. aureus*, GBS, and Gram-negative bacteria. Intravenous vancomycin together with an aminoglycoside or a third generation cephalosporin (usually cephotaxime) are suitable options.

Therapy should be modified on the basis of the isolated organism and its sensitivity spectrum. If no microorganism is isolated, the initial empirical treatment should be continued until there is clinical improvement. Lack of response to initial antibiotic therapy should raise the suspicion of antibiotic resistance or the presence of an abscess, to be investigated by appropriate imaging.

Antibiotic therapy should be continued for at least 4–6 weeks or longer and until the clinical condition, radiological and laboratory investigations indicate resolution. Courses shorter than 3 weeks are associated with a high risk of relapse.

Estimates of the frequency of residual complications following osteomyelitis during the neonatal period vary from 6 to 50%. They are due to bone growth abnormalities, asymmetric limb size, gait defects and pathologic fractures [84, 85]. Factors affecting prognosis include the delay between the onset of symptoms and start of antibiotic treatment, the duration of antibiotics, and which joint is affected [84, 85]. The risk for bone deformities is highest for the hip and knee and diagnostic delays longer than 3–4 days [86].

116.2.8 Miscellaneous

116.2.8.1 Ophthalmia Neonatorum

Ophthalmia neonatorum (neonatal conjunctivitis) is the term for any purulent conjunctivitis starting during the first 28 days of life [88, 89]. It may have infectious and non infectious etiologies. Non infectious conjunctivitis is mainly chemical

conjunctivitis following prophylaxis of ophthalmia neonatorum with 1–2% silver nitrate. Infectious causes were identified by Amini et al [88], who reported 198 neonates with conjunctivitis. Bacteria included *S. aureus* (31%), *E. coli* (23%), *S. epidermis* (22%), *Klebsiella* (10%), *N. gonorrhoeae* (3%), *C. trachomatis* (2%), and *Pseudomonas aeruginosa* (2%). Viruses have also be implicated [90–92]. In developed countries, the most frequently isolated pathogen is *C. trachomatis*, with a reported incidence in the USA of 8.2/1000 live births [88, 93]. In developing countries, the most frequently isolated organisms are *S. aureus* and *C. trachomatis* [88, 89].

The clinical picture, regardless of etiology, is characterized by hyperemia of the conjunctivae, swelling and hyperemia of eyelids, and purulent conjunctival exudate [94]. Although the disease may be benign if treated promptly, neglected neonatal conjunctivitis may result in blindness.

After the introduction of Crede prophylaxis with 2% silver nitrate solution, first described in 1881 [95], there was a reduction in neonatal gonococcal conjunctivitis (the most important cause of blindness in the XVIII century) , and in infantile blindness. Since then, several agents have been proposed to combine wide antimicrobial protection with a reduced incidence of chemical conjunctivitis due to silver nitrate. These agents included 0.5% erythromycin, 1% tetracycline, and gentamicin [96, 97]. Isenberg et al [98] in a clinical trial on 3,117 newborn infants in Kenya, compared the use of 2.5% povidone-iodine with 1% silver nitrate or 0.5% erythromycin. The povidone-iodine solution was more effective than silver nitrate or erythromycin and less toxic. Richter et al [99] showed that 1.25% povidone-iodine solutions have no effect on thyroid function.

Although 0.5% erythromycin and 1% aureomycin are most used, 1% fusidic acid ophthalmic ointment is effective against the most frequent pathogens causing ophthalmia neonatorum (including *N. gonorrhoeae* and *C. trachomatis*), has a prolonged effect (for more than 12 hours) and is well tolerated.

116.2.8.2 Acute Otitis Media

Acute otitis media (AOM) is the presence of a purulent exudate in the middle ear, associated with clinical signs of acute disease. It may present as isolated disease, or in association with sepsis, meningitis, or pneumonia. Risk factors include the presence of meconium-stained amniotic fluid, the need for neonatal resuscitation, mechanical ventilation, prolonged tracheal intubation, and cleft palate. Breast fed neonates are less likely to be affected than formula fed infants [59].

Turner et al [100] studied 137 babies aged < 2 months with suspected AOM. At tympanocentesis, the most frequently isolated organism was *Streptococcus pneumoniae* (46%), followed by *Haemophilus influenzae* (34%), Group A *streptococcus* (10%), Gram-negative bacilli (7%), *Moraxella catarrhalis* (2%) and *Streptococcus faecalis* (1%). Mixed infections were observed in 20 cases: *S. pneumoniae* + *H. influenzae*, *H. influenzae* + *M. catarrhalis*, *S. pneumoniae* + *H. influenzae* + *M. catarrhalis*, and *Klebsiella* + *Enterobacter*.

Otitis presenting duuring first weeks is usually caused by the same organisms as neonatal sepsis (*S. aureus*, GBS and Gram-negative bacilli). By contrast, otitis presenting after the first 2 weeks in neonates without associated diseases is usually community acquired and frequently caused by *S. pneumoniae* [59].

The diagnosis of AOM is based on physical examination. Non specific signs, such as poor feeding and irritability may be the first clinical signs, with or without purulent exudate in the external ear. In the study by Turner et al [100], presentation was with fever (70%), conjunctivitis (46%), respiratory distress (27%), lower respiratory tract infections (13%), vomiting (4%), diarrhea (4%). Both ears were affected in 45% of infants. At otoscopic examination, there is hyperemia and bulging of the tympanic membrane, which is often cloudy with impaired mobility, and an air-fluid level or bubble visible in the middle ear. Tympanocentesis, when indicated, may decompress the middle ear and allows culture of the purulent exudate.

The presence of fever at presentation is not reliably predictive of increased risk of progression to sepsis [100, 101] Treatment should take account of the baby's age and possible pathogens.

The initial antibiotic treatment should be ampicillin in combination with an aminoglycoside or a third generation cephalosporin for 10 days for infants aged < 2 weeks or those who have clinical signs of systemic infection or who are hospitalized. For non-hospitalized neonates aged > 2 weeks and without associated diseases, the most probable infecting agent is *S. pneumoniae* and the first line antiobiotic is amoxicillin for at least 10 days [59].

116.2.8.3 Omphalitis

Omphalitis is infection of the umbilical cord. The incidence varies from 0.7% in developed countries and 6.2% in developing countries [102]. In a recent study by Mullany et al in Nepal on 17,198 infants [103], the incidence of omphalitis was 5.5%. Risk factors include prolonged labor, prolonged rupture of membranes, maternal infections, prematurity, low birth weight at birth, and the presence of umbilical cord catheters [102]. Mullany et al reported an increased risk for infants whose umbilical cord was disinfected with non hygienic solutions, and found that good hand hygiene of health care workers was protective [103].

Most frequently isolated organisms include *S. aureus*, *S. epidermidis*, Group A and Group B streptococci, *E. coli*, *Klebsiella*, *Pseudomonas*, *C. difficile* and anaerobic bacteria. In developing countries, *C. tetani* remains an important pathogen for omphalitis [102, 103].

Omphalitis is characterized by edema and hyperemia of the periumbilical skin, with or without purulent exudate. The

infectious process may progress deeper in soft tissues causing cellulitis and lymphangitis of the abdominal wall, sometimes involving the subcutaneous fat and deeper layers [102, 103].

Although omphalitis is a localized disease, it may progress to systemic disease if untreated. After infection of the periumbilical skin, dissemination of the infection may occur if there is umbilical vessel involvement. The most frequent complications of omphalitis are sepsis, necrotizing fasciitis, abscesses (of pelvis, retroperitoneum, skin, liver), peritonitis and hepatic vein thrombosis.

Prevention of omphalitis using 4% chlorexidine as first choice disinfectant has been recently evaluated by Mullany et al [104]: a randomized clinical trial compared the use of 4% chlorexidine (4,934 infants) with cleansing with soap and water (5,107 infants) or dry cord care (5,082 infants), and found a reduction of infections and of neonatal mortality in the chlorexidine group. Severe omphalitis requires urgent intravenous antibiotic treatment effective against staphylococci, streptococci and Gram-negative bacteria.

116.2.8.4 Impetigo Bullosa and Staphylococcal Scalded Skin Syndrome

Impetigo bullosa is a disease characterized by friable non-erythematous cutaneous vesicles, filled with a yellowish fluid, usually located in the periumbilical skin and the folds of the skin in the axialla or neck. It is caused by *S. aureus*, and has a benign course. The skin lesions are focal, but wider skin dissemination has been reported. Treatment is based on topical skin disinfectants, but systemic antibiotics are needed in the case of resistance to local disinfection.

Staphylococcal scalded skin syndrome (SSSS, previously known as Ritter's disease) is a disease characterized by cutaneous desquamation after light rubbing (Nikolsky's sign) that involves extensive areas of the skin. It is an exfoliative process indistinguishable from toxic epidermal necrolysis (TEN). The difference between the two clinical pictures is in the etiology: SSSS is caused by *S. aureus*, while TEN refers to cutaneous exfoliation caused by non-infectious agents or by infectious agents other than *S. aureus*.

The pathogenesis of SSSS is linked to the ability of some strains of *S. aureus* to produce exfoliative toxins A and B, which detach the stratum granulosum from deeper layers of the skin, leading to desquamation and rash, usually without fever, systemic symptoms, or bacteremia [105].

Pending the results of microbiological tests, the differential diagnosis between SSSS and TEN is by cytology of a smear from a swab of the detached skin: big epithelial cells with small nuclei and lack of inflammatory cells can be observed in SSSS, while cuboidal cells with large nuclei and of inflammatory cells can be observed TEN [10].

Treatment options for SSSS are β-lactam-resistant penicillins (oxacillin, flucloxacillin) or vancomycin, while corticosteroids, contraindicated for SSSS, may be used for TEN.

116.2.8.5 Neonatal Toxic Shock Syndrome-like Exanthematous Disease

In adults, the toxic shock syndrome toxin-1 (TSST-1) is caused by strains of *S. aureus*. A fulminant clinical picture is characterized by fever, hypotension, macular cutaneous rash associated with desquamation of the skin and multiorgan dysfunction. Sporadic neonatal cases have been reported.

Takahashi et al, in 1998 [106] reported 20 newborn infants with a clinical picture characterized by rash (appearing between 2 and 5 days of life) without desquamation and lasting 2–3 days. Associated thrombocytopenia at the time of the rash is sometimes preceded by fever lasting 1 day. All were colonized by a strain of methicillin-resistant *S. aureus* (MRSA) producing TSST-1. This clinical picture was described as a new nosologic entity and defined neonatal toxic shock syndrome-like exanthematous disease (NTED). The pathogenic mechanism seems to be linked to the ability of TSST-1 to act as a superantigen expanding the T cell compartment. High maternal antibody titers (anti-TSST-1 IgG) appear to be protective for NTED. Recently the same authors performed a case-control study of NTED in Japanese neonatal intensive care units and summarized the clinical findings of 540 patients. The number of NTED patients decreased over the 5-year period from 2000 to 2005 although there were more than 100 patients with NTED in Japan in 2005. Most patients recovered within 5 days of the onset of the exanthematous process without active treatment, but two preterm infants died during the recovery phase [106].

116.2.8.6 Noma Neonatorum

Noma neonatorum is a rare gangrenous process, frequently associated with bacteremia, involving the nose, mouth, eyelids, and perineum [107]. It mainly affects low birth weight or preterm infants, has a fulminant course, and a high mortality within the first 1-3 days after presentation. In most cases reported in the literature, there was an association with the isolation of *P. aeruginosa*. Treatment is based on antibiotics against *P. aeruginosa*.

116.2.8.7 Neonatal Tetanus

Neonatal tetanus is a severe condition, although rare in developed countries. It is caused by *Clostridium tetani*, which is a Gram-positive, obligate anaerobic, rod-shaped, spore-forming bacterium. Because it is an obligate anaerobe, localization of *C. tetani* in the periumbilical region may be prevented by disinfection of the umbilical cord with H_2O_2.

Prevention is by maternal tetanus immunization and neonates born to mothers with anti-tetanus toxin antibodies are protected from the disease by transplacental transfer of specific IgG. Aseptic obstetric and neonatal practices are also vital.

The time of incubation between inoculation of the spores and onset of symptoms varies from 3 to 21 days. About 90% of neonates with tetanus develop the disease during the first 3–14 days of life (mostly between days 6 and 8). The baby becomes febrile and presents with difficulty in opening the mouth for suction. There is muscle rigidity and spasms extending progressively to the chest wall and limbs and to the diaphragm, leading to respiratory failure. Laryngeal or glottal spasm may lead to airway obstruction or aspiration pneumonia. Episodes of cyanosis and apnea are common in uncontrolled severe disease. Before mechanical ventilation and the availability of effective agents to control muscle spasm, mortality was mainly because of respiratory failure. Autonomic dysfunction may lead to hypertension or hypotension, tachycardia, bradycardia, and arrhythmias that can result in life-threatening hemodynamic instability and cardiac arrest [108].

Neonatal tetanus is an emergency. Therapy consists of the use of antibiotics (penicillin), hyperimmune anti-tetanus toxin immunoglobulin (500 UI i.m.), and benzodiazepines (intravenous diazepam, 0.3–0.5 mg/kg/dose, repeatable). Endotracheal intubation and mechanical ventilation may be necessary to treat respiratory failure. The prognosis is characterized by a high mortality, but immediate and effective intensive care may reduce mortality to less than 20% [108].

116.3 Fungal Infections

The great majority of fungal infections in the neonate are caused by *Candida* spp, and less frequently by *Malassezia* spp. *Candida* is a commensal organism that usually colonizes the skin and mucous membranes of the gastrointestinal tract and respiratory airways. In the immunocompromised host it behaves as a pathogen, by invading host tissues and entering the circulation.

About 10% of term neonates and 27–63% VLBW neonates admitted to NICUs during the first weeks of life are colonized by fungi [13]. In a study conducted in six NICUs between 1993 and 1995 on 2,847 neonates by Rangel-Frausto et al, the incidence of sepsis caused by *Candida* was 12.3/1000 admissions (0.64/1000 patients-days); reported species were *C. albicans* (63%), *C. parapsilosis* (29%), *C. glabrata* (6%) and other species (3%: *C. tropicalis*, *C. kruse*, *C. lusitaniae*, *C. guilliermondii*, *C. dubliniensis*) [109].

In a survey conducted in 27 NICUs (20,565 neonates) in Spain, 118 babies (0.57%) had a systemic infection caused by *Candida*. *Candida* spp. were isolated from the blood culture of 79 neonates, from urine cultures of 33, and from the CSF of four. The frequency of infection was significantly higher in VLBW infants (4.8%) than in infants with birth weight >1500 g (0.2%) ($P < 0.001$) [110].

Candida may be acquired by horizontal or, less frequently, vertical transmission. Horizontal transmission occurs mainly through the contaminated hands of health care workers. In a multicenter study involving six NICUs [111], *C. albicans* was isolated from the hands of 5% of health care workers, and *C. parapsilosis* from 19%. 486 neonates out of 2,157 (23%) were colonized by *Candida*: 299 (14%) by *C. albicans*, 151 (7%) by *C. parapsilosis* and 74 (3%) by other species. Other sources of infection may be parenteral nutrition solutions or contaminated infusion circuits. Rarely, the reservoir is the environment.

Invasive *Candida* infections are generally preceded by colonization. In a multicenter study of 2847 neonates [112], candidemia was preceded by colonization in 15/35 (43%) cases.

Both neonatal risk factors and the virulence of the microorganism are implicated in the pathogenesis of invasive *Candida* infections. The most important neonatal risk factors for nosocomial candidiasis are prolonged administration of broad spectrum antibiotics (courses longer than 21 days), extreme prematurity (gestational age at birth < 28 weeks) because of impaired humoral and cellular imunity, and the presence of venous catheters (especially if prolonged). Additionally, Saiman et al [112] found that total parenteral nutrition and intravenous lipid solutions, administration of H2-blockers, , endotracheal intubation, disseminated intravascular coagulation and prolonged hospital stay were also significant risk factors for invasive *Candida* infections ($P < 0.05$). All types of catheter (vascular, vesical, peritoneal catheters, ventriculoperitoneal and thoracic drains, endotracheal tubes) favor adhesion, growth and penetration of microorganisms [113]. Feja et al [114] recently reported associations between invasive *Candida* infections and gastrointestinal tract diseases (NEC and focal intestinal perforation; OR = 4.57) and previous bacterial sepsis (OR = 8.02). Benjamin et al, studying 4,579 extremely low birth weight infants (< 1000 g; ELBW), found that delay in starting enteral nutrition was an added risk factor. Steroid therapy, hyperglycemia, neutropenia, and abdominal or cardiac surgery are additional risk factors [113].

The virulence of the microorganism is linked to its ability to form hyphae (that permit tissue invasion), to the infecting species (*C. albicans* is the most virulent), to the expression of adhesins, and to the ability to form a biofilm that protects the microorganism from the host immune response and from exposure to antifungal drugs. Mixed biofilms (*Candida* together with CONS) are not infrequent. Adam et al [115] found that the slime produced *in vitro* by *S. epidermidis* inhibits the penetration of fluconazole, and that the slime produced by *C. albicans* protects staphylococci from the action of vancomycin.

Once the cutaneous and mucous surfaces are colonized, *Candida* may invade tissues locally, leading to parenchymal destruction, sometimes with the formation of abscesses, which are difficult to eradicate. Circulatory involvement may lead to the development of sepsis with end-organ dissemination (endocardium, kidney, central nervous system, bone) [116].

There are three clinical pictures: congenital candidiasis, mucocutaneous candidiasis, and fungal sepsis.

Congenital candidiasis is the congenital infection of the fetus by *Candida* species in the presence of *Candida*

chorioamnionitis. It is a rare event, accounting for 0.8% of cases of chorioamnionitis [13, 117]. In about 25% of cases it occurs in women with intrauterine devices and heavily colonized by *Candida* [13]. Affected infants present with pustules, vesicles, skin abscesses, and an erythematous maculopapular rash on the trunk and extremities that sometimes evolves to desquamation [118]. Histologic evaluation of the umbilical cord and placenta shows microabscesses, hyphae, and granulomas, confirming the diagnosis [13]. Clinical features and evolution of the disease are generally more severe in the preterm infant than in those born at term. Darmstadt et al, reviewing the literature of infants with congenital candidiasis, found that those with birth weight < 1000 g were at higher risk of systemic infection than those > 1000 g (67% *vs* 10%) [118]. Preterm neonates may present with organ involvement (pneumonia, disseminated dermatitis, hyphae in urine, blood and CSF).

Mucocutaneous candidiasis is the most common manifestation of the disease. It usually presents during the second or third week of life as a diffuse erythematous rash affecting the napkin area and white patches on the oral mucosa, gingivae and tongues. As the disease progresses, the skin rash becomes more widespread, affecting the abdominal skin and chest. The rash may be papular or pustulous or associated with cutaneous desquamation [119].

Cutaneous involvement may precede systemic spread [120]. The clinical manifestations of fungal sepsis are similar to those of bacterial sepsis. Thrombocytopenia is nonspecific: Guida et al [121] found that 84% of infants with fungal sepsis, 75% of infants with Gram-negative sepsis, and 48% of infants with Gram-positive sepsis had platelet counts < 100,000/mm^3.

Frequently, at the time of diagnosis, the infection is already disseminated to organs. *Candida* spp. may cause organ infections as endocarditis, meningitis, endophthalmitis and chorioretinitis, dermatitis, peritonitis, osteomyelitis, and septic arthritis, and may form abscesses in the central nervous system, kidneys, liver, spleen, and gut. In a recent meta-analysis, the rate of positive urine cultures was 61% among neonates with candidemia, but ultrasound findings of renal involvement were found in only 5% of cases. The rate of meningitis was 15%, cerebral abscesses or ventriculitis were found in 4% of cases, endocarditis in 5% and endophthalmitis in 3% [122].

Urine and CSF cultures, together with blood cultures, should always be performed in infants with suspected *Candida* sepsis. Microscopic examination of the urine may reveal hyphae and ultrasound may show evidence of renal tract involvement. Other imaging studies may include cardiac and cerebral ultrasound and ophthalmologic examination if ophthalmitis is suspected [113].

The identification of the gene coding for 18S rRNA by PCR is under investigation. This gene is present in the genome of almost all clinically relevant fungal species is absent in the human genome. Löffler et al [123] compared the identification of the 18S rRNA gene with traditional culture methods for the diagnosis of fungal infection in 600 samples from febrile and neutropenic adult patients with neoplastic diseases. Compared to traditional cultures, the PCR showed 100% sensitivity and 98% specificity for fungal infections.

Sepsis by *Candida* is associated with increased mortality and morbidity. In a study by the Neonatal Research Network [6], the mortality rate for VLBW neonates with fungal sepsis was three-fold higher than for those without.

Sepsis caused by *C. albicans* is associated with a higher mortality compared to sepsis caused by other *Candida* species. In a study of 45 newborn infants, Faix et al [124] found that deaths attributable to infection by *Candida* were 7/29 in infants with infection by *C. albicans* and 0/16 in infants with infection by *C. parapsilosis* (P = 0.034). In the study by the Neonatal Research Network, the mortality rate for VLBW infants with *C. albicans* infection was 43.9% compared with 15.9% for *C. parapsilosis* [6].

In a study conducted between 1988 and 1996 on ELBW neonates with sepsis and/or meningoencephalitis caused by *Candida*, the outcome at 2 years corrected age was compared with a cohort of ELBW neonates without *Candida* infection. Case fatality rate was similar. However, all survivors in the *Candida* group had chronic lung disease at discharge, compared with 33% of the control cases (P = 0.0001). There was a high incidence of periventricular leukomalacia (26% *vs* 12%, P = 0.06) and increased severe retinopathy of prematurity (22% *vs* 9%, P = 0.04). 60% of the *Candida* group had adverse neurologic outcomes at 2 years corrected age compared with 35% in the control group, and 41 *vs* 12% had severe disabilities (P = 0.005) [125].

The first line antifungal drug for the treatment of fungal sepsis is amphotericin B, which is generally well tolerated by the neonate. The dosage is 0.1 mg/kg/day administered intravenously in a single daily dose in 2 hours. The dose may be progressively increased to a maximum of 1 mg/kg/day. In some studies on adult patients, levels achieved in the CSF are about 5–10% of plasma levels, but in a small study of 13 preterm infants, CSF levels were 40–90% of plasma levels.

Liposomal amphotericin B is less toxic and can be administered at higher dosages. Amphoteriocin B is potentially nephrotoxic, and if renal function is compromised, the liposomal formulation of amphotericin B is indicated. Liposomal amphotericin B is prescribed at 1–5 mg/kg/day. The effectiveness and safety of a dose of 5–7 mg/kg/day of liposomal amphotericin B was studied prospectively by Juster-Reicher et al [126] in 2003. In 41 cases of systemic candidiasis, the authors found it to be highly effective (recovery in 95% of cases) without side effects except for one infant who had a transient increase in liver enzymes. The time required for eradication was 10.9 ± 4.8 days for infants who had previously received other antifungal drugs and 8.7 + 4.5 days for infants in whom liposomal amphotericin B was used as the treatment of first choice. The recommended dose for intravenous liposomal amphotericin B is 1 mg/kg/day administered over 2 hours, increasing progressively to a maximum of 5 mg/kg/day.

Fluconazole is the most studied azole in the neonatal age range. Its use for the prevention of fungal infections in high

risk neonates has been evaluated by several studies, but amphotericin B is the first choice for treatment of an infection. Several studies recommend intravenous 5-fluorocytosine in combination with amphotericin B for severe fungal infections. 5-fluorocytosine achieves high CSF concentrations, and is recommended for fungal meningitis. However, it should never be used as a single antifungal because of the frequent emergence of resistant strains. The recommended dose is 50–150 mg/kg/day intravenously over 15 minutes in 4 daily doses.

A new class of drugs, the echinocandins, act through noncompetitive inhibition of the synthesis of the 1,3-β-glucan in the cellular wall and have been used in adults. Studies to evaluate their effectiveness and safety in the neonate are ongoing.

The duration of antifungal treatment should be decided on the basis of clinical and microbiological factors: the fungal species, the presence of a central venous catheter, which should always be removed in infants with fungal infections, the number of positive cultures, CSF cell count and chemistry, imaging (echocardiography, renal ultrasound, ophthalmologic examination and imaging of the central nervous system). In infants with systemic fungal infections, intravenous treatment should be prolonged for at least 2–4 weeks after the last negative blood culture. Longer courses may be needed for meningitis and end-organ dissemination. Starting empirical antifungal treatment before the availability of culture results has not been the subject of prospective studies. Some high risk populations, such as ELBW neonates with sepsis and risk factors for fungal infections (presence of a central venous catheter, endotracheal tube, thrombocytopenia, prolonged treatment with cephalosporins or carbapenems, gestational age < 28 weeks) may be helped by empirical treatment while awaiting culture results, especially if antibiotics are not apparently effective.

116.4 Prevention of Early- and Late-Onset Infections

116.4.1 Prevention of Early-Onset Group B Streptococcal Infection

116.4.1.1 Intrapartum Antibiotic Prophylaxis (IAP)

Intrapartum antibiotic prophylaxis (IAP) is currently the most important preventive measure against early-onset group B streptococcal (GBS) disease. There are two strategies. One is based on universal prenatal screening while the other is based on the presence of intrapartum risk factors. The former was proposed by the Centers for Disease Control and Prevention (CDC) [127]. The latter is based on the presence of intrapartum risk factors and is recommended by the UK Royal College of Obstetricians and Gynaecologists (RCOG) [128]. Several studies, in particular a case-control study of 5144 births published by Schrag et al to compare the two strategies showed that the screening-based approach was better than the risk-based approach [129]. The introduction and the widespread use of IAP and especially the implementation of guidelines issued by the CDC have led to a substantial reduction in the incidence of early-onset GBS disease. A recent retrospective study demonstrated that screening for GBS before delivery increased from 48% in 1998–1999 to 85% in 2003–2004 and women with an indication for IAP who received prophylaxis increased from 74 to 85% [130]. This has resulted in a reduction in the incidence of early-onset GBS disease in the USA from 1.7 to 0.35/1000 live births [131]. The drug of choice for IAP is penicillin G i.v. (5 million units followed by 2.5 million units every 4 hours until birth). This drug is not generally available and an alternative is intravenous ampicillin (2 g followed by 1 g every 4 hours until birth) [132].

The screening-based method requires a vaginal-rectal swab to be performed on all pregnant women at 35–37 weeks of gestation and the administration of *intrapartum* antibiotics to colonized women at the time of labor.

The 2010 CDC guidelines provide criteria for identification of candidates to receive intrapartum antibiotic prophylaxis to prevent early-onset GBS disease (Table 116.4). The following are key components of the screening strategy [127]:

- Women with GBS isolated from the urine at any time during the current pregnancy or who had a previous infant with invasive GBS disease should receive intrapartum antibiotic prophylaxis and do not need third trimester screening for GBS colonization. Women with symptomatic or asymptomatic GBS urinary tract infection detected during pregnancy should be treated according to current standards of care for urinary tract infection during pregnancy and should receive intrapartum antibiotic prophylaxis to prevent early-onset GBS disease.
- All other pregnant women should be screened at 35–37 weeks' gestation for vaginal and rectal GBS colonization.
- At the time of labor or rupture of membranes, intrapartum antibiotic prophylaxis should be given to all pregnant women who tested positive for GBS colonization, except in the instance of cesarean delivery performed before onset of labor on a woman with intact amniotic membranes.
- For circumstances in which screening results are not available at the time of labor and delivery, intrapartum antibiotic prophylaxis should be given to women who are <37 weeks and 0 days' gestation, have a duration of membrane rupture ≥18 hours, or have a temperature of ≥100.4°F (≥38.0°C).
- In the absence of GBS urinary tract infection, antimicrobial agents should not be used before the intrapartum period to eradicate GBS genitorectal colonization, because such treatment is not effective in eliminating carriage or preventing neonatal disease and can cause adverse consequences.
- Intrapartum antibiotic prophylaxis to prevent early-onset GBS disease is not recommended as a routine practice for cesarean deliveries performed before labor onset on women with intact amniotic membranes, regardless of the GBS colonization status of the woman or the gestational

Table 116.4 Indications for intrapartum antimicrobial prophylaxis (IAP) to prevent early-onset GBS disease. Modified from [127]

Intrapartum GBS prophylaxis indicated	Intrapartum GBS prophylaxis not indicated
• Previous infant with invasive GBS disease	• Colonization with GBS during a previous pregnancy (unless an indication for GBS prophylaxis is present for current pregnancy)
• GBS bacteriuria during any trimester of the current pregnancy[1]	• GBS bacteriuria during previous pregnancy (unless an indication for GBS prophylaxis is present for current pregnancy)
• Positive GBS vaginal-rectal screening culture in late gestation[2] during current pregnancy[1]	• Negative GBS vaginal-rectal screening culture in late gestation[2] regardless of intrapartum risk factors
• Unknown GBS status at the onset of labor (culture notdone, incomplete, or results unknown) and any of the following: – Delivery at <37 weeks' gestation – Amniotic membrane rupture ≥18 hours – Intrapartum temperature ≥100.4°F (≥38.0°C)[3] – Intrapartum NAAT[4] positive for GBS	• Cesarean delivery performed before onset of labor on a woman with intact amniotic membranes, regardless of GBS colonization status or gestational age

[1] Intrapartum antibiotic prophylaxis is not indicated in this circumstance if a cesarean delivery is performed before onset of labor on a woman with intact amniotic membranes.
[2] Optimal timing for prenatal GBS screening is at 35–37 weeks' gestation.
[3] If amnionitis is suspected, broad-spectrum antibiotic therapy that includes an agent known to be active against GBS should replace GBS prophylaxis.
[4] Nucleic acid amplification tests (NAAT) testing for GBS is optional and might not be available in all settings. If intrapartum NAAT is negative for GBS but any other intrapartum risk factor (delivery at <37 weeks' gestation, amniotic membrane rupture at ≥18 hours, or temperature ≥100.4°F [≥38.0°C]) is present, then intrapartum antibiotic prophylaxis is indicated.

age of the pregnancy. The use of perioperative prophylactic antibiotics to prevent infectious complications of cesarean delivery should not be altered or affected by GBS status. Women expected to undergo cesarean deliveries should undergo routine vaginal and rectal screening for GBS at 35–37 weeks' gestation because onset of labor or rupture of membranes can occur before the planned cesarean delivery, and under those circumstances GBS-colonized women should receive intrapartum antibiotic prophylaxis.

There are two main limitations to the universal screening-based strategy: a) the possibility that the woman delivers before vaginal swabs have been taken or before the results are available; b) the possibility of colonization between obtaining a negative swab and delivery. Yancey et al [133] showed that swabs performed 5 weeks before delivery predict colonization at delivery. A retrospective study reported negative screening results in 61% of GBS early onset disease, an unexpectedly high percentage. The authors suggest several reasons for false negative results: screening outside the 5 week window before delivery, errors in collecting and processing swabs and possible errors in the communication of results [130]. There is debate about the minimum duration of effective IAP. The CDC protocol recommends IAP administration at least 4 hours before delivery, but the RCOG recommends at least 2 hours.

In a prospective study of 21 women treated with ampicillin before elective cesarean section, Colombo et al [134] demonstrated bactericidal levels of ampicillin in cord blood 30 minutes after ampicillin administration. The cord blood ampicillin concentration is higher than the maternal blood concentration and both continue to be above minimal bactericidal concentrations 5–6 hours after administration. Ampicillin levels decreased more rapidly in the maternal than the fetal compartments, suggesting decreased clearance of ampicillin by the newborns. Lijoi et al observed significantly lower colonization in babies of mothers given IAP more than 4 h before delivery (3.7%) than those born to mothers who received IAP closer to the time of birth (12.3%) [135].

In conclusion, beta-lactam antibiotics for GBS prophylaxis administered for ≥4 hours before delivery have been found to be highly effective at preventing vertical transmission of GBS and early-onset GBS disease. Shorter durations of appropriate antibiotics might provide some protection.

116.4.1.2 Side Effects of IAP

The striking success of this preventive strategy, however, has raised the issue of possible side effects resulting from the adoption of intrapartum antibiotic prophylaxis on a large scale.

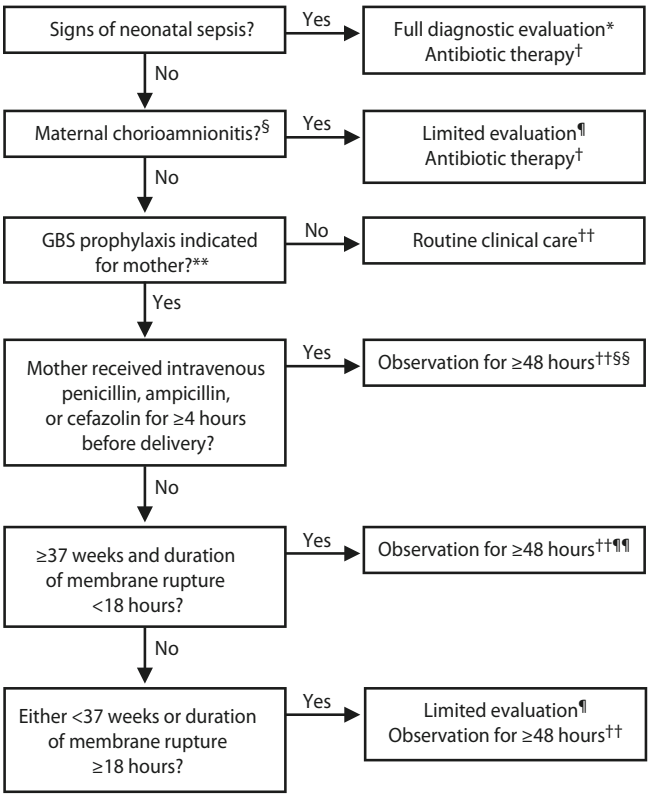
Van Dyke et al in a study of 7691 births found no cases of anaphylaxis after IAP [130].

The effect of IAP on neonatal infections by multi-resistant microorganisms other than GBS has been considered by Moore et al [136] who reviewed 412 articles and explored potential associations between IAP use and changes in the causes of early-onset sepsis. They found: a) a decreased incidence of GBS early-onset infections and some other bacteria, b) an increase in non-GBS or antimicrobial-resistant early-onset sepsis amongst preterm babies, and c) no change in the incidence of early onset disease by other organisms. These conclusions led Baltimore to suggest that the risks and benefits of IAP should be monitored in preterm and VLBW infants [137]. GBS resistance to erythromycin and clindamycin has been described but never to date to penicillin, ampicillin, cefazolin and vancomycin. In a review of 21 studies published between 1996 and 2006, Barcaite et al [138] reported no GBS strains resistant

to penicillin, ampicillin, cafazolin and vancomycin. Between 4 and 21% of GBS strains were resistant to erythromycin and between 3 and 20% were resistant to clindamycin [139–144].

116.4.1.3 Neonatal Management

Any baby who is unwell with clinical signs compatible with infection must be investigated and treated with antibiotics regardless of any risk factor that may or may not be present. In 2010 the CDC has provided an algorithm for secondary prevention of early-onset GBS disease among newborns (Fig. 116.2) [127].



* Full diagnostic evaluation includes a blood culture, a complete blood count (CBC) including white blood cell differential and platelet counts, chest radiograph (if respiratory abnormalities are present), and lumbar puncture (if patient is stable enough to tolerate procedure and sepsis is suspected).
† Antibiotic therapy should be directed toward the most common causes of neonatal sepsis, including intravenous ampicillin for GBS and coverage for other organisms (including *Escherichia coli* and other gram-negative pathogens) and should take into account local antibiotic resistance patterns.
§ Consultation with obstetric providers is important to determine the level of clinical suspicion for chorioamnionitis. Chorioamnionitis is diagnosed clinically and some of the signs are nonspecific.
¶ Limited evaluation includes blood culture (at birth) and CBC with differential and platelets (at birth and/or at 6–12 hours of life).
** See Table 116.4 for indications for intrapartum GBS prophylaxis.
†† If signs of sepsis develop, a full diagnostic evaluation should be conducted and antibiotic therapy initiated.
§§ If ≥37 weeks' gestation, observation may occur at home after 24 hours if other discharge criteria have been met, access to medical care is readily available, and a person who is able to comply fully with instructions for home observation will be present. If any of these conditions is not met, the infant should be observed in the hospital for at least 48 hours and until discharge criteria are achieved.
¶¶ Some experts recommend a CBC with differential and platelets at age 6–12 hours.

Fig. 116.2 Algorithm for secondary prevention of early-onset GBS disease among newborns. Modified from [127]

Treatment of a healthy GBS colonized neonate can create resistant bacteria, does not eliminate colonization, and therefore, does not prevent possible late infection [145]. Superficial swabs in neonates during the first hours of life have not been found to be useful [146, 147]. Indeed, about 90% of early onset disease occurs during the first 24 hours of life when the results of the cultures are not available [146] and 99% of the colonized neonates do not become infected. Guidelines for the prevention of perinatal GBS disease are available at the website www.cdc.gov/groupbstrep/guidelines/guidelines.html.

116.4.2 Prevention of Nosocomial Infections

Neonatal nosocomial infections are late onset infections (appearing after the first 72 hours of life) in hospitalized infants [1]. The incidence of infections varies widely among NICUs, depending on environmental factors and on differences in clinical practice. A survey by the World Health Organization (WHO) reported that nosocomial infection rates between 7 and 19% in Europe, and 14% in the USA [148]. Immunological immaturity, the frequent invasive procedures and prolonged hospitalization all account for the high incidence of infection amongst neonates. Infections may prolong the time of hospitalization and increase mortality and morbidity.

Prevention of health care associated infections is based on strategies that aim at limiting susceptibility to pathogens by reducing risk factors while enhancing host defenses, at interrupting transmission of organisms by health care workers, and at promoting the judicious use of antimicrobials [149].

Strategies for the prevention of nosocomial infections include hand hygiene practices, prevention of central venous catheter-related bloodstream infections, appropriate use of antimicrobials for therapy and chemoprophylaxis, skin care and early enteral feeding with human milk.

116.4.2.1 Hand Hygiene

Since Ignaz Semmelweis demonstrated dramatic reductions in puerperal sepsis after instituting a hand washing regimen in 1847, hand hygiene has been known to reduce health care associated infections and is recommended by the CDC as the single most effective method of preventing the spread of nosocomial infections [150]. Hand washing is a simple, inexpensive procedure that prevents the transmission of infectious pathogens. However, hand hygiene compliance remains low among health care workers, with reported adherence rates ranging from 20 to 50% [151].

In a multicenter clinical trial by Pittet et al [152], an intense campaign to promote hand hygiene practices led to a

significant increase in compliance with protocols (from 48 to 66%, P < 0.001), and a concomitant decrease in the overall frequency of nosocomial infections (from 16.9 to 9.9%, P = 0.04) and of infections caused by MRSA (from 2.16 to 0.93 cases/10,000 patients-days, P < 0.001).

The choice of the best method of hand hygiene is still a matter of debate. Many authors agree that hand rubbing with alcohol-based products (mainly 2-propanol-based solutions and alcohol-based preparations with 0.5% chlorhexidine) is microbiologically more effective than traditional hand washing with soap and water. It seems to be the best method of increasing compliance, being faster and less irritating for the skin. Antiseptic hand rub solutions can be placed at the bedside of each patient [153].

Guidelines for hand hygiene by the CDC Healthcare Infection Control Practices Advisory Committee (HICPAC) [154] (http://www.cdc.gov/mmwr/PDF/rr/rr5116.pdf) recommend hand washing with antimicrobial or non-antimicrobial soap and water when hands are visibly soiled or contaminated with proteinaceous material, and hand decontamination with an alcohol-based hand rub if hands are not visibly soiled and before engaging in direct contact with patients. Additional recommendations include avoiding wearing artificial fingernails and rings, bracelets and watches when engaging in direct contact with patients.

116.4.3 Prevention of Central Venous Catheter-Related Infections

Strategies for the prevention of central venous catheter-related infections include: 1) precautions during insertion and management of the central venous catheter; 2) reduction of indwelling times; 3) central venous catheters removal after positive blood culture results.

Central venous catheter contamination and colonization may occur during insertion and line management [155]. Good hand hygiene combined with proper aseptic technique during catheter insertion and manipulation affords protection against infection. Standard aseptic techniques (caps, masks, sterile gowns, sterile gloves, and large sterile drapes) during insertion substantially reduce the incidence of catheter-related bloodstream infections compared with standard precautions (sterile gloves and small drapes) [156, 157]. Proper management of the central venous catheters should include the establishment of a sterile field and rubbing the hub vigorously with alcohol at the time of hub entry or disconnection [27], avoiding the use of multilumen catheters, blood withdrawal through the catheter, and daily assessment of the site of insertion and of the integrity of the dressing [158]. Recently, Garland et al [159] conducted a surveillance study during a randomized trial to assess the safety and efficacy of a prophylactic vancomycin-heparin catheter-lock solution for the prevention catheter-related bloodstream infections. Nosocomial bloodstream infection was identified in 23 of the 82 neonates in the cohort. Fifteen of these infections were considered catheter-related bloodstream infections, which were intraluminally acquired in 10 (67%) of 15 patients (isolation of the same organism from the hub and blood cultures but not from the tip of the catheter), extraluminally acquired in three (20%, isolation of the same organism from the tip of the catheter and from blood cultures), and indeterminate in two (13%). The authors emphasized the importance of strategies for preventing intraluminally acquired catheter-related bloodstream infections.

The US Department of Health and Human Services Centers for Disease Control recommend a 2% aqueous chlorhexidine gluconate solution for skin disinfection before vascular access [160]. Administration sets should be replaced every 48–72 hours; lipid-containing sets should be replaced every 24 hours [156].

Reducing the indwelling time of central venous catheters is the easiest way to reduce the risk of catheter-related infection. Several studies demonstrated a direct correlation between times of indwelling catheters and incidence of sepsis in newborn infants [155].

In a prospective study by the NICHD Neonatal Research Network on VLBW infants, peripherally inserted central venous catheters placed for < 7 days increased the risk of infection 1.9 times (P < 0.001), but the risk increased to 3.7 times (P < 0.001) for catheters in place for 22 or more days [6].

Central venous catheters should be promptly removed when blood cultures are positive. Benjamin et al found that the outcome for patients in whom the central catheter was not removed within 24 hours of bacterial organism identification was significantly worse (increased risk of infectious complications defined as the presence of end-organ damage, multiple positive blood cultures drawn at separate times within one episode of sepsis, or death) than for those whose catheters were removed promptly (8% *vs* 46%; OR = 9.8) [161]. In a retrospective study by Karlowicz et al, central venous catheter removal within 3 days of the first positive blood culture for *Candida* species was associated with a shorter duration of fungemia (3 *vs* 6 days, P=0.0002) and a reduced mortality rate (2 *vs* 19%, P = 0.008) [162].

Central venous catheters should be removed as soon as bacteremia and fungemia are detected. When blood cultures are positive for CONS, catheter sterilization may be attempted, but the catheter should be promptly removed if subsequent cultures are positive.

116.4.4 Antimicrobial Prophylaxis

116.4.4.1 Antibiotic Prophylaxis

There is no good evidence to support antibiotic prophylaxis for high risk infants. In a Cochrane meta-analysis, antibiotic

prophylaxis for infants with central venous catheters slightly reduced the incidence of sepsis but this effect was not associated with a reduction in mortality. There were no data on neurodevelopmental outcome and on the emergence of resistant bacterial strains and antibiotic prophylaxis cannot be routinely recommended [163].

A Cochrane meta-analysis of five clinical trials studying the use of prophylactic vancomycin for the prevention of central venous catheter-related infections [164] reported that prophylactic vancomycin in low doses reduced the incidence of sepsis but the authors concluded that routine prophylaxis with vancomycin should not be undertaken at present.

An alternative approach for prophylaxis of central venous catheter-related nosocomial infections is "antibiotic flush" or "antibiotic lock" prophylaxis. In a prospective randomized clinical trial [165], VLBW infants with a newly placed peripherally inserted central venous catheter were randomized to having the catheter locked 2 or 3 times daily for 20 or 60 minutes with heparinized normal saline or heparinized saline containing vancomycin 25 μg/mL. The incidence of catheter-related bloodstream infections was significantly higher in the control than in the treated group (17.8 *vs* 2.3 per 1000 catheter days) [166]. No vancomycin-resistant enterococci or CONS were recovered from any cultures.

116.4.4.2 Antifungal Prophylaxis

Oral antifungal prophylaxis has been considered by a Cochrane review and there is insufficient evidence to support the use of prophylactic oral antifungal agents in VLBW infants in the NICU [167].

Randomized studies have shown that prophylactic intravenous fluconazole lowered the risk of invasive fungal infections and colonization [168, 169] and does not select resistant *C. albicans* strains [170]. Although fluconazole prophylaxis seems effective and well tolerated, further studies are needed to better establish subpopulations among neonates admitted to the NICU who could benefit from the drug [169, 171].

116.4.4.3 Immune Prophylaxis

Several studies have evaluated the effectiveness of immunoglobulins in preventing nosocomial infections in the preterm infant. The overall conclusion is that the small reduction in nosocomial sepsis is insufficient to support the routine use of immunoglobulins [46, 172]. Some benefit has been demonstrated for high risk infants of birth weight <1000–1250 g treated with intravenous immunoglobulin but the incidence of sepsis in the control group was very high (15–20%) [14].

Recently, DeJonge et al evaluated INH-A21, a plasma-derived, donor-selected polyclonal antistaphylococcal human immunoglobulin but failed to reduce the incidence of staphylococcal late onset sepsis in premature infants [173]. Another antistaphylococcal immune globulin, directed against serotypes 5 and 8 of *S. aureus*, is at present under investigation.

116.4.5 Skin Care

The skin barrier is compromised in the neonate, particularly if preterm, because of a thinner stratum corneum (3–16 layers, depending on gestational age at birth), which is easily damaged by handling, adhesives, and alcohol and povidone iodine applications. A Cochrane review concluded that the prophylactic application of topical ointments increased the risk of CONS infection and any nosocomial infection and that this treatment should not be used routinely in preterm infants [174].

A trial of daily massage with sunflower seed oil or Aquaphor (petrolatum, mineral oil, mineral wax, lanolin alcohol) found no significant reduction in the risk of infection, although skin applications of sunflower seed oil gave some protection against nosocomial infections [79]. The question whether topical skin ointment should be used for VLBW infants is still debatable and further trials are needed.

116.4.6 Breast Milk, Probiotics and Lactoferrin

The age of introduction of enteral feeds and the administration of human milk affects the incidence of nosocomial sepsis. The incidence of infection is reduced by human milk compared to formula [40] and early enteral feeding is also beneficial [175]. Possible mechanisms include: 1) prevention of gastrointestinal atrophy; 2) prevention of intestinal bacterial contamination; 3) decreased use of total parenteral nutrition and intravenous devices; 4) enhancement of mucosal immunity [175].

Several factors present in breast milk have an anti-infectious activity, including immune globulins, cytokines, complement, fibronectin, enzymes (lysozyme, leukocyte enzymes), macrophages (~60%), neutrophils (~25%), lymphocytes (~10%).

Studies of probiotics to prevent nosocomial sepsis [176, 177] have reported conflicting data and larger multicenter trials are needed to assess the risks and benefits of probiotics [178]. Recently, Manzoni et al [179] established that bovine orally administered lactoferrin, a mammalian milk glycoprotein involved in innate immune host defenses, alone (100 mg/day) or in combination with the probiotic *Lactobacillus rhamnosus* GG (6x109 colony-forming units/day) from birth until day 30 of life (day 45 for neonates < 1000 g at birth) significantly reduces the incidence of a first episode of bacterial and fungal LONS in VLBW neonates (risk ratio for lactoferrin *vs* control groups: 0.34; 95% CI, 0.17–0.70; P = 0.002. Risk ratio for lactoferrin plus *Lactobacillus rhamnosus vs* control groups: 0.27; 95% CI, 0.12–0.60; P < 0.001) [179, 180].

Neonatal Septic Shock

Rajesh K. Aneja, Ruby V. Aneja, Robert Cicco, Joseph A. Carcillo

117.1 Introduction

Group B *Streptococcus* (GBS) continues to be a leading infectious cause of neonatal morbidity and mortality in the United States [1]. Overall, the incidence of GBS early onset disease (EOD) over the last 3 decades has decreased from 1.7 to 0.4 per 1,000 live births, a 70% reduction [2]. This success has largely been attributed to the institution of intrapartum prophylaxis. Since implementation of Group B streptococcal (GBS) prophylaxis, there has been a reduction in GBS EOD from 5.9 to 1.7 per 1000 live births of infants weighing 401–1500 g, but a concomitant increase in the rate of *Escherichia coli* sepsis from 3.2 to 6.8 per 1000 live births [3].

Investigators used hospital discharge data (from approximately one quarter of the U.S. population) to estimate that 10% of infants and children with severe sepsis (bacterial or fungal infection plus organ failure) died in 1995 [4, 5]. The incidence of sepsis in the neonatal population was 3.06 per 1000 children. A decade later, in a follow-up study, the authors noted that the incidence of sepsis in the neonatal population had decreased to 2.22 per 1000 children. Despite the decline in the overall incidence of sepsis, one cohort that demonstrated a significant increase in the incidence of sepsis was the very low birth weight (VLBW) group, defined as less than 1500 g (26.5% *vs* 9.2% in 1995) [6]. Similar observations were made by Stoll and colleagues who published a series of epidemiologic evaluations of newborn sepsis/septicemia/septic shock using United States Vital Statistics as well as the National Institute of Child Health and Human Development sponsored newborn infection registry. Neonatal mortality steadily decreased over the past decade, but remained most prominent in low birth weight neonates, defined as less than 2500 g [7–9]. Low birth weight newborns with EOD are more likely to die than those without infection (37% *vs* 13%). Twenty one percent of low birth weight newborns also have one or more episodes of blood culture positive late onset disease (LOD) and are also more likely to die (18% *vs* 7%). In VLBW newborns with LOD, the common causative organisms were gram positive (70%), followed by gram negative (17.6%) and fungal (12.2%) organisms. In the same study, mortality was higher in patients with gram negative organisms or fungal sepsis [9].

117.2 Early Recognition and Treatment/ Resuscitation Improves Outcome in Sepsis and Septic Shock

Clinical signs of apnea or tachypnea, poor feeding and temperature instability should be considered as sepsis until proven otherwise and the clinician should consider antibiotic therapy. In the nursery setting, fetal and neonatal tachycardia remain the most important early clinical predictors of sepsis and septic shock [10, 11]. Prompt fluid and inotrope resuscitation to normalization of heart rate well before hypotension occurs appears prudent in this population. Laboratory tests can also have a role in increasing early suspicion of newborn sepsis. Many investigators have demonstrated that measurement of cord or newborn blood quantitative levels of cytokines including interleukin-6 (IL-6), procalcitonin, IL-1 receptor antagonist, IL-8, IL-10, tumor necrosis factor (TNF), and C-reactive protein (CRP) can attain over 95% sensitivity in diagnosis of EOD and LOD before blood culture results are available [12–20]. These author's believe that universal implementation of these clinical laboratory tests will allow more judicious use of antibiotic therapy than the present standards of care, which do not utilize these biomarkers.

Bang and colleagues [21] evaluated the effect of early treatment of sepsis on neonatal outcome in rural India when a rural health intervention initiative taught health workers to give intramuscular (IM) gentamycin and oral co-trimoxazole to premature and term newborns who developed apnea,

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

tachypnea, poor feeding, temperature instability or diarrhea. Remarkably, fatality rates were decreased from 16.5 to 2.8%. The cost of treatment per infant was $ 5 US. Interestingly only 7% of newborns in this study met these criteria and received antibiotics. In developed countries, 10% of newborns similarly receive antibiotics either antepartum or postpartum.

Shock remains the most prominent risk factor for death in neonatal sepsis (adjusted odds ratio 11.82 confidence interval 5.4–69.4) [15]. Best outcomes are attained with early reversal of shock in newborns using NRP/ACCM/PALS guidelines (see below) [22]. Aggressive, timely emergency department fluid and inotrope resuscitation directed to oxygen delivery/consumption goals has also been shown to improve outcome in adult septic shock in a large randomized controlled trial [23]. This preponderance of evidence suggests that early recognition is the key to survival in newborn sepsis and septic shock. Experimental and clinical literature show that early and aggressive fluid resuscitation with antibiotic therapy turns off inflammatory gene expression, prevents thrombosis, and results in 95% or greater survival. Delayed resuscitation on the other hand results in inflammatory gene expression, endothelial activation, thrombosis, the development of thrombocytopenia associated multiple organ failure, and high mortality rates [24–27].

117.3 Neonatal Shock

Adult septic shock is classically described as a high cardiac output and low systemic vascular resistance state. The systemic vasodilatation reduces afterload on the heart, thereby improving cardiac output. Death is usually attributed to refractory vasoplegia. In response to the decreased cardiac function (decreased stroke volume) adults compensate in part by tachycardia (Table 117.1). In contrast, term newborns and infants have a remarkably different cardiovascular response to septic shock. Healthy newborns have higher resting heart rates than adults. Hence, in response to shock, newborns compensate by increasing systemic vasoconstriction. This increased vasoconstriction increases afterload and further impairs cardiac output. Hence, death in the majority of newborns and infants with fluid/dopamine resistant shock is a result of cardiac failure, not vasoplegia.

Table 117.1 Clinical definition of sepsis and septic shock

Sepsis	Clinical suspicion of infection with the following signs; tachycardia, tachypnea or apnea, poor feeding, temperature instability, diarrhea
Septic shock	Clinical suspicion of infection with the following signs; tachycardia or bradycardia, tachypnea or apnea,poor peripheral perfusion, prolonged capillary refill > 2 seconds, decreased urine output*

* Hypotension is considered a late confirmatory sign.

Neonatal septic shock is often complicated by lack of the physiologic transition from fetal to neonatal circulation. *In utero*, 85% of fetal circulation bypasses the lungs through the patent ductus arteriosus and foramen ovale. This flow pattern is maintained by suprasystemic pulmonary artery pressures prenatally. At birth, inhalation of oxygen triggers a cascade of biochemical events that ultimately result in reduction in pulmonary artery pressure and transition from fetal to neonatal circulation with blood flow now being directed through the pulmonary circulation. Closure of the patent ductus arteriosus and foramen ovale complete this transition. Pulmonary artery pressures can remain elevated and the ductus arteriosus can remain open for the first 6 weeks of life. Sepsis-induced acidosis and hypoxia increases pulmonary vascular resistance, subsequently increasing the pulmonary artery pressure leading to patent ductus arteriosus. This results in persistent pulmonary hypertension (PPHN) and persistent fetal circulation (PFC) in the newborn. Neonatal septic shock with PPHN is associated with increased right ventricle afterload. Despite in utero conditioning, the thickened right ventricle may fail in the presence of systemic pulmonary artery pressures. Decompensated right ventricle failure can be clinically manifested by tricuspid regurgitation and hepatomegaly. Newborn animal models of Group B streptococcal and endotoxin shock have also documented reduced cardiac output, and increased pulmonary, mesenteric, and systemic vascular resistance. Therapies directed at reversal of right ventricle failure, through reduction of pulmonary artery pressures, are commonly needed in neonates with fluid refractory shock and PPHN. New therapies such as inhaled nitric oxide, extracorporeal membrane oxygenation (ECMO), and vasodilators have little to no role in adult septic shock, but are potentially lifesaving in newborns, infants, and children.

117.4 Management of Neonatal Shock

Management of neonatal shock (Fig. 117.1) is challenging due to many factors. First, there is lack of consensus about the definition of hypotension in the extremely premature infants [28]. The commonly used NICU criteria for mean arterial blood pressure is that it should be maintained at or greater than the mean gestational age in weeks [29, 30]. This is not supported by any published evidence but continues to be the standard of care in many NICUs around the world. In the absence of a precise evidence based definition, it is difficult to interpret the hemodynamic response to hypotension. Adult and pediatric data suggest that blood pressure cannot be used as a surrogate for adequate oxygen delivery in critically ill patients. Secondly, there is lack of data about the correlation of central venous pressure (CVP) with circulating blood volume in VLBW infants. Lastly, there is paucity of data regarding the use of lactate as a surrogate for inadequate tissue oxygen delivery in preterm infants. Serum lactate levels pose a unique challenge

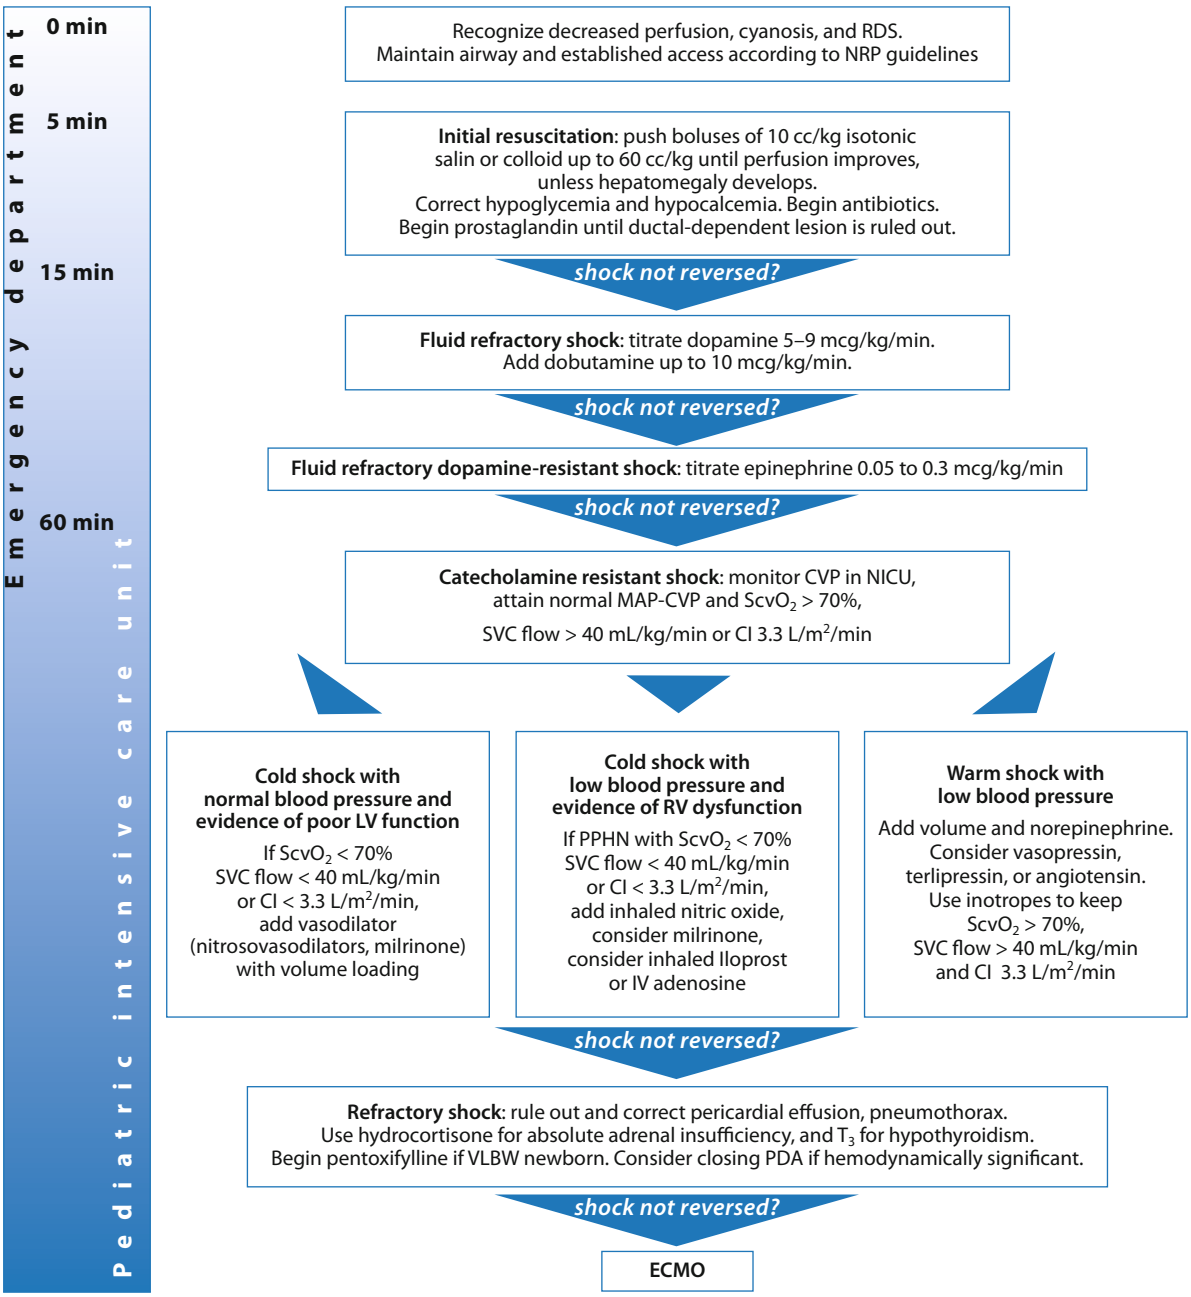

Fig. 117.1 Algorithm for time sensitive, goal-directed stepwise management of hemodynamic support in newborns. Proceed to next step if shock persists. 1) **First hour goals** Restore and maintain heart rate thresholds, capillary refill ≤2 sec, and normal blood pressure in the first hour. 2) **Subsequent intensive care unit goals** Restore normal perfusion pressure (*MAP-CVP*: mean arterial pressure-central venous pressure), preductal and postductal O_2 saturation difference <5%, and either central venous O_2 saturation ($ScvO_2$) >70%, superior vena cava (*SVC*) flow >40 mL/kg/min or cardiac index (*CI*) >3.3 L/min/m^2 in neonatal intensive care unit (*NICU*). *RDS* respiratory distress syndrome, *NRP* neonatal resuscitation program, *PDA* patent ductus arteriosus, *ECMO* extracorporeal membrane oxygenation

as neonates have high blood lactate concentrations at birth. These levels normalize by 12 hours after birth. Wardle and colleagues examined two groups of ventilated preterm infants with mean gestational age of 27 weeks. They found no difference in median lactate levels between normotensive and hypotensive preterm infants (1.20 *vs* 1.22 mmol/L). Despite the median lactate levels being similar in the two groups, persistent high lactate levels were associated with an adverse outcome (death or peri-ventricular hemorrhage) [31]. Thus, recognition and treatment of shock in low birth weight infants should encompass clinical signs (peripheral pulses, perfusion and urine output) along with biochemical values, i.e., serum

lactate levels. Standard practices in resuscitation of premature infants in septic shock employ a more graded approach compared to resuscitation of term neonates and children. This more cautious approach is a response to reports that premature infants at risk for intraventricular hemorrhage (< 30 weeks gestation) can develop hemorrhage after rapid shifts in blood pressure [32, 33]; however, some now question whether long-term neurologic outcomes are related to periventricular leukomalacia (a result of prolonged under perfusion) more than to intraventricular hemorrhage. To summarize, while cerebral under perfusion is a set up for periventricular leukomalacia, aggressive resuscitation of critically ill VLBW can predispose them to cerebral hemorrhages. Hence the resuscitation of a VLBW neonate is challenging and needs to be studied further.

Several other developmental considerations influence therapies for shock. Relative initial deficiencies in the thyroid and parathyroid hormone axes have been appreciated and can result in the need for supplementation with thyroid hormone, and/or calcium replacement. Adrenal insufficiency and the need for hydrocortisone has been documented in this population as well [34]. In a double-blind, randomized, controlled study, 48 VLBW infants who had refractory hypotension and required dopamine (> 10 μgm/kg/ min) were assigned to receive stress dose of hydrocortisone (1 mg/kg Q8H) for 5 days or placebo solution. A significantly higher number of hypotensive VLBW infants treated with hydrocortisone were weaned off vasopressor support 72 hours after starting treatment. There was decreased use of volume expanders and less cumulative dose of dopamine and dobutamine in steroid treated patients as compared to control infants [35]. Other factors that impact the neonate's response to shock include reduced glycogen stores and muscle mass. These are important for gluconeogenesis; hence attention should be paid to maintenance of serum glucose in a critically ill neonate.

Studies of therapies specifically directed at premature very low birth weight infants with septic shock are needed. A single center randomized control trial reported improved outcome with use of daily 6 hour pentoxifylline infusions (a systemic vasodilator) in very premature infants with sepsis. The Cochrane analysis agrees that the smaller trials are promising but suggests that larger multicenter trials would be helpful [24].

The American College of Critical Care Medicine (ACCM) set a priority to establish clinical practice parameters and guidelines for the management of septic shock. As a follow-up to their original guidelines published in 2002, ACCM issued an update published in 2007 [36, 37]. Although the intent was to develop guidelines for the management of premature as well as term newborns, the literature review on septic shock in the premature was relatively sparse. The evidence and expert opinion-based document found age-specific differences in both pathophysiology and response to therapies [38–74]. Rapid fluid resuscitation is the hallmark of therapy. It should be implemented when newborns are in compensated shock and directed to reversal of tachycardia. Newborns with fluid refractory shock can have any hemodynamic state. Some have the classic adult form of septic shock with high cardiac output and low vascular resistance; however, the majority have a low cardiac output state commonly associated with elevated, not reduced vascular resistance. If there is heightened concern for a ductal dependent heart lesion, all newborns with shock should be started on prostaglandin E. Newborns have an age-specific resistance to dopamine and dobutamine, hence epinephrine (cold shock) can be more commonly required. Newborns with septic shock have a higher incidence of true adrenal insufficiency (cortisol < 18 μg/dL) when requiring epinephrine. These patients may benefit from hydrocortisone therapy. In patients with low cardiac output and elevated systemic vascular resistance, vasodilators are effective in reversing shock. ECMO is life saving for refractory newborn septic shock. Inhaled nitric oxide decreases ECMO use but does not improve outcome in ECMO centers. ECMO is recommended for term infants with refractory shock.

117.5 Thrombocytopenia Associated Multiple Organ Failure

Thrombocytopenia, platelet count < 100,000 mm^3, is an independent risk factor for the development of multiple organ failure and death in critical illness, in part because it is a recognizable clinical sign of endotheliopathy with platelet thrombi. This syndrome is accounted for by variations on two prototype thrombotic microangiopathies. The consumptive coagulopathy (reduced fibrinogen levels) occurs when tissue factor complexes with factor VII and initiates the coagulation factor consumption cascade. This is commonly called disseminated intravascular coagulation (DIC). Román and colleagues have documented that newborns with sepsis/septic shock have a pro-thrombotic/anti-fibrinolytic state with excessive thrombosis – pro-coagulant (Factor II, VII) and anti-coagulant factors (i.e., protein C and anti-thrombin III) are both consumed [26, 27]. This leads to a paradoxical observation, overwhelming thrombosis (when the anti-coagulant factors are depleted) and then overwhelming bleeding (when the pro-coagulant factors are consumed). Newborns have lower protein C levels than children and adults. Activated protein C (APC) has 40 times the fibrinolytic activity as protein C concentrate and it is associated with intracranial bleeding. The pediatric arm of the "Extended Evaluation of Recombinant Activated Protein C" or ENHANCE trial noted increased incidence of significant bleeding in 27% of the patients enrolled and 3% had a central nervous system bleed [75]. Due to the adverse risk to benefit ratio associated with use of APC, it is not being used by most practitioners.

The second prototype is a non-consumptive coagulopathy (normal or increased fibrinogen levels), which is characterized by low ADAM TS 13 activity leading to platelet thrombi. Newborns have lower ADAM TS 13 activity than children and adults. This condition has been named infection-associated

thrombotic thrombocytopenic purpura. It responds to daily centrifugation-based plasma exchange therapy for a median of 14 days. Plasma exchange machines are not approved for infants under 5 kg so their use is limited in the newborn period. Nevertheless, newborns have reduced ADAM TS 13 activity and increased circulating ultra large vWF multimers (thrombogenic multimers) which puts the newborn at risk for non-consumptive coagulopathy. The use of fresh frozen plasma remains a standard approach to both forms of coagulopathy in newborns. Some have reported improved outcome with whole blood exchange but not blood component exchange therapy [76, 77].

117.6 Why Do Newborns Have Difficulty Eradicating Infection?

117.6.1 Hypogammaglobulinemia

Newborns and premature newborns in particular have a reduced ability to eradicate infection at almost all levels of immunity. Most notorious is the common deficiency of IgG levels in the VLBW infant. Prophylaxis with intravenous immunoglobulin (IVIG) therapy has not reduced late onset sepsis in this group of patients, but IVIG therapy in newborns with hypogammaglobulinemia and septic shock is thought to be of benefit. A recent meta analysis demonstrated that the use of immunoglobulin preparation rich in IgG, IgA and IgM reduces the mortality in neonatal sepsis or septic shock by 50% [78]. Hence, IVIG therapy should be considered in newborns with hypogammaglobulinemic septic shock or toxic shock [79–82].

117.6.2 Neutropenia

Neutropenia is commonly seen in newborns with sepsis/septic shock. Some have defined it as an absolute neutrophil count < 1500/mm^3. Granulocyte macrophage-colony stimulating factor (GM-CSF) therapy at 5 μg/kg/day over 12 hours for 7 days has been reported to improve outcomes in newborns with neutropenic septic shock [83]. G-CSF has also been studied in newborns with non-neutropenic sepsis and was found to be associated with a shortened length of stay [84]. In a multicenter trial in the United Kingdom, 280 small for gestational age neonates of ≤ 31 weeks gestation were randomized within 72 h of birth to receive GM-CSF 10 μg/kg per day subcutaneously for 5 days or standard management. The primary outcome was sepsis-free survival to 14 days from trial entry. The investigators found that neutrophil counts increased significantly more rapidly in infants treated with GM-CSF than in control infants during the first 11 days, however there was no significant difference in sepsis-free survival for all infants [85]. Hence, GM-CSF can be used to increase the neutrophil count but may not provide any survival benefit in septic neonates [86–90].

117.6.3 Prolonged Monocyte Deactivation and Immune Paralysis

Monocyte deactivation (< 30% HLA-DR expression or 8,000 HLA-DR molecules, or ex vivo whole blood tumor necrosis factor [TNF] response < 200 pg/mL for > 5 days) is associated with immune paralysis and increased risk of late onset sepsis from a secondary infection in children and adults [91]. Hallwirth and collegues have reported that cord monocyte deactivation is a reliable parameter for predicting EOD in VLBW infants [92]. The anti-inflammatory cytokine, IL-10, and the reactive oxygen species, nitric oxide, and peroxynitrite radicals both deactivate monocytes. This common response becomes pathogenic when it lasts for more than 5 days. GM-CSF and interferon reverse this process *ex vivo*.

117.6.4 Prolonged Lymphopenia and Lymphoid Depletion Syndrome

Lymphopenia (< 1000/mm^3 for > 7 days) is associated with the development of secondary infection, unresolving multiple organ failure, and the finding of lymphoid depletion at autopsy in children [93]. Gurevitch et al [94] examined autopsies from low birth weight newborns with sepsis similarly reported lymphoid depletion. At present prophylactic and empiric antifungal/antiviral strategies may be appropriately considered in these patients as per the clinical experience with patients with low CD4 counts from other immunodeficiency diseases. IVIG therapy should be considered if B-cell numbers are substantially depleted along with hypogammaglobulinemia (IgG level < 500 mg/dL).

117.6.5 Antibiotic Prophylaxis, Empiric Therapy and Antibiotic Resistance

Because EOD is commonly caused by GBS and LOD is commonly caused by *Staphylococcus epidermidis*, antibiotic prophylaxis therapies have been considered (Table 117.2). Antepartum and intrapartum antibiotic use has markedly reduced the incidence of GBS EOD; but not surprisingly, has led to increased incidence of neonatal sepsis caused by resistant organisms. Vancomycin and teicoplanin prophylaxis are both effective in reducing LOD with *Staphylococcus* species [95], but routine prophylaxis is not yet recommended because of concern for emergence of resistant organisms. Fluconazole

Table 117.2 Suggested treatments to reverse immune insufficiency and/or to prevent nosocomial infection and sepsis

Sepsis/MODS	Neutropenia	Prolonged lymphopenia ALC < 1000/mm^3 for 7 days, or IgG < 500 mg/dL	Monocyte deactivation HLA-DR < 30% or 8,000 molecules > 5 days
Give GM-CSF	Yes		Yes?
Give IVIG		Yes if IgG < 500	
Consider empiric and prophylactic antibiotic/protozoal fungal strategies	Yes	Yes	Yes?

prophylaxis has been very effective in preventing *Candida* sepsis in VLBW infants and is recommended [96]. Empirical antifungal therapy should be strongly considered for infants with gestational age < 25 weeks, thrombocytopenia, history of third-generation cephalosporin or carbapenem exposure for 7 days [97]. Empiric use of amphotericin for VLBW babies with risk factors for fungal infection has also been recommended [98, 99].

117.7 Supporting Organs During Multiple Organ Failure: What's New?

117.7.1 Acute Respiratory Distress Syndrome

Overdistention of alveoli results in systemic inflammation with systemic release of inflammatory cytokines and depression of immunity. Lung protection ventilation strategies which limit volutrauma are prudent [100].

117.7.2 Acute Renal Failure

Investigators have demonstrated the efficacy of continuous veno-venous hemofiltration in children with meningococcal septic shock [101]. A recent randomized controlled adult study showed survival benefit with daily dialysis compared to intermittent dialysis therapy in patients with acute renal failure in the ICU [102]. Peritoneal dialysis/hemofiltration, continuous veno- venous hemofiltration, or continuous arterio- venous hemofiltration can be successfully performed in newborns [103].

117.7.3 Insulin Therapy

An adult randomized controlled trial showed a survival benefit in patients with sepsis/multiple organ dysfunction syndrome (MODS) when insulin was used to maintain normal glucose levels during critical illness [104].

117.7.4 Steroid and Drug Metabolism

Reactive oxygen species impair cytochrome P450 activity. This leads to reduction of cortisol and aldosterone synthesis and reduced drug metabolism during sepsis and multiple organ failure. Newborns have an age-specific reduced cortisol synthesis for a given substrate (17-OH progesterone), as well as reduced drug metabolism due to an immature cytochrome P450 system [105].

Relative adrenal insufficiency is considered pathologic in adults with catecholamine resistant septic shock and mortality is reduced when these patients are treated with a 7 day course of hydrocortisone and fludrocortisone [106]. Hydrocortisone has reversed epinephrine resistant septic shock in premature infants with adrenal insufficiency. In a retrospective observational study, 117 infants treated with hydrocortisone for refractory hypotension were reviewed. Refractory hypotension was defined as a mean arterial pressure (MAP) less than the gestational age (GA) despite a total inotrope dose of 20 μg/kg/min. Patients treated with hydrocortisone demonstrated improved hemodynamics and decreased inotropic dose at 6, 12 and 24 h. The incidence of side effects, i.e., intraventricular hemorrhage, periventricular leukomalacia, sepsis and spontaneous intestinal perforation was similar to institutional historic controls [107].

117.8 Summary

Newborn sepsis remains a major international health care problem, particularly in low birth weight infants. It is a significant cause of mortality and neurologic morbidity including cerebral palsy. As with all major health care problems, resources should be invested in prevention and early intervention programs. Antepartum GBS prophylaxis has been successful in reducing incidence and mortality.

When sepsis is not recognized and treated early, septic shock becomes the predominant predictor of mortality and neurologic morbidity. In contrast to adults, septic shock in neonates occurs primarily secondary to cardiac failure, not vascular failure. This state of cardiac failure is commonly

associated with systemic pulmonary hypertension. Hence therapies including volume resuscitation, inotropic support and right ventricle afterload reduction are the mainstay. ECMO is life-saving for term newborns with refractory shock. At present no specific therapies have been approved for thrombotic complications (DIC or TTP/HUS) in newborns, hence plasma therapies remain the mainstay.

Sepsis is all too common in very low birth-weight newborns (20–30% of the neonatal population) with a predominant late (after 72 hrs) rather than early onset. Development of early diagnostic tests, infection prevention practices, and immunostimulant therapies are urgently needed for this population not only to improve survival but to reduce periventricular leukomalacia.

Neonatal Viral Infections: Enteroviruses, and Respiratory Syncytial Virus

Paolo Manzoni, Elisa Antonielli d'Oulx and Pier-Angelo Tovo

118.1 Enteroviruses

118.1.1 Introduction

The detection and identification of viral infections in newborns has been greatly improved by the recent development of rapid and highly sensitive diagnostic methods, particularly polymerase chain reaction (PCR) techniques. Data from a retrospective analysis of neonates admitted to a Neonatal Intensive Care Unit (NICU) in the Netherlands during a 12 year period confirmed viral infection in about 1% of cases. Enterovirus or parechovirus (EV/PeV) were the most frequent causes (39% of cases), followed by respiratory syncytial virus (RSV) at 29% (Table 118.1). EVs caused the highest mortality rate and serious sequelae [1].

EV and PeV are non-enveloped, single-stranded RNA viruses belonging to the Picornaviridae family (pico = small). Until 1999, EV were divided into five classes, based on their replication properties in tissue culture and animal models: polioviruses 1–3, Coxsackie viruses (Coxsackie virus A, Coxsackie virus B), echoviruses, and EV. On the basis of sequence analysis, the EV genus was recently reclassified into five species. Polioviruses and Human EV A, B, C, and D. Echovirus 22 and echovirus 23 were reclassified as PeV1 and PeV2 genuses, respectively. New PeVs have recently been identified: PeV3 and PeV4 [2].

Table 118.1 Viral infections in a Neonatal Intensive Care Unit over a 12-year period (number of infants 5396; viral infections 51)

Virus	Percentage
Enterovirus/Parechovirus	39%
Respiratory syncytial virus	29%
Rotavirus	10%
Cytomegalovirus	6%
Adenovirus	4%
Parainfluenza virus	4%
Herpes simplex virus	4%
Rhinovirus	2%
Rubella	2%

Data from [1].

Turin, Italy

118.1.2 Epidemiology and Pathogenesis

EV and PeV infections occur throughout the year, but mostly during the summer and autumn in temperate climates [2]. EVs spread from person-to-person by fecal-oral or oral-oral (respiratory) routes. Transmission has been documented by the contaminated hands of health care personnel and by fomites. Mother-to-child transmission may occur in utero, during or after delivery. Disease severity is greater in neoantes than in older children. The pathogenesis and pathology of EV infections depend on virulence, tropism and inoculum virus concentration, as well as host factors.

The portal of entry is the pharynx and lower alimentary tract. Within one day, the infection extends to the regional lymph nodes. On about the third day, minor viremia occurs with subsequent spread to secondary infection sites {e.g., liver, heart, central nervous system [CNS]) where virus replication causes local damage. Within a week, there is major viremia with associated clinical manifestations. EVs are usually cytolytic. Symptoms and signs are related to the extent and location of cell death. Cessation of viremia correlates with the appearance of serum antibody. Infection may persist in the lower intestinal tract.

118.1.3 Clinical Aspects

In neonates, most nonpolio EV infections are asymptomatic although they can cause mild, nonspecific febrile illness,

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

occasionally with rash. Their onset is characterized by mild irritability, a fever varying between 38°C and 39°C, frequently accompanied by poor feeding and, in some infants, by vomiting and/or diarrhea [3].

A serious complication of nonpolio EVs is a sepsis-like illness, which has been most frequently observed with Coxsackie virus types B2 to B5 and echovirus types 5, 11 and 16. It is characterized by high fever, abdominal distension, irritability, lethargy, and hypotonia. Other clinical features include diarrhea, vomiting, seizures, shock, disseminated intravascular coagulation, thrombocytopenia, hepatomegaly and jaundice [4].

Respiratory illness associated with non-polio echoviruses is sporadic, except for echoviruses 11 and 22. The clinical presentation includes rhinitis and pharyngitis, and, to a lesser extent, laryngitis or interstitial pneumonitis. Coxsackie virus A9 and B4 or echovirus 9, 11, 17 and 31 are more frequently associated with pneumonia [4].

Coxsackie viruses and echoviruses can cause vomiting, diarrhea and hepatitis with various degrees of hepatic necrosis. Some Coxsackie virus serotypes can cause pancreatitis or necrotizing enterocolitis [4].

Most cases of neonatal myocarditis are caused by Coxsackie virus B infections and, less frequently, by echovirus 11 and 19 [4]. There is often an abrupt onset with listlessness, anorexia and fever. Progression is rapid and there may be circulatory failure (tachycardia, cardiomegaly, electrocardiographic changes and transitory systolic murmurs, respiratory distress and cyanosis). The mortality rate is high.

Neonatal exanthema has been noted with Coxsackie virus B1 and B5 and other echoviruses, a macular, maculopapular, or (rarely) petechial rash appearing between the third and fifth day of the illness [4].

Echoviruses, particularly Coxsackie virus B1 to B5, may cause meningitis and meningoencephalitis. Cerebrospinal fluid (CSF) examination shows variations in protein, glucose and cellular values, which may mirror a bacterial disease. In particular, hypoglycorrachia is noted in about 10% of newborns with enteroviral meningitis.

A monolateral facial paralysis with transitory loss of abdominal reflexes due to Coxsackie virus B2 has been described [4].

Coxsackie virus A4, A5, A8, B3, echovirus 11 and 22 have been related to sudden infant death syndrome.

Postnatally acquired poliovirus infection may be asymptomatic or cause various symptoms and signs, including paralysis (Table 118.2). Some infants who acquired poliomyelitis died within the first 2 weeks of life. Neonatal infections due to PeV1 or 2 are observed sporadically and mostly cause mild gastrointestinal and respiratory disturbances. Recently, the new PeV3 has been associated with severe disorders, including involvement of the CNS with mild-to-severe white matter injury. PeV4 was isolated from an infant with fever [2].

The diagnosis is by virus culture, direct antigen detection and/or PCR.

118.1.4 Differential Diagnosis

Hypothermia and hyperthermia in association with other nonspecific signs are common in neonatal enteroviral infections and in bacterial sepsis. An increase in serum C-reactive protein concentrations, considered indicative of bacterial infection, is also seen in infants with EV infections and less frequently in patients with PeV infections. In meningitis, the CSF findings in bacterial and viral illnesses may be similar and bacterial culture and PCR assays are essential. Skin lesions are common in generalized herpes simplex infections and scraping a lesion should allow a rapid diagnosis.

Neonatal seizures due to enteroviral meningoencephalitis may be difficult to differentiate from seizures related to hypoxic-ischemic encephalopathy in full-term infants. The differences are that patients with enteroviral infection may have a history of a viral infection in the family and an uneventful pregnancy and delivery, later onset of seizures, and a possible rash. Neonates with PeV infection cannot be distinguished

Table 118.2 Clinical manifestations of Enterovirus infection in newborns

General symptoms	Specific symptoms
No symptoms	–
Sepsis-like	Fever, poor feeding, abdominal distension, irritability, rash, lethargy and hypotonia, diarrhea, vomiting, seizures, shock, disseminated intravascular coagulation, thrombocytopenia, hepatomegaly, jaundice and apnea
Respiratory	Rhinitis, pharyngitis, laryngitis, herpangina, coryza, laryngotracheobronchitis, bronchitis, interstitial pneumonitis
Gastrointestinal	Vomiting and diarrhea, hepatitis, hepatic necrosis, pancreatitis, necrotizing enterocolitis
Cardiological	Tachycardia, cardiomegaly, electrocardiographic changes, transitory systolic murmurs, myocarditis, respiratory distress, cyanosis, signs of neurologic involvement
Dermatological	Macular or maculopapular or petechial rash
Neurological	Anorexia, fever, lethargy, jaundice, vomiting, seizures, apnea, tremulousness, general increased tonicity, meningitis, meningoencephalitis, paralysis
Sudden infant death	–

from those with EV infection by clinical signs only. There are similar white matter abnormalities on cranial imaging. However, the diagnosis may be made by reverse transcription PCR for EV and PeV on blood and/or CSF because of genetic differences between the viruses [2].

Fever or hypothermia, lethargy, weakness and characteristic electrocardiographic changes differentiate neonatal myocarditis from congenital heart disease.

118.1.5 Prognosis

Both EV and PeV may lead to severe cerebral disease with associated serious sequelae [2]. In one study of six infants with CNS involvement, three babies born preterm had abnormal neurodevelopmental outcomes, while the three born at term developed normally. This is likely to be due to the different vulnerability of the white matter during maturation [5].

Poliovirus infections in neonates are generally severe, causing death or persistent paralysis in a consistent number of patients.

118.1.6 Therapy and Treatments

There is no specific therapy for any EV infection. Human immune serum globulin may be considered when there is severe and generalized neonatal infection on the assumption that the infant did not receive protective antibodies from the mother.

Treatment is generally supportive. The use of corticosteroids in neonatal encephalitis, myocarditis or other severe illnesses, is debated with some authors taking a view that they should not be used during acute EV infections, with others supporting their use in Coxsackie virus myocarditis, although deleterious effects have been observed in mice.

Meningoencephalitis is often associated with convulsions, cerebral edema and fluid and electrolyte balance disturbances. Serum electrolyte levels and fluids should be closely monitored because inappropriate antidiuretic hormone secretion is common.

In case of serious outbreaks in a nursery, passive protection with immunoglobulins for all exposed infants should be considered. The worldwide use of vaccination with inactivated polio vaccine (IPV) and the oral polio vaccine (OPV) developed by Sabin in the early sixties made it possible to control the epidemic in most areas. However, logistic problems and the cost of vaccination have meant that poliomyelitis remains endemic in Central Africa and the Indian sub-continent [6]. Infants with paralytic poliomyelitis should be observed carefully for evidence of respiratory paralysis with positive-pressure ventilation for respiratory failure. Passive movements of the paralysed limbs should be started soon after the disappearance of fever.

118.2 Respiratory Syncytial Virus (RSV)

RSV is a ubiquitous paramyxovirus. It has a peak during the winter months. Neonates, particularly those born before 35 weeks of gestation, are at-risk of severe RSV infection and respiratory failure [7].

118.2.1 Epidemiology and Pathogenesis

RSV is extremely contagious. Transmission occurs by aerosol inhalation of droplet nuclei from an infected person. Contaminated objects may be important sources of infection and the hand carriage of contaminated secretions by nursery personnel may contribute to spread.

118.2.2 Clinical Aspects

RSV may be asymptomatic or cause a disease that varies from a mild afebrile upper respiratory tract infection to severe bronchiolitis or pneumonia with hyperinflated lungs and hypoxemia. The A subtype of RSV appears to be more serious than the B subtype. The risk of severe illness is highest in infants born prematurely and in those with underlying lung disease, significant congenital heart defects or immune deficiencies [7]. Infants younger than 1 month have higher viral titers in their secretions than older ones.

After a few days of incubation, the first symptom is usually non-purulent rhinorrhea, followed by cough and wheezing, with or without dyspnea, bronchiolitis, pneumonia and fever. Irritability, lethargy and poor feeding may be the initial manifestations in infants. Chest X-ray abnormalities may precede the clinical manifestations of lower respiratory tract involvement by a few days.

118.2.3 Diagnosis

Rapid diagnosis is made by detecting viral antigens in nasopharyngeal specimens by specific assays, such as immunofluorescent or enzyme immunoassay. Viral isolation may be difficult because RSV is a labile virus.

118.2.4 Prognosis

Many infants with severe RSV bronchiolitis experience recurrent wheezing in later childhood and there is evidence that early RSV bronchiolitis may predispose some infants to the development of childhood asthma, although this association remains poorly understood [7].

118.2.5 Therapy and Treatments

As RSV-related bronchiolitis and pneumonia may cause severe disease in high-risk infants, supportive care, such as intravenous hydration, management of bacterial complications and mechanical ventilation may be needed. The use of 3% saline and aerosolized ribavirin treatment for infants with lower respiratory tract infections caused by RSV remains debatable [8]. Candidates for ribavirin therapy are infants at risk for complications of RSV due to congenital heart disease, chronic lung disease or immunodeficiency, infants with severe illness and signs of respiratory failure or those with a prolonged illness because of an underlying medical condition [9].

Because of the limitations associated with the management of RSV disease, prevention remains paramount, especially in patients at high risk of severe disease. Palivizumab is a humanized mouse monoclonal antibody which has been shown to be a safe and efficacious, significantly reducing the burden of RSV-related disease in premature infants below 35 weeks of gestational age. Its use in such high-risk patients is recommended by specific national guidelines of a number of countries in Europe, America and Asia [10].

Palivizumab is administered at a dosage of 15 mg/kg in a single monthly intramuscular injection for 5 months during the epidemic season.

Important measures for the prevention and control of viral epidemics are careful hand washing by nursery personnel after handling each infant, restricting the nursery area to personnel and visitors free of respiratory illnesses, and barrier nursing sick infants.

Vaccinations and Neonatal Immunity

Alberto G. Ugazio and Alberto E. Tozzi

119.1 Immunological Development of the Neonate

The fetus can be compared to a haploidentical graft, sharing only half of the histocompatibility antigens of the "mother host". As such, the fetus should be rejected by the immune system of the mother. At the same time, since the fetal immune system starts developing around the 9th week of gestation, the fetus should also mount a "graft-versus-host" reaction against those histocompatibility antigens that it has not inherited from the "mother host". It follows that survival of the fetus – indeed of all mammalian species – is strictly dependent on a wide variety of mechanisms preventing graft rejection by the mother and graft-versus-host reaction by the fetus [1]. Among the latter, a major role is certainly played by the slow intrauterine maturation of the fetal immune function, ultimately resulting in the physiological immune deficiency of the neonate that involves both innate and adaptive immunity. This immune immaturity – more severe in preterm and in very low birth weight infants - results in a weak immune response to antigen challenge and in the production of a poor immunological memory [2].

After birth, the immune responsiveness quickly matures in both term and preterm neonates, rapidly reaching levels comparable with those observed in children and adults. The duration of this maturation process is variable, and also depends on the type of antigen to which immunity is directed. The optimal period for vaccination is decided therefore on a balance between the need of protecting the newborn as soon as possible against potential infectious threats, and the opportunity to trigger protective and durable immune responses.

119.2 General Recommendations

Routine immunizations are often delayed in preterm and low birth weight infants, due to their impaired ability to develop protective immunity, and to the perception that they are more susceptible to side effects [3–6]. However, the safety profile and immunogenicity of routinely administered vaccines are similar to those measured in full-term infants. Therefore, in most cases, preterm and low birth weight infants should be immunized according to their chronological age [7, 8]. In addition, vaccine dosage should not be reduced or divided [7].

The site of choice for intramuscular vaccine administration is the anterolateral thigh, and needle length should be chosen on the basis of the available muscle mass [8].

Preterm infants may suffer from cardiorespiratory instability at the time of immunization and vaccine administration has been suspected to trigger apnea, desaturation, and bradycardia, especially in children with pre-existing cardiorespiratory symptoms [9–15]. Moreover, infants that presented apnea in the 24 hours before the immunization have been considered more likely to develop post-immunization apnea [15]; post-immunization apnea has been reported to occur more frequently in the presence of severe illness at birth, younger age, and lower weight [15]. None of the cardiorespiratory or other adverse events observed in preterm or low birth weight infants had sequelae in the studies published so far, and all of them were transient [15, 16]. However, based on the data from these observational studies, it has been recommended that infants still hospitalized at the time immunization is due should be monitored in hospital for 48 hours after vaccine administration [16]. Severe cardiorespiratory events after the first vaccine dose may occasionally predict similar episodes at the second dose [17]. More recently, a randomized trial in preterm children immunized with DTaP demonstrated that the rate of prolonged episodes of apnea or bradycardia is similar in immunized infants and controls [18].

An increase in C reactive protein (CRP) is commonly found in infants after immunization, although such an increase

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

has not been observed with HBV and IPV immunizations [14]. The finding of normal CRP values before immunization suggests that high CRP values following immunization are possibly induced by vaccine administration [14].

Early and timely immunization of preterm and low birth weight infants is safe and essential for protecting them against diseases to which these infants are particularly susceptible and that may even be fatal. The benefits of early and timely immunization of fragile children far exceed the risk of inducing suboptimal protection. In addition, immunization of households and contacts of preterm and low birthweight infants against pertussis and influenza may be effective in decreasing the likelihood of exposure before immunization (pertussis) and before full maturation of immune defence mechanisms (influenza).

119.3 Vaccines That Can Be Administered at Birth

Since the neonate is not able to mount robust immune responses to most vaccines, immunizations are mostly delayed until the second or third month of age. Nonetheless, in some circumstances where the risk of acquiring some infectious diseases is high, early administration of vaccines, soon or shortly after birth, is crucial for avoiding infections.

BCG BCG is administered to neonates in many countries where the prevalence of tuberculosis is high. Studies in which preterm babies were compared with term infants showed similar responses to the tuberculin reaction after immunization and comparable cellular immuno responses [19, 20]. In one study the authors found a weaker delayed hypersensitivity to tuberculin after BCG in preterm infants compared with full-term neonates, and therefore recommended to delay BCG administration in newborns younger than 33 weeks of gestational age [21]. Other authors found a positive relationship between a positive tuberculin test after BCG and postnatal weight [22]. Administration of BCG in preterm infants does not result in an increased reactogenicity compared with full-term babies [19].

Hepatitis B Virus (HBV) Immunization of newborns against hepatitis B together with hepatitis B immunoglobulin (HBIG) administration within 12 hours of birth is recommended in children born to hepatitis B surface antigen (HbsAg) positive mothers or to those whose HBV status is unknown [23]. It has been shown that HBV vaccine administration in newborns who weigh less than 2,000 g results in decreased seroconversion rates [24]. These children should be immunized as well within 12 hours of birth, although the initial vaccine dose should not be counted towards completion of the HBV series. In some countries as the US, HBV is administered to all newborns regardless of mother's HBV status [23]. Preterm infants weighing less than 2,000 g and born to HBsAg-negative mothers should receive the first dose of the HepB series at 1 month of chronological age or at hospital discharge in order to take advantage of the increased maturity of the newborn's immune system [25–27].

119.4 Vaccines That Can Be Administered in Infancy

As previously mentioned, immunization schedules start as a rule during the second to third month of life and usually include, in industrialized countries, diphtheria, tetanus, pertussis, polio, *Haemophilus* type b and hepatitis B vaccines. Some schedules also include either conjugated pneumococcal vaccine or conjugated meningococcal C vaccine. In developing countries the schedule may include a more limited number of vaccine components. Unfortunately, good quality efficacy and safety studies have been carried out only for a limited number of vaccines. A synthesis of the available evidence for each specific vaccine is presented below.

Diphtheria-Tetanus-Pertussis Vaccine Diphtheria, tetanus, and pertussis (DTP) immunogenicity has been demonstrated in different studies even when these components are combined with other vaccine antigens [28–31]. Conflicting results have been obtained for the immunogenicity of the pertussis component, with some studies showing low titres in preterm compared with full-term infants [28–31]. To date, a serological correlate of protection from pertussis has not been identified. Therefore, the finding of low titres of antibodies directed against antigenic components of the pertussis vaccine is of doubtful significance. Tolerability of vaccines including DTP antigens in preterm infants is similar to that observed in full-term babies [28, 29, 32].

Polio Vaccine Inactivated polio vaccine has been shown to be immunogenic and well tolerated in preterm infants even when administered within combined vaccines [29, 30, 33, 34]. Lower geometric mean titers have been observed for serotypes 2 and 3 in comparison with full-term infants [29, 35]. Oral polio vaccine, which is still in use in some countries, does not seem to be influenced in its response by gestational age [36].

Haemophilus Type b Vaccine (Hib) Tolerability of the Hib component has been shown in several studies carried out with combined vaccines [31, 32]. Percentage of responders and antibody titers have been shown to be lower in preterm infants [35, 37, 38]. Available data show an increase in vaccine failures in preterm compared with full-term infants when an accelerated schedule is used (2, 3, and 4 months of age) [39].

Hepatitis B Vaccine HBV is well tolerated in preterm and low birth weight infants and is fully immunogenic when administered in babies > 2,000 g or older than 60 days [29, 32, 40].

Conjugate Pneumococcal Vaccine Heptavalent conjugate pneumococcal vaccine seems to elicit a similar immune response in preterm and full-term infants [41, 42] although one study reported a lower immunogenicity in preterm infants immunized with an accelerated schedule (2, 3, and 4 months of age) [43]. Most importantly, efficacy of this vaccine in preterm and low birth weight infants is very high, similarly to what is observed in full-term infants [42]. Local reactions are observed more commonly in preterm and low birth weight than in full-term infants [42].

Conjugate Meningococcal C Vaccine The conjugate meningococcal C vaccine is well tolerated and immunogenic when administered to preterm infants, although the only available studies were performed with an accelerated schedule (2, 3, and 4 months of age) [44, 45].

Measles-Mumps-Rubella and Varicella A single study showed similar geometric mean titers and proportions of responders to measles, mumps, rubella and varicella in severely preterm as compared to full-term infants immunized at 15 months of age [46]. It must be taken into account that preterm infants lose maternal antibodies to measles early after birth [16]. Therefore, preterm infants may safely be immunized during outbreak periods between 6 and 9 months of age [16].

Rotavirus A pentavalent live attenuated rotavirus vaccine has proved safe and efficacious in preterm babies [47]. Although so far no epidemiological study has investigated the horizontal transmission of vaccine strains, vaccine virus shedding can be observed up to 15 days after administration. Children of appropriate age and still hospitalized may be immunized on the day of discharge.

Influenza One study carried out in infants born prematurely and immunized after 6 months of age with an inactivated influenza vaccine showed greater T-cell proliferative responses to influenza antigen in full-term children than in the preterm children, but similar proportions of responders [48].

119.5 Immunological Memory in Preterm Infants

A potential cause of concern is whether vaccines administered to preterm infants induce a good immunological memory. DTaP-IPV-Hib-HBV vaccine has been shown to induce immunological memory in most preterm infants primed with the same vaccine for all the components [38]. Other studies indicate that the immune response after primary immunization with conjugate meningococcal C or pneumococcal vaccine may be weaker in preterm than in full-term infants, and that it wanes after one year if an accelerated schedule is used (2, 3, and 4 months of age) [43, 45].

119.6 Children Treated with Corticosteroids

Preterm infants are often treated for variable periods with corticosteroids. Dexamethasone-treated preterm infants show significantly reduced antibody levels to diphtheria, tetanus, and to pertussis antigens after primary immunization [49]. It is not known how much this decreased response reflects on protection, especially for diphtheria and pertussis. A negative effect of dexamethasone treatment has been noted also on immune response to Haemophilus influenzae b vaccine [50], whereas it does not seem to decrease the immune response to conjugate meningococcal vaccine given at 12 months of age [51]. In general, care should be taken when dexamethasone-treated infants travel to endemic areas.

119.7 The Effect of Mercury Additives in Vaccines

Concern has been raised on the potential neurotoxicity of thimerosal containing vaccines administered early after birth. Since 1999, several international agencies including the European Medicine Agency and the Centers for Diseases Control have recommended that thimerosal be eliminated from vaccines as a precautionary measure [52, 53]. Epidemiological studies have shown that administration of thimerosal containing vaccines is not associated with an impaired neuropsychological development or with clear developmental disorders later in life [54–56].

119.8 The Future of Immunization of Newborns

Advances in immunization have been achieved throughout the last few decades bringing sophisticated means to protect children and the general population from severe transmissible diseases. Still, new approaches to the development of efficacious strategies to prevent some diseases are needed in the perinatal and infancy periods. Incidence of several diseases such as meningococcal and pneumococcal invasive infections, pertussis, and influenza is highest in infancy, and preterm babies often pay the highest toll in terms of morbidity. Moreover, given the relative immaturity of the immunologic system, these children, even when properly vaccinated, may not be optimally protected. Vaccines which stimulate the innate and the adaptive immune response may allow induction of better protection of the high risk newborn [57]. New routes of immunization may help to achieve the goal of inducing mucosal immunity [58].

Immunizing mothers to induce protection in the newborn may also represent a future development of immunization

strategies for protecting newborns [59]. Finally, new vaccines may help to prevent other diseases such as Group B streptococcal infections [60].

These goals may be achieved within a few years and provide us with new and more efficacious preventive tools for the special category of high risk newborns.

120.1 Introduction

Inborn errors of metabolism are disorders of great importance to physicians treating newborns because rapid diagnosis and appropriate treatment of these conditions are directly related to the patient's outcome in terms of mortality and morbidity. Although individually rare, as a group these diseases are relatively frequent and collectively their incidence may approach 1 in 800 to 2500 births [1, 2]. The presentation of these disorders may occur in any age group, from fetuses and newborns to adulthood. Neonatal onset is common because the newborn period is a time of substantial catabolism. The main problems facing the physician caring for the sick newborn are when to consider an inborn error of metabolism, what test to order to determine quickly and efficiently whether the patient has an inborn error of metabolism, and what therapy to initiate given a specific or a suspected diagnosis. Unfortunately, given the limited repertoire of symptoms of the newborn, the early presentation is generally non-specific and usually includes poor feeding, breathing difficulties, lethargy, hypotonia, vomiting, hypothermia, and seizures. Therefore, patients with acute metabolic presentation are often misdiagnosed with other more common conditions such as sepsis, pulmonary disease, pyloric stenosis, and Reye syndrome. However, clues from the history, from the clinical presentation or from basic biochemical studies should raise the suspicion of a metabolic disease (Tables 120.1–120.7). A wide range of tests are required for the diagnosis of inborn errors of metabolism and the level of clinical and biochemical experience required is often substantial. Nevertheless, the neonatologist can initiate appropriate investigation with a relatively small number of laboratory tests which are readily available in most hospitals (Table 120.8). In many circumstances, the prevention of death or permanent neurologic sequelae is dependent on early diagnosis and institution of appropriate treatments. In addition, an accurate diagnosis is of primary importance for parental counselling.

Intensive efforts are currently ongoing to implement programs of expanded newborn screening using tandem mass spectrometry (MS/MS) with the goal of detecting a large number of inborn errors of metabolism in their pre-symptomatic early phase and have the potential to significantly change the natural history, the management, and the treatment of these disorders in the next few years.

120.2 Etiology and Pathogenesis

Metabolism is regarded as the sum of all chemical reactions that operate in a living cell. Enzymes play an essential role in facilitating each of these reactions serving as catalysts in the conversion of one metabolite to another. Inborn errors of metabolism are genetic disorders caused by alterations of specific chemical reactions in metabolism. The consequences of these alterations can be mediated by: 1) direct toxicity of accumulating upstream metabolites; 2) deficiency of downstream metabolites; 3) feedback inhibition/activation by the metabolite on the same or different pathway; and 4) diversion of metabolic

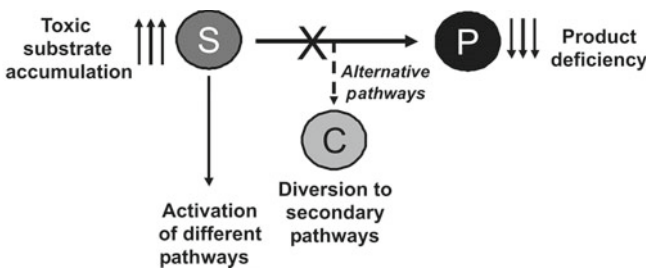

Fig. 120.1 An enzymatic blockage results in: 1) direct toxicity of accumulating upstream substrate (S); 2) deficiency of downstream product (P); 3) activation of alternative pathways; 4) diversion of metabolic flux to secondary pathways and alternative metabolite (C) production

  - Hyperammonemia
  - Lactic acidemia
- Post mortem
  - Fatty liver or cardiomyopathy

flux to secondary pathways and buildup of toxic metabolites (Fig. 120.1). The majority of the inborn errors of metabolism are autosomal recessive but a few are X-linked. In addition, several of these disorders are included in the group of mitochondrial cytopathies which can exhibit matrilinear, autosomal recessive, autosomal dominant, and X-linked inheritance.

120.3 Clinical Presentations

The clinical presentation of metabolic diseases may include findings in virtually every system. From a clinical standpoint, inborn errors of metabolism can be classified according to the time of onset in prenatal or postnatal onset diseases. It is also useful to separate maternal inborn errors of metabolism affecting the fetus as well as fetal diseases affecting the mother. The postnatal group can be further classified according to the main symptom and laboratory findings at the time of disease onset [3]. It should be noted that patients with inborn errors of metabolism have often complex and overlapping problems which are a serious limitation of any classification system including the one used in this chapter.

Table 120.2 Inborn errors of metabolism with cardiac presentation in the neonatal period

	Main clinical features	Laboratory abnormalities	Diagnostic test
Fatty acid oxidation disorders	Cardiomyopathy Arrhythmias Hypotonia Sudden death	Hypoketotic hypoglycemia Hyperammonemia Elevated creatine kinase	Acylcarnitine profile Molecular analysis
Propionic acidemia and methylmalonic acidemia	Cardiomyopathy Encephalopathy Vomiting	Metabolic acidosis Bone marrow suppression	Organic acid analysis Acylcarnitine profile
Methylmalonic aciduria and homocystinuria CblC type	Structural cardiac defects	Metabolic acidosis Methylmalonic aciduria Increased blood homocysteine	Organic acid analysis Homocysteine determination
Tyrosinemia type I	Liver disease Cardiomyopathy	Elevated tyrosine	Elevated succinylacetone
Sugar alchol disorders	Progressive myocardial hypertrophy	Hypoalbuminemia; decreased coagulation factors	Urinary polyols
Mitochondrial disease	Cardiomyopathy Arrhythmias Hypotonia	Lactic acidosis Pancytopenia	Electron transport chain assay/ DNA testing
Pompe disease	Cardiomyopathy Hypotonia Wolf-Parkinson-White syndrome	Vacuolated lymphocytes Enlarged QRS complexes	Acid α-glucosidase activity
Glycogen storage disease type IV	Cardiomyopathy	Elevated creatine kinase	Glycogen branching enzyme activity
Heart-specific phosphorylase kinase deficiency	Cardiac enlargement	Hypoglycemia Short PR interval	Phosphorylase kinase activity
Mucopolysaccharidosis VI (Maroteux-Lamy disease)	Endocardial fibroelastosis Dysostosis multiplex	Increased urinary mucopolysaccharides	Galactosamine-4-sulphatase activity
Congenital disorders of glycosylation	Cardiomyopathy Pericardial effusion Hypotonia Dysmorphic features	Hypoalbuminemia Decreased coagulation factors Low thyroxine-binding globulin Increased transaminases	Transferrin isoelectrofocusing

  - Tyrosinemia type I
  - Ataxia-teleangectasia

120.4 Inborn Errors of Metabolism with Prenatal Onset

The fetus with a metabolic disorder is usually protected in utero by the metabolically normal mother through placental exchange of metabolites. Therefore, the majority of inborn errors of metabolism become clinically evident only after birth. The prenatal onset involves a group of disorders in which the maternal-placental unit cannot compensate for the underlying pathogenetic mechanisms thus resulting in fetal developmental defects. On a molecular basis, these disorders can be broadly divided into disorders involving large molecules and those of small molecules. Small molecule diseases involve organic acids, amino acids, carbohydrates, fatty acids, nucleotides, and ammonia. Large molecule diseases arise from either synthetic or degradative processing of polymeric molecules, such as glycoproteins and glycolipids.

120.4.1 Small Molecule Diseases

Small molecule diseases with prenatal onset present at birth with complex malformations rather than with acute decompensation. However, there is no rigid distinction and disorders

Table 120.8 Investigation for suspected inborn errors of metabolism

First line investigation
• Blood
– Complete blood counts
– Electrolytes
– Bilirubin
– Glucose
– Urea
– Blood gases and acid-base analysis
– Ammonia
– Lactate
– Uric acid
– Ketones
• Urine
– Reducing substances
– pH
– Ketones
• Cerebrospinal fluid
– Glucose
– Lactate
*Second line investigation**
• Urinary organic acid analysis
• Plasma, cerebrospinal fluid, urine amino acid analysis
• Plasma acylcarnitine profile
• Urine orotic acid
• Copper and ceruloplasmin
*Specialized investigation**
• Special biochemical assay (very long chain fatty acids [VLCFA], bile acid analysis, transferrin isoelectrofocusing, urine purine and pyrimidine, urine sugar alcohols)
• Enzyme assays
• DNA studies

* Before sending samples for second line for specialized investigations it is recommended to: 1) call the laboratory to indicate urgency, 2) give details on drug, diet, and previous blood transfusions, 3) arrange suitable transport of the samples, 4) discuss which tests are indicated with the metabolic consultants, and 5) freeze and save urine of the newborn.

such as nonketotic hyperglycinemia, which are associated with acute illness after birth, may also present with brain malformations. Similarly, mitochondrial diseases and fatty acid oxidation defects can exhibit features indicating prenatal onset damage [4, 5]. Accumulation of methylmalonic acid and homocysteine also appears to be involved in various types of congenital heart defects (Table 120.2) [6].

Disorders of serine biosynthesis are notable for their severe effects on prenatal development and present at birth with microcephaly, intractable seizures, and spastic tetraparesis. They are diagnosed by amino acid analysis in blood and cerebrospinal fluid (CSF) showing reduced levels of serine and glycine. The biochemical abnormalities are more pronounced in CSF rather than in plasma, and therefore, CSF amino acid analysis is preferable for the diagnosis. Early recognition of these defects is important because treatment with supplemental serine and glycine has beneficial effects [7].

Disorders of cholesterol biosynthesis have also significant effects on the fetus as exemplified by Smith-Lemli-Opitz syndrome, a multiple congenital anomaly syndrome caused by the deficiency of 7-dehydrocholesterol reductase catalyzing the reduction of 7-dehydrocholesterol to cholesterol in the last step of cholesterol biosynthesis. The clinical presentation of Smith-Lemli-Opitz syndrome is heterogeneous and severely affected infants have multiple major congenital anomalies of brain (holoprosencephaly, agenesis of the corpus callosum), heart (atrial and ventricular septal defects, atrioventricular canal defect), lungs (abnormal segmentation) or gastrointestinal tract (pyloric stenosis and colonic aganglionosis). Postnatal growth failure, microcephaly, typical facial features, ambiguous genitalia, limb anomalies such as postaxial polydactyly and syndactyly of the second and third toes are common findings. Desmosterolosis, lathosterolosis, X-linked chondrodysplasia punctata type II (Conradi-Hunermann syndrome), congenital hemidysplasia with ichthyosiform erythroderma and limb defects (CHILD syndrome), hydrops-ectopic calcification-moth-eaten skeletal dysplasia (HEM dysplasia), and a subset of cases with Antley-Bixler syndrome are due to defects in other steps of cholesterol biosynthesis and their clinical presentation partially overlap with Smith-Lemli-Opitz syndrome. These disorders are diagnosed by analysis of plasma sterols by gas chromatography/mass spectrometry (GC/MS) [8].

Another example of an inborn error of metabolism resulting in a complex malformative syndrome is the deficiency of glutamine synthetase presenting with severe brain malformations, multiorgan failure, and neonatal death [9]. The identification of this disorder on the basis of reduced glutamine levels is unusual because the interpretation of plasma amino acid profiles and the expanded newborn screening are usually directed toward increased (Table 120.9), rather than decreased metabolite levels.

120.4.2 Large Molecule Diseases

120.4.2.1 Lysosomal Storage Disorders

Lysosomal storage disorders are due to defects in lysosomal enzymes, cofactors, and transport proteins resulting in progressive accumulation of undegraded products within the lysosomes. These disorders usually present in infancy or early childhood with hepatosplenomegaly, skeletal dysostosis, and mental retardation. In the rare neonatal presentation they manifest as non-immune hydrops [10, 11]. The presence of dysmorphism, gum hyperplasia, inguinal and umbilical herniae, extensive Mongolian spots, and corneal clouding (Tables 120.5–120.7) [12] on physical exam and of placental vacuolization, vacuolated mononuclear cells in the peripheral smear, and bone marrow storage histiocytes on pathology are suggestive of these disorders [13].

A definitive diagnosis requires enzyme analysis which can be performed either on leukocytes or fibroblasts depending on the specific disease. Although lysosomal storage disorders represent the major cause, there is a growing awareness that several small molecules disorders can also result in

Table 120.9 Interpretation of plasma amino acid profile

Amino acid	Increase	Decrease
Alanine	Energy production defects Hyperammonemia	Maple syrup urine disease (during acute decompensation)
Alloisoleucine	Maple syrup urine disease	Normally not detected
Arginine	Argininemia Citrin deficiency	Prematurity Urea cycle disorders (deficiency of CPS, OTC, ASS, ASL)
Argininosuccinic acid	Argininosuccinic aciduria	Normally not detected
Citrulline	Citrullinemia Argininsuccinic aciduria Citrin deficiency Pyruvate carboxylase deficiency Lysinuric protein intolerance	OTC deficiency CPS deficiency
Glutamic acid	Sample mishandling	–
Glutamine	Hyperammonemia	Glutamine synthetase deficiency
Glycine	Nonketotic hyperglycinemia Organic acidemias	Disorders of serine biosynthesis
Histidine	Histidase deficiency*	–
Free homocysteine**	Homocystinuria† Methylenetetrahydrofolate reductase (MTHFR) deficiency	Isolated sulfite oxidase deficiency Molybdenum cofactor deficiency
Branched chain amino acids (Isoleucine, valine, and leucine)	Nonfasting Maple syrup urine disease	Hepatic dysfunction Ammonia scavenger treatment
Lysine	Hyperlysinemia*	Lysinuric protein intolerance
Methionine	Homocystinuria Methionine adenosyltransferase deficiency* Glycine-N-methyltransferase* Citrin deficiency Hepatic dysfunction	MTHFR deficiency
Ornithine	Ornithine aminotransferase I deficiency Hyperornithinemia-hyperammonemia-homocitrullinuria (HHH) syndrome	Lysinuric protein intolerance
Phosphoethanolamine††	Alkaline phosphatase deficiency	–
Phenylalanine	Phenylketonuria Hepatic dysfunction	–
Proline	Hyperprolinemia type I Hyperprolinemia type II	–
Serine	Nonfasting	Disorders of serine biosynthesis
S-sulfocysteine†††	Isolated sulfite oxidase deficiency Molybdenum cofactor deficiency	–
Threonine	Citrin deficiency Cholestasis Nonfasting	–
Tyrosine	Tyrosinemia type I Tyrosinemia type II Tyrosinemia type III Transient tyrosinemia of the newborn Citrin deficiency Hepatic dysfunction	–

* Clinical relevance of these biochemical abnormalities is not conclusive.
** Free homocysteine is usually not detected in plasma when standard amino acid analysis is performed.
† Can be present in cystathionine β-synthase or defects of vitamin B12 synthesis (*cblC*, *cblE*, *cblD*, *cblF*, *cblG*), absorption (hereditary folate malabsorption), and transport (transcobalamin II deficiency).
†† Phosphoethanolamine is not an amino acid but it is usually detected in the routine plasma amino acid analysis.
††† Measurement of sulfocysteine requires special sample preparation.

Table 120.10 Inherited metabolic diseases presenting as non-immune hydrops

Disease	Metabolic abnormality
Erythrocyte enzymopathies	
Glucose-6-phosphate dehydrogenase deficiency [51]	Glucose-6-phosphate dehydrogenase
Pyruvate kinase deficiency [51]	Pyruvate kinase
Glucose-phosphate isomerase deficiency [51]	Glucose-phosphate isomerase
Lysosomal storage diseases	
• Oligosaccharidoses	
– GM_1 gangliosidosis [52]	β-galactosidase
– Sialidosis [53]	Neuraminidase
– Galactosialidosis [52]	Protective protein/cathepsin A
– Gaucher disease type II [54]	Acid β-glucosidase
– Niemann-Pick disease, type A [52, 55]	Sphingomyelinase
– Niemann-Pick disease, type C [55]	NPC1
– Farber lipogranulomatosis [52]	Acid ceramidase
– Wolman disease [55]	Lysosomal acid lipase
– I-cell disease [52]	Multiple defects affecting mannose-6-phosphate receptor
– Infantile sialic storage disease [56]	Sialin
– Multiple sulfatase deficiency [57]	Sulfatase-modifying factor-1
• Mucopolysaccharidoses	
– Hurler disease (MPS I) [55]	α-L-iduronidase
– Sly disease (MPS VII) [56]	β-glucuronidase
– Morquio A disease (MPS IVA) [58]	Galactosamine-6-sulfate sulfatase
Others	
Congenital disorders of glycosylation type Ia; Ik; I/IIx [59–62]	Phosphomannomutase; β-1,4-mannosyltransferase; ?
Glycogen storage disease type IV [63]	Glycogen branching enzyme
Long-chain hydroxyacyl CoA dehydrogenase deficiency [64]	Long-chain hydroxyacyl-CoA dehydrogenase
Smith-Lemli-Opitz syndrome [65]	Sterol-Δ^7-reductase
3β-hydroxysterol-Δ^{14}-reductase deficiency [66]	3β-hydroxysterol-Δ^{14}-reductase
Citric acid cycle-defect [67]	Fumarase
Pearson syndrome and other respiratory chain defects [68]	Respiratory chain defects
Transaldolase deficiency [69]	Transaldolase
Congenital erythropoietic porphyria [70]	Uroporphyrinogen III cosynthetase

non-immune hydrops (Table 120.10). Besides hydrops, Gaucher disease may have a perinatal lethal presentation with colloidon membrane, hepatosplenomegaly, and arhtrogryposis [14]. In addition, a significant number of infants with Niemann-Pick type C presents in the newborn period with hypotonia, jaundice, hepatosplenomegaly, and liver failure [15]. Cardiomyopathy in the neonatal period has been reported as rare complication of glycogen storage disease type II (pompe disease) and of some muchopolysaccharidoses (Table 120.2) [12].

120.4.2.2 Peroxisomal Disorders

In contrast to lysosomal storage disorders, most peroxisomal disorders are expressed in the neonatal period. Zellweger syndrome, the prototype of these disorders, classically presents in the newborn period with craniofacial anomalies including a large anterior fontanel with widely spaced sutures, broad forehead and micrognathia, and neurological abnormalities. The presence of hypotonia and the hypo/areflexia in these patients may raise the possibility of spinal muscular atrophy [16]. Neuronal migration defects, especially pachygyria and polymicrogyria, are observed along with white matter abnormality and are often associated with seizures. The liver is enlarged and fibrotic with micronodular cirrhosis. Renal cysts and chondrodysplasia punctata are also common. Apart from Zellweger syndrome with its neonatal onset and early fatal course, the peroxisomal disorders include neonatal adrenoleukodystrophy and infantile Refsum disease with the least severe course. The clinical features between Zellweger syndrome, neonatal adrenoleukodystrophy, and infantile Refsum disease are overlapping and it is often difficult to assign a particular patient to one of these clinical subtypes. Most peroxisomal defects can be detected by analysis of very long-chain fatty acids (VLCFA) in plasma. Additional studies such as plasmalogen levels in red blood cells, plasmatic phytanic acid, and molecular analysis are necessary for further confirmation of the diagnosis [17].

120.4.2.3 Congenital Disorders of Glycosylation

The congenital disorders of glycosylation are multisystemic diseases due to a deficiency of carbohydrate residues of glycoproteins and other glycoconjugates [18]. In the neonatal

period the neurologic picture comprises abnormal slow-rolling vertical or horizontal eye movements, axial hypotonia, and hyporeflexia. Many patients have dysmorphic features, abnormal adipose tissue distribution, inverted nipples, moderate hepatomegaly, and cerebellum hypoplasia. Some patients develop pericardial effusion and cardiomyopahty (Table 120.2) or non-immune hydrops (Table 120.10). The screening and diagnosis are based on plasma glycosylated transferrin by isoelectrofocusing.

120.5 Maternal Metabolic Diseases Affecting the Fetus

Phenylketonuria is a disorder with increased concentration of phenylalanine in the body fluids resulting from the reduced activity of the phenylalanine hydroxylase or from defects in the synthesis or recycling of its cofactor, tetrahydrobiopterin. Untreated patients with classic phenylketonuria are normal at birth, but develop microcephaly, seizures, and severe mental retardation. In contrast, affected children detected and effectively treated before the 3 weeks of age show none of these abnormalities. Therefore, most newborns in developed countries are screened by determination of phenylalanine blood levels. Women with phenylketonuria who have been treated since infancy and become pregnant have an increased risk for fetal malformations such as microcephaly, mental deficiency, and congenital heart disease [19]. These adverse consequences originate in the first trimester and are preventable by a phenylalanine restricted diet. There is a strong relationship between increasing phenylalanine levels and the severity of neonatal abnormalities. The current recommendation is to maintain the phenylalanine levels < 6 mg/dL at least 3 months before conception [20]. Maternal riboflavin and vitamin B12 deficiency may also affect the newborn. Maternal riboflavin deficiency results in clinical and biochemical findings of multiple acyl-CoA dehydrogenase deficiency [21], while maternal vitamin B12 deficiency, often secondary to vegetarian diet, pernicious anemia, and gastric bypass, results in non-specific clinical presentation with developmental delay, failure to thrive, and irreversible neurologic damage. Early detection and intervention, facilated by MS/MS newborn screening [22], are critical and both conditions can be treated with vitamin supplementation.

120.6 Fetal Diseases Affecting the Mother

Mothers who are pregnant with a fetus affected with long-chain 3-hydroxy-acyl-coenzyme A dehydrogenase (LCHAD) deficiency have a high risk of developing preeclampsia, HELLP (hemolysis, elevated liver enzymes, low platelets) syndrome or acute fatty liver of pregnancy (AFLP) [23]. Therefore, screening of offspring of women with AFLP and HELLP syndrome has been proposed, at least when MS/MS screening is not available, because LCHAD is potentially treatable.

120.7 Inborn Errors of Metabolism with Postnatal Onset

The clinical presentation of this group of disorders results from the accumulation of toxic compounds proximal to the metabolic defect or from deficiency in energy production. The disorders of the *intoxication* group do not interfere with the embryofetal development and present with a symptom-free interval ranging from hours to weeks, and indeed even months or years, depending on the severity of the metabolic block and/or the nature of the environmental triggers. The typical clinical features are non-specific and include poor feeding, vomiting, lethargy, irritability, seizures, and tachypnea if metabolic acidosis is present. Most of these disorders are treatable and require emergency removal of the toxin by special diet, drugs to increase clearance of toxic metabolites, and hemodialysis. The disorders of energy production are less amenable to therapy and affect primarily liver, myocardium, muscle, and brain. Although there is a significant overlap among the different conditions, from a clinical practice standpoint it is useful to classify the disorders with postnatal onset on the basis of their main clinical and/or laboratory findings at presentation [3].

120.7.1 Disorders Presenting with Metabolic Acidosis

Metabolic acidosis is very common in neonates and can be observed in a large variety of circumstances, such as infections, severe catabolic states, tissue hypoxia, and dehydration. These conditions can also be the trigger for acute decompensation in inborn errors of metabolism. The presence or absence of ketonuria is a major clinical key to the diagnosis, particularly in the neonatal period, during which significant ketonuria is highly suspicious of an inborn error of metabolism. An increased anion gap $[([Na^+]+[K^+])-([Cl^-]+[HCO_3^-])]$ greater than 25 mmol/L (normal range: 12–16 mmol/L) resulting from the accumulation of organic anions is observed in several metabolic diseases. Secondary hypoglycemia and hyperammonemia along with accumulation of organic anions result in acute encephalopathy. A number of disorders presenting with acidosis affects the catabolic pathways of the branched chain amino acids or other amino acids and are usually detected by GC/MS or MS/MS on urine specimens. A flowchart for the evaluation of infants with metabolic acidosis is presented in Fig. 120.2. The number of the disorders

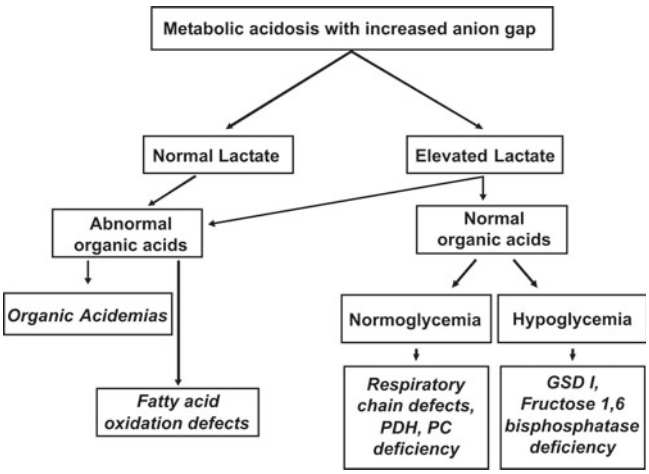

Fig. 120.2 Diagnostic approach to neonatal metabolic acidosis

of organic acid metabolism and their range of presentations is large. However, some of these conditions merit specific discussion because are relatively more common.

120.7.1.1 Propionic Acidemia and Methylmalonic Acidemia

Propionic acidemia is caused by deficiency of propionyl-CoA carboxylase which requires biotin as cofactor. Methylmalonic acidemia instead is caused by the deficiency of either the methylmalonyl-CoA mutase or the enzymes involved in the synthesis of its vitamin B12-derived cofactor, 5'-deoxyadenosylcobalamin. Patients with defects in the cofactor synthesis are responsive to vitamin B12 treatment. In most cases of both propionic acidemia and methylmalonic acidemia, the onset of the disease is in the neonatal period with the non-specific feeding difficulties, vomiting, neurological manifestations such as hypotonia, lethargy, and seizures and hematological complications (Table 120.4). If not promptly and appropriately treated, patients progress into coma with brain edema and die or develop permanent brain damage. Hyperammonemia, which may be as high as in urea cycle disorders, may complicate the initial episode of decompensation. Elevated glycine in the blood is an important clue to the diagnosis (Table 120.9) which is based on the presence of characteristic organic acids in urine as detected by GC/MS (Table 120.11) and of propionylcarnitine (C3) elevation in blood by MS/MS (Table 120.12). Cell studies on leukocytes or cultured skin fibroblasts and/or DNA studies are used for diagnostic confirmation.

120.7.1.2 Multiple Carboxylase Deficiency

There are two distinct disorders resulting in multiple carboxylase deficiency: biotinidase deficiency and holocarboxylase synthetase deficiency. Biotinidase deficiency, which is far more frequent, is due to defects in the recycling and release from dietary protein of biotin, a co-factor for the human carboxylases. Whereas patients with partial deficiency (residual activity 10–30% of mean control value) usually do not develop clinical symptoms, untreated patients with profound deficiency (residual activity < 10% of mean normal value)

Table 120.11 Urinary organic acid profiles in organic acidemias

Disease	Urine metabolites
Propionic acidemia	3-Hydroxypropionic, methylcitric, tiglylglycine, propionylglycine
Methylmalonic acidemia and cobalamin defects	Methylmalonic, 3-hydroxypropionic, methylcitric, propionylglycine
Isovaleric acidemia	3-Hydroxyisovaleric, isovalerylglycine
Glutaric acidemia type I	Glutaric, 3-hydroxyglutaric, glutaconic
Glutaric acidemia type II	Glutaric, 2-hydroxyglutaric, adipic, suberic, sebacic, dodecanoic
Malonic aciduria	Malonic, methylmalonic
Ethylmalonic aciduria	Ethylmalonic, methylsuccinic
3-Hydroxy-3-methylglutarylCoA deficiency	3-Hydroxy-3-methylglutaric; 3-methylglutaconic; 3-hydroxyisovaleric, 3 methylglutaric
3-MCC deficiency	3-Methylcrotonic, 3-methylcrotonylglycine, tiglylglycine, 3-hydroxyisovaleric
β-ketothiolase deficiency	2-Methyl-3-ketobutyric; 2-methyl-3-hydroxybutyric, 3-hydroxyisovaleric, tiglylglycine, 2-Ethyl-3-hydroxypropionic
Fumarase deficiency	Fumaric
Canavan disease	N-Acetyl-aspartic
Semialdehyde dehydrogenase deficiency	4-Hydroxybutyric; 3-hydroxypropionic, 3,4-dihydroxybutyric
Glutathione synthetase deficiency	5-Oxoproline
Methylglutaconic aciduria	3-Methylglutaconic, 3-methylglutaric
Tyrosinemia type I	Succynilacetone; p-hydroxyphenylacetic, p-hydroxyphenyllactic
Barth syndrome	3-Methylglutaconic, 3-methylglutaric
Amish lethal microcephaly	α-ketoglutaric

3-MCC 3-methylcrotonyl-CoA carboxylase.

Table 120.12 Plasma acylcarnitine patterns associated with various diseases*

Acylcarnitine name	Chain-length designation	Associated abnormality	Disorder
Free carnitine	C0 (low)		Primary carnitine deficiency
Free carnitine	C0	C16 (low); C18 (low)	CPT I deficiency
Propionyl	C3		Propionic acidemia Methylmalonic acidemia Succinyl-CoA synthetase deficiency
Malonyl	C3DC		Malonyl-CoA carboxylase deficiency
Butyryl	C4		Short-chain acyl-CoA dehydrogenase (SCAD) deficiency** Ethylmalonic encephalopathy
Isobutyryl	C4		Isobutyryl-CoA-dehydrogenase deficiency**
Isovaleryl	C5		Isovaleric acidemia
Methylbutyryl	C5		Methylbutyryl-CoA dehydrogenease deficiency**
3-Hydroxybutyryl	C4-OH		3-α-hydroxyacyl-CoA dehydrogenase deficiency
3-Hydroxyisovaleryl	C5-OH		3-Methylcrotonyl-CoA carboxylase (3-MCC) deficiency** Holocarboxylase deficiency 3-Hydroxy-3-methylglutaryl-CoA lyase deficiency Biotinidase deficiency 3-Methylglutaconyl-CoA hydratase deficiency
3-Hydroxy-2-methylbutyryl	C5-OH		2-Methyl-3-hydroxybutyryl-CoA dehydrogenase deficiency β-ketothiolase deficiency
Glutaryl	C5-DC		Glutaric acidemia type I
Octanoyl	C8	C6; C10; C10:1	MCAD
Tetradecenoyl	C14:1	C14; C14:2	VLCAD deficiency
Palmitoyl	C16	C18; C18:1; C18:2	CPT II deficiency CACT deficiency
3-Hydroxy-palmitoyl	C16-OH	C16:1-OH; C18-OH; C18:1-OH	LCHAD deficiency Trifunctional protein deficiency

* Acylcarnitine abnormalities include elevations over normal range unless specified otherwise.
** Clinical relevance of these biochemical abnormalities is not conclusive.

may develop various neurological deficits, skin abnormalities (Tables 120.5, 120.7), and metabolic ketoacidosis early in life. Because early recognition and oral biotin supplementation (2–20 mg/day) may completely prevent clinical and neurological deficits in biotinidase deficiency, biotinidase newborn screening has been implemented in various countries. Patients with holocarboxylase synthetase deficiency present with the characteristic skin manifestations and an overwhelming illness similar to that of propionic acidemia. In this condition the activities of all carboxylases in leukocytes or fibroblasts are reduced. Various degrees of response to biotin treatment have been reported.

120.7.2 Disorders Presenting with Ketosis

Maple urine syrup urine disease is one of the most common aminoacidopathies and presents in the newborn period with neurologic deterioration and ketosis. The disease is caused by deficiency of the branched-chain α-keto acid dehydrogenase which is involved in the catabolism of the branched-chain amino acids (leucine, isoleucine, and valine). The accumulation of leucine is neurotoxic and results in progressive brain damage. Vomiting, feeding difficulties, and lethargy are common early symptoms. Seizures occur frequently especially when cerebral edema develops. The characteristic odor may be noted as soon as neurological symptoms develop but it may be absent in a patient who has not received protein for a prolonged period of time. The diagnostic plasma amino acid pattern shows an increase of branched-chain amino acids, the accumulation of alloisoleucine, which is normally not detected, and a reduction of alanine (Table 120.9).

120.7.3 Disorders Presenting with Lactic Acidosis

Increased lactic acid is an important hallmark of metabolic diseases. However, this is also increased in hypoxic-ischemic encephalopathy, sepsis, and other conditions resulting in poor

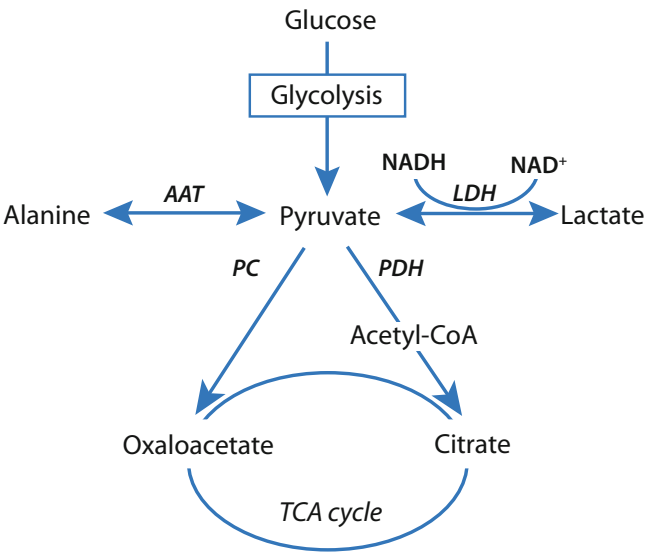

Fig. 120.3 Pyruvate metabolism. Lactate dehydrogenase (LDH), pyruvate dehydrogenase (PDH), pyruvate carboxylase (PC), alanine aminotransferase (AAT), tricarboxylic acid (TCA) cycle

vascular perfusion. Nevertheless, the most common reason for elevated lactate in blood is improper sampling technique (use of tourniquet or struggle in obtaining the sample). The measurement of pyruvate in conjunction with lactate is helpful because an increase in the plasma lactate-pyruvate ratio suggest inadequate oxygen supply. However, to obtain reliable measurements of this ratio, the plasma sample for pyruvate needs to be deproteinized at the bedside which is not practical in most clinical settings. Defects of pyruvate metabolism or of the respiratory chain result in primary lactic acidosis and should be considered in patients with persistent increase of lactic acid and normal urine organic acids. Lactic acidosis may result from an increased pyruvate production as in the case of glycogen storage disease type I or from a decreased pyruvate oxidation as a consequence of either pyruvate carboxylase (PC) or pyruvate dehydrogenase (PDH) deficiency (Fig. 120.3). In addition, it may result from defects in NADH oxidation due to mitochondrial cytopathies caused by defects of the electron transport chain. In the neonatal period, primary lactic acidoses may present with drowsiness, poor sucking, severe hypotonia, abnormal movements, seizures, respiratory distress, liver failure, optic atrophy, and fatal ketoacidotic coma.

120.7.4 Disorders Presenting with Hypoglycemia

Severe and persistent or otherwise unexplained hypoglycemia should be investigated for an underlying metabolic or endocrine cause. Recurrent, unpredictable post-prandial hypoglycemia are observed in hyperinsulinism or growth hormone deficiency and related disorders while organic acidemias or defects of gluconeogenesis (glycogen storage disease type I or fructose 1,6-bisphosphatase deficiency) usually present with associated ketoacidosis. The presence of nonglucose reducing substances in the urine is characteristic of classic galactosemia and hereditary fructose intolerance. Both diseases are generally associated with other prominent clinical problems such as liver failure. Hyperinsulinism and fatty acid oxidation disorders are the most frequent causes of hypoketotic hypoglycemia. Hyperinsulinism due to endocrine causes are described in greater detail in Chapter 121. Congenital hyperinsulinism may also be due to metabolic causes as in the case of the hyperinsulinism/hyperammonemia syndrome due to autosomal dominant mutations in the glutamate dehydrogenase (*GDH*) gene (Fig. 120.4) [24]. In this disorder, the hypoglycemia occurs with fasting but can also be triggered by protein feeding [25]. In contrast to the urea cycle disorders, the hyperammonemia is mild, stable, and without fluctuations related to fasting or protein feeding. This disorder does not present elevations of plasma glutamine which are typically seen in hyperammonemia [24]. The capacity to derive energy from mitochondrial fatty acid oxidation is critically important especially during stress and starvation. Therefore, the inherited disorders of fatty acid oxidation are an important and treatable cause of neonatal hypoglycemia.

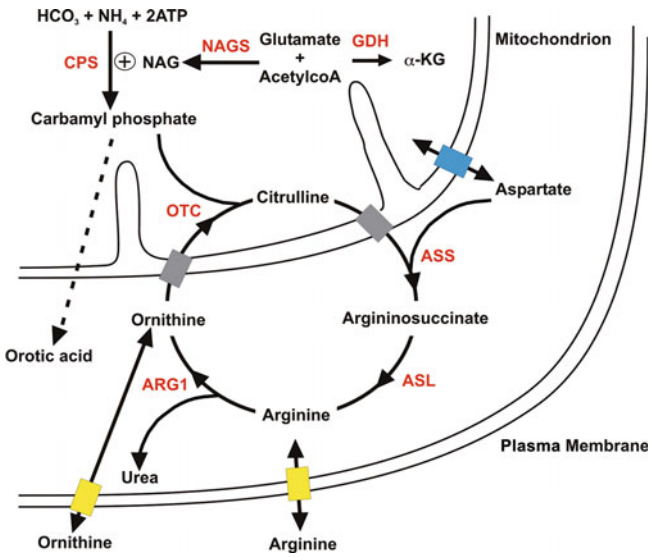

Fig. 120.4 The urea cycle. The urea cycle converts nitrogen, derived from dietary protein intake and the breakdown of endogenous protein (catabolism), into urea which can be excreted from the body. The six enzymes involved are indicated in red. The dashed *black arrow* depicts the overflow of excess carbamyl phosphate into pyrimidine synthesis and, hence, to orotic acid, which is excreted in the urine. The *gray cylinders* denote the ornithine and citrulline transporters, and the *yellow cylinders* represent the cationic-amino-acid transporter found on intestinal and kidney epithelial cells. The *blue cylinder* denotes citrin, a mitochondrial aspartate and glutamate transporter

120.7.4.1 Fatty Acid Oxidation Disorders

Mitochondrial fatty acid oxidation is a complex process involving transport of activated fatty acid molecules into the mitochondria and sequential removal of acetyl-CoA units used as fuel for the tricarboxylic acid cycle or for the production of ketone bodies. This process is critical in supplying energy during fasting and metabolic stress, and therefore patients with fatty acid oxidation defects develop hypoketotic hypoglycemia during periods of low glucose intake or intercurrent illnesses. Disorders of fatty acid oxidation may present at any age and have a broad clinical spectrum ranging from severe malformations or sudden death to almost completely asymptomatic adults [26]. They include defects of the uptake and activation of carnitine (primary carnitine deficiency); defects of the carnitine cycle [deficiency of carnitine palmitoyltransferase I (CPT I) and II (CPT II), deficiency of carnitine-acylcarnitine translocase (CACT)], required for mitochondrial entry of fatty acids; and defects of the β-oxidation enzymes. This latter group of disorders is further classified according to the length of the carbon chain of the fatty acids that accumulate and includes medium-chain acyl-CoA dehydrogenase (MCAD) deficiency, very long-chain acyl-CoA dehydrogenase (VLCAD) deficiency, and LCHAD deficiency. Cardiomyopathy, arrhythmias, encephalopathy, and myopathy are frequent findings in these disorders. MCAD deficiency is one of the most common inborn errors of metabolism with an incidence of 1/10,000–20,000 births [27]. Up to one quarter of the cases present in the newborn period with fasting hypoketotic hypoglycemia [28]. The treatment of MCAD is based on the avoidance of catabolism during fasting or illness and neonatal screening is effective in reducing deaths and severe adverse events [29].

As outlined above, the clinical presentation of fatty acid oxidation defects is highly variable and includes, in the case of the severe lethal neonatal variant of CPT II deficiency, a complex malformation syndrome with dysmorphic features, microcephaly, cataracts, brain and kidney anomalies, periventricular and hepatic calcifications, hypoglycemia, cardiac arrhythmias, seizures, and liver disease [5]. Expanded newborn screening has facilitated the detection of neonatal CPT II deficiency that, given its presentation, may not raise a high index of suspicion for metabolic diseases [30]. The expanded newborn screening has also allowed the identification of newborns with primary carnitine deficiency, a treatable disorder characterized by urinary carnitine losses and reduced plasma carnitine levels. The affected newborn is protected by the placental transfer and therefore, the disease onset typically occurs in infancy or childhood [31]. A few infants have also been found to have extremely low carnitine levels on newborn screening because they were born to mothers with primary carnitine deficiency who had remained asymptomatic all their lives [32].

Acylcarnitine profile analysis by MS/MS helps to establish the diagnosis of these disorders (Table 120.12). However, intermittent and reversible abnormalities can be missed if the biological specimen is collected outside the critical period. In the context of newborn screening, blood samples taken at age 48–72 hours are more likely to be diagnostic [33]. As for plasma amino acid and urinary organic acid analyses, interpretation of the results of the acylcarnitine profile is based on pattern recognition, rather than on individual abnormal values (Table 120.12). A definitive diagnosis is based on enzyme assays and/or molecular testing.

120.7.5 Disorders Presenting with Hyperammonemia

Hyperammonemia is a clinical emergency which may result in serious derangements of neurological function and structure. The degree of neurological damage is dependent on the duration of the hyperammonemia [34] and therefore, prompt recognition and intervention are important. Although the measurement of ammonia levels can be of foremost importance in making the diagnosis of a metabolic disorder, ammonia determination is unfortunately highly susceptible to artifacts resulting in false elevations. Several precautions should be followed to avoid incorrect test results: 1) the specimen must be placed on ice at the bedside; and 2) the

Table 120.13 Causes of neonatal hyperammonemia

Inherited diseases

- Urea cycle disorders
  - Carbamyl phosphate synthetase deficiency
  - Ornithine transcarbamylase deficiency
  - Argininosuccinic acid synthetase deficiency
  - Argininosuccinic acid lyase deficiency
  - N-acetylglutamate synthetase deficiency
  - Citrin deficiency
  - Lysinuric protein intolerance
  - Hyperornithinemia-hyperammonemia-homocitrullinemia (HHH) syndrome
  - Hyperinsulinism with hyperammonemia
- Other metabolic disorders
  - Propionic acidemia
  - Methylamalonic acidemia
  - Isovaleric acidemia
  - β-ketothiolase deficiency
  - Multiple carboxylase deficiency
  - Fatty acid oxidation defects
  - Pyruvate dehydrogenase deficiency
  - Mitochondrial cytopathies
  - Glutaric aciduria type II

Acquired disorders

- Any severe illness
- Transient hyperammonemia of prematurity
- Perinatal asphyxia
- Herpes simplex infection
- Total parenteral nutrition
- Vascular bypass of the liver

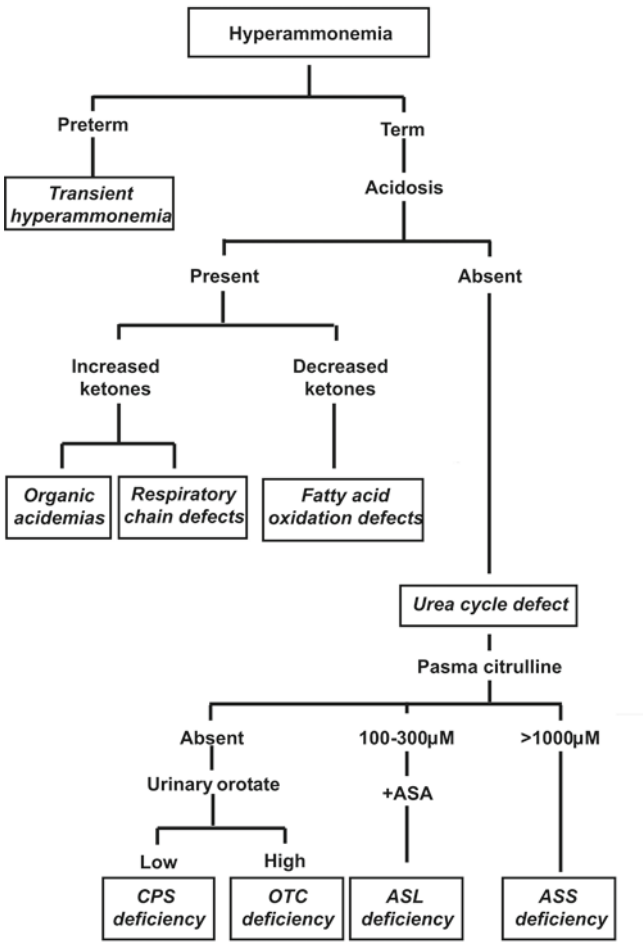

Fig. 120.5 Diagnostic approach to neonatal hyperammonemia

sample needs to be processed in a timely manner with immediate transfer to the laboratory for instant processing. Elevation of blood ammonia occurs in urea cycle disorders as well as in various other inborn errors of metabolism and in a significant proportion of premature and asphyxiated infants (Table 120.13).

The urea cycle disorders include defects of the N-acetyl glutamate synthetase (NAGS), the carbamyl phosphate synthetase (CPS), the ornithine transcarbamylase (OTC), the argininosuccinic acid synthetase (ASS), the argininosuccinic acid lyase (ASL), and arginase (ARG1) (Fig. 120.4). With the exception of OTC deficiency which is X-linked, all these disorders are inherited in an autosomal recessive pattern. Infants with urea cycle disorders appear initially normal but rapidly develop cerebral edema and the related signs of lethargy, anorexia, hypothermia, seizures, neurologic posturing, and coma. Hyperventilation is a common early finding and results in respiratory alkalosis. Hypoventilation and respiratory arrest due to an increased pressure on the brain stem may also occur [35]. The concentration of citrulline is central in the diagnostic evaluation. If citrulline is markedly elevated, the newborn has citrullinemia (ASS deficiency) and if it is low a deficiency of OTC, CPS, or NAGS is more likely. Normal or moderately elevated levels of citrulline generally indicate ASL or aginase deficiency (Fig. 120.5). Enzymatic testing on erythrocytes, fibroblasts, and liver is available along with DNA mutation detection to confirm the diagnosis. Lysinuric protein intolerance, hyperornithinemia-hyperammonemia-homocitrullinuria syndrome, and citrin deficiency are caused by defects in the transporters for the urea cycle intermediates resulting in depletion of urea cycle intermediates and decreased urea cycle activity in spite of normal urea cycle enzyme function (Fig. 120.4) [36].

120.7.6 Disorders Presenting without Hyperammonemia and without Ketoacidosis

Hypotonia and/or seizures in the absence of blood pH alteration and hyperammonemia are the main clinical findings in this group of disorders. Hypotonia is rarely isolated in patients with metabolic diseases and is commonly seen in association with other findings. Seizures are the most distinctive signal of neurological disease in the newborn period and can be caused by a broad range of systemic and central nervous system disorders. Among the metabolic defects, it is important to recognize the pyridoxine (vitamin B6)-dependent seizures because an effective treatment is available for this disorder. Pyridoxine-dependent seizures have an onset in utero or in the first hours of life [37] and are diagnosed empirically by cessation of seizures and normalization of the EEG within minutes after the intravenous injection of 50–100 mg of pyridoxine. Patients affected with pyridoxine 5' phosphate oxidase deficiency do not respond to pyridoxine but alternatively respond to the administration of pyridoxal phosphate (PLP), the active form of pyridoxine [38].

Nonketotic hyperglycinemia (also known as glycine encephalopathy) is caused by defective activity of the glycine cleavage system resulting in the accumulation of glycine in all body tissues and fluids. It typically manifests in the first hours to days of life with progressive lethargy, hypotonia, and myoclonic jerks. Mothers of affected children often report reduced fetal movements and in utero hiccups. Most affected newborns will have repeated episodes of severe and prolonged apnea, to which they succumb unless ventilatory support is provided until normal spontaneous respiration resumes after several days or weeks. Those infants regaining spontaneous respiration have an extremely poor outcome with profound mental retardation and intractable seizures [39]. Blood levels of glycine are usually increased although the elevation is occasionally modest. The laboratory diagnosis is based on simultaneous determination of CSF and plasma glycine showing an abnormal CSF-to-plasma glycine ratio (above 0.08). It is important to note that the presence

of any blood in the CSF invalidates the results. The differential diagnosis for hyperglycinemia includes disorders resulting in ketotic hyperglycinemia such as propionic acidemia and methylmalonic acidemia (Table 120.9). Organic acidemia can be distinguished from glycine encephalopathy by history, determination of urine organic acids (Table 120.11), and acylcarnitine profile (Table 120.12). Confirmatory tests include enzymatic analysis in liver tissue and/or mutation analysis [40].

Neurologic abnormalities, including seizures with neonatal onset and refractory to treatment, are also prominent in molybdenum cofactor deficiency and sulfite oxidase deficiency which can be recognized based on elevated urinary S-sulfocysteine, xanthine and hypoxanthine, reduced serum levels of uric acid, and nearly undetectable total plasma homocysteine. Seizures and encephalopathy are also features of severe methylenetetrahydrofolate reductase (MTHFR) deficiency and cerebral folate deficiency which are potentially treatable with betaine and folinic acid, respectively. The main biochemical abnormalities are homocystinuria with low or low normal plasma methionine in MTHFR deficiency and decreased CSF serum folate in cerebral folate deficiency.

120.7.7 Disorders Presenting with Liver Failure

Severe liver dysfunction in the neonate can occur in a wide variety of metabolic disorders including tyrosinemia type I, galactosemia, hereditary fructose intolerance, mitochondrial hepatopathy, fatty acid oxidation defects, sugar alcohol defects, and congenital disorders of glycosylation (Table 120.3). Neonatal hepatic failure is also a rare presentation of α_1-antitrypsin deficiency and of some bile acid synthetic defects which are described in more details in Chapters 85 and 86.

Tyrosinemia type I has been rarely described in neonates with severe liver dysfunction, hyperbilirubinemia, hypoglycemia, and hyperammonemia. The interpretation of elevated tyrosine levels is challenging because it is seen in several conditions with liver dysfunction. The diagnosis of tyrosinemia type I is confirmed by increased succinylacetone in urine or plasma.

Galactosemia will not manifest in an affected newborn until the patient is receiving galactose. Breast milk and most formulas contain lactose (a disaccharide of glucose and galactose); most soy formulas do not. Typical clinical features are hyperbilirubinemia (which may be unconjugated initially but later becomes mainly conjugated), hepatomegaly, liver dysfunction with coagulopathy, hypoalbuminemia, and hypoglycemia. Cataracts may be diagnosed as early as the disease presents in the neonatal period. If undetected the disease may progress into encephalopathy with cerebral edema, metabolic acidosis, and renal dysfunction. Patients with galactosemia have an increased risk for *E. coli* sepsis. Classic galactosemia is diagnosed by measurement of galactose-1-phosphate in serum which is increased and of the defective enzyme, galactose-1-phosphate uridyltransferase, in red blood cells. Treatment with galactose restriction in the diet results in complete resolution of the acute illness. Therefore, a galactose-free diet is recommended in case of neonatal liver failure until the diagnosis of classical galactosemia has been ruled out.

Hereditary fructose intolerance does not manifest in the newborn period unless fructose or sucrose are added to the diet.

Mitochondrial hepatopathies with deficiency of the respiratory chain enzymes have been recognized in newborns with acute neurologic impairment and liver failure [41]. In some cases, after an initial normal course, a viral infection or some other undefined event triggers hepatic and neurologic deterioration [42]. A fulminant liver failure may also be triggered by sodium valproate and therefore this medication should be avoided if there is suspicion of mitochondrial cytopathy [43]. The presence of lactic acidosis and hypoglycemia are useful diagnostic features, as is the detection of elevated tyrosine. However, these findings are rather non-specific. Respiratory chain complex analysis of liver or muscle generally shows reduced activity of respiratory chain complexes.

Sugar alcohol disorders including transaldolase deficiency and ribose-5-phosphate isomerase deficiency [44, 45] are also responsible for liver failure with neonatal onset [46, 47]. Assessment of sugar alcohol in body fluids is usually not a component of the metabolic work-up and therefore, several cases are likely to remain undiagnosed.

120.7.8 Disorders Presenting with Cholestasis

Genetic disorders are an important cause of neonatal cholestasis and α_1-antitrypsin deficiency accounts for a significant portion of these cases. α_1-antitrypsin deficiency and the inborn errors of bile acid synthesis are discussed in Chapters 85 and 86 while this section will focus on the other metabolic disorders responsible for neonatal cholestasis. Prolonged neonatal cholestatic jaundice associated with progressive hepatosplenomegaly is the most common sign in Niemann-Pick type C. Spontaneously resolving by 2–4 months of age in most patients, it may lead to liver failure in about 10% of cases. Children with this rapidly fatal neonatal cholestatic form die before the age of 6 months, without neurologic symptoms [48].

Patients with neonatal intrahepatic cholestasis caused by citrin deficiency (Fig. 120.4) have low birth weight, growth retardation, hypoproteinemia, decreased coagulation factors, and increased transaminases. Symptoms disappear by the age of 1 year with fat-soluble vitamin supplementation and lactose-free formulas or formulas containing medium-chain triglycerides. In adulthood, these patients may develop an adult-onset disease

Table 120.14 Pattern of MRI abnormalities in inborn errors of metabolism

Gray matter	White matter	Gray and white matter	Cerebellum
Cortical – Neuronal ceroid lipofuscinoses – Mucolipidoses – Lysosomal storage disorders *Striatum* – Mitochondrial diseases – Propionic acidemia – Glutaric aciduria type I – Molybdenum cofactor deficiency – Hypoglycemia *Pallidus* – Urea cycle disorders – Methylmalonic acidemia – Isovaleric acidemia – Succinic semialdheyde dehydrogenease deficiency – Pyruvate dehydrogenase deficiency – Guanidinoacetate methyltransferase (GAMT) deficiency	*Subcortical* – Mitochondrial diseases – Galactosemia – Alexander disease *Deep white matter* – Krabbe disease – Metachromatic leukodystrophy – GM_2 gangliosidosis – Peroxisomal disorders (with neuronal migration defects) – Lowe syndrome (with small cysts) – Mucolipidosis type IV – Vanishing white matter disease – Merosin deficient congenital muscular dystrophy	*Leukodystrophy and striatum* – Mitochondrial diseases – Propionic acidemia – Glutaric aciduria type I – Molybdenum cofactor deficiency – Hypoglycemia *Leukodystrophy and pallidus* – Canavan disease – Methylmalonic acidemia – L-2-hydroxyglutaric aciduria – Mitochondrial diseases – Maple syrup urine disease	– Pyruvate dehydrogenease deficiency – Leigh disease – Congenital disorders of glycosylation

with recurring episodes of hyperammonemia. The diagnosis of citrin deficiency is based on biochemical findings, including elevated ammonia, increased concentrations of citrulline and arginine, increased threonine-to-serine ratio (Table 120.9), and increased serum concentration of pancreatic secretory trypsin inhibitor. Galactose is also elevated in some cases. Conversely, patients with galactosemia can exhibit an amino acid profile resembling the profile seen in citrin deficiency [49].

120.8 Investigations for Inborn Errors of Metabolism

The first line of investigations with relatively rapid and inexpensive evaluations may provide important clues for the diagnosis of metabolic disorders in the newborn (Table 120.8). Electrolytes, blood gases, anion gap, ammonia, and lactate are useful to discriminate among the different disease groups. Blood ammonia and lactate should be determined in all neonates with unexplained lethargy and neurologic deterioration. Plasma amino acid by HPLC, urine organic analysis by GC/MS, and acylcarnitine profile by MS/MS are essential aid in the diagnosis (Tables 120.9, 120.11, 120.12). Amino acid analysis of urine is not usually performed in the evaluation of newborns and there are only a few indications for this test, such as to rule out lysinuric protein intolerance, hyperornithinemia-hyperammonemia-homocitrullinuria syndrome, and cystinuria. Most sick neonates undergo lumbar puncture for CSF collection as part of sepsis evaluation. In the context of a patient with encephalopathy, it is recommended to save an aliquot of CSF for lactate and amino acid determination.

Neuroimaging studies can provide important clues for the diagnosis of metabolic disorders. Patterns of brain involvement can be useful in the diagnostic process [50]. The first important assessment is to establish whether the disease involves primarily gray matter, primarily white matter, or both gray and white matter (Table 120.14). Moreover, proton magnetic resonance spectroscopy (MRS) can be helpful for diagnosis and monitoring in a selected number of disorders.

The diagnosis of inborn errors of metabolism should be confirmed by enzyme analysis and/or DNA tests. The choice

Table 120.15 Specimens to be collected in the event of death when metabolic disease is suspected

Plasma (> 2 mL)	Heparinized, separated and frozen at –80°C
Blood	Spots on filter paper for MS/MS
Urine (5-20 mL)	Deep frozen in a plain tube
CSF	1 mL stored at –80°C
Sample for DNA	Blood anticoagulated with EDTA and frozen at –80°C*
Skin for fibroblast culture	Taken with sterile precautions into tissue culture medium and stored at 4°C
Liver	Snap frozen (–80°C) for histochemistry/enzymology
Muscle	Snap frozen (–80°C) for histochemistry/enzymology

* Skin fibroblasts or other tissues may also be used for DNA extraction.

Table 120.16 Medications for acute decompensation in inborn errors of metabolism

Condition	Medication	Route	Recommended dose
Organic acidurias Fatty acid oxidation defects	L-carnitine	IV, PO	100 mg/kg/day
Hyperammonemia	Na benzoate	IV	250 mg/kg bolus over 2-4 hours followed by infusion of 250 mg/kg over 24 hours
Urea cycle disorders	L-arginine	IV	200-600 mg/kg followed by infusion of 250 mg/kg over 24 hours
Methylmalonic acidemia	Vitamin B12	IV, IM	1–2 mg/day
Pyridoxine-responsive seizures	Pyridoxine	IV	100 mg
Pyridoxal phosphate-responsive seizures	Pyridoxal phosphate	PO	30 mg/kg/day
Cerebral folate deficiency	Folinic acid	IV, PO	5–15 mg/day
Maple syrup urine disease	Thiamine	IV	25–100 mg
Propionic acidemia, multiple carboxylase deficiency	Biotin	IV, PO	10 mg

of one or both of these tests is usually dictated by the availability of laboratory offering these analyses. Enzyme tests can be performed on different tissues (blood, liver, fibroblasts) depending on the specific disease. DNA tests instead are performed on DNA extracted from blood. Biochemical methods (detection of metabolites in amniotic fluid and enzyme assays using cultured cells) as well as DNA analysis (mutation detection) are used for prenatal diagnosis. Helpful resources to localize a laboratory for a specific biochemical or molecular test are GeneTests (www.ncbi.nlm.nih.gov/sites/GeneTests/) or Orphanet (www.orpha.net/).

Inborn errors of metabolism can result in sudden unexplained death. Under these circumstances, it is particularly important to perform a *metabolic autopsy*, skeletal survey, and collect appropriate biologic samples to perform further diagnostic tests (Table 120.15). The findings of these investigations may have important implications for genetic counseling.

120.9 Treatment of the Acute Decompensation

The management of the acutely ill neonate must be initated early and must be aggressive. The conventional approach to the treatment of inborn errors of metabolism involves the following basic principles: 1) restriction of upstream essential nutrients to prevent intoxication; 2) supplementation of downstream nutrients to prevent secondary deficiency; and 3) stimulation of alternative routes for disposal of precursor metabolites.

During the acute phase of decompensation, treatment to keep catabolism to a minimum and remove toxic metabolites is required in most disorders. These measures can be started before a precise diagnosis is known. First, any nutrient that may have precipitated the illness, such as galactose or protein, should be halted and an intravenous high energy intake made up to 10% dextrose (~10 mg/kg/min) with mantainance electrolytes should be started. The need to provide adequate glucose may require the use of concentrated solutions through a central line which can be useful in case extracorporeal dialysis is needed. With high rates of glucose infusion, blood glucose concentrations should be monitored and if hyperglycemia occurs, insulin may be started. In this context, insulin has the additional advantage of promoting anabolism. Intravenous fluid should be administered with caution to avoid fluid overload and cerebral edema which may occur in maple syrup urine disease and urea cycle disorders. Metabolic acidosis can be corrected by sodium bicarbonate administration often required in large doses.

Hypoventilation due to cerebral depression is the most common reason for poor tissue oxygenation and most affected newborns require mechanical ventilation. Many patients with metabolic decompensation may develop sepsis which may aggravate the catabolism and results in therapeutic failure. Therefore, an aggressive search and treatment of infections are crucial for a successful intervention. Sodium benzoate is used to treat the hyperammonemia (Table 120.16). Carnitine is effective for the elimination of some toxic metabolites and it may be given even before a specific diagnosis is known. In the presence of severe lactic acidosis or unexplained metabolic acidosis, biotin and intramuscular vitamin B12 treatment can be initiated until multiple carboxylase deficiency and methylmalonic acidemia have been excluded (Table 120.16). Sometimes the metabolic derangement cannot be controlled by the approaches outlined above. Given that neurological complications are related to the concentration and duration of the exposure to the toxic metabolites, such as ammonia and leucine, more aggressive therapies such as hemodialysis are required.

It is highly recommended that a neonate who is suspected to have an acute decompensation due to a metabolic disorder be immediately referred to a newborn intensive care unit with expertise in the treatment of metabolic patients.

Endocrine Diseases of Newborn

Paolo Ghirri, Antonio Balsamo, Massimiliano Ciantelli, Antonio Boldrini and Alessandro Cicognani

121.1 Hypopituitarism

Congenital hypopituitarism results from a deficiency of any or all of the hormones secreted by the anterior pituitary gland (adreno-corticotropic hormone [ACTH]; growth hormone [GH]; thyroid-stimulating hormone [TSH]; luteinizing hormone [LH]; follicle stimulating hormone [FSH]; prolactin [PRL]) or by the posterior pituitary gland (antidiuretic hormone [ADH]). It is uncommon. The annual incidence ranges from 1 to 42 new cases per million and a prevalence of 300–455 cases per million [1].

121.1.1 Etiology

The incidence variability depends on the heterogeneity of cases. Some cases have a genetic etiology, others with lesions in the sellar region have been attributed to traumatic events or perinatal complications (cesarean section, breech, prolonged or rapid delivery, and low Apgar score) [2]. It is, however, difficult to determine whether perinatal insults lead to hypopituitarism because of traumatic disruption of the pituitary stalk, or whether hypopituitarism with structural hypothalamo-pituitary defects [3] results in an increased prevalence of perinatal complications.

Congenital hypopituitarism may be due to hypothalamic dysplasia or specific releasing hormone deficiencies (corticotropin-releasing hormone [CRH]; growth-hormone releasing hormone [GHRH]; gonadotropin-releasing hormone [GnRH]; thyrotropin-releasing hormone [TRH]). Other causes are due to anterior pituitary dysplasia or specific anterior pituitary deficiencies. Posterior pituitary deficiency may be familial (X-linked or autosomal dominant), idiopathic or secondary to inflammatory events (e.g., meningitis), disseminated intravascular coagulation (DIC), intraventricular hemorrhage, trauma/asphyxia and maternal drugs (e.g., lithium). Congenital rubella and toxoplasmosis have also been implicated.

Recently, mutations in a several genes encoding transcription factors that are implicated in normal hypothalamic-pituitary (H-P) development have been linked both with hypopituitarism in humans and with structural abnormalities on neuro-imaging. Mutations in genes that are implicated in somatotrope proliferation and GH secretion, such as *GH1* and *GHRHR*, are also associated with GH deficiency and with magnetic resonance imaging (MRI) abnormalities. These transcription factors and signaling molecules are expressed either exclusively in the developing pituitary or also in structures such as the hypothalamus and forebrain. A mutation in any one of these can lead to either a pituitary-specific phenotype (Table 121.1) or a broader clinical presentation such as septo-optic dysplasia, agenesis of the corpus callosum, persistent septum pellucidum, central cleft lip/palate, anencephaly/holoprosencephaly, familial pituitary hypoplasia and Wolfram syndrome.

121.1.2 Clinical Presentation

Congenital hypopituitarism must be suspected in any child presenting hypoglycaemia and dysmorphic features with midline defects, prolonged jaundice, poor weight gain, hypothermia, cryptorchidism and/or micropenis in a male infant. Early diagnosis of this condition may prevent impairment of cognition, poor growth and metabolic abnormalities.

In anterior hypopituitarism, there may be optic nerve hypoplasia/dysplasia. Babies tend to be small, sometimes severely growth restricted. In posterior hypopituitarism, polyhydramnios may be followed by postnatal dehydration, weight loss, irritability, hypernatremia and seizures. In

Table 121.1 Clinical phenotypes, mode of inheritance, and MRI presentation in pituitary hormone deficiencies involving gene alterations. Modified from [3]

Gene	Inheritance	Deficiency	Anterior hypophysis	Posterior hypophysis	Other abnormalities
HESX1	AR or AD	GH, (TSH, LH, FSH, ACTH, PRL variable)	Hypoplasic	Ectopic	Septo-optic dysplasia
PROP1	AR	GH, TSH, LH, FSH, (ACTH variable)	Enlargement with waxing and waning and eventual hypoplasia	Normal	Transient AP hyperplasia
LHX3	AR	GH, TSH, LH, FSH, PRL	Variable	Normal	Abnormalities of head rotation
LHX4	AD	GH, TSH, (LH, FSH, ACTH variable)	Hypoplasic	Variable	Cerebral malformations
POU1F1 (*PIT1*)	AR or AD	GH, TSH, PRL	Hyperplasia and later hypoplasia	Sometimes ectopic	–
SOX2	AD	HH, variable GHD	Hypoplasic	Normal	An/microphtalmia, esophageal atresia, genital tract abnormalities, hypothalamic hamartoma, sensorineural hearing loss, diplegia
SOX3	XL	IGHD or CPHD	Hypoplasic	Ectopic	Mental retardation
TBX19 (*T-PIT*)	AR	ACTH	Normal	Normal	Neonatal
GH1		GH	Empty sella, hypoplasia	Normal	
-IA (del/severe mutations)	AR				IA no GH and GH Ab on treatment
-IB (splice site, missense mutations)	AR				IB low detectable GH, no Ab
-II (splice site, splice site enhancers, missense muts)	AD				II less severe short stature
GHRHR	AR	High GH	–	Normal	–

AR autosomal recessive, *AD* autosomal dominant, *XL* X-linked, *Ab* antibodies.

breast-fed babies, the clinical features are similar but of more gradual onset. In patients with both arginine vasopressin and ACTH deficiency, diabetes insipidus, characterised by polyuria and polydipsia, may be masked by ACTH deficiency – cortisol is essential for the excretion of a water load. Treatment with hydrocortisone may unmask diabetes insipidus (DI).

121.1.3 Investigations

Biochemical/hormonal Measurements

First check blood glucose levels. If there is severe or symptomatic hypoglycaemia, the levels of GH, cortisol and ACTH should be measured. If found to be high because of stress (e.g., difficult venous cannulation), then pituitary function tests may be avoided. Baseline TSH, and free thyroxine (fT4) or LH/FSH levels may also be useful as they should be relatively high in the first days of life.

Tests of pituitary function should be undertaken under the direction of an endocrinologist. A glucagon stimulation test will assess both GH and adrenal axes, but late hypoglycemia may be dangerous. An ACTH stimulation test is safe but only indirectly evaluates ACTH. A CRH test measuring cortisol and ACTH response may be more useful. A gonadotropin-releasing hormone (GnRH) test to stimulate LH and FSH may be helpful for later management of puberty and fertility.

The diagnosis of ADH deficiency is made by monitoring weight, fluid balance, and urine and plasma osmolalities (low urine and high plasma osmolality).

Imaging

Cranial ultrasound and MRI scan (hypothalamus and pituitary gland are not visible on ultrasound scan) may reveal associated structural anomalies of the brain, hypothalamic-pituitary axis, and the optic nerves (Table 121.1).

Genetic Analysis

The relevant genetic analysis should be undertaken in patients with multiple pituitary hormone deficiencies, a family history of hypopituitarism or consanguinity or with associated anatomic abnormalities (Table 121.1).

121.1.4 Management

Acute Interventions

Correction of hypoglycemia is the first step. Substitution therapy with deficient hormones must be undertaken as soon as possible. ACTH, TSH and ADH deficiencies need replacement with hydrocortisone (8–12 mg/m^2/day orally, in three divided doses), thyroxine (8–12 μg/kg/day, orally once a day) and vasopressin (0.5–2.0 mU/kg/h as a continuous IV infusion) or DDAVP (0.25–10 μg 12 h intranasally, or 0.02–0.2 μg 12 h intravenously, according to response), respectively. When hypoglycemia is caused by GH deficiency, then subcutaneous hGH at 7 mg/m^2/weekly dose may be useful.

Discharge Instructions

Intramuscular injections to take home (hydrocortisone hemisuccinate, 70 mg/m^2/8 h) need to be prescribed in case of vomiting or profuse diarrhea. In the case of intercurrent illness, instructions from a pediatric endocrinologist should be given to double (non-febrile illness) or treble (febrile illness) the oral hydrocortisone doses. A steroid card should be provided.

Parents should be instructed in the use of glucose monitoring (sticks) and the management of hypoglycaemia (1 μg s.c. glucagon injections).

In presence of a micropenis, the use of testosterone injections (25 mg/IM monthly, for 3 months) or dihydrotestosterone gel (0.2–0.3 mg/kg topically once a day for 3–4 months) during the first 6 months of life may help further virilization.

Optic nerve involvement mandates ophthalmic referral.

Long-Term Follow-up

Generally, the anterior pituitary deficiencies need a permanent substitution treatment, while the posterior pituitary may recover. Genetic counseling should be provided for inherited causes of hypopituitarism.

121.2 Adrenal Insufficiency

Reduced cortisol and/or aldosterone production may be the consequence of primary cortical adrenal deficiency or damage. Isolated cortisol insufficiency may also be a consequence of pituitary/hypothalamic ACTH/CRF deficiency (secondary/tertiary adrenal insufficiency, respectively). The clinical presentation will differ according to the underlying cause.

121.2.1 Adrenal Development from Fetal to Postnatal Adrenal Gland

Coelomic epithelial cells of mesodermal origin on the urogenital ridge give rise to the kidney, gonadal and adrenal cortical structures (Fig. 121.1). The fetal adrenal cortex separates from the other structures and differentiates into a larger inner fetal zone, which produces DHEA and DHEA-S from early gestation, but 3-β-HSD expression is absent after 12 weeks. After 9 weeks' gestation, there is a thinner outer definitive zone, which is quiescent until late gestation. An intermediate transitional zone appears after 24 weeks' gestation and contains the enzymes for cortisol production (expression of 3-β-HSD activity). Shortly after birth, the fetal zone regresses. By 6 months of age the definitive (adult) adrenal cortex consists of the mineralocorticoid-producing zona glomerulosa and the glucocorticoid-producing zona fasciculata. The zona reticularis does

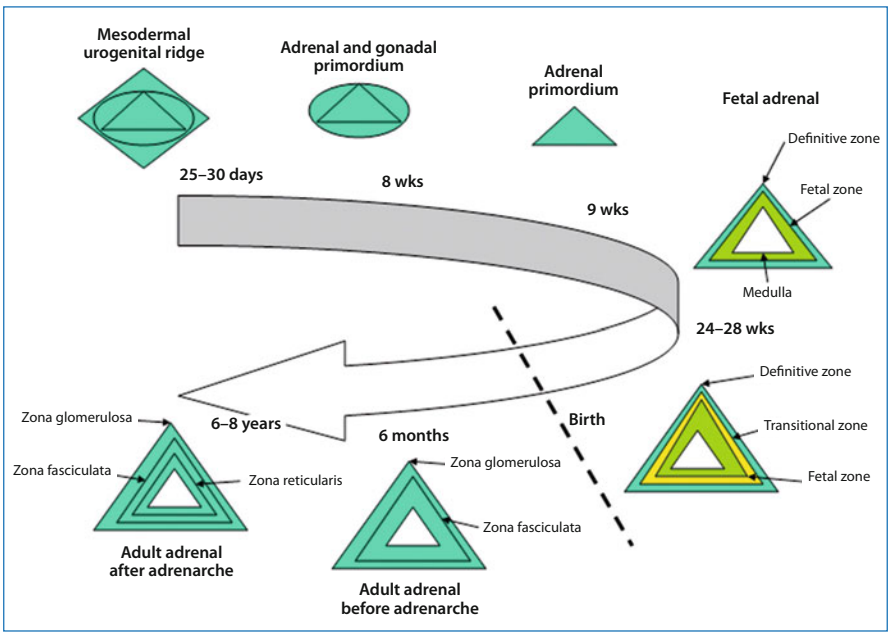

Fig. 121.1 Scheme of temporal adrenal development in humans. Modified from [8]

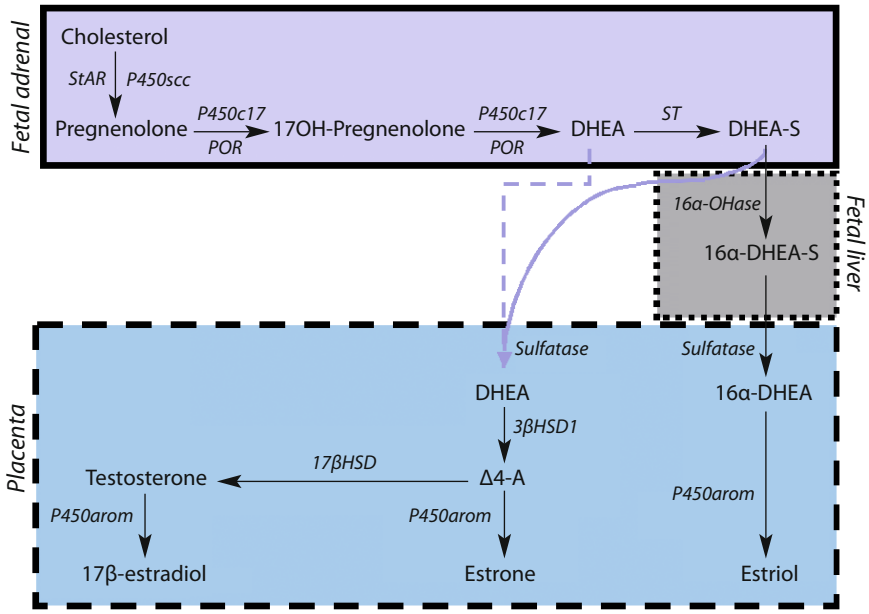

Fig. 121.2 Steroidogenesis of the fetal-adrenals/-placental unit. DHEA and its sulphate are the main products of the fetal adrenal cortex after 12 weeks' gestation in humans. DHEA-S is produced from the adrenals and converted to oestriol in the placenta through previous 16α-hydroxylation in the fetal liver, or converted directly to oestrogens in the placenta

not appear until the end of year 3 and only by around 6 years of age starts to produce adrenal androgens (adrenarche) [4].

Fetal DHEA-S production is important because it is either 16α-hydroxylated in the fetal liver before being converted to estriol (90% of the maternal circulation) or directly converted to estrone and estradiol in the placenta (50% of the maternal circulation) (Fig. 121.2).

The fetus seems to be protected from high levels of cortisol in utero because cortisol is converted to biologically inactive cortisone through 11β-HSD2 activity in placental and fetal tissues. However, transient expression (weeks 7–12 of gestation) of 3β-HSD2 in the fetal adrenal has been recently demonstrated [5] and serves to protect female fetuses from genital virilization. It enables the fetal adrenal to produce cortisol by 8 weeks of gestation and activates the negative feedback on pituitary ACTH which in turns reduces the early production of androgens in the critical time window for genital development [6].

121.2.2 Molecular Basis of Adrenal Insufficiency

More than 65 genes are thought to be involved in adrenal development, including genes coding for steroidogenic enzymes, signaling molecules, transcription and growth factors, regulators of cell cycle and angiogenesis, and extracellular matrix proteins [7, 8]. The exact role of most of these factors remains unclear.

Studies of patients with adrenal insufficiency due to gene mutations have revealed that transcription factors such as *GLI3*, *SF1* and *DAX1* have a central role in the first steps of adrenal formation. Adrenal differentiation requires ACTH stimulation and signaling through biosynthetic steps involving POMC, PCI, TPIT, MC2R and ALADIN, all of which determine adrenal hypoplasia when mutated. Mutations in some of the steroidogenic enzymes cause congenital adrenal hyperplasia, autosomic recessive inherited diseases impairing both cortisol and/or aldosterone synthesis.

121.2.3 Etiology

121.2.3.1 Congenital

Congenital adrenal insufficiency comprises a group of disorders including: 1) defects of adrenal development; 2) disordered adrenal steroidogenesis; 3) degenerative metabolic disorders affecting the adrenals (e.g., adrenoleukodystrophy); 4) disturbed endocrine communication between the pituitary gland and the adrenals. Table 121.2 summarizes the most frequent inherited conditions associated with neonatal adrenal insufficiency.

Primary Forms

Adrenal congenital hypoplasia (ACH) can present as different clinical forms of primary adrenal insufficiency:

1. An autosomal recessive form with a characteristic miniature adult adrenal morphology, with small glands with a permanent cortical zone but a diminished fetal zone. The molecular basis of this form is still unclear, but lack of late gestational or early postnatal stimulation by pro-opiomelanocortin (POMC) peptides or ACTH signaling is possible;

Table 121.2 Congenital causes of adrenal insufficiency (AI) in the newborn

[2] [a] Cortisol deficiency; [b] Aldosterone deficiency.
OMIM Online mendelian inheritance in man, *TF* transcription factor, *NR* nuclear receptor, *MR* membrane receptor, *AP* accessory protein.

2. An X-linked cytomegalic form, in which the normal three zone architecture of the adrenal cortex is absent and is replaced by large, vacuolated cells resembling fetal adrenocortical cells. It is caused by mutations in the *DAX1* gene that also cause hypogonodotropic hypogonadism and impaired spermatogenesis [9];
3. ACH, caused by mutations in the *SF1* gene, can be dominantly or recessively inherited. It is associated with adrenal failure and XY sex-reversal with the presence of müllerian structures. Since the developing adrenals appear less *SF1* dose-dependent than the testes, not all affected patients may have adrenal insufficiency;

4. IMAGe syndrome (Intrauterine growth restriction, Metaphyseal dysplasia, Adrenal hypoplasia, Genital abnormalities) comprises a cluster of abnormalities (see Table 121.2) that suggest it may be caused by a novel gene involved in the development of bone, adrenal cortex, and anterior pituitary [10].

Congenital adrenal hyperplasia (CAH) (*CYP21A2* mutations account for more than 90% of cases) is one of the most frequent forms of cortisol and aldosterone deficiency in the newborn. Other rarer enzymatic defects in this pathway (Table 121.2) can cause varying degrees of virilization of females and undervirilization of males. Patients with P450 oxidoreductase (*POR*) mutations, a recently described form of CAH, may be at risk of adrenal insufficiency and Addisonian crisis, especially at times of severe febrile illness or major surgery. In these conditions, the hypertrophic adrenals maintain their histological structure. Gene analysis, especially for 21-hydroxylase deficiency, makes it possible to perform prenatal diagnosis and treat female affected fetuses (see also Chapter 123).

In isolated hypoaldosteronism (*CYP11B2* deficiency, *CMO I* and *CMO II* forms) and pseudohypoaldosteronism (PHA, affecting the kidney only or where there is multi-organ resistance to mineralocorticoids), the adrenal cortex is normal. Both *CYP11B2* deficiency and systemic pseudohypoaldosteronism (PHA) inheritance are autosomal recessive disorders, while the renal PHA form is autosomal dominant [11]. An acquired form of PHA also exists and it is important to recognize it during the neonatal period when an urinary tract malformation is detected by prenatal ultrasound. In the case of obstructive uropathy, the risk of salt loss is very high when the cause of obstruction is treated by surgery.

Adrenoleucodistrophy is an X linked (X-ALD) severe neurodegenerative disorder causing progressive demyelinization of the central and peripheral nervous system, adrenal insufficiency, and accumulation of very-long-chain fatty acids in plasma, fibroblasts and tissues. It is caused by impaired beta-oxidation in peroxisomes due to mutations in the *ABCD1* gene. The onset generally does not occur below 3 years of age, but a contiguous *ABCD1 DXS1357E* deletion syndrome (CADDS) has recently been described with neonatal onset [12]. Its phenotype is similar to that of either peroxisomal biogenesis disorders (PBD) or single-enzyme deficiencies (SED) in the peroxisomal beta-oxidation pathway (acyl CoA oxidase deficiency and bifunctional protein deficiency), which also accumulate very-long-chain fatty acids, but are transmitted in an autosomal recessive fashion and present as neonatal onset ALD (Table 121.2). Neonatal screening by tandem mass spectrometry can be used for early diagnosis, reducing morbidity due to these conditions [13].

Secondary Forms

ACTH deficiency may recur as an isolated feature (IAD) or as part of a multiple pituitary hormone deficiency syndrome (Table 121.2). IAD is rare and may occur in the neonatal period, but also in later childhood. After consideration of candidate genes (*POMC*, *PC1*, *CRH* and its receptor *CRH-R1*), only mutations in *TPIT* have been found in about 25% of the patients with the isolated, early onset form. Multiple pituitary hormone deficiencies (MPHD) may result from abnormal hypothalamic-pituitary development caused by anomalous expression of the transcription factors reported in Table 121.2. ACTH insensitivity syndromes comprise a group of disorders which all manifest as familial glucocorticoid deficiency (FGD). The type 1 (FGD1) depends on autosomal recessive mutations in the G-protein-coupled ACTH receptor (melanocortin receptor 2, MC2R), while the type 2 (FGD2) is caused by mutations in the gene encoding *MC2R* accessory protein (*MRAP*) [14]. Other forms of FGD (type 3) still remain without corresponding identified gene mutations. ACTH resistance is one of the three components of the Triple A syndrome (Achalasia-Addisonianism-Alacrima, the Allgrove syndrome), caused by mutations in the *AAAS* gene, encoding a protein named ALADIN, and which manifests itself during the first decade.

121.2.3.2 Acquired

AIDS, meningococcus, adrenal hemorrhage (Waterhouse-Friderichsen), maternal Cushing's disease/syndrome, adrenal suppression following antenatal steroid therapy to the fetus or to the mother, may all cause severe adrenal insufficiency in neonates. The use of dexamethasone postnatally has been largely abandoned because of likely effects on brain growth and more physiological doses of hydrocortisone are currently being used in the context of clinical trial for treatment of the controversial relative adrenal insufficiency [15].

121.2.4 Clinical Presentation

Generally, primary congenital adrenal insufficiency may present with hypoglycemia, cardiovascular collapse, hypotension, ambiguous genitalia, skin pigmentation and hyponatremia/ hyperkalemia. Patients with congenital adrenal hypoplasia, steroidogenic defects or pseudohypoaldosteronism present with clinical signs of salt wasting within the first 20 days after the birth. They may have failure to thrive, anorexia, vomiting, and severe hyponatremic/hyperkalemic dehydration. Skin hyperpigmentation, typical for the forms with reactive ACTH overproduction (congenital adrenal hyperplasia/hypoplasia, familial isolated glucocorticoid deficiency, adrenoleukodystrophy) may color genitalia, umbilicus, nipples and axillae. Other symptoms at onset, mainly in neonates with severe glucocorticoid deficiency (congenital adrenal hyperplasia, familial isolated glucocorticoid deficiency), may be hypoglycemia with possible ketosis, due to gluconeogenic substrate deficiency.

Hyperpigmentation and salt craving are not observed in patients with secondary adrenal insufficiency. Unless there is a history of recent glucocorticoid therapy, secondary adrenal insufficiency is usually associated with signs of other pituitary hormone deficiencies such as hypoglycemia, growth failure, secondary hypothyroidism, and/or diabetes insipidus (polyuria and polydipsia).

121.2.5 Diagnostic Evaluation

When the adrenal failure is not extremely severe, a pre-treatment blood sample for cortisol, electrolyte, glucose, ACTH levels, plasma renin activity and aldosterone level should be taken. A further diagnostic evaluation under the supervision of a pediatric endocrinologist may need an ACTH test (0–60 mins, half standard dose: 125 μg IV or low dose: 0.5–1 μg/1,73 m^2) to assess the adrenal response. A normal cortisol response is a rise of 200 nmol/L from baseline, although equivocal results may occur during the neonatal period. A peak 17OH-progesterone of more than 150 nmol/L is suggestive of 21-hydroxylase deficiency (for other specific steroidogenic defects see Table 121.2 and Chapter 123, Table 123.4). Urine steroid profile may be useful for AHC or CAH differentiation and adrenal ultrasound scan for hemorrhage or hypertrophy. Aldosterone levels are generally low in salt-wasting congenital adrenal hyperplasia/hypoplasia. When isolated aldosterone deficiency is suspected, very high levels of the hormone indicate possible pseudohypoaldosteronism. Plasma renin activity (PRA) levels are elevated when salt wasting is latent or manifest due to aldosterone deficiency or resistance. In aldosterone steroidogenic defects, the PRA/aldosterone ratio is elevated even when mineralocorticoid levels are normal.

121.2.6 Treatment

For the standard treatment of glucocorticoid and/or mineralocorticoid deficiencies, see Chapter 123. Secondary adrenal insufficiency or familial glucocorticoid deficiency do not need mineralocorticoid substitution. Patients with isolated aldosterone deficiency do not need glucocorticoids and milder forms may be treated by the simple addition of salt to the diet, obviating the need for mineralocorticoid substitution. In patients with pseudohypoaldosteronism, where mineralocorticoid treatment is ineffective, dietary supplementation with sodium chloride is the only possible treatment.

In acute adrenal crisis, an initial hydrocortisone IV bolus of 60–70 mg/m^2 is recommended, followed by 60–70 mg/m^2 per day divided into four IV doses. For restoration of intravascular volume, we recommend an infusion of 5% glucose and 0.9% saline solutions (120–150 mL/kg/24 hrs). The combination of saline and large doses of hydrocortisone maintains mineralocorticoid function during the first hours of treatment. Fludrocortisone (0.05–0.2 mg/day in two divided doses) may be administered orally; intramuscular administration of 1–2 mg/ twice a day of corticosterone acetate is a less comfortable way of achieving mineralocorticoid replacement. Additional glucose should be administered parenterally when hypoglycemia is severe.

121.3 Hyponatremia and Hypernatremia

Total body water and osmolality is regulated by the renal action of antidiuretic hormone (ADH), the renin-angiotensin-aldosterone system, norepinephrine and by the thirst mechanism. Abnormalities in water balance are manifested as sodium disturbances. Mild to moderate hyponatremia (plasma sodium > 125–134 < mmol/L) and severe hyponatremia (<125 mmol/L) are found in about 15–30% and 1–4% of patients, respectively. It is useful to distinguish between water overload (excessive intake or inadequate excretion) and sodium depletion (excessive salt loss). Common causes of hyponatremia are listed in Table 121.3. Hypernatremia

Table 121.3 Causes of hyponatremia and hypernatremia in the newborn

Hyponatremia
Water overload
– Iatrogenic: excess maternal (prenatal) or neonatal i.v. fluid administration
– Renal failure
– Syndrome of inappropriate antidiuretic hormone secretion (SIADH)
Salt depletion
– Immaturity
– CAH, AHC
– Renal impairment: polyuric phase of acute tubular necrosis (ATN), congenital nephrotic syndrome, Bartter syndrome, congenital renal abnormality (previous polydramnios)
– Gut loss: secretory diarrhea, stoma output following gut resection, congenital chloride diarrhea
– Iatrogenic: repeated cerebral spinal fluid removal by ventricular taps
– Aldosterone biosynthetic defect or resistance
Hypernatremia
Water depletion
• Inadequate fluid intake:
– milk intake: frequent in breastfeeding mothers at first pregnancy
– i.v. fluid infusion: e.g. estreme preterm infant with high insensibile percutaneous or respiratory tract loss
• Excessive fluid loss:
– urine: diabetes insipidus (DI), renal concentrating defect, osmotic diuresis secondary to glicosuria
– gut: vomiting or naso-gastric aspirates, secondary diarrhea
– skin: cystic fibrosis
Salt excess
– Sodium bicarbonate infusion
– i.v. saline, including flushes
– Malicious salt poisoning

(plasma sodium > 145 mmol/L) is caused by primary water deficit (with or without sodium loss) and commonly occurs because of insufficient water intake or impaired thirst mechanism (Table 121.3).

121.3.1 The Renin-Angiotensin-Aldosterone System

Aldosterone secretion is primarily regulated by the renin-angiotensin system and potassium (Fig. 121.3), and secondarily by ACTH. Hyponatremia, hypovolemia, low blood pressure and reduced renal perfusion stimulate the juxta-glomerular apparatus (cells surrounding the renal afferent arteriole, close to the macula densa) to secrete the proteolytic enzyme renin. Renin activates angiotensin I and II through angiotensinogen (liver) and angiotensin converting enzyme (ACE, lung), respectively. Angiotensin II has a potent vasopressor activity and, like potassium, acts directly on the glomerulosa cells in the adrenal cortex to stimulate aldosterone production. The distal tubule and collecting ducts of the kidney respond to increased aldosterone levels by increasing sodium reabsorption and excreting potassium and hydrogen. The mineralocorticoid receptor (MR) is responsive to both cortisol and aldosterone actions, but 11β-hydroxysteroid dehydrogenase (11β-HSD) activity at renal level prevents the conversion of cortisol to cortisone, which has very low mineralocorticoid receptor affinity. Aldosterone increases blood pressure by raising blood volume, and by increasing the sensitivity of arterial muscle to vasoconstrictors.

121.3.2 Antidiuretic Hormone

Antidiuretic hormone (ADH) or arginine vasopressin (AVP) is a nonapeptide that is synthesized as a large prohormone in the paraventricular and supra-optic nuclei of the hypothalamus. The most potent stimuli to ADH release are severe hy-

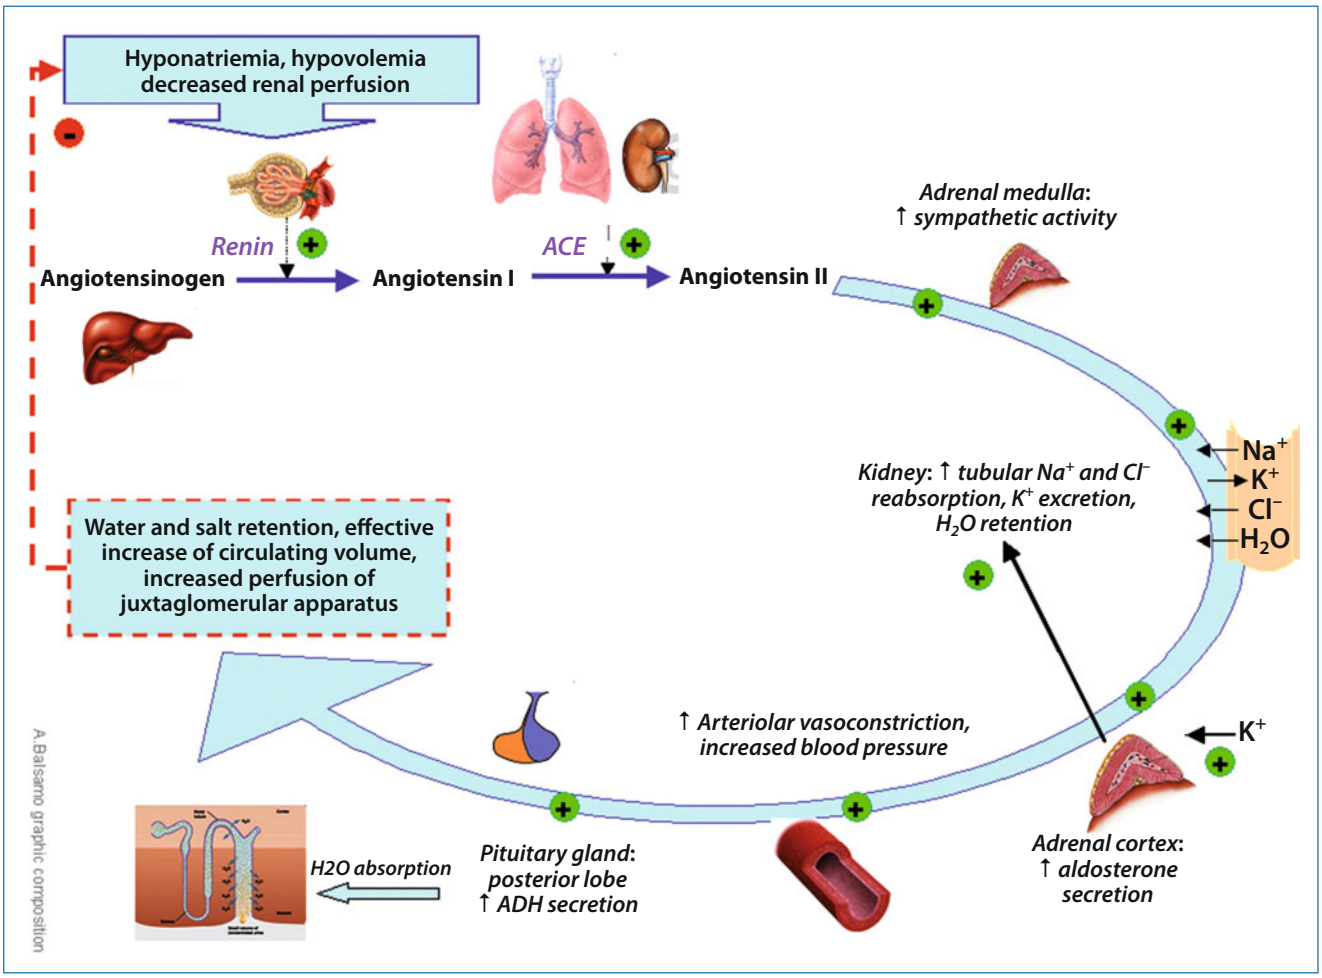

Fig. 121.3 Renin-angiotensin-aldosterone system

povolemia and increased plasma osmolality [16]. ADH acts via vascular V1 receptors and renal tubular V2 receptors. V1 receptor stimulation causes arterial vasoconstriction, and V2 stimulation increases renal free water re-absorption (due to the high interstitial osmolality). Relative or absolute deficiency of ADH causes DI. Central DI may be primary and is usually associated with other hypothalamo/pituitary gland developmental alterations and multiple hormone deficiencies. In ACTH deficiency, reduced cortisol levels may mask the effects of ADH deficiency, and fluid balance should be monitored at the start of hydrocortisone treatment for pituitary deficiency.

DI may rarely be caused by renal resistance to ADH (nephrogenic DI), an X-linked disease (Xq2.8), which is due to mutations in the arginine-vasopressin receptor 2 gene (*AVPR2*) [17].

In the newborn, ADH excess is more frequent than deficiency, and often due to underlying intracranial (e.g., cerebral hypoxic-ischemic) or lung (atrial natriuretic peptide) pathologies. Inappropriate ADH secretion is usually transient. The diagnosis is made by observing urine that is inappropriately concentrated in the presence of a low plasma osmolality. It is treated by fluid restriction.

121.3.3 Investigations

Attention to fluid balance is critical. This is achieved by daily or 12-hourly weighing with serial measurements of the acid-base status, blood concentrations of sodium, potassium, glucose, urea, creatinine, lactate and osmolality, and urine electrolytes and osmolality.

Urine and blood analysis for reducing substances may be indicated when there is a history of vomiting or jaundice and galactosemia is suspected.

In hyponatremic patients, measure plasma 17-OH-progesterone (steroid profile when available) and karyotype or FISH/PCR for Y fragments in case of genital ambiguity, for the diagnosis of CAH.

Ultrasound scans should be performed for the identification of kidney abnormalities (dysplasia, polycystic disease, renal vein thrombosis), adrenal hyperplasia or hemorrhage. Intracranial abnormalities (e.g., midline defects) in the presence of salt-water imbalance may indicate specific hormonal investigations.

121.3.4 Management

The goal for treating hyponatremia is normalization of the blood sodium concentration by identifying and treating the underlying disease. Patients with mild hyponatremia are almost always asymptomatic. Acute and severe hyponatremia requires prompt and careful administration and monitoring of serum sodium to avoid overcorrection and neurological damage. The long-term treatment depends on the diagnosis. If there is underlying renal disease, involvement by a pediatric nephrologist is indicated.

Management of hypernatremia involves fluid replacement, avoiding neurological complications due to rapid reduction of plasma sodium levels [18]. Fluid balance should be carefully monitored.

When DI is suspected, a vasopressin test may distinguish between central or nephrogenic DI [19]. This may be by continuous IV infusion of aqueous vasopressin with a starting dose of 1 mU/kg/h; range: 0.5–20 mU/kg/h) or DDAVP (IV or s.c. administration: start with 0.02 μg every 12 h and increase gradually until a suitable response is achieved) or by intranasal solution (start with 0.25 μg every 12 h, increasing gradually according to response; usual maximum dose 5-20 μg every 12 h).

121.4 Hypoglycemia and Hyperinsulinism

121.4.1 Hypoglycemia

The definition of the lower normal limit of blood glucose is controversial. A common definition of hypoglycemia is a plasma glucose level < 35 mg/dL (1.9 mmol/L) in term or < 40 mg/dL (2.2 mmol/L) in premature infants, although some studies have suggested 47–55 mg/dL (2.6–3.1 mmol/L). It is important to be aware that the blood glucose concentration usually decreases to 35 mg/dL (1.9 mmol/L) 1–2 hour after birth and then rises; about 15% of appropriate for gestational age (AGA) healthy full-term neonates have a blood glucose level < 50 mg/dL (2.8 mmol/L) during the first 72 hours of life [20–22]. Preterm and small for gestational age (SGA) newborn babies are unable to produce alternative fuels (ketone bodies) and are at increased risk of neuroglycopenia. In these babies, a blood glucose level above 55 mg/dL (3.1 mmol/L) is likely to be safer.

The overall incidence of hypoglycemia is about 1–5/1000 live births, although it can be as high as 15% in preterm infants and in those with intrauterine growth restriction (IUGR) or 37% in infants of diabetic mothers.

121.4.2 Classification and Causes

- Transient hypoglycemia: IUGR, SGA or large for gestational age (LGA) infants, premature or postmature neonates, infants of diabetic mothers (IDMs), intrapartum administration of glucose, perinatal stress, sepsis, birth asphyxia, hypothermia, polycythemia, hyperviscosity, shock, maternal drugs (terbutaline, propranolol, oral hypoglycemic agents) [23].

Table 121.4 Causes of hyperinsulinism

Condition	Inheritance	Features
Genetic forms		
Recessive K_{ATP} hyperinsulinism	AR	LGA at birth; unresponsive to diazoxide therapy
Focal K_{ATP} hyperinsulinism		Histologically appears as adenomatosis; LGA at birth, unresponsive to diazoxide therapy
Dominant K_{ATP} hyperinsulinism	AD	LGA at birth; responsive to diazoxide therapy; hypoglycaemia present at birth or later in infancy
GCK hyperinsulinism	AD	Responsive to diazoxide therapy; hypoglycaemia present at birth or later in infancy
GDH hyperinsulinism	AD	Persistent symptomatic hypoglycaemia and persistent asymptomatic hyperammonemia; responsive to diazoxide therapy
SCHAD hyperinsulinism	AD	Responsive to diazoxide therapy; severe hypoglycemia
Other		
Beckwith-Wiedemann syndrome	Various	LGA at birth; macroglossia, abdominal wall defects, hypoglycemia
Sotos syndrome		Macrocephaly, large hands and feet, hypertelorism, sometimes hypoglycemia
Pancreatic adenoma		
Oral sulfonylurea drugs		

AR autosomal recessive, *AD* autosomal dominant, *GDH* glutamate dehydrogenase, *SCHAD* short chain 3-hydroxyacyl CoA dehydrogenase.

- Persistent or recurrent hypoglycemia:
  - hyperinsulinism: see Table 121.4;
  - endocrine disorders: deficiency of GH, glucagon, cortisol, thyroid hormones, epinephrine;
  - inborn errors of carbohydrate metabolism: glycogen storage disease, glycogen synthase deficiency, galactosemia, fructose intolerance;
  - inborn errors of amino acid metabolism: maple syrup urine disease, propionic academia, methylmalonic academia, hereditary tyrosinemia, 3-hydroxy-3-methyl glutaric academia, glutaric academia type II;
  - inborn errors of fatty acid metabolism: defects of carnitine metabolism, acyl-coezyme dehydrogenase defects.

121.4.3 Clinical Presentation

Asymptomatic hypoglycemia is relatively common.

Symptomatic hypoglycemia may present with:

- Irritability, lethargy, abnormal cry, coma
- Sucking difficulty
- Tremors, seizures
- Pallor, cyanosis, sweating
- Hypothermia
- Hypotonia
- Apnea, irregular respiration
- Tachycardia.

121.4.4 Screening

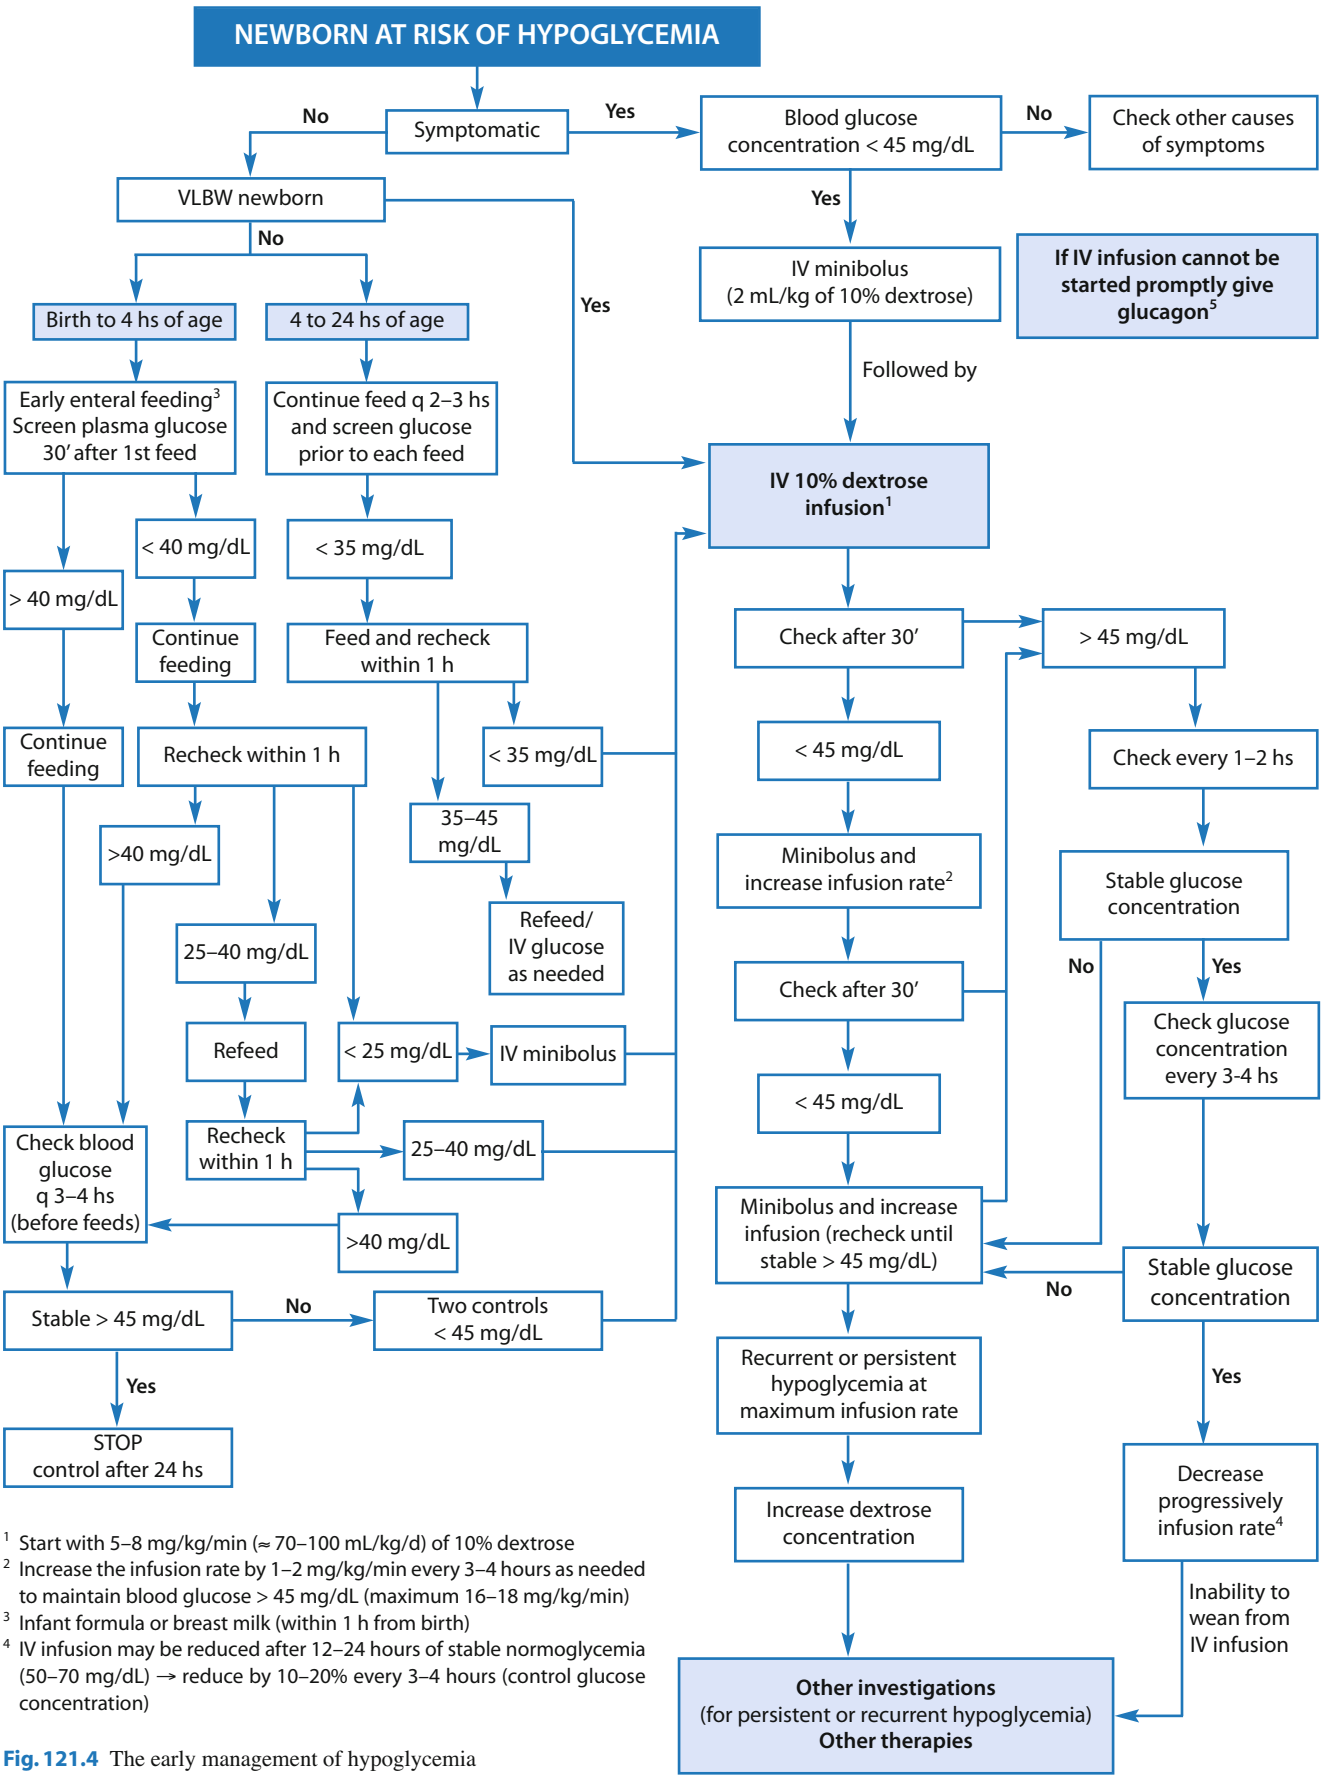
- High risk neonates
  - Birthweight > 4 kg or < 2 kg
  - SGA, LGA or intrauterine growth restriction
  - Infants of diabetic mothers (IDMs)
  - Preterm
  - Septic neonates
  - Clinical features of hypoglycemia.
- Mild to moderate risk neonates
  - Birth asphyxia, respiratory distress, low Apgar score
  - Neonates of mother treated with hypoglycemia-inducing drugs
  - Suspected inborn error of metabolism
  - Macroglossia or hemihypertrophy (Beckwith-Wiedeman syndrome).

121.4.5 Diagnosis

Semi-quantitative measurement of blood glucose levels should be used only as a screening test. To confirm the diagnosis, plasma or serum glucose levels should be measured in the laboratory by chemical analysis. Plasma glucose levels are about 10–18% higher than blood levels.

Other possible investigations (persistent or recurrent hypoglycemia): sample to be taken during hypoglycemia.

- First stage:
  - Insulin and C-peptide
  - Ultrasound imaging of pancreas
  - Ketones
  - Insulin/glucose (I/G) ratio. An I/G ratio > 0.30 suggests a hyperinsulinemic hypoglycemia. The diagnosis of hyperinsulinism is based on inappropriately high insulin levels.
- Second stage:
  - Cortisol, ACTH
  - GH
  - fT3, fT4, TSH
  - Glucagon
  - Free fatty acid
  - Amino acids (serum and urine)
  - Organic acids (urine)
  - Lactate, pyruvate, urate, acetoacetate
  - Ammonia
  - IGF-I, IGF-BPs
  - CT scan of the pancreas.



[1] Start with 5–8 mg/kg/min (≈ 70–100 mL/kg/d) of 10% dextrose
[2] Increase the infusion rate by 1–2 mg/kg/min every 3–4 hours as needed to maintain blood glucose > 45 mg/dL (maximum 16–18 mg/kg/min)
[3] Infant formula or breast milk (within 1 h from birth)
[4] IV infusion may be reduced after 12–24 hours of stable normoglycemia (50–70 mg/dL) → reduce by 10–20% every 3–4 hours (control glucose concentration)

Fig. 121.4 The early management of hypoglycemia

121.4.6 Management

For early management of hypoglycemia, see Fig. 121.4. The following points should also be considered:

- if postprandial glucose concentration is normal but the value before the next feed is low → IV therapy;
- IV glucose infusion should be the first line treatment in symptomatic hypoglycemia, and for newborns unable to tolerate enteral feeds, or with chronic or severe hypoglycemia (preterms, IUGR, infants of diabetic mothers, sepsis, suspected inborn errors of metabolism or endocrine disorders);
- persistent glucose infusion rate > 8 mg/kg/min suggests hyperinsulinism.

121.4.6.1 Persistent or Recurrent Hypoglycemia

In case of persistent or recurrent hypoglycemia, other treatments should be considered in association with IV glucose infusion:

- Corticosteroids: hydrocortisone (2.5 mg/kg over 3–5 min bid or tid).
- Diazoxide: PO 2–5 mg/kg tid; start with 5 mg/kg tid and reduce to the minimal dose effective. It is useful in hyperinsulinemic hypoglycemia. Concurrent administration of a diuretic (e.g., hydrochlorathiazide 3–5 mg/kg bid) is recommended → reduce fluid retetion due to diazoxide use and enhance diazoxide effects on blood sugar levels. Control blood pressure and glucose levels. If hypoglycemia is not responsive to 15 mg/kg/day, start octreotide infusion.
- Octreotide: starting dose 1 μg/kg qid IV or SC. Increase according to clinical effect to a maximum of 10 μg/kg qid. Some success in insulinomas and neonatal persistent hypoglycemia (nesidioblastosis). Recently the combination of octreotide with glucagon IV infusion (0.01–0.02 mg/kg/h → max 1 mg/24 h) has been reported for severe hypoglycemia secondary to hyperinsulinism. Monitor ECG and glucose levels during infusion.
- Growth hormone: 0.1–0.2 U/day SC; administer only when GH deficiency confirmed.
- Pancreatectomy: subtotal or total pancreatectomy following unsuccessful medical treatment of persistent neonatal hypoglycemia due to hyperinsulinism [24].

121.4.7 Beckwith-Wiedemann Syndrome

Beckwith-Wiedemann syndrome (BWS) is a rare congenital overgrowth disorder which occurs in about 1 out of every 13–17,000 live births.

Commonest clinical features in Table 121.5.

Table 121.5 Main clinical features of BWS

Clinical findings	Frequency
– Macrosomia (weight and length)	90%
– Hemihypertrophy (↑ risk for cancer)	10–15%
– Macroglossia	80%
– Cranio-facial anomalies (midface hypoplasia, a prominent occiput, and nevus flammeus)	60–70%
– Ear defects (creases or pit)	
– Anterior abdominal wall defects (omphalocele, umbilical hernia, diastasis recti abdominis)	75% 80%
– Hypoglycemia	50%
– Cardiac defects	25%
– Visceromegaly (liver, kidney, spleen)	
– Tumors (Wilms' tumor, hepatoblastoma, adrenal carcinoma, nephroblastoma)	7–20%

Table 121.6 Genetic alterations in BWS

Alterations detected on 11p15.5 region	Frequency*
– Duplication, translocation, inversion	1–2%
– Paternal uniparental disomy	10–20%
– Methylation abnormalities	55–65%
– CDKN1C mutations	5–10%

* In patients with "certain" clinical diagnosis of BWS.

121.4.7.1 Etiology

Only 15% of cases are familial due to complex inheritance. Chromosomal abnormalities in the highly imprinted region at chromosome 11p15.5 have been reported both in sporadic and familial cases (see Table 121.6) [25]. Several genes in the 11p region have been implicated, e.g. CDKN1C, IGF-2, and H19.

Diagnosis is based on clinical findings and on analysis of the 11p15 region.

121.4.7.2 Management and Prognosis

Glycemia should be monitored during the first days of life. Parents should be taught the clinical features of hypoglycemia to avoid hypoglycemia after discharge.

Blood alpha fetoprotein (AFP) concentration should be measured during the first years of life (hepatoblastoma).

Abdominal ultrasound scanning every 6 months to identify tumors. Repeated chest X-rays for the early diagnosis of thoracic neuroblastoma. Abdominal wall defects may require surgical treatment. Respiratory and feeding difficulties as well as speech abnormalities may be related to macroglossia and also require surgery.

Usually the prognosis is good, although an increased risk of cancers has been reported.

Developmental milestones are usually normal. Mental retardation is rare, provided that hypoglycemia is avoided [26].

121.5 Hyperglycemia

The definition of the upper normal limit of blood glucose in the newborn remains uncertain. A blood glucose level higher than 125 mg/dL (6.9 mmol/L) or plasma glucose level >150 mg/dL, regardless gestational age or postnatal age, are usually considered abnormal [27]. Nevertheless most neonatologists tolerate blood glucose levels of 150–180 mg/dL (8.3–11.1 mmol/L) in preterm infants. Plasma glucose levels are about 15% higher than blood levels because of the presence of erythrocyes which metabolise glucose.

Hyperglycemia is relatively common in extremely low birth weight infants (ELBW) and in SGA as a consequence of impaired glucose homeostasis. The incidence is inversely related to birth weight and gestation age. About 80% of neonates < 750 g are hyperglycemic during the first days of life. In full-term appropriately grown newborns (AGA), hyperglycemia is rare and mainly affects seriously ill neonates. Neonatal diabetes mellitus occurs in about 1:400.000 live births [29].

121.5.1 Causes

- Impaired glucose homeostasis: preterm and SGA infants.
- Iatrogenic hyperglycemia: excessive intravenous glucose infusion.
- Drugs: corticosteroids, caffeine, theophylline and phenytoin or maternal diazoxide.
- Stress: sepsis, intraventricular hemorrhage, birth asphyxia, painful procedures.
- Neonatal diabetes mellitus: transient or permanent.
- Absence of enteral feeding: diminished "incretin" secretion.

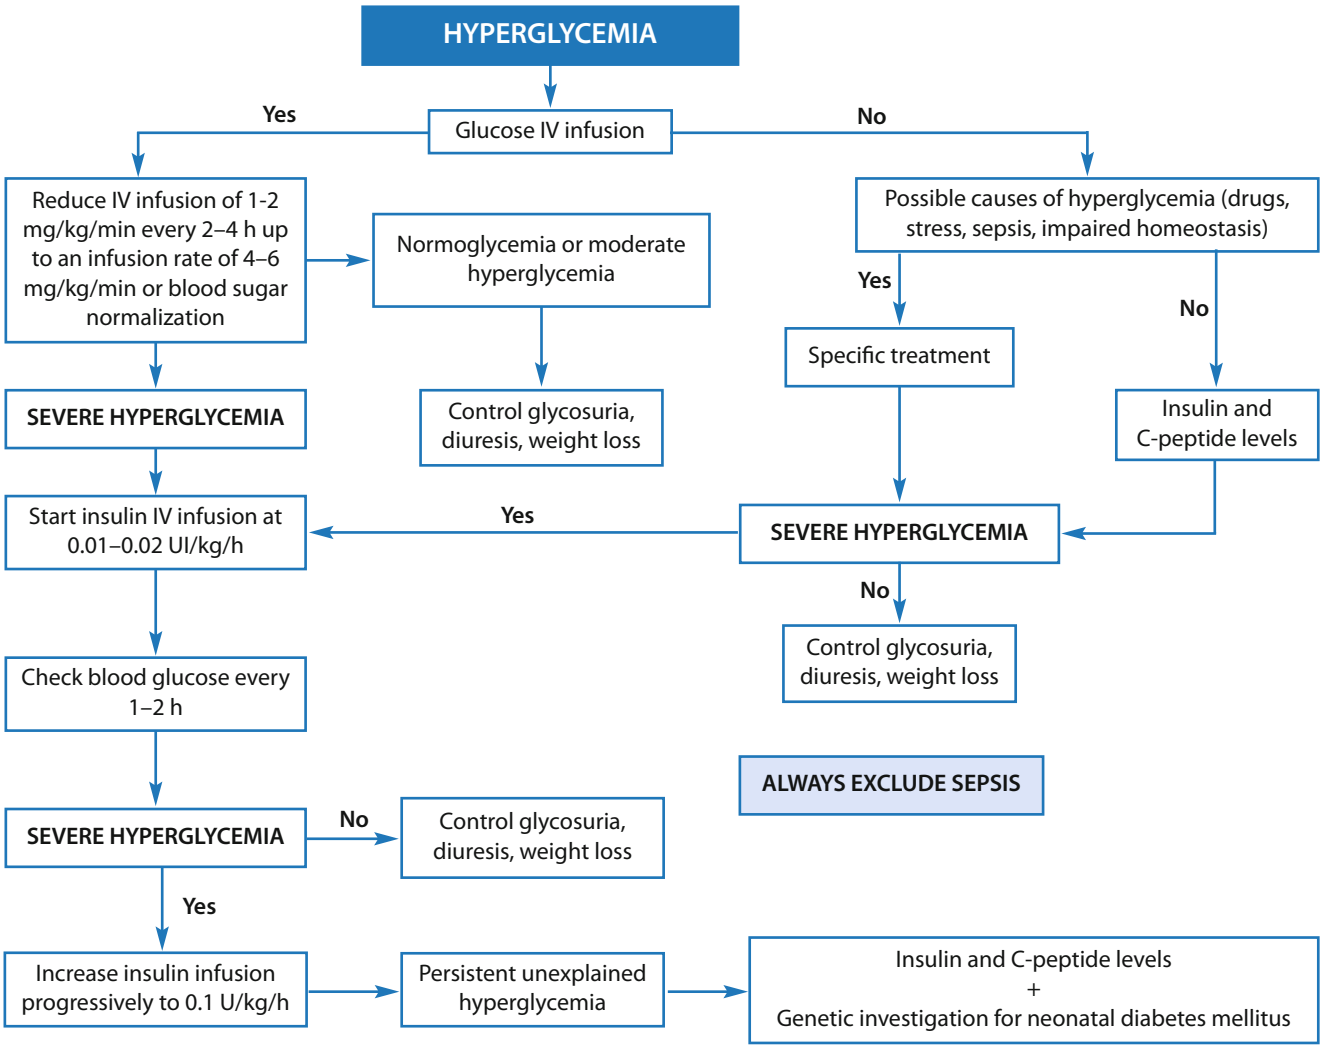


Fig. 121.5 The management of hyperglycemia. Based on evidence from [28]

121.5.2 Clinical Presentation and Diagnosis

Hyperglycemia may be associated with polyuria, dehydration, failure to thrive; rarely ketoacidosis. Semi-quantitative evaluation of blood glucose levels by reagent strips should only be carried out for screening. To confirm the diagnosis and before starting treatment, plasma or serum glucose concentrations should be measured by quantitative chemical analysis.

121.5.2.1 Other Investigations

- First stage:
  - acid/base status → diabetic ketoacidosis
  - serum osmolarity → each 18 mg/dL (1.0 mmol/L) rise in blood glucose causes an increase in serum osmolarity of 1 mOsm/L
  - urine glucose level → osmotic diuresis
  - blood examination → sepsis
- If persistent unexplained hyperglycemia:
  - blood insulin concentration
  - blood C-peptide concentration
  - genetic investigations for neonatal diabetes mellitus.

121.5.3 Complications

Hyperglycemia has been associated with high sepsis and mortality rates. There is an increased risk of intraventricular hemorrhage with high plasma osmolarity.

An osmotic diuresis increases the risk of dehydration and electrolytes imbalance.

121.5.4 Neonatal Diabetes Mellitus

Neonatal diabetes mellitus (NDM) is a rare monogenic metabolic disorder which presents as uncontrolled hyperglycemia during the first six months of life. The estimated incidence is about 1/300,000–500,000 live births. Two different clinical phenotypes have been recognized: transient neonatal diabetes mellitus (TNDM) and permanent diabetes mellitus (PNDM), which differ in the duration of insulin dependence. In TNDM, insulin treatment may be discontinued within 18 months after diagnosis although about 50% relapse during childhood or adulthood. Almost all neonates affected by NDM are SGA, although some with PNDM are not SGA [29].

121.5.4.1 Etiology

About 60–70% of patients affected by TNDM show abnormalities in the 6q24 region. TNDM is usually sporadic, although about one-third of cases have paternal transmission (paternal duplications, paternal isodisomy, methylation defect).

Most patients with PNDM carry mutations of the KATP channel (50–70%). Other genetic defects associated with PNDM are less common (Table 121.7).

121.5.4.2 Clinical Presentation

NDM presents as hyperglycemia, failure to thrive, dehydration and ketoacidosis during the first months of life. PNDM may occur as an isolated abnormality or as a part of a syndrome (Table 121.7). Patients with mutations of the ATP-sensitive potassium (KATP) channel (*KCNJ11* and *ABCC8* genes) may present with DEND syndrome (delayed development, epilepsy, NDM) or iDEND phenotype (DEND without epilepsy).

Table 121.7 Genes involved and clinical features of neonatal diabetes mellitus

Condition	Chromosome	Inheritance	Neonatal features
β-cell dysfunction			
ABCC8	11p15.1	AD	NDM +/– DEND
KCNJ11	11p15.1	AD	NDM +/– DEND o iDEND
Glucokinase	7p15-13	AR	PNDM
β-cell mass reduction			
FOXP3	Xp11.23-Xq13.3	X-linked	Exfoliative dermatitis, diarrhea, hemolitic anemia, thyreopathy, PNDM (IPEX syndrome)
INS	11p15	AD	PNDM
EIF2AK3	2p12	AR	PNDM, spondyloepiphysel dysplasia, hepatomegaly, renal failure, mental retardation (Wolcott-Rallison syndrome)
Abnormal islet development			
HNF1b	17cen-q21.3	AD	TNDM, renal abnormalities, genital malformation
PTF1 a	10p12.3	AR	PNDM, cerebellar hypoplasia
IPF1	13q21.1	AR	Pancreatic agenesis (PNDM and exocrine failure)
GLIS 3	9p	AR	PNDM, hypothyroidism

AR autosomal recessive, *AD* autosomal dominant.

121.5.4.3 Diagnosis

Persistent unexplained hyperglycemia during the first 6 months of life should be investigated for NDM. TNDM patients are usually younger and have lower insulin requirements. PNDM cannot be generally differentiated from TNDM on the basis of clinical features alone. Genetic investigations (chromosome 6, *KCNJ11*, *ABCC8*) allow the diagnosis for the majority of patients affected by NDM [30].

First line examination involves insulin and C-peptide. Second line examination involves genetic investigations.

121.5.4.4 Prognosis

Prognosis is related to the severity of the disease and to the rapidity of diagnosis and treatment. PNDM associated with other syndromes has a variable prognosis. Patients affected by TNDM should have long-term follow-up because of the risk of later relapse.

121.5.4.5 Treatment

Insulin therapy and high caloric intake are crucial for good metabolic control. We recommend the initial administration of intravenous insulin at 0.01–0.02 U/kg/h, adjusted according to blood glucose levels, followed by subcutaneous ultralente insulin at 0.4–0.6 U/kg/24 h.

When good metabolic control has been achieved, switching to oral sulfanylurea therapy may be attempted in patients affected by the *KCNJ11* and *ABCC8* gene mutations. The dose of glibenclamide may be as high as 0.8 mg/kg/day [30].

121.6 Hypocalcemia

Hypocalcemia is defined as a total serum calcium level < 2.1 mmol/L (8.5 mg/dL) or as an ionized calcium level < 1.1 mmoL (see also Chapter 49). Physiological hypocalcemia occurs after birth as a consequence of the end of transplacental calcium transfer, an insufficient supply through feeding and immaturity of the parathyroid glands with consequent reduced secretion of parathyroid hormone (PTH). The nadir in calcium levels occurs during the first 36–48 h of life.

Hypocalcemia is relatively common in neonates, affecting 30% of very low birth weight infants and 80–90% of infants born below 32 weeks [31, 32].

121.6.1 Clinical Presentation

Hypocalcemia is often asymptomatic. Clinical presentation includes non-specific symptoms and signs: signs of neuromuscular irritability (tremulousness, myoclonic jerks, exaggerated startle responses, seizures), lethargy, apnea, cyanosis, tachypnea, poor feeding, abdominal distension, vomiting, laryngospasm, tachycardia, prolonged QT interval on ECG, decreased myocardial contractility and heart failure.

121.6.2 Causes and Differential Diagnosis

The causes of neonatal hypocalcemia can be classified by time of onset (Table 121.8). The history should consider maternal, peripartum and postnatal events. The clinical examination

Table 121.8 Causes of hypocalcemia

Timing and causes	Mechanism
Early onset (within 72-96 h)	
– Preterm birth	Poor intake, increased calcitonin, decreased responsiveness to vit. D, hypoalbuminemia (decreased total but normal ionized calcium)
– Perinatal asphyxia	Increased calcitonin production and endogenous phosphate load, alkali therapy
– Infant of diabetic mother	Hypomagnesemia in the mother and the fetus leading to hypoparathyroidism in the infant
– Preeclampsia	
– Maternal hyperparathyroidism	Hypercalcemia with suppression of parathyroid activity in the fetus and the newborn (hypocalcemia may be prolonged)
Late onset (after 96 h)	
– Iatrogenic	Excessive intake of phosphate (phosphate therapy, feeding with phosphate-rich formula or cow's milk), citrated blood products, lipid infusion, bicarbonate therapy, loop diuretics and thiazide diuretics, glucocorticoids, *gentamicin use*
– Osteopenia of prematurity	Reduced calcium and phosphorus and increased ALP and PTH
– Parathyroid related disorders	See Table 121.9
– Vitamin D deficiency and resistance	Maternal deficiency of vitamin D often associated with use of anticonvulsants, inherited disorders of vitamin D metabolism (impaired 1-α-idroxilation-vitamin D dependent rickets type I and rarely 25-α-idroxilation), resistance to actions of vitamin D (vitamin D dependent rickets type II)
– Malabsorption of calcium or vitamin D	
– Renal failure	

Table 121.9 Parathyroid related disorders

Classification and mechanism	Diseases
Congenital or inherited parathyroid disorders	
– Aplasia or hypoplasia	DiGeorge syndrome, Velocardiofacial syndrome, HDR syndrome, Kenny-Caffey syndrome, Kearns-Sayre syndrome, X linked or autosomally inherited hypoparathyroidism, Vater association, Charge association, Gestational diabetes mellitus, fetal exposure to retinoic acid
– Impaired secretion of PTH	PTH gene mutations, activating mutations of the calcium sensing receptor
– Target organ resistance	Pseudohypoparathyroidism Type I (IA, IB, IC), Type II, Pseudo-pseudohypoparathyroidism
Non-congenital causes of parathyroid disorders	Hypomagnesemia and respiratory alkalosis

should look for dysmorphic features attributable to the 22q deletion syndrome (DiGeorge syndrome: cardiac defect, facial dysmorphisms, thymic aplasia, cleft palate). Other causes are hypoglycemia, hypomagnesemia, sepsis, meningitis, intracranial hemorrhage. Early onset hypocalcemia is usually self-limiting although hypocalcemia due to maternal hyperparathyroidism may be prolonged. Late onset hypocalcemia is often iatrogenic but vitamin D deficiency, renal failure and a parathyroid related disorders should be excluded (Tables 121.8 and 121.9).

121.6.3 Investigations

- Total and ionized calcium, phosphorus, magnesium, alkaline phosphatase
- pH, blood total protein, creatinine and electrolyte concentrations
- Blood parathyroid hormone, 25-OH vitamin D, 1,25-OH vitamin D concentrations
- Molecular genetic studies (if indicated)
- Urinary calcium, phosphorus, creatinine, cyclic adenosine monophosphate (cAMP) concentrations – measure calcium/creatinine ratio, tubular reabsorption of phosphate
- Maternal serum calcium and phosphorus concentrations.

Maternal hyperparathyroidism is characterized by high calcium, phosphorus and parathyroid hormone (PTH) levels, whereas, calcium and vitamin D levels are low in maternal vitamin D deficiency. Hypocalcemia associated with parathyroid dysfunction is distinguished by low serum calcium, increased serum phosphate, low or undetectable PTH levels. Inappropriately normal PTH levels may be present if some degree of PTH production is preserved. Serum $1,25(OH)_2D_3$ is low because PTH and hypophosphatemia are the main stimuli for the production of renal 25(OH)D 1α-hydroxylase. Elevated levels of PTH are present in syndromes associated with target organ resistance to PTH. Hypomagnesemia and respiratory alkalosis can cause transient abnormality of PTH secretion and target organ resistance to PTH.

Hypocalcemia secondary to vitamin D deficiency, inherited disorders of vitamin D metabolism or peripheral resistance to the action of vitamin D is differentiated by the presence of hypophosphatemia and elevated PTH levels.

In severe vitamin D deficiency or inherited disorders of vitamin D metabolism, the level of $1,25(OH)_2D_3$ is low. In moderate vitamin D deficiency, $1,25(OH)_2D_3$ levels may be normal or high due to the stimulation of the renal 1α-hydroxylase by PTH and hypophosphatemia. Levels of $1,25(OH)D_3$ may be high when there is peripheral resistance to the action of vitamin D (Table 121.8).

121.6.4 Congenital Parathyroid Disorders

Among some rare syndromes, hypoparathyroidism is associated with multiple malformations with various inheritance patterns (Table 121.9). Familial isolated hypoparathyroidism is caused by a mutation in the gene for the transcription factor *GCMB*, which is expressed in the PTH-secreting cells of the developing parathyroid [33]. An interstitial deletion/insertion at *Xq27.1* near *SOX3* gene is responsible for X-linked hypoparathyroidism [34]. Specific mutations in the parathyroid hormone gene have been found in families affected by congenital hypoparathyroidism [35].

Activating mutations in the calcium sensing receptor causes impaired PTH secretion and hypocalcemia with inappropriately normal PTH levels. There is clinical variability with cases affected by hypocalcemia and seizures and cases with asymptomatic hypocalcemia in the same family [36]. The term pseudohypoparathyroidism (PHP) refers to congenital forms of PTH resistance when hypocalcemia is associated with increased PTH levels and the administration of PTH fails to increase serum calcium levels and causes a phosphate diuresis. The first cases of PTH resistance were described by Albright. These patients were hypocalcemic and hyperphosphatemic and showed several features (rounded face, foreshortened fourth and other metacarpals, subcutaneous calcifications, short stature, obesity) that are now included in the syndrome, Albright's hereditary osteodystrophy (AHO). The classification of pseudohypoparathyroidism (see Appendix, p. 987) [37] is based on the variable presence of AHO and renal resistance to PTH.

121.6.5 Treatment

Oral treatment (3–4 mL/kg/day of calcium gluconate 10% in divided doses) should be given to babies with mild to moderate asymptomatic hypocalcemia or with mild neuromuscular irritability. Oral supplementation should be avoided for neonates at risk of necrotizing enterocolitis.

If there is symptomatic hypocalcemia, give IV 0.5–1 mL/kg of diluted solution of calcium gluconate 10% (1 mL = 9.3 mg of elemental calcium) slowly over 10 minutes (risk of bradycardia or cardiac asystole). The use of a central line is preferred. Maintenance IV treatment should be continued at 2–6 mL/kg/day.

The concomitant presence of hypomagnesaemia may lead to refractory hypocalcemia: give an initial dose of 100–200 mg/kg IV over 30 minutes (do not exceed 150 mg/minute) or as an IM injection and then continue with 20–50mg/kg/hour of diluted solution (usual dilution 4 grams magnesium sulphate to make 50 mL with 5% dextrose = 80 mg/mL; 0.25 mL × weight = 20 mg/kg/hour).

Hypoparathyroidism should be treated with alphacalcidiol 0.02–0.05 μg/kg/day.

If vitamin D deficiency is present, it should be treated first with oral supplementation: 5–50 μg/day (200–2000 U/day).

There is a single case report of recombinant PTH therapy in infants: safety and long-term effects are not known [38].

121.7 Hypercalcemia

During the neonatal period, hypercalcemia is less common than hypocalcemia. Hypercalcemia can be defined as ionized calcium (iCa) > 1.36 mmol/L (5.44 mg/dL) or total calcium (tCa) concentration > 2.75 mmol/L (11 mg/dL). tCa and iCa usually increase simultaneously but tCa is not predictive of iCa. Hypercalcemia may be due to iatrogenic causes (e.g., maternal intake of vitamin D), increased bone turnover or excessive intestinal or renal absorption.

121.7.1 Clinical Presentation

Mild hypercalcemia is often asymptomatic. Moderate to severe hypercalcemia usually presents with non-specific signs and symptoms: anorexia, vomiting, constipation, lethargy or irritability, hypotonia, seizures, coma, hypertension, polyuria and dehydration, bradycardia and shortening of the QT interval on the ECG. In its chronic form, the most common presentation is failure to thrive.

Physical examination is usually normal, except when there are syndromes or subcutaneous fat necrosis, Bony deformities may affect patients with severe hyperparathyroidism.

121.7.2 Causes

Neonatal hyperparathyroidism may become clinically manifest during the first 6 months of life. It can be primary or secondary to maternal pathological conditions (Table 121.10).

- Secondary hyperparathyroidism is due to maternal disease. Hypocalcemia, hypoparathyroidism or pseudohypoparathyroidism during pregnancy may lead to transient neonatal hyperparathyroidism. The prognosis is good and bone disease usually resolves within few months.
- Primary hyperparathyroidism
  - Familial hypocalciuric hypercalcemia is due to an inactivating mutation (autosomal dominant heterozygous) of the CaSR gene. Familial hypocalciuric hypercalcemia usually presents with an asymptomatic hypercalcemia, hypophosphatemia, mild hypermagnesemia, moderate hypocalciuria and inappropriately normal PTH. Hyperparathyroidism may resolves over several months.
  - Neonatal severe hyperparathyroidism is due to homozygous or double heterozygous mutations of the CaSR gene. Neonatal severe hyperparathyroidism presents with severe hypercalcemia, bone demineralization and hyperparathyroidism. Hypotonia, constipation and respiratory distress usually occur during the first days of life and may lead to death within a few weeks. Total parathyroidectomy and partial autotransplantation, and, more recently, pamidronate treatment may improve the outcome.

Williams syndrome is related to a microdeletion of chromosome 7 (q11.23). It is characterized by inconstant hypercalcemia, elfin facies, cardiovascular disease (80% have supravalvar aortic stenosis) and mental retardation.

Jansen's metaphyseal chondrodysplasia is attributable to a heterozygous mutation in the parathyroid hormone receptor (PTHR) which is situated in the kidney, bone, and growth plate. At birth, these children may have either a normal phenotype or micrognathia, prominent eyes, hypertelorism and progressive short-limbed dwarfism.

Blue diaper syndrome is a familial disease resulting from a defect in the intestinal transport of tryptophan. Hypercalcemia and nephrocalcinosis are usually manifest a few months after birth. The blue color of the urine is due to a tryptophan metabolite. The clinical presentation is with failure to thrive, gastrointestinal disturbances, recurrent fever and irritability.

Idiopathic infantile hypercalcemia is often considered part of Williams syndrome. The clinical phenotype is variable but symptomatic hypercalcemia generally resolves during childhood. Hypercalcemia is secondary to increased intestinal calcium absorption, although the pathogenesis and inheritance are not clear.

Subcutaneous fat necrosis (SFN) may induce hypercalcemia probably due to excessive intestinal calcium uptake because of increased $1,25(OH)_2D_3$ production in the lesion. SFN

Table 121.10 Causes of hypercalcemia

Causes	Description
Iatrogenic	Excessive intake of calcium or vitamin A (increased bone resorption) or vitamin D (increased intestinal uptake); thiazide diuretics (reduced renal clearance); phosphate deficiency (especially in VLBW infants with low phosphate in parenteral nutrition)
Parathyroid related	Secondary hyperparathyroidism: maternal hypocalcemia, hypoparathyroidism or pseudohypoparathyroidism Primary hyperparathyroidism: familial hypocalciuric hypercalcemia, neonatal severe hyperparathyroidism
Syndromic form	Williams syndrome, Jansen's metaphyseal chondrodysplasia, Blue diaper syndrome, idiopathic infantile hypercalcemia; IMAGe syndrome (IUGR, metaphyseal dysplasia, adrenal hypoplasia congenita, and genital anomalies)
Other form	
– Subcutaneous fat necrosis	Excessive intestinal calcium uptake due to increase $1,25(OH)_2D_3$ production from macrophages infiltrating the lesion
– Distal renal tubular acidosis	Acidosis enhance calcium bone resorption; reduced renal excretion is secondary to reduced glomerular filtration rate
– Severe infantile hypophosphatasia	Severe hypercalcemia and bone deformity; low ALP
– Congenital endocrine diseases (congenital hypothyroidism, adrenal insufficiency)	Unknown mechanism
– Metabolic disorders	Congenital carbohydrate malabsorption (disaccharidase deficiency, congenital lactase, glucose-galactose or sucrase-isomaltase deficiency), glycogen storage disease type 1a
– Tumor-related hypercalcemia	Increased production of PTH related protein (hepatic sarcoma, renal adenoma, rhabdoid tumors…)

usually affects large for gestational age term newborns with birth trauma. There have been reports of SFN following hypothermia and birth asphyxia. It presents as indurated plaques or nodules. Hypercalcemia is rarely associated with SFN, but is a severe complication which may lead to death if not promptly treated [39].

Severe infantile hypophosphatasia is an autosomal recessive disorder (chromosome 1) associated with extremely low serum and tissue alkaline phosphatase. These patients have severe bone demineralization. The clinical presentation ranges from a lethal form that presents soon after birth to a milder form that presents later. Laboratory findings include hypercalcemia, low serum alkaline phosphatase, and high urinary pyrophosphate and phosphoethanolamine concentrations.

Tumor related hypercalcemia (paraneoplastic syndrome) is secondary to an elevated level of PTHrP that lead to osteoclast rebsorption of bone, renal resorbtion of calcium, renal loss of phosphate.

121.7.3 Diagnostic Evaluation

A blood ionized calcium concentration > 1.36 mmol/L (5.44 mg/dL) and/or total serum calcium concentration > 2.75 mmol/L (11 mg/dL).

In the presence of acidemia or hypoalbuminemia, total serum calcium concentration may be normal in the presence of high ionized calcium levels.

121.7.4 Other Investigations

Calcium, phosphorus, vitamin A and vitamin D intake of the mother and baby. Birth trauma (subcutaneous fat necrosis), drugs during pregnancy and inherited disease should be considered.

- First stage
  - Electrolytes: total and ionized blood calcium, phosphorus and magnesium concentrations
  - Blood: pH, total protein and albumin, creatinine, alkaline phosphatase concentrations
  - Urine: calcium, phosphorus, creatinine concentrations
  - Other investigations: ECG, chest and limb X-rays, renal ultrasound
- Second stage
  - Parathyroid hormone, 25-OH vitamin D, 1,25-OH vitamin D, parathyroid hormone-related protein (PTHrP)
  - Molecular genetic studies

121.7.5 Management

Asymptomatic mild hypercalcemia should be managed conservatively. Hypercalcemia following maternal hypocalcemia is reduced by appropriate intake of Ca/P.

Moderate to severe hypercalcemia requires prompt intervention:

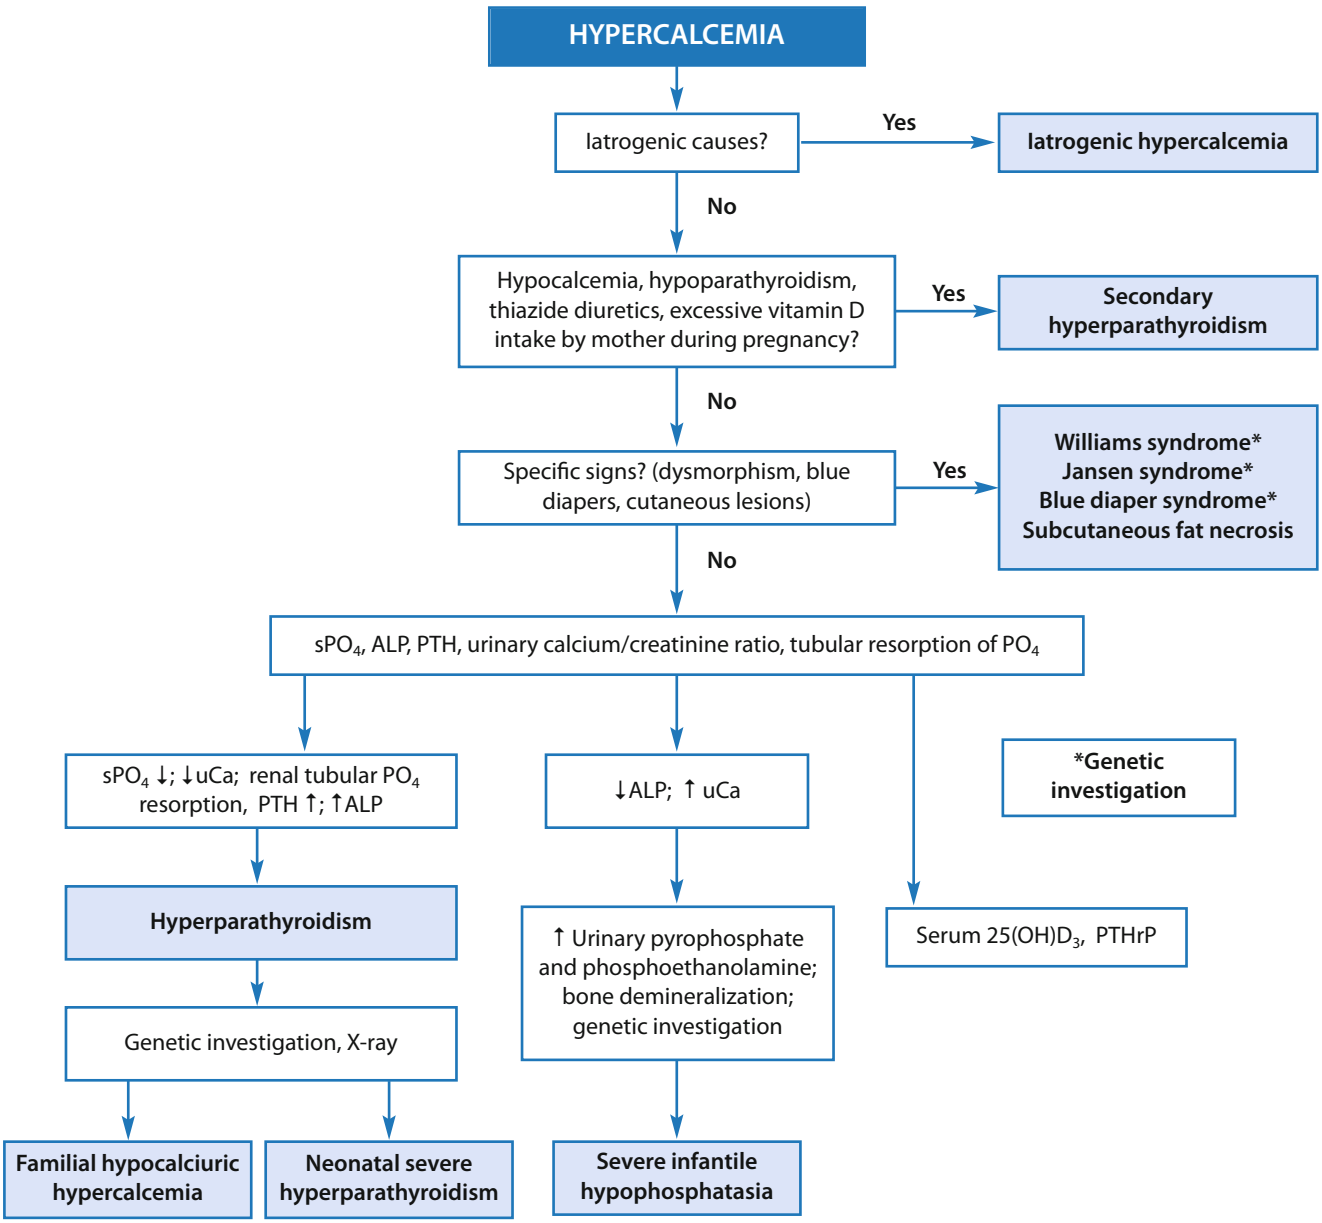

Fig. 129.6 Differential diagnosis of hypercalcemia

- Limit Ca and vitamin D intake (suspend oral/parenteral supplementation)
- Hyperhydration with normal saline (about twice maintenance requirements)
- Loop diuretics (furosemide 2 mg/kg) to increase calciuria → avoid dehydration and electrolyte imbalance

121.7.5.1 Other Specific Interventions

- Prednisone (2 mg/kg) → short course may decrease intestinal calcium absorption and bone resorption and increase renal excretion; especially useful in vitamin D excess (avoid long-term use → side effects)
- Calcitonin (4–8 IU/kg IV or IM every 12 hours) → reduces serum calcium concentration but the effect is short lasting.
- Bisphosphonates such as pamidronate (0.5–2.0 mg/kg) are used in the treatment of subcutaneous fat necrosis and may delay parathyroidectomy in neonatal severe hyperparathyroidism (NSHPT) → risk of severe hypocalcemia.
- Total parathyroidectomy and partial autotransplantation may be necessary in the severe form of NSHPT [40].

Appendix "Rare diseases" with associated hormone abnormalities. (*On behalf of A. Balsamo, P. Ghirri, A. Cicognani and A. Boldrini*)

Disease/OMIM	Gene/OMIM/ map gene locus	Clinical and diagnostic features	Possible specific treatment
Aarskog-Scott S./ 305400 and 100050	*FGD1*/300546 Xp11.21	Aarskog syndrome affects mainly males, but females may have a milder form. *Short stature*, hypertelorism, and *shawl scrotum* are the main clinical features. Facial dysmorphisms may include rounded face, widow's peak hairline, hypertelorism, blepharoptosis, downslanting eye slits, small nose with anteverted nostrils, broad philtrum, and ear anomalies. Other signs described:" simian crease" in the palm of hand, clinodactyly of the 5th finger, brachydactyly, *delayed sexual maturation*, *criptorchidism*, pectus excavatum. Mild to moderate mental problems are usually present.	–
Antley-Bixler S./207410	*FGFR2*/176943 10q26	There is evidence that the ABS can be caused by mutation in a fibroblast growth factor receptor gene (FGFR2) and is characterised by craniosynostosis (trapezoidocephaly, midface hypoplasia, proptosis, choanal stenosis or hypoplasia), humeroradial synostosis, bowing of the femora and ulnas, long bone fractures, long slender fingers with camptodactyly, cardiac and renal malformations.	–
	POR/124015 7q11.2	ABS-like phenotype with *ambiguous genitalia and disordered steroidogenesis*, is a distinct disorder caused by mutations in the cytochrome P450 oxidoreductase (POR) gene (see Chapter 123). *Steroid profile between 21-OHase and 17-OHase deficiency*.	Hydrocortisone
Beckwith-Wiedemann S./ 130650	*CDKN1C*/600856 *H19*/103280 *IGF2*/147470 11p15.5, 11p15.5, 11p15.5, 5q35	See § 121.4.7	See § 121.4.7
CHARGE association/214800	*SEMA3E*/608166 *CHD7*/608892 8q12.1 7q21.11	Patients affected presents with a various association of: Coloboma, Heart defects, choanal Atresia, Renal and *Genital anomalies*, and Ears abnormalities. Frequently reported features include: facial palsy, cleft palate, dysphagia and *growth retardation*. May be associated with *hypocalcemia*.	Support theraphy, correction of choanal atresia and heart . defects
Denis Drash S./194080	*WT1*/607102 11p13	*Genital ambiguity*, congenital nephropathy and Wilms' tumor. *Proteinuria*, *renal impairment*. Frasier syndrome and Meacham syndrome are allelic disorders with similar clinical features.	Surgery for Wilms' T.
Frasier S./136680	*WT1*/607102 11p13	*Genital ambiguity*, *streak gonads*, and XY karyotype; frequently develop gonadoblastoma; progressive glomerulopathy; Wilms' tumor is not a usual feature. Often the diagnosis is during adolescence or adulthood. No mutant protein is produced by the mutations in WT1 causing Frasier syndrome. Instead, the mutation results in an altered ratio of the 2 splice isoforms of the protein, those with and those without the extra 3 amino acids (KTS).	Prophylactic bilateral gonadectomy; dialysis and renal transplantation
Meacham S./608978	*WT1*/607102 11p13	*46,XY karyotype, with complex sex reversal or ambiguous genitalia* (retention of müllerian annexes, double vagina), and congenital diaphragmatic hernia. Other symptoms, including heart, pulmonary, and genital defects, are variable. All patients die early in life. None has renal mesangial sclerosis or Wilms' tumor. Heterozygous mutations in the WT1 gene were identified in some cases.	Surgical correction of malformations
DiGeorge S. (***DGS***)/188400	*TBX1*/602054 22q11.2	A deletion on Cr 22 alters the migration of *neural crest*-derived tissues, affecting development of the pharyngeal pouches and arches. The main clinical features of Digeorge syndrome are cardiac abnormality (mainly tetralogy of Fallot, interrupted aortic arch, ventricular septal defect, and persistent truncus arteriosus), Abnormal facies (hypertelorism), T cell deficit secondary to thymic hypoplasia, Cleft palate and Hypocalcemia due to *hypoparathyroidism*. The acronym "CATCH phenotype" has been used to describe this association. Recurrent infections are due to T-cell deficit; seizures secondary to *hypocalcemia* are common.	Cardiac surgery, antibiotics and Vitamin D and calcium supplementation

		Renal anomalies, hearing loss, skeletal anomalies, autoimmune diseases, feeding difficulties, and developmental delay have been frequently reported. DGS is overlapped with other 2 syndromes: conotruncal anomalies face (CTAF) and velocardiofacial syndrome (VCFS)	
Dubowitz S./223370	? / – AR inheritance	Developmental disorder involving IUGR, short stature, microcephaly, mild mental retardation. Behavior problems, eczema, and unusual and distinctive facies are constant features. Various minor malformations, such as pilonidal dimples, submucous clefts, hypospadias, cryptorchidism, ptosis, high-pitched voice and sparse hair, were also seen. *Persistent low serum lipid levels and an arachnoid cyst have been recently associated*.	–
EEC1 S./129900	? / – 7q11.2-q21.3	Ectrodactyly, Ectodermal dysplasia with severe keratitis and Cleft lip palate (EEC type 1); EEC1 can be associated with *GH deficiency and/or genital anomalies* secondary to developmental defects of the hypothalamus. Another form of the disorder, designated EEC3 is caused by mutation in the *TP63* gene, but without apparent endocrine disorders.	GH treatment
Fanconi Anaemia/227650	*FANCA*/607139 16q24.3	FA-A is the most common complementation group, accounting for approximately 65% of all affected individuals. All marrow elements are usually affected, resulting in anemia, leukopenia, and thrombocytopenia (may not manifest in the neonatal period). Pigmentary changes in the skin (cafè-au-lait spots) and malformations of the heart, kidney, and limbs (aplasia of the radius, thumb deformity) are associated congenital features. *Abnormal sexual development* (especially in males) may be present and represents *hypergonadotropic hypogonadism*. *The gold-standard screening test for FA is based on the characteristic hypersensitivity of FA cells to the crosslinking agents, such as mitomicin C or diepoxybutane.This is usually a reliable technique to identify FA homozygotes but could not be able to identify individual FA heterozygotes*.	Stem cell transplantation
Fanconi-Bickel S./227810	*SLC2A2*, *GLUT2*/ 138160 3q26.1-q26.3	Is a metabolic syndrome secondary to impaired utilization of glucose and galactose. Glycogen is accumulated in the liver and in the kidney. The proximal renal tubular dysfunction leads to polyuria and dehydration. The impaired utilization of glucose and galactose induces fasting hypoglycemia and post-prandial hyperglycemia and hypergalactosemia. *Growth is compromised* and rickets and osteoporosis later in life were constant	Diet (low galactose intake, vitamin D, phosphate, water and electrolytes supplementation)
IMAGe association/300290	*DAX1*/300473 Other genes	See § 121.7	–
Kallmann S.: ***KS1*** 308700/ ***KS2*** 147950/***KS3*** 244200/ ***KS4*** 610628/***KS5*** 612370/ ***KS6*** 600483	*KAL1*/308700 Xp22.3 *FGFR1*/136350 8p11.2-p11.1 *PROKR2*/607123 20p13 *PROK2*/607002 3p21.1 *CHD7*/608892 8q12.1 *FGF8*/600483 10q24	KS1: hypogonadotropic hypogonadism and anosmia (constantly); sometimes: midline cranial anomalies (choanal atresia and cleft lip or palate), optic nerve atrophy, deafness, cryptorchidism, renal agenesis. Loss-of-function mutations in KAL1 and FGFR1 account for approximately 20% of all cases of Kallmann syndrome and mutations in the PROKR2 and PROK2 genes account for an additional 10%. No postnatal increase of LH and testosterone; blunted response to GnRH and hCG tests.	Since therapeutic success with substitution therapy is probably age dependent, early diagnosis is important.
Kearns-Sayre S./530000	Various mitochondrial deletions	The main features reported for KSS are: ophthalmoplegia, pigmentary degeneration of the retina, and cardiomyopathy. Other signs and symptoms are: muscle weakness, ptosis, cns dysfunction (cerebellar ataxia and mental retardation), cataracts, cardiac involvemement (bradycardia or congestive cardiac failure), endocrine dysfunction (hypogonadism, *diabetes mellitus*, *growth hormone deficiency* and *hypoparathyroidism*).	Coenzyme Q10 administration and vitamin supplements

		Diagnosis is confirmed with muscle biopsy of the orbicularis muscle. Blood lactate and pyruvate levels are usually elevated. CSF analysis shows elevated proteins (>100 mg/dL) and lactate levels.	
Kenny-Caffey S. type 1/244460 ***Kenny-Caffey S. type 2***/127000	*TBCE*/604934 1q42-q43	KCS is a skeletal disorder characterized by growth retardation, craniofacial anomalies and small hands and feet. Bone X-rays show cortical thickening of long bones with medullary stenosis and absent diploic space in the skull. Hypocalcemia consequent to *hypoparathyroidism* may lead to convulsions. *Blood examinations reveal low levels of calcium, phosphorus and PTH*. In type 2 hypocalcemia may be transient.	Prevent severe hypocalcemia
Laron S./262500 5p13-p12	*GHR*/600946	A GH receptor mutation lead to a *GH insensitivity*. Neonatal birthweight and leght are usually normally. Postnatal growth is severely compromised. Developmental milestones are delayed and mental retardation may be present. Facial dysmorphism may be present at birth (frontal bossing, hypoplastic nasal bridge, shallows orbits, blue sclera, decreased vertical dimension face). Muscoloskeletal involvement include hip dysplasia, hypotrophic musculature and osteopenia. Obesity is usually present. Sexual development is impaired with *micropenis in childhood* but normal genital growth during adolescence. The puberty is delayed but the reproductive function is conserved. *Blood investigations may reveal hypoglycemia and hyercolesterolemia. IGF-I levels are low despite serum levels of GH normal or elevated. X-ray investigations show bone age delay*.	Treatment with synthetic IGF1
Laurence-Moon S./245800 & ***Bardet-Biedl S.***/209900	*BBS1-14*/ 209901-606151-608845-600374-603650-604896-607590-608132-607968-610148-602290-610683-609883-610142 11q13/;16q21; 3p12-q13; 15q22.3; 2q31; 20p12; 4q27; 14q32.11; 7p14; 12q; 9q33.1; 4q27; 17q23; 12q21.3	BBS is a genetically heterogeneous disorder. Polydactyly, *obesity*, retinitis pigmentosa, renal anomalies, mental retardation with progressive ataxia and spastic diplegia. These patients have *hypogonadism*. There has been longstanding uncertainty as to the relationship between the Laurence-Moon syndrome and the Bardet-Biedl syndrome.	Support therapy (physiotherapy, rehabilitation,…)
Majewski S./263520	–	Malformations included median cleft lip, pre- and postaxial polysyndactyly, short ribs and limbs (tipically disproportionate shortening of the tibia), *ambiguous genitalia* and anomalies of epiglottis, kidney, CNS and lung.	–
Mitochondrial trifunctional protein deficiency/609015	*HADHA*/600890 *HADHB*/143450 2p23, 2p23	Trifunctional protein deficiency lead to a decreased activity of 3 enzymes. Clinically it may presents with SIDS, a Reye-like syndrome, cardiomyopathy, and/or skeletal myopathy. Early onset symptoms are *hypotonia*, feeding difficulties, *lethargy* and hypoketotic *hypoglycemia*. Liver, *heart*, and respiratory system may be involved and may lead to sudden death. The late-onset form is usually milder.	Dietary treatment
Müllerian duct aplasia, unilateral renal agenesis, and cervicothoracic somite anomalies (MURCS)/601076	–	MURCS is probably the second most frequent cause of *primary amenorrhoea* after Turner syndrome. It is an association of: müllerian duct aplasia, Unilateral Renal aplasia, and Cervicothoracic Somite dysplasia. Other features reported in literature: *absent vagina*, Klippel-Feil deformity of the cervical spine, *short stature*, and conductive deafness.	–
Noonan S.: ***NS1*** 163950/ ***NS2*** 605275/***NFNS*** 601321/ ***NS3*** 609942/***NS4*** 610733/ ***NS5*** 611553 /	*PTPN11*/176876 *NF1*/162200 *KRAS*/190070 *SOS1*/182530 *RAF1*/164760 12q24.1, 17q11.2, 12p12.1, 2p22-p21, 3p25	The estimated incidence is of 1 in 1,000 to 2,500 live births. Mutations in the *PTPN11* gene accounted for about half the patients reported (NS1). Mutations in the *NF1* (site of mutations causing classic neurofibromatosis type I) have been found in neurofibromatosis-Noonan syndrome (NFNS). De novo germline mutations of the KRAS gene account for less than 5% of NS3 cases. Other forms of Noonan syndrome, such as NS2, NS4 and NS5 have been identified.	GH treatment may be usefull in some cases

		The syndrome is characterized by hypertelorism, a downward eyeslant, and low-set posteriorly rotated ears Other features include *short stature*, a short neck with webbing or redundancy of skin, cardiac anomalies, epicanthic folds, deafness, motor delay, and a bleeding diathesis. *Metacarpophalangeal pattern profile (MCPP) analysis may be useful as a diagnostic tool in screening subjects for Noonan syndrome (PubMed ID: 10797437).*	
Pallister-Hall S./146510	*GLI3*/165240 7p13	Hypothalamic hamartoblastoma (may be lethal in neonatal period), postaxial polydactyly, and imperforate anus. Sometimes had laryngeal cleft, abnormal lung lobation, renal agenesis or dysplasia, short 4th metacarpals, nail dysplasia, multiple buccal frenula, *hypoadrenalism*, *genital anomalies (microphallus or hypospadia)*, congenital heart defect, and *IUGR*.	–
Pendred S./274600	*SLC26A4*/605646 7q21	PDS is the most common syndromal form of deafness; typical features are: bilateral sensorineural hearing loss and *goitre* (usually associated with compensated hypothyroidism) with occasional overt *hypothyroidism*. Mental retardation has been reported.	*Cochlear implants*, speech support and sometimes thyroxine
Permanent and transient neonatal diabetes mellitus/ 606176/601410/610374/ 610582/610199/609069/ 304790/226980/137920/ 260370	*ABCC8*/600509 *KCNJ11*/600937 *GCK*/138079 *ZFP57*/612192 *PLAGL1*/603044 *ABCC8*/600509 *GLIS3*/610192 *PTF1A*/607194 *FOXP3*/300292 *EIF2AK3*/604032 *HNF1B*/189907 *IPF1*/600733 See § 121.5.4 for chromosome mapping	See § 121.5	See § 121.5
Prader-Willi S./176270	*NDN*/602117 *D15S227E*/600161 *D15S226E*/600161 *SNRPN*/182279 15q11-q13	Muscular hypotonia, respiratory distress and feeding difficulties may be present at birth. Later in life: *obesity* and hyperphagia, mental retardation, *short stature*, *hypogonadotropic hypogonadism*, and small hands and feet. It can be considered an autosomal dominant disorder caused in 75% of the patients by deletion of the 15q11-q13 and in 24% by maternal uniparental disomy of the proximal arm of chromosome 15.	GH treatment may improve growth management
Robinow S./AD 180700; AR 268310	? / – *ROR2*/602337 9q22	Is a genetically heterogeneous disorder characterized by short-limbed *dwarfism*, abnormal face (fetal face with short, upturned nose, prominent forehead and flat nasal bridge) and *external genitalia* (micropenis, hypospadia, reduced size clitoris and underdeveloped labia minora). Adult fertility in females seems to be normal which may explain a lack of male to male transmission in the AD form. The AR form tends to be more severe.	–
Sanjad-Sakati S. or ***Hypoparathyroidism-retardation-dysmorphism S. (HRD)***/241410	*TBCE*/604934 1q42-q43	HRD is a rare form of congenital *hypoparathyroidism* associated with growth and mental retardation and seizures. Facial dysmorphism are typical: deep-set eyes, abnormal external ears, depressed nasal bridge with beaked nose, long philtrum, thin upper lip, micrognathia. *Hypocalcemia is associated with hyperphosphatemia and very low concentrations of PTH.*	–
Septo-optic Dysplasia/182230	*HESX1*/601802 3p21.2-p21.1	Clinically heterogeneous disorder defined by any combination of optic nerve hypoplasia, pituitary gland hypoplasia, and midline abnormalities of the brain, including absence of the corpus callosum and septum pellucidum. See § 121.1.	Hormone deficient substitutive treatment
Silver-Russel S./180860	*H19*/103280 and *IGF2*/147470 11p15.5, 7p11.2	SRS is caused by the epigenetic changes of DNA hypomethylation at the telomeric imprinting control region (ICR1). SRS can also be caused by maternal uniparental disomy of chromosome 7. Severe IUGR, poor postnatal growth, craniofacial features such as a triangular shaped face and a broad forehead, body asymmetry, and a variety of minor malformations.	GH treatment; GnRH analogues

Smith-Lemli-Opitz S./270400	*DHCR7*/602858	See Chapter 123	–
Sotos S./117550	*NSD1*/606681 5q35	Also known as cerebral gigantism, is characterized by excessive growth during the first 2-3 years, *mental retardation*, delayed developmental milestones and *hypotonia*. Birth length is increased (90-97th centiles), as well as skull dimension. Facial dysmorphism included protrusive forehead, *hypertelorism*, downslanting eyes, highly arched palate, prognathism, pointed chin, large ears and pointed chin. *Scoliosis*, seizures, heart and kidney defects, hearing loss, and problems with vision. Are less common features. An increased risk of developing tumors is associates with Sotos syndrome. *X-ray investigations show an advanced bone age*.	
Urioste S./235255 (müllerian derivatives, persistence of, with lymphangiectasia and postaxial polydactyly)	? / – AR or X linked	*Genital ambiguity* (46,XY with müllerian duct remnants), IUGR, lung anomalies, redundant nuchal skin, postaxial polydactyly and lymphangiectasia are constant. Hepatic failure and hypoproteinemia are frequent.	Usually early death
VATER association/192350	*PTEN*/601728 10q23.31	The acronym means: Vertebral defects, Anal atresia, Tracheaesophageal fistula associated with Esophageal atresia, Radial and Renal abnormalities. VACTERL association includes Cardiac malformations and Limb anomalies. May be associated with *hypocalcemia*.	Surgical correction of malformation
Very long-chain acyl-coenzyme A dehydrogenase deficiency (VLCAD)/201475 ***Long-chain acyl-coenzyme A dehydrogenase deficiency (LCAD)***/201460 ***Medium-chain acyl-coenzyme A dehydrogenase deficiency (ACADM)***/201450	*ACADVL*/609575 17p13 *ACADL*/609576 2q34-q35 *ACADM*/607008 1p31	VLCAD: usually presents with nonketotic *hypoglycemia*, *lethargy* and *muscle* weakness. High prevalence of liver dysfunction and life-threatening events (heart disease) have been reported. *Diagnosis is confirmed by VLCAD protein in skeletal muscle biopsies*. LCAD: nonketotic hypoglycemia, hepatomegaly, cardiomegaly, and hypotonia are the main clinical features. *Total plasma carnitine concentration is low. As in ACADM dicarboxylic acids in the urine are relatively low*. ACADM: may presents with intolerance to prolonged fasting and recurrent episodes of hypoglycemic coma. *Laboratory findings include medium-chain dicarboxylic aciduria, impaired ketogenesis, and low plasma and tissue carnitine levels*.	
Vitamin D-dependent rickets, type I (VDDRI)/264700 ***Vitamin D-dependent rickets type II (VDDRII)***/277440	*CYP27B1*/609506 12q13.1-q13.3 *VDR*/601769 12q12-q14	VDDR I is an hereditary selective enzymatic deficiency that lead to lack of the active form of vitamin D (1,25-dihydroxyvitamin D3). Usually presents with defective bone mineralization and clinical features of rickets (hypotonia, tetany, hypocalcemic seizures, irritability, motor retardation, deformations, and growth failure). *Laboratory findings include hypocalcemia, increased phosphaturia, markedly decreased serum 1,25-dihydroxyvitamin D3, normal serum 25-hydroxyvitamin D3, aminoaciduria, hyperparathyroidism, and absence of 1-α-hydroxylase activity*. VDDR II is caused by autosomal recessive mutations of the vitamin D receptor. Most patients have total alopecia in addition to rickets. Patients display rapidly progressing rachitic bone changes, hypocalcemia and secondary hyperparathyroidism. *Serum levels of 1,25(OH)$_2$D$_3$ are very high*.	VDDR I: large doses of vitamin D2 and physiologic doses of 1-α-hydroxyvitamin D$_3$ VDDR II: limited success to high doses of oral calcium and supraphysiologic doses of 1,25(OH)$_2$D$_3$ (1058)
Hypophosphatemic rickets X-linked dominant (XLH)/307800 ***Hypophosphatemic rickets autosomal dominant (ADHR)***/193100 ***Hypophosphatemic rickets autosomal recessive (ARHR)***/241520 ***Hypophosphatemic rickets X-linked recessive***/300554 ***Hypophosphatemic rickets with hypercalciuria***/241530	*PHEX*/300550 Xp22.2-p22.1 *FGF23*/605380 12p13 *DMP1*/600980 4q21 *CLCN5*/300008 Xp11.22 *SLC34A3*/609826 9q34	XLH is is the most common disease associated with hyperphosphaturia in infancy. Clinical features include growth retardation with rachitic and osteomalacic bone disease. renal defects in phosphate reabsorption and vitamin D metabolism. Vitamin D treatment do not prevent growth failure. The bone disease is much less severe in females. ADHR: patients frequently present with bone pain, rickets, and tooth abscesses. The penetrance is incomplete and the age at onset is variable (childhood to adult). Resolution of the phosphate-wasting defect has been described in rare cases ARHP: clinical festures very similar to those observed in ADHR, but the inheritance is recessive. X-recessive form presents with rickets, osteomalacia, and early onset lower extremity deformities. It may progress in renal insufficiency during adulthood.	X-liked: oral phosphate supplementation and 1(OH)D$_3$ or 1,25(OH)$_2$D$_3$. This therapy improves but does not cure the bone disease, causes nephrocalcinosis in 60% of the patients and may cause renal failure or hyperparathyroidism. Thiazide diuretics decrease urinary calcium excretion and

		Hypophosphatemic rickets with hypercalciuria: presents with rickets, bone pain, muscle weakness, failure to thrive. *XLH: hypophosphatemia and increased alkaline phosphatase, normal or low serum levels of 1,25-dihydroxyvitamin D_3.* *ADHR: hypophosphatemia, and inappropriately normal 1,25-dihydroxyvitamin D_3 (calcitriol) levels.* *X-recessive: hypercalciuria, hypophosphatemia, nephrocalcinosis, proteinuria.* *Hypophosphatemic rickets with hypercalciuria: hypophosphatemia with hyperphosphaturia, normocalcemia with hypercalciuria, high plasma 1,25$(OH)_2D_3$ concentration, low PTH concentration, and elevated plasma alkaline phosphatase activity.*	prevent progression of nephrocalcinosis. ADHR: phosphate and high doses of vit. D. Hypercalciuric form: supplemental phosphate.
Pseudohypoparathyroidism type IA (PHP IA)/103580 ***Pseudopseudohypoparathyroidism (PPHP)***/612463 ***Pseudohypoparathyroidism type IB (PHP IB)***/603233 ***Pseudohypoparathyroidism type IC (PHP1C)***/612462 ***Pseudohypoparathyroidism type II (PHP II)***/203330	*GNAS*/139320 20q13.2 *STX*/603666 20q13.32, 20q13.2, 20q13.2	PHP is heterogeneous group of disorders characterized by resistance to the *parathyroid hormone*. Its pathogenesis has been linked to dysfunctional *G Proteins* (*Gs alpha subunit* (GNAS)) **PHP IA**: presents with a constellation of developmental and skeletal defects, collectively termed Albright hereditary osteodystrophy (AHO). These features include short stature, rounded face, shortened fourth metacarpals and other bones of the hands, obesity, dental hypoplasia, and soft-tissue calcifications. Mental retardation has been reported in some patients. PHP1A is also associated with resistance to TSH, glucagon and gonadotropins. Alterations may even affect ADH, ACTH, and GH–releasing hormone. GNAS1 mutation is in the maternally-derived allele. **PPHP**: AHO phenotype without endocrine abnormalities. GNAS1 mutation is in the paternally-inherited allele **PHP IB**: renal PTH resistance without AHO features; the Gs activity is normal but an imprinting/methylation defects at the GNAS locus results in lack of expression of the maternal allele in renal tissue. Classically, patients do not have features of AHO. TSH resistance has been reported. **PHP IC**: probably is a variant of PHPIA; the only difference is a normal GNAS activity. **PHP II**: isolated renal PTH resistance in patients without AHO phenotype. The resistance may be transient. The Gs activity is normal. The disease seems to be a heterogeneous clinical disorder secondary to a defect in PTH responsiveness distal to cAMP. *Laboratory findings: hypocalcemia, hyperphosphatemia, inappropriately high PTH.* ***PHP1A**, **PHPIB**, **PHP IC**: decreased urinary cAMP response to PTH infusion and decrease urinary PO4 response to PTH.* ***PPHP**: normal urinary cAMP response to PTH infusion and normal urinary PO4 response to PTH.* ***PPH II**: normal urinary cAMP response to PTH infusion and decreased urinary PO4 response to PTH.*	Symptomatic hypocalcemia needs intravenous calcium administration. Oral calcium and calcitriol should be initiated in every patient with a diagnosis of PHP. The goals of therapy are to maintain serum total and ionized calcium levels within the reference range to avoid hypercalciuria and to maintain PTH levels to normal.
WAGR S./194072	*WT1*/607102 *PAX6*/607108 *BDNF*/113505 11p13	Wilms' tumor, Aniridia, Genitourinary anomalies (ambiguous genitalia or gonadoblastoma of testes or avaries) and mental Retardation. Obesity is present in the subtype WAGRO (mutation of the *BDNF* gene).	–

Disorders of Thyroid Function

Paolo Cavarzere and Luciano Tatò

122.1 Origins of the Thyroid Gland

The thyroid is a bilobed gland located in the neck region, made up of two types of cells: the follicular cells which produce thyroxine and the parafollicular cells which produce calcitonin. The follicular cells are the predominant cell population in the gland and they derive from the endoderm, whereas parafollicular cells are of neuroectodermal origin [1]. These different types of cells migrate from their respective sites of origin to ultimately merge in the definitive thyroid gland. The follicular cells organize into thyroid follicles whereas the other type of cells scatters into the interfollicular space [2]. Most thyroid function disorders are related to developmental or enzymatic defects involved in the process of thyroid hormone production.

122.1.1 Thyroid Organogenesis

Thyroid embryogenesis begins between the 20th and 22nd days of fetus development with the appearance of the thyroid bud as a thickening in the pharynx floor. It is the first recognizable endocrine structure. On the 26th day of development, the thyroid diverticulum begins its migration towards its definitive pretracheal position which it reaches between the 48th and 50th day of embryonic life. By the 28th day of development, the thyroid is connected to the pharynx by a small pedicle known as the thyroglossal duct [3, 4]. This duct disconnects from the pharynx around the 33th day of development and by the 40th day it disappears completely. In some cases, this structure persists and gives origin to thyroglossal duct cysts during infancy [5]. The gland already has a bilobed shape by the 28–30th day of fetal development. Around the 44th day of development, the two cell populations join together and the parafollicular cells are incorporated into the gland. The formation of thyroid follicles and gene expression involved in hormonogenesis begin when migration ends. Hormone synthesis begins during the l0–12th week of development with the incorporation of iodine into the thyroid hormones [3, 4, 6].

122.1.2 Genetic Regulation

Several factors are involved in the process of thyroid organogenesis, in particular the *Nkx2.1*, *Pax-8*, and *Ttf-2* transcription factors which are mostly thyroid-specific. However, none of them is exclusively expressed in the thyroid gland. In addition to transcription factors, the receptor for thyroid stimulating hormone (TSH) plays an important role in gland morphogenesis. Whereas *Nkx2.1*, *Pax-8* and *Ttf-2* are expressed by thyroid follicular cells from the very start of their differentiation, the TSH receptor (TSHR) takes part in the proliferation and function of the thyroid follicular cells, but it is not required for early organogenesis or for the migration process [2, 7–9]. Mutations in all these genes are related to changes in thyroid morphogenesis; they have been detected in patients with thyroid dysgenesis [10, 11]. In addition, other genes have been found to be expressed during thyroid development in mice models. In particular, *Hhex* seems to be involved at early stages of morphogenesis, whereas *Hoxa3* and *Eya1* seem to be involved in the later stages of thyroid organogenesis [12].

122.2 Function of the Thyroid Gland

122.2.1 Fetal Thyroid Hormone Production

The main function of the thyroid gland is to produce thyroid hormones. In the early period of gestation, the fetus is entirely dependent on maternal transfer of thyroid hormones;

P. Cavarzere (✉)
Department of Life and Reproduction Sciences, University of Verona
Verona, Italy

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

consequently, total serum T4 and T3 levels in early gestation are low, depending entirely on the function of the placenta and maternal thyroid status.

During the first weeks of gestation, the human fetal thyroid gland begins to synthesize only minute amounts of T4 and T3. Around the 20th week of gestation, the fetal hypothalamic-pituitary-thyroid axis begins to function and fetal production of TSH and T4 progressively rises to peak in the month before term [13]. Total T3 levels in fetal blood remain low until the 26–30th week of gestation due to the immature activity of the deiodinase type I enzyme which converts T4 into T3. However, during gestation, both deiodinase types III and II are found to be active. The former, of fetal and placental, origin, converts T4 into inactive reverse T3 and T3 into di-iodothyronine. The latter mediates the production of T3 from T4 in selected fetal tissues, especially in the brain, where it is actively transferred by MCT8. The maturation of type I occurs gradually in the fetal liver during the last weeks of gestation, although the levels of T3 rise only moderately around term because placental deiodinase III remains at high levels throughout the gestation period [14–16]. Moreover, plasma thyroid hormone levels are correlated to gestational age; consequently, preterm infants present lower T3, T4 and FT4 values than term infants [17–20].

Finally, it is well known that the limited transplacental passage of thyroid hormones during gestation is sufficient to preserve fetal brain development and its function, in case there is an abnormality in the thyroid ontogenesis [13, 21, 22]. On the contrary, when both maternal and fetal hypothyroidism present, there is significant impairment in neuro-intellectual development despite adequate therapy soon after birth [21]. Maternal hypothyroidism can lead to mild but significant cognitive impairment of the offspring [5, 23, 24].

Table 122.1 Etiologies of congenital hypothyroidism

Permanent
- Thyroid dysgenesis (75-85%)
  - Athyrosis (20%)
  - Ectopy (75%)
  - Hypoplasia, hemiagenesia (~5%)
- Dyshormonogenesis (10–20%)
  - Iodine transport defect (Na/I symporter)
  - Thyroglobulin defect
  - Pendrin defect (Pendred syndrome)
  - TPO defect
  - DUOX2 and DUOXA2 defect
- Resistance to TSH (rare)
  - TSH receptor mutations
  - Pseudohypoparathyroidism Ia (Gα protein alteration)
- Central hypothyroidism (rare)
  - TRH deficiency, resistance to TRH
  - TSH deficiency
  - Mutations in transcription factors implied in pituitary development (*PIT1*, *PROP1*, *LHX3*, *LHX4*, *HESX1*)
  - Hypothalamic-pituitary defect
- Peripheric hypothyroidism (rare)
  - Resistance to thyroid hormone
  - Alteration of thyroid hormone transporter (MCT8 mutation)

Transient
- Iodine deficiency
- Iodine overload
- Maternal anti-thyroid treatment
- Trans-placental passage of blocking TSH antibodies
- DUOX2 heterozygous mutations

122.2.2 Perinatal Thyroid Hormone Modification

At birth, the rapid fall in ambient temperature causes a peak in the newborn TSH level within 30 minutes after delivery, with a consequential increase in FT4 levels. In term infants, FT4 levels fall within 4–6 weeks of life, whereas in preterm newborns, the increase is blunted and related to gestational age. In infants born after 30–32 weeks of gestation, the FT4 peaks slowly and is comparable to that of term babies; on the contrary, preterm infants born before 30 weeks or with low (LBW) or very low birth weight (VLBW) present a decline in FT4 with a peak at 1–2 weeks of life, without an increase in TSH [19, 25].

122.3 Congenital Hypothyroidism

122.3.1 Epidemiology

Congenital hypothyroidism (CH) has an incidence of 1:3500 live births in iodine-sufficient regions [26]. CH is more frequent in females than in males (ratio 2:1); infants with Down syndrome have a higher risk of developing CH [27].

122.3.2 Etiology

Whereas the hypothalamic-pituitary-thyroid axis maintains a stable concentration of FT4 in normal subjects, in children with hypothyroidism there is an under-function of the gland with an increase in TSH concentrations in an attempt to compensate for the hormone deficiency (Table 122.1). Exceptions to this mechanism are central hypothyroidism and other rarer conditions.

122.3.2.1 Thyroid Dysgenesis

Thyroid dysgenesis is the most frequent cause of CH [28]. It includes athyrosis, due to the complete absence of thyroid tissue; ectopic gland, due to an abnormal migration of the embryonic thyroid; and thyroid hypoplasia, due to defective

growth of the gland following complete migration. The most frequent type of thyroid dysgenesis is ectopy; the majority of these patients presents a thyroid in the dorsum of the tongue or, less frequently, located in a sublingual position [29].

Thyroid dysgenesis can be correlated to a mutation in the *Nkx2.1*, *Ttf-2* and *Pax-8* genes, as mentioned above [10, 11]. In particular, *Nkx2.1* mutations are associated with predominant neurological phenotype, pulmonary lesions and thyroid dysfunction [30, 31]; homozygous mutations of *Ttf-2* have been related to athyrosis, cleft palate and choanal atresia, whereas heterozygous conditions lead to euthyroidism [32]; finally, mutations in the *Pax-8* gene have been detected in isolated thyroid phenotypes in some cases associated with renal anomalies [33–35].

122.3.2.2 Thyroid Dyshormonogenesis

When thyroid gland is in situ, the disorder may be related to inborn errors of metabolism during one of the several steps required for normal thyroid hormone synthesis (thyroid dyshormonogenesis). Different mutations were reported in the genes encoding the thyroglobulin protein, the sodium iodide symporter and the pendrin channel, as well as in the thyroid peroxidase (TPO), and more recently in the dual oxidases 2 (DUOX2) enzyme and its maturation factor DUOXA2 [36–46].

Whereas thyroid dyshormonogenesis invariably displays a recessive mode of inheritance, thyroid dysgenesis is usually sporadic (only 2% of familial cases) [47].

122.3.2.3 Resistance to TSH

In this rare condition, the response to bioactive TSH may be impaired at the thyroid follicular cell level and the cause could be found in mutations that inactivate the TSHR [9]. Total insensitivity to TSH leads to a small orthotopic gland with a phenotype ranging from CH to euthyroid hyperthyrotropinaemia [48]. Rarely, patients with pseudohypoparathyroidism Ia also present resistance to glycoprotein TSH, LH and FSH hormones [49]. Unresponsiveness to TSH has also been described as an autosomal dominant condition associated with unknown molecular defects [50].

122.3.2.4 Central Congenital Hypothyroidism

Central CH occurs in 1 out of every 50,000 newborns. It is often related to abnormalities during development of the hypothalamus or the pituitary glands and associated with multiple pituitary hormonal deficiencies. Rarer causes of central CH may be ascribed to TRH deficiency, resistance to TRH, isolated TSH deficiency related to mutations in the TSH-β chain and mutations in transcription factors involved in pituitary development and hormone expression [9, 51–53].

Central CH was also described in babies born from mothers with gestational hyperthyroidism. One cause could be insufficient treatment of the mother during pregnancy and, consequently, the hyperthyroid environment that impairs maturation of the fetal hypothalamic-pituitary-thyroid axis [54].

122.3.2.5 Peripheric Hypothyroidism

This rare form of CH can be due to tissue resistance to the action of thyroid hormones, caused by inactivating mutations of the β-receptor of triiodothyronine or to abnormalities in thyroid hormone transport across the cell membrane, as in MCT8 mutations [55]. In the first condition, free thyroid hormones increase and TSH is inappropriately normal or higher; in the second case, FT3 is higher, whereas FT4 is low and TSH is normal or increased. Clinically, children affected by the first condition show a variable phenotype ranging from isolated biochemical abnormalities to variable features of hypothyroidism; those affected by the second condition present severe neurological symptoms with major hypotonia and delay of acquisitions [56].

122.3.2.6 Transient Congenital Hypothyroidism

CH is sometimes transient and often has an environmental or iatrogenic origin. Transient CH may be related to a deficiency of iodide or to exposure to an excess of iodine, usually due to the application of iodinated disinfectants on the skin [57]. Other causes are treatment with anti-thyroid drugs and, more seldom, the trans-placental crossing of antibodies blocking the action of TSH [58]. Recently, heterozygous mutations in the DUOX2 gene have been found in patients with transient CH [44].

122.3.3 Clinical Signs

The trans-placental passage of maternal thyroid hormone protects newborns with CH for about 2 weeks [59]; consequently, at birth, only 1–4% of newborns with CH are detected by clinical examination [60]. Infants with CH are usually overdue, have a high birth weight for their gestational age [61]. Other signs of CH are represented in Table 122.2.

Children with central CH often have clinical manifestations of other associated hormonal deficiencies such as hypoglycemia, micropenis and cryptorchidism [58]. Malformations of the median line have also been associated with central CH. Cardiac malformations represent the most frequent birth defect associated with thyroid dysgenesis, although the influence of heart development on thyroid organogenesis has not been demonstrated yet [62].

Table 122.2 Symptoms of congenital hypothyroidism

- Prolonged jaundice
- Skin mottling
- Large anterior and/or posterior fontanel
- Abdominal distension
- Umbilical hernia
- Hypotonia
- Constipation
- Poor feeding
- Failure to thrive
- Hoarse cry
- Hearing impairment
- Neurodevelopmental delay
- Irreversible mental retardation (in absence of precocious diagnosis)
- Goiter (rare at birth)

122.3.4 Neonatal Screening

The diagnosis of CH is made through mass neonatal screening within the 5th day of life. The purpose is to prevent mental retardation due to CH. As a screening method, it can be used as a primary T4 strategy or, more frequently, as a primary TSH strategy or a combined primary approach, which is the ideal screening approach [63].

Screening should be done between 48 hours and 4 days of life, in any case before discharge from the nursery. It must be performed before a transfusion or the diagnosis could possibly be missed. In critically ill or preterm babies, blood for screening should be obtained within 7 days of life. Infants in the Neonate Intensive Care Unit usually have more urgent medical problems, but in any case the sample must be collected before discharge or a transfer to another hospital. Nowadays, a negligible number of infants with CH are missed by newborn screening programs [64]. This deficiency in the screening program is often related to errors in specimen handling, testing, data analysis or result reporting. In other cases, the TSH increase can occur later, usually in preterm infants, because of the immature function of the hypothalamic-pituitary axis [64–66].

122.3.5 Procedures to Confirm Diagnosis

All newborns with abnormal results at screening for CH must undergo FT4, FT3 and TSH serum measurements to confirm the diagnosis; newborns with hypothyroidism typically present low FT4 and high TSH concentrations [64–66]. In addition, it is imperative to make TSH and FT4 measurements as quickly as possible in all cases of clinical suspicion of hypothyroidism, regardless of screening results.

Etiological diagnosis of CH is based on scintigraphy, ultrasound analysis and measurements of thyroglobulin serum. High thyroglobulin levels may suggest dyshormonogenesis, absent levels an athyreosis [60, 64, 67]. In addition, serum and urinary iodide, as well as tests for thyroid autoimmunity (anti-peroxidase, anti-TSH receptor, and anti-thyroglobulin antibodies), are helpful in making a complete etiologic diagnosis [64, 68, 69].

122.3.5.1 Thyroid Scintigraphy

Iodine-123 scintigraphy of the thyroid gland is helpful in obtaining information about the function of the thyroid gland. More frequently scintigraphy is performed with Pertechnetate, which is easily available [70]. This allows diagnosis of an ectopic gland and enables the identification of the exact area of the contrast.

The absence of iodine or pertechnetate allows the diagnosis of athyreosis or, in the presence of high doses of thyroglobulin, the diagnosis of mutations that inactivate the TSHR, NIS mutation or maternal antibodies against TSH [71]. When scintigraphy shows a normally located thyroid gland a positive perchlorate discharge test will enable the diagnosis of iodine organification defects [72].

122.3.5.2 Thyroid Ultrasonography

Thyroid ultrasonography is helpful in defining the structure of a normally positioned gland. It is less useful in making a diagnosis because it does not allow the diagnosis of an ectopic gland [73]. On the other hand, fetal ultrasound can make a prenatal diagnosis of dysgenesis or fetal goiter [74]. At present, the best approach for a postnatal diagnosis of CH is to do both an ultrasound, to determine thyroid-gland size and morphology, and scintigraphy, to detect functional thyroid tissue [75].

122.3.5.3 Further Diagnostic Tools

At diagnosis of CH, the absence of one knee's epiphyses at radiography is a marker of fetal origin of the disease and therefore an indication that the infant is at a higher risk of developmental retardation. Serum and urinary iodide measurements aid in determining iodide deficiency or excess. Tests for thyroid autoimmunity allow the physician to associate CH with trans-placental passage of maternal antibodies [76–79].

122.3.6 Therapy

Treatment with L-thyroxine must be initiated as soon as possible [80]. The goal of the therapy is to normalize T4 levels within 2 weeks and TSH values within 1 month. This way, it

is possible to assure the normal growth and development of babies with neuro-cognitive outcome similar to the child's genetic potential. An initial dosage of 10–15 μg/kg/die is recommended [64]. In general, patients with athyreosis require higher doses compared to patients with ectopy, and these require higher doses compared to children with CH due to dysormonogenesis [81].

The drug must be taken in the morning at least 30 minutes before breakfast. L-thyroxine tablets should be crushed and mixed with a few millilitres of liquid to prepare the daily dose. Several substances such as soy protein, iron and calcium are reported to interfere with thyroxine. There have been no proven advantages so far to the association of L-thyroxine with triiodothyronine treatment [82].

If permanent hypothyroidism has not been confirmed, it is advisable to stop the therapy after 3 years and to wait 4 weeks and reassess thyroid function [83]. If it is normal, transient hypothyroidism is presumed and treatment can be permanently interrupted. However, the interruption of treatment must be limited to infants with a normally developed or enlarged thyroid gland that shows, during replacement therapy, TSH levels in the normal range.

122.3.7 Follow-up

Newborns with CH must be assessed after 2 and 4 weeks from the start of therapy, then every 1–2 months for the first 6 months of life and later on every 3–4 months until the first year of life. After that age, a follow-up check-up must be done every 6 months until 3 years of life, then every year [60, 64]. During follow-up, the dosage of the drug must be changed in relation to TSH and FT4 levels, especially during the first 3 years of life when growth is most rapid. Serum FT4 and TSH should be monitored every 4 weeks after any change in L-thyroxine dosage. FT3 measurements are not helpful in monitoring the treatment because this test may be normal despite low FT4 and high TSH levels [59].

In the first months of life it is essential to be aware of possible prolonged hyperthyroidism that can be associated with premature craniosynostosis. Four or more episodes of insufficiently suppressed TSH after the age of 6 months is the most important variable associated with poor school performance [84]. At follow-up visits, regular height and weight must be observed. Delayed bone age usually becomes compatible with the actual age within the third year of life [60].

Neurodevelopmental delay is not common in patients with CH in therapy from the first month of life [85]. Nevertheless, it is possible to notice slight difficulties in motor skills and impairment of visuospatial processes and selective memory, presumable signs of poorly compensated fetal hypothyroidism [86, 87]. However, children with properly treated CH do not show differences in school performance compared with healthy children [88, 89].

122.4 Thyroid Dysfunctions in Preterm Infants

122.4.1 Thyroid Function in Preterm Infants

Alterations of thyroid function in preterm infants are often transient and, in most cases, do not require any treatment. The function of the hypothalamic-pituitary-thyroid axis in preterm newborns is attenuated at birth for an unknown postnatal duration. In preterm babies there is reduced hypothalamic TRH production, an immature response of the thyroid gland to TSH, an inefficient capacity of the thyroid follicular cells to organify iodine and a low capacity to convert T4 into active T3. The responses of TSH and T4 to TRH are normal, so the site of immaturity seems to be the hypothalamus [90]. Moreover, neonatal health conditions related to preterm delivery, such as respiratory distress, can influence serum thyroid hormone levels [91].

122.4.2 Hypothyroxinemia of Prematurity

Approximately 12% of preterm infants present low T4 and FT4 with normal TSH values. This condition is known as transient hypothyroxinemia of prematurity [92]. The cause is not clear; we can hypothesize an immaturity of the hypothalamic axis, the withdrawal of maternal-placental T4 transfer, developmental constraints on the synthesis, immature peripheral metabolism of iodothyronines, iodide deficiency and non-thyroidal illness. Associations have been shown between transient hypothyroxinemia and prolonged oxygen supplementation, mechanical ventilation, intraventricular hemorragia and cerebral white matter damage [93–95]. Bacteremia, persistent ductus arteriosus, necrotizing enterocolitis and the use of drugs such as aminophylline, caffeine, glucocorticoids and dopamine have also been found to be significantly associated with transient hypothyroxinemia [96]. This condition is present in the majority of infants born under 30 weeks of gestation and can be associated with later neurodevelopmental deficits [97]. However, it remains unclear whether morbidity and developmental disabilities are caused by, or simply associated with, hypothyroxinemia of prematurity [25, 98]. Treatment with L-thyroxine has not been shown to be beneficial; on the contrary, it may be detrimental. Presently, in the absence of high TSH, the evidence does not support a cognitive benefit of L-thyroxine treatment for this condition in premature infants [25, 99, 100].

122.4.3 Hypothyroidism with Delayed TSH Elevation

Some LBW or VLBW newborns or critical ill neonates frequently present CH characterized by low FT4 and delayed

TSH elevation. The incidence of this condition is 1:250 for VLBW babies and 1:1589 for LBW newborns. Serum TSH in these babies increases during the first few weeks of life until concentration levels are typical of primary hypothyroidism. It is not known if this type of CH is transient or permanent, or whether it depends on an abnormality of pituitary-thyroid feedback regulation. If TSH is still high at 6 weeks of age, the infant must begin therapy [64].

122.4.4 Transient Congenital Hypothyroidism

Approximately 5% of preterm infants admitted to neonatal intensive care present a transient form of CH with low FT4 and increased TSH [101]. Causes vary from maternal exposure to antithyroid drugs to maternal TRB antibody status. There is evidence suggesting a relationship between this clinical finding and the exposure to iodine-containing antiseptics used in neonatal units. The therapy should begin immediately just as it is for permanent CH; an attempt should be made later in life to suspend treatment. On the contrary, the hormone levels in babies born from mothers in treatment with antithyroid drugs usually return to the normal range within 1–3 weeks without therapy [64].

122.5 Asymptomatic Neonatal Hyperthyrotropinemia

Asymptomatic hyperthyrotropinemia is defined as a high serum TSH level associated with normal T4, FT4 and T3 values [64]. This subclinical condition, transient or permanent, is relatively frequent with a prevalence of 1:8000 newborns in Europe, and it is more frequent in infants with Down syndrome [102].

122.5.1 Diagnosis

Affected newborns are detected by neonatal screening. About 60–70% of infants with increased TSH levels at neonatal screening present normal or nearly normal serum TSH values with normal FT4 levels and require follow-up during childhood [102, 103].

122.5.2 Etiologies

The cause is not known, though it is possible that the same factors involved in the origins of CH, when they are less severe, are responsible for subclinical hypothyroidism. Some studies have identified genetic abnormalities, thyroid gland malformations and autoantibodies in children with hyperthyrotropinemia [103]. These defects often present different degrees of severity and therefore could increase TSH concentrations moderately and intermittently [103]. This clinical finding appears more evident at birth because the thyroid gland is less mature and there is a greater thyroid hormone requirement during neonatal life. Other causes of asymptomatic hyperthyrotropinemia are defects in the biological activity of TSH or of its receptor, subtle developmental defects such as hemithyroid, and a disturbance in the TSH feedback control system [66].

122.5.3 Evolution

Repeated thyroid function evaluation is essential because TSH values in the same individual can spontaneously fluctuate around the upper normal range [104]. With age this condition can become clinically evident as the disease progresses, as in overt hypothyroidism [105]. In other cases, high TSH values in very young children may subsequently normalize; perhaps the cause is due to reduced thyroid hormone requirements in more advanced childhood [102, 103]. In any case hyperthyrotropinemia requires periodic follow-up visits to assess thyroid gland function.

122.5.4 Treatment

Whether subclinical hypothyroidism requires treatment or not is still a matter of debate also because only few studies have investigated the effect of L-thyroxine therapy in children with subclinical hypothyroidism. Nevertheless, there is a general consensus to treat all subjects with TSH levels over 10 mU/L and normal FT4 [103]. Over-treating must be avoided and the therapy discontinued after 3 years of age in order to reassess thyroid function [64, 106].

122.6 Neonatal Hyperthyroidism

Neonatal hyperthyroidism is a relatively rare condition (incidence varying between 1:4,000 and 1:40,000) that could be due to maternal thyroid autoimmune disorders, to continually activated TSH receptor or to McCune-Albright syndrome.

122.6.1 Graves' Disease

The most frequent cause of neonatal hyperthyroidism is the mother suffering from Graves' disease, which occurs in

0.1–0.4% of pregnant women. However, only 1% of neonates born to these affected women presents hyperthyroidism and in all cases this form of disease is transient [107].

122.6.1.1 Etiology

The transplacental passage of maternal immunoglobulin stimulates the fetal thyroid by activating the TSH receptor. Consequently, thyroid hormone secretion in the uterus is already increased by thyrotoxicosis that continues after birth until the maternal antibodies have disappeared from the infant's circulation [108]. This fetal condition begins in the second trimester of gestation when fetal TSH receptor begins to respond to TSH stimulation; it is related to the severity of the mother's disease and goes away within 4 months of postnatal life [108].

122.6.1.2 Clinical Signs

Thyrotoxic fetus may present growth restriction, fetal tachycardia, increased fetal motility, goiter and hydrops [90, 109, 110]. These are frequently premature births [111]. In other cases the symptoms are only noticed at birth or several days afterward when the effect of maternal drugs have disappeared, and the maternal immunoglobulins, which have a longer half-life, have increased thyroid hormone production allowing the clinical signs of the disease to become evident [112]. The neonatal symptoms vary from tachycardia and hyperexcitability to increased appetite with poor weight gain, vomiting or diarrhea, fever with sweating or erythema, tachypnea in some cases and goiter in 50% of newborns [90, 107, 109] (Table 122.3). Often the goiter is the first sign of thyroid dysfunction and already appears during fetal life [113]. Mortality has been reported to be between 12–20% [114]. Heart failure is one of the major risks; consequently, early diagnosis and treatment are necessary for a good prognosis [109]. In thyrotoxic newborns, jaundice, cholestasis and thrombocytopenia are also indicated as signs of the disease. Hepatomegaly and splenomegaly can be present and liver function abnormalities can occur even in the absence of heart failure [90, 109]. Stare and eyelid retraction are present, whereas exophthalmia is related to the autoimmune process [115]. The fontanels are small and some infants show craniosynostosis; bone maturation is often advanced as a result of fetal hyperthyroidism [90, 109].

Table 122.3 Signs and symptoms of congenital hyperthyroidism

- *Fetal signs*
  - Growth restriction
  - Fetal tachycardia
  - Goiter
  - Idrops
  - Premature births (*frequent*)
  - Increased fetal motility
- *Neonatal signs*
  - Tachycardia
  - Hyperexcitability
  - Increased appetite with poor weight gain
  - Vomiting
  - Diarrhea
  - Fever with sweating or erythema
  - Tachypnea
  - Goiter (50% of newborns)
- *Thyrotoxic signs*
  - Heart failure
  - Jaundice
  - Cholestasis
  - Thrombocytopenia
  - Hepatomegaly
  - Splenomegaly
  - Liver function abnormalities (also in absence of heart failure)
  - Stare and eyelid retraction
  - Exophthalmia
  - Small fontanels
  - Craniosynostosis
  - Advanced bone maturation

122.6.1.3 Diagnosis of Fetal Hyperthyroidism

Diagnosis of prenatal hyperthyroidism is based on high maternal TSH receptor binding antibody titers, accelerated fetal bone maturation and a fetal heart rate over 160 bpm, in the last part of gestation [108]. If a fetal goiter is present, it is necessary to determine whether the cause is hyperthyroidism related to maternal Graves' disease or hypothyroidism related to maternal anti-thyroid drugs. To make a correct diagnosis, it is helpful to use a Doppler of the fetal thyroid which indicates hypothyroidism when it shows a flash confined to the periphery of the gland [116]. Finally, a fetal blood sample is the gold standard to differentiate fetal hypothyroidism from fetal hyperthyroidism, but it is not easy to obtain and can be risky for abortion and fetal infection [109, 117]. Assessment of fetal thyroid hormones during pregnancy must be done only in cases when the status of the fetus is in doubt, the mother has positive TSH receptor binding antibody titers and takes anti-thyroid drugs and when intra-amniotic L-thyroxine therapy may be necessary to resolve the fetal clinical condition [110]. Fetal FT4 levels are related to maternal FT4 values: a fetal euthyroidism can be achieved by maintaining maternal FT4 in the upper normal-to-mild thyrotoxic range during treatment with anti thyroid drugs [109, 115].

122.6.1.4 Diagnosis of Neonatal Hyperthyroidism

The diagnosis of neonatal hyperthyroidism is confirmed by high FT4 and FT3 levels with low values of TSH. Since a delayed appearance of hyperthyroidism is possible, these tests should be repeated a few days after the first serum test [90, 109]. The determination of antibodies is a useful marker of the etiology of the disease [115].

122.6.1.5 Treatment

It is essential to treat newborns for hyperthyroidism soon after birth in order to avoid short-term and long-term morbidity [107]. Propylthiouracil, which promptly restores a normal heart rate, is the drug of choice for this condition. It should be administered orally at a dosage of 5–10 mg/kg/day divided into three doses [90, 109]. Its advantages are to block the secretion of thyroid hormones, blocking iodide organification and the coupling of iodothyronine residues, and to decrease the peripheric conversion of T4 to T3 [118].

In place of propylthiouracil, methimazole may also be used to block thyroid hormone secretion.

It is less frequently used to treat neonatal hyperthyroidism; when it is used, the dosage is 0.25–1 mg/kg/day divided into two doses [119]. Propranolol, which inhibits deiodination of T4 to T3 and controls symptoms caused by adrenergic stimulation, may be given at a dosage of 1–2 mg/kg/day divided into three doses when tachycardia is present [119]. In the most severe cases of the disease, a saturated solution of potassium iodide (1 drop/day) or Lugol's solution (1–3 drops/day) can be added in order to decrease thyroglobulin proteolysis and thyroid hormone production. Sodium iopanoate (iopanic acid, 500 mg orally once every third day) and glucocorticoids (prednisone 2 mg/kg/day) are rarely used to decrease thyroid hormone production and to inhibit T4 conversion to T3 [120].

Other helpful measures such as high liquid and calorie intake and sedatives are also useful in the treatment of these newborns [90, 109]. The therapy should be continued until maternal antibodies are no longer present. During treatment, the patients must be seen weekly until they are stable and then every 1–2 weeks, reducing the dosage as soon as possible. In some cases, it might be helpful to treat the newborns with fixed doses of anti-thyroid drugs and to add L-thyroxine when plasma FT4 levels reach the hypothyroid range. This combined treatment is usually required for 1 month [107].

Treating the mother with propylthiouracil or methimazole, at a dosage under 150 mg/day and 30 mg/day respectively, does not mean breast-feeding should be discontinued since the quantity of drugs that the newborn would ingest is minimal; however, it is necessary to do periodic assessments of neonatal thyroid function [121]. Fetal hyperthyroidism must be treated with maternal anti-thyroid drugs and in this context propylthiouracil is preferred because of what has been reported on carbimazole and methimazole embryopathy [122].

122.7 Mutations of TSH Receptors

Activating mutations of the TSH receptor cause constitutive activation of the receptor, which is not related to an autoimmune mechanism and is dominantly transmitted [123]. The phenotype appears with neonatal hyperthyroidism. This permanent condition is often associated with a severe course with moderate or diffuse goiter due to the mitogenic effects of cyclic AMP on thyroid follicular cells, possible developmental delay, absence of extrathyroidal signs of Graves' disease and recurrence after treatment. Sporadic congenital non-autoimmune hyperthyroidism may be also caused by de novo mutation of the TSH receptor gene. Definitive treatment with a thyroidectomy and radioiodine therapy is possible at older ages [114].

122.7.1 McCune-Albright Syndrome

McCune-Albright syndrome results from an activating mutation in the gene encoding the α-subunit of the stimulatory G proteins; in some cases its symptoms are similar to neonatal hyperthyroidism. Clinically besides symptoms of hyperthyroidism, cafè-au-lait spots are present with irregular borders, polyostotic fibrous dysplasia and other endocrinological alterations. The medical treatment is the same as Graves' disease but it must be prolonged during postnatal life. Once euthyroidism has been restored, an ablative approach is possible [124].

122.7.2 Hashimoto's Thyroiditis

Maternal Hashimoto's thyroiditis may cause hyperthyroidism in the newborn but usually there are no consequences in the fetus, even though antibodies against TPO or thyroglobulin can cross the placenta and be found in the fetus. However, cases of fetal and neonatal hyperthyroidism have been found in the offspring of affected mothers [125].

122.7.3 Resistance to Thyroid Hormones

Resistance to thyroid hormones is a rare condition characterized by decreased responsiveness to thyroid hormones. High FT3 and FT4 are present with inappropriately normal or elevated TSH concentrations [126]. Clinically, the affected patients show a variable phenotype ranging from isolated biochemical abnormalities to variable features of hypo- or hyperthyroidism in the rare case of pituitary resistance [127]. Asymptomatic patients do not require any treatment whereas therapy must be initiated to resolve the symptoms of hypo- or hyperthyroidism.

Disorders of Sexual Development

Antonio Balsamo, Alessandro Cicognani, Paolo Ghirri, Rosa T. Scaramuzzo, Franco D'Alberton, Silvano Bertelloni and Antonio Boldrini

123.1 Sex Determination and Differentiation

123.1.1 Sex Development

It is rare to be unable at birth to differentiate a male from a female newborn because of the presence of ambiguous genitalia, but abnormalities of the external genitalia that need further investigation may occur in about 1 in 4000 births [1]. Antenatal ultrasound scanning has improved our ability to predict these conditions.

Sex development is a genetically and hormonally controlled process, which in humans starts immediately at fertilization by the establishment of the chromosomal sex (XX or XY). This is the first step of a process of sex determination which continues with the formation of the gonad (testis or ovary). Following this, sex determination depends on the sex-chromosome complement of the embryo and is established by multiple genetic and molecular events that direct the development of germ cells, their migration to the urogenital ridge, and the formation of either a testis in the presence of the Y chromosome (46,XY), or an ovary in the absence of the Y chromosome and the presence of a second X chromosome (46,XX).

The second step in sex development concerns sex differentiation, which refers to the formation of the phenotypic sex (appearance of the external genitalia and internal annexes) and the subsequent acquisition at puberty of secondary sex characteristics and reproductive potential. This process depends on the sex-specific response of tissues to hormones produced by the gonads after they have differentiated in a male or female pattern.

Sex outcome at birth is thus the result of a coordinated and sequential series of developmental events controlled by a system of temporally expressed genes, transcription factors and hormones. Any condition affecting this complex pathway may result in a disorder of sex differentiation and a child with an indeterminate genetic, gonadal or phenotypic sex.

123.1.2 Gonads

In humans, bipotential gonads begin their development at around 4–5 weeks' gestation, separating from the adrenal primordium. They arise as paired condensations of the coelomic epithelium at the medioventral region of the mesonephros on either side of the dorsal aorta. The gonad contains both somatic and germ cells. The primordial germ cells, which migrated into the gonads from the yolk sac, generate the gametes (spermatocytes or ova). Until about 40 days' gestation the primitive gonads remain bipotential. The presence, or absence, of testicular determining genes depends on chromosomal sex and determines whether the gonads differentiate into testes or ovaries.

Four major cell types are present in the indifferent gonads: supporting, steroidogenetic, germ lineage and connective cells that will differentiate:

- In the testes as: Sertoli cells, Leydig cells, spermatogonia and peritubular myoid cells, respectively. The Sertoli cell is the first cell type that differentiates to produce the anti-müllerian hormone (AMH) and its role is essential for the nutrition of germ cells; the Leydig cells are steroidogenic cells that produce testosterone. Both hormones serve as an essential step for the normal progression versus male fetal development.
- In the ovary as: granulose/follicular cells, steroid producing cells (theca cells produce androgens, that are converted to estrogens in the granulose cells, that also produce progesterone), oocytes and stromal cells, respectively. Ovarian differentiation starts 1 week later than testis differentiation and its steroidogenic function seems to be of little importance prior to puberty.

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

123.1.3 Internal Ducts

At 6 week's gestation both the wolffian ducts (from which arises the seminal vesicles, the vas deferens and the epididymis) and the müllerian ducts (from which arise the fallopian tubes, the upper vagina and the uterus) are present. In normal male differentiation, the regression of the müllerian structures and the inhibition of FSH is dependent on AMH and inhibin B (InB) production through Sertoli cell activity. Neonatal pituitary luteinizing hormone (LH) and placental human chorionic gonadotropin (hCG) stimulate Leydig cells to produce testosterone, indispensable to stabilize the wolffian derivates, while dihydrotestosterone (DHT), deriving from peripheral conversion of testosterone by 5-α-reductase, acts to complete virilization of the external genitalia and the scrotal migration of testes.

In normal female differentiation, the lack of testosterone and AMH leads to regression of the wolffian structures and development of müllerian derivatives. However, recent studies of gene expression have shown that there is a series of specific genes actively implicated in ovarian development and integrity, rendering the latter process more active than previously hypothesized [2].

123.1.4 External Genitalia

The external genitalia are initially identical, regardless of the genetic or gonadal sex and consist of a genital tubercle, urogenital folds and the genital swellings. Male differentiation occurs when sufficient amounts of testosterone and DHT is produced from the 7–8th weeks of gestation, and when the fetus has developed sensitivity to androgens. In this case the genital tubercle develops as a penis, the urethral folds fuse to create a tubular penile urethra with the meatus located at the tip of the penis, and the genital swellings join to form a scrotum.

If androgenic effects are lacking, the genital tubercle forms a clitoris, and the urethral folds and the genital swellings develop into the labia minora and majora, respectively. Finally, in the absence of AMH production, a normal vagina is formed [3].

123.1.5 Psychosexual Development

Psychosexual development refers to a number of distinct components that comprise whether a person views themselves as a man or woman (gender identity), whether that person is viewed by the other members of the society as masculine or feminine (gender role), and their choice of sexual partner and erotic interest (heterosexual, bisexual, homosexual) including behavior, fantasies and attractions (sexual orientation).

123.1.6 Understanding Normal Sex Development by Genetic Advancements

Sex development requires the interaction of several factors together with the production of hormones and their consequent signalling action. It is therefore not surprising that an increasing number of genes have been discovered that contribute both early and late to the process of sex determination and differentiation, and there will undoubtedly be more. Knowledge of the molecular basis of these pathways will influence the diagnosis and management of these conditions. Transcription factors and signaling molecules play an important role in the formation and differentiation of the gonad, processes which are genetically determined. In contrast, genes that cause postgonadal 46,XY or 46,XX disorders of sexual development (DSD) often encode enzymes or factors necessary for sex steroid biosynthesis or action.

123.2 Nomenclature and Classification

Terms like intersex, hermaphroditism or pseudohermaphroditism have been considered unacceptable by affected individuals and support groups. Thus, a new nomenclature has been proposed [4, 5]. The inclusion of congenital in the definition of DSD excludes disorders such as precocious or delayed puberty. Table 123.1 outlines the nomenclature and the classification system based on causes, workable in clinical practice. According to karyotype, DSD are divided in disorders with normal or abnormal sex chromosomes. In the two groups with normal karyotype, the causes of DSD are subdivided into disorders of gonadal development or post-gonadal disorders (hormonal or receptor defects, syndromic forms, etc). In 2008 a European consortium on DSD was created (EuroDSD, www.eurodsd.eu), based on a research project supported by the EU Commission within the 7th Framework Programme. It is a collaborative project involving clinical and genetic experts. At the heart of EuroDSD is a European Registry, that is a targeted virtual environment supporting the sharing of data with respects to security and ethics. The project links patients data collection and analysis tools with research on development of novel diagnostic strategies to identify new causes of DSD, in conjunction with a strong programme on functional molecular biology of the androgen receptor, thereby allowing for an in-depth analysis of a key factor in the pathogenesis of DSD. EuroDSD also provides for an e-learning environment [6].

123.3 DSD with Karyotype Abnormalities

These disorders include diseases in which the number of sex chromosome is impaired (Table 123.2). The first two of these

Table 123.1 DSD classification (Chicago Consensus Conference, 2006)

Sex Chromosome DSD	46,XY DSD		46,XX DSD	
A: 47,XXY (Klineflter syndrome and variants)	A: Disorders of gonadal (testicular) development	1. Complete or partial gonadal dysgenesis (*SRY*, *SOX9*, *SF1*, *WT1*, *DHH*, etc.) (Swyer syndrome)	A: Disorders of gonadal (ovarian) development	1. Testicular dysgenesis (*SRY*+, dup *SOX9*)
		2. testis regression		2. Gonadal dysgenesis
		3. ovotesticular DSD		3. Ovotesticular DSD
B: 45,X0 (Turner syndrome and variants)	B: Disorders of androgen synthesis or action	1. Androgen biosynthesis/ metabolism defect (17-OH-steroid-dehydrogenase deficiency, 5α-reductase deficiency, StAR mutations, etc.)	B: Androgen excess	1. Fetal (21α-hydroxylase deficiency, 11α-hydroxylase deficiency, glucocorticoid receptor mutations)
		2. Androgen action defect (CAIS, PAIS, drugs and environmental modulators)		2. Feto-placentar (aromatase deficiency)
		3. LH-receptor defect (Leydig cell hypoplasia or aplasia)		3. Maternal (luteoma, androgenic drugs, etc.)
		4. AMH or AMH-receptor defect (persistent müllerian duct syndrome)		
C: 45,X0/46,XY (mixed gonadal dysgenesis, ovotesticular DSD)	C: Other	Syndromic associations, hypospadias, cloacal extrophy, cryptorchidism, vanishing testis syndrome, etc.	C: Other	Syndromic associations, MURCS (müllerian aplasia, renal aplasia and cervico-thoracic somite dysplasia), cloacal extrophy, vaginal atresia, etc.

Table 123.2 Sex chromosome DSD

Condition	Karyotype	Gonad	Müllerian structures	External genitalia	Possible neonatal features
Klinefelter's S.	47,XXY and variants	Hyalinized testes	–	Male	Micropenis, hypospadias, cryptorchidism
Turner's S.	46,X and variants	Streak gonad or immature ovary	Uterus	Female	Lymphedema, web neck, cardiac defect and coartation of the aorta, renal and urinary abnormalities
Mixed gonadal dysgenesis	45,X/46,XY and variants	Testis or dysgenetic gonad	+/–	Female, ambiguous, male	Possible presence of some features of Turner's syndrome; increased risk of gonad tumors
Ovotesticular DSD	46,XX/46,XY chimerism Africa 46,XX; rare 46,XY	Dysgenetic testis	+/–	Ambiguous	Possible increased risk of gonad tumors

Tables 123.2, 3, 5, 6, 7 have been modified from Achermann JC, Hughes IA (2007) Disorders of sex development. In: Kronenberg H, Melmed S, Polonsky K, Larsen PR (eds) Williams Textbook of Endocrinology, 11th edn. Saunders Elsevier, Philadelphia.

conditions will generally escape neonatal diagnosis and will only be diagnosed in late pubertal or adult life due to related features [7], e.g., impairment of puberty, or infertility. However, a recent paper by Lee et al [8] reported seven Klinefelter patients (KS) (47,XXY and variants; incidence between 1:500 and 1:1000 live births [9]) with abnormalities of genitalia ranging from mild anomalies (chordee) to moderate undervirilization (bifid scrotum and perineal hypospadias). In the same paper, a review of other cases revealed a range of mild-to-severe abnormalities that underline the importance of recognizing this condition as one of the causes of abnormal genitalia at birth. Early diagnosis and treatment might improve the quality of life of men with KS since they are born with spermatogonia and lose large numbers of germ cells during puberty. The classic form of Turners' syndrome (TS) (about 1:2,500 live birth [10]) is characterized by a 45,X0 karyotype and occurs in about 50% of cases; mosaic forms (45,X/46,XX) and forms with structural anomalies of the X chromosome are

each found in 25% of cases. None of these show genital ambiguity. However, a prenatal diagnosis of TS may be made incidentally (advanced maternal age, detection of increased occipital translucency on fetal ultrasound scan) following amniocentesis (AC) or chorionic villous sampling (CVS). During the neonatal period the diagnosis may be suspected in females with lymphoedema, occipital folds, low hair line, or left sided heart defects. Girls with classic TS have ovarian dysgenesis, an observation which underlines the need for two copies of the X chromosome for regular ovarian development. Gonadectomy is indicated for TS patients when there is a Y fragment containing the *TSPY* locus because of the increased risk of developing gonadoblastoma.

The true prevalence of classic mixed gonadal dysgenesis (MGD) (45,X/46,XY mosaicism) is unknown. The clinical phenotype of this condition is highly variable and cases described in the literature are mainly the most severe forms. The genital phenotypes vary from normal female external genitalia or mild clitoromegaly to all stages of ambiguous genitalia including hypospadias or a normal penis [11]. Gonadal phenotypes vary from streak gonads, through dysgenetic testes to testes with normal histological structure. The position of the gonad reflects the level of structural differentiation with streak-like gonads being more likely to be found intra-abdominally and well formed testes in the inguinal or scrotal region. Müllerian structures may be present in the most severe cases due to impaired AMH production by Sertoli cells. Gonadal development may be very different between the right or the left side, or even within a single gonad; the more the gonad is affected on one side, the less the müllerian structures are inhibited on the same side (paracrine action of AMH). Somatic features may vary from a Turner syndrome-like appearance (occipital folds, cardiac and renal anomalies) to normal male newborn. Recent amniocentesis data report that up to 90% of fetuses diagnosed as having a 45,X/46,XY mosaic karyotype with the condition confirmed postnatally have a normal male phenotype and apparently normal testis development [12]. Thus, there seems to be limited correlation between the degree of mosaicism on peripheral blood sampling and gonad or somatic phenotype. A number of MGD variants may be present: e.g., 45,X/47,XYY or 45,X/46,XY/47,XYY.

Ovo-Testicular DSD (OT DSD) (46,XX/46,XY chimerism, and variants; old definition true hermaphroditism) has been described in about 500 individuals worldwide and is likely to represent a number of different etiologies. In this syndrome, both ovarian and testicular tissues are present either in the same or in a controlateral gonad. The finding of pure 46,XX/46,XY chimerism is quite rare and has occasionally been described in North American or European patients. By contrast, OT DSD with a 46,XX karyotype is quite common in Africa and the Middle East [13]. The molecular basis of this disorder still needs elucidation; transmission in familial cases reported in the literature is either by autosomal recessive or sex limited autosomal dominant transmission. OT DSD with a 46,XY karyotype is rare and may be explained either by cryptic gonadal mosaicism with a Y chromosome deletion or by an early sex-determining gene mutation [2].

Asymmetry of the gonads and therefore of reproductive ducts and external genitalia is common, with testes, ovaries, and ovotestes present in various combinations. In 50% of unilateral cases, there is an ovotestis on one side and an ovary or testis on the other. In 30% of bilateral cases, testicular and ovarian tissue are present bilaterally, usually as an ovotestis. In 20% of cases, there is a testis on one side, mostly the right, and an ovary on the other side. The ovary tends to maintain its normal anatomical position; the testis, by contrast, may be found anywhere along the pathway of testicular descent, most often in the right inguinal region. Generally, in this disorder, gonadal dysgenesis is less severe than in patients with mixed gonadal dysgenesis [14]. A prevalence of 3–4% of gonadoblastoma and/or germinoma has been estimated in the testicular tissue of patients with 46,XX OT DSD; since the ovotesticular tissue is usually dysgenetic, the removal of this testicular tissue has been recommended [15].

123.4 46,XX DSD

In this section, three different groups of disorders will be described: (1) disorders of ovarian development, (2) disorders of androgen excess, and (3) other conditions affecting sex development.

The first group (ovarian dysgenesis or resistance) are not usually manifest until puberty, when a failure of estrogenization becomes apparent. However, a number of non-metabolic causes of premature ovarian failure (POF) have recently been described (*Xq26-q28*; *Xq22*; *Xq21*; *3q22*; *Xp11.2*; *7q35*; *2p12*; *9q33*), as well as mitochondrial disorders affecting ovarian development (mutant mitochondrial DNA polymerase gamma) [2]. It is possible that more severe forms of these disorders might interfere with earlier aspects of ovarian development and that a prenatal or neonatal ultrasound examination might reveal some anatomic dysgenetic features. Other conditions that can be included in this group, such as 46,XX OT DSD or 46,XX testicular DSD (XX males), have been described previously and there be sufficient testicular tissue in the gonad to produce androgenization of the phenotype and regression of müllerian structures (Table123.3).

The second group of disorders is characterized by androgen excess in 46,XX individuals and congenital adrenal hyperplasia (CAH) due to 21-hydroxylase deficiency (21-OHD), which is the commonest cause of ambiguous genitalia of the newborn [16]. It may be caused less commonly by 11-hydroxylase (11-OHD), 3β-hydroxysteroid dehydrogenase (3β-HSD2) and P450 oxidoreductase (P450-OR) deficiencies (Fig. 123.1, Table 123.4). The clinical presentation is characterized by various degree of genital virilization (Prader staging) with possible genital pigmentation (expression of excessive ACTH

Table 123.3 Genes involved in 46,XX gonadal DSD, with testicular development

Gene / protein type	Chrom. location	Inheritance	Gonad	Müllerian structures	External genitalia	Other associated features

production). A salt losing crisis may be the first presentation in patients with 21-OHD misdiagnosed as males or in the patients with severe 3β-HSD2 and only mild clitoromegaly (due to the peripheral conversion of DHEA to T by 3β-HSD1). 11-OHD can cause marked virilization because of excess testosterone production. Deoxycortocosterone (DOC) is also produced in excess and acts as a mineralocorticoid able to prevent a salt losing crisis, which has been reported as a rare transient manifestation when starting glucocorticoid treatment. Hypertension due to DOC excess is very rare in the neonatal period.

Mutations in the gene encoding the steroidogenetic acute regulatory protein (StAR protein) can also cause CAH, as can P450 oxidoreductase deficiency, which causes mild virilization with biochemical features of both 21-OHD and 17-OHD. Table 123.4 summarizes clinical and hormonal data that are helpful in making a differential diagnosis of the adrenal steroid enzyme defects and lipoid CAH. Diagnosis is based on increased levels of basal and/or ACTH stimulated steroid precursor(s) that accumulate above the enzymatic block, with the exceptions of StAR and P450scc deficiencies in which almost no steroids are produced (Table 123.4).

Table 123.4 Clinical and hormonal data helpful for a differential etiologic diagnosis of the adrenal/gonadal steroid enzyme defects and lipoid CAH

Enzyme deficiency	Sexual ambiguity		Symptoms		Hormonal findings (plasma levels)

[a] Severe forms were thought to be incompatible with survival due to placental failure to produce progesterone. The recent report of several cases demonstrated that severe disruption of P450scc could be compatible with survival in rare instances. Furthermore, heterozygote carriers were healthy and fertile. The possibility of P450scc-independent pathways of steroid synthesis in addition to the current concept of luteo-placental shift of progesterone synthesis in humans has to be questioned.
[b] Normal or elevated for normal girls, or decreased in boys.

All CAH are genetic disorders with autosomal recessive inheritance. The genes involved in all the defects have been isolated and characterized, and specific mutations have been identified (Table 123.5). Genetic analysis for the identification of mutations of the genes involved is informative for the index case and for future prenatal diagnosis [17]. Fig. 123.2 describes the allelic frequencies of the most common *CYP21A2* gene mutations found in a sample of Italian patients affected by 21-OHD and followed at the Bologna Pediatric-Endocrinologic Centre. This center is able to neonatally screen almost all classical patients of the Emilia-Romagna Region and to prevent salt losing crises of affected males who are most likely to miss early diagnosis [18]. Preterm babies have higher 17-OHP levels than those born at term and specific gestational age and/or weight related data are required [19].

In families at risk for a virilized female baby (because of an index case affected by classical 21-OHD or 11-OHD), prenatal diagnosis and treatment may be undertaken. Early administration (before eight weeks' gestation) of dexamethasone to the mother (20 mcg/kg/pre-pregnancy) prevents genital virilization in most affected females. Treatment has to be started before chorionic villus sampling (CVS) for sex and genetic analyses can be performed at 10–11 weeks' gestation and only female affected fetuses need to be treated throughout

Table 123.5 Genes involved in 46,XX DSD due to androgen excess

Gene/protein type	Chrom. location	Inheritance	Gonad	Müllerian structures	External genitalia	Other associated features
HSD3B2/enzyme	1p13.1	AR	Ovary	+	Female or ambiguous	CAH, primitive adrenal insufficiency, partial androgenization

the pregnancy. To reduce the number of fetuses exposed to dexamethasone unnecessarily, polymerase chain reaction (PCR) testing for cell-free Y DNA in maternal blood at 5–6 weeks of gestation for prenatal sexing is now available as an experimental technique [20, 21]. Due to possible maternal side effects (Cushing syndrome) and lack of long-term trials for its safety, antenatal dexamethasone treatment should be carried out in specialized centers with the use of approved protocols [22].

Aromatase deficiency is a recent, well characterized disorder of steroidogenesis in which there is exposure of the mother and a female fetus to fetal androgens that are normally aromatized by the fetally derived placenta. The lack of aromatase action has a virilizing effect on the mother and on her female newborn [23].

Maternal causes of androgen excess that may virilize a female fetus are either endogenous because of secretion by adrenal and ovarian tumors, or exogenous because of maternal ingestion of androgenic compounds (Danazol).

The third group of disorders refer to some syndromic associations that can cause developmental genital abnormalities in 46,XX girls. Abnormalities of uterine development can result in a bicornuate uterus, uterine hemiagenesis or hypoplasia, or uterine agenesis.

These conditions can be associated with renal, cardiac and cervical spinal abnormalities as part of the Mayer-Rokitansky-Kuster-Hauser syndrome. Uterine anomalies have also been associated with maturity onset diabetes of the young type 5 (*MODY 5*, mutations in *HNF1β*) and with vaginal abnormalities with hand-foot-genital syndrome (mutations in *HOXA13*) and McKusick-Kaufman syndrome (mutations in *BBS6*). Relative clitoral hypertrophy can be associated with conditions such as Frasier syndrome or neurofibromatosis and careful assessment is necessary before a hyperandrogenic cause is diagnosed. Apparent clitoromegaly may be a common finding in premature babies or when there is little labial adipose tissue present: assessment by a physician with experience of normal variability in clitoral size is important.

123.5 46,XY DSD

46,XY DSD are divided into: (1) disorders of gonadal development, (2) disorders of testosterone biosynthesis, metabolism or action, (3) other conditions (Table 123.1).

123.5.1 Disorders of Gonadal Development

Total gonadal agenesis or bilateral gonadal streak (Swyer syndrome) is rare and has been described in 46,XY subjects. There are both internal and external female genitalia, due to the complete absence of testicular determination, with persistent müllerian structures due to insufficient AMH production. The origin of this disorder remains uncertain but may be due to a defect in genes critical to bipotential gonad development [24].

Partial gonadal dysgenesis has been reported in some clinical conditions, characterized by impaired testicular development, ambiguous external genitalia with or without müllerian structures (similarly to 45,X0/46,XY conditions). Mutations in the *SRY* gene have been related to this phenotype in about 20% cases (mostly as de novo mutations). Heterozygous mutations in SF1 gene have also been recently found to be causative of XY DSD without apparent adrenal involvement [25].

In ovotesticular DSD, which is a very rare disorder, the gonad has both ovarian and testicular tissue. The karyotype is usually not 46,XY but a mosaic.

Testicular regression syndrome is a condition in which a testis is thought to have once existed but has atrophied and disappeared during early development. The timing of the regression process is critical. If this process occurred before differentiation of the male external genitalia is completed, the newborn will have an undervirilized appearance (DSD), while if it happens later in gestation, the male newborn will have cryptorchidism with undetectable testis (vanishing testis).

Genetic mutations and chromosomal changes involved primarily in 46,XY gonadal DSD may be associated with other clinical features (Tables 123.6, 123.7).

123.5.2 Disorders of Testosterone Biosynthesis

During intrauterine male development, both maternal hCG and fetal LH act on Leydig cells by a hCG/LH common-G-protein coupled receptor, stimulating testosterone production. A mutation in this receptor gene may cause Leydig cell hypoplasia with complete or partial impairment of hormone secretion, so that an undervirilized variable phenotype arises at birth [26].

Testosterone biosynthesis, like all steroidal hormones, starts from cholesterol as precursor.

7-Dehydrocholesterol reductase (DHCR7) deficiency is a disorder affecting the cholesterol biosynthesis pathway and

Table 123.6 Genes involved in 46,XY gonadal DSD

Gene/protein type	Chrom. location	Inheritance	Gonad	Müllerian structures	External genitalia	Other associated features
SRY/TF	Yp11.3	Y	Dysgenetic testis or ovotestis	+/–	Female or ambiguous	–
SOX9/TF	17q24-25	AD	Dysgenetic testis or ovotestis	+/–	Female or ambiguous	Camptomelic dysplasia
WT1/TF	11p13	AD	Dysgenetic testis	+/–	Female or ambiguous	Wilms' tumor, nephropathies, gonadoblastoma (WAGR, Denys-Drash and Frasier syndromes)
SF1 (NR5A1)/ TF (NR)	9q33	AD/AR	Dysgenetic testis	+/–	Female or ambiguous	+/– Primitive adrenal insufficiency
DHH/sign. molecule	12q13.1	AD/AR	Dysgenetic testis	+	Female	+/– Minifascicular neuropathy (1 case)
ATRX/Helicase	Xq13.3	X	Dysgenetic testis	–	Female, ambiguous or male	α-Thalassemia, mental retardation
ARX/TF	Xp22.13	X	Dysgenetic testis	–	Ambiguous	+ Lissencephaly, epilepsy, temperature instability

TF transcription factor, *NR* nuclear receptor, +/– present or absent.
AD autosomal dominant (or de novo mutation), *AR* autosomal recessive, *Y* Y-linked, *X* X-linked.

Table 123.7 Chromosomal changes involved in 46,XY gonadal DSD

Candidate gene/ protein type	Chrom. location	Inheritance	Gonad	Müllerian structures	External genitalia	Other associated features
DAX1 (NROB1)/ TF (NR)	Xp21	Dupl Xp21	Dysgenetic testis or ovary	+/–	Female or ambiguous	
DMRTs/TF	9p24.3	Del 9p24.3 red. penetrance	Dysgenetic testis or normal testis	+/–	Female or ambiguous	Mental retardation, somatic dismorphisms
WNT4/sign. molecule	1p35	Dupl 1p35	Dysgenetic testis	+	Ambiguous	Mental retardation

TF transcription factor, *NR* nuclear receptor.
+/– present or absent.

causes Smith-Lemli-Opitz syndrome (which includes microcephaly, mental retardation, facial dysmorphism, polydactyly genital anomalies; renal hypoplasia and unilobar lung are also commonly associated).

Lipoid adrenal hyperplasia due to deficiency of StAR protein, which facilitates the rapid movement of cholesterol from the outer to the inner mitochondrial membrane, is rare in Europe and America, but more common in Japan. Patients are phenotypic females (despite having a testis) with enlarged adrenal cortex, engorged by cholesterol and cholesterol esters. Severe adrenal insufficiency is the main potentially lethal consequence, since virtually no steroids are made [27].

Enzymatic defects altering the normal testosterone bio-synthesis, cholesterol side chain cleavage (*CYP11A1*), 3β-hydroxysteroid dehydrogenase (*3β-HSD2*), 17α-hydroxylase/17-20-lyase (*CYP17*), and P450 oxidoreductase (POR) enzyme deficiencies, are inherited as autosomal recessive conditions. The clinical presentation of this group of DSD is characterized by various degree of genital under-masculinization with possible genital pigmentation due to excessive ACTH production in cases associated with antenatal insufficiency. A salt losing crisis and hypoglycemia may be the first clinical sign. Babies with severe deficiency are often misdiagnosed as females.

P450scc (*CYP11A1*) is the mitochondrial enzyme that converts cholesterol to pregnenolone and is therefore responsible for the first rate-limiting step in steroid synthesis, which is required for pregnenolone production by the placenta as well as for mineralcorticoid, glucocorticoid and androgen production by the adrenal glands and gonads.

P450c17 or *CYP17* (gene locus in 10q24.3) are expressed both in the zona fasciculata and in the zona reticularis of the adrenal cortex and in gonadal tissues as a steroidogenic enzyme with dual functions, hydroxylation and as a lyase. The first activity results in hydroxylation of pregnenolone and progesterone at the C17 position to generate 17α-hydroxypregnenolone and 17α-hydroxyprogesterone. The latter enzyme activity cleaves the C17–C20 bond of 17α-hydroxypregnenolone and 17α-hydroxyprogesterone to form dehydroepiandrosterone and androstenedione respectively.

Patients with *3β-HSD2* usually show some degree of virilization (due to peripheral conversion of DHEA to T by 3β-HSD1) or hypospadias, which suggests the diagnosis. In

17-OHD deficiency the genital phenotype may vary from that of a complete female to severe hypospadias; corticosterone (C) and deoxycortocosterone (DOC) are produced in excess and have glucocorticoid and mineralocorticoid functions, respectively. Hypertension due to DOC excess is very rare during the neonatal period. In 17-20 lyase deficiency, the genital phenotype is similar, but there is no cortisol deficiency and no mineralocorticoid excess.

As in 46,XX patients, P450 oxidoreductase deficiency may cause mild virilization of a male fetus, with the biochemical features of both 21-OHD and 17-OHD [28]. Table 123.4 summarizes the clinical and hormonal data for the differential etiologic diagnosis of adrenal steroid enzyme defects and lipoid CAH. For the enzymatic diagnosis see discussion of congenital adrenal hyperplasia in § 123.4 on 46,XX DSD.

46,XY DSD due to mutations in the *HSD17B3* gene (encoding the 17β-HSD3 isoenzyme) is characterized by female-like or ambiguous genitalia at birth, with the presence of a blind vaginal pouch, intra-abdominal or inguinal testes. Impaired conversion of androstenedione into testosterone explains the virilization defect. Since virilization occurs at puberty, most affected males have been raised as females and changes to male gender role behavior at puberty have been reported [29].

123.5.3 Disorders in Testosterone Metabolism: 5-Alpha-Reductase Deficiency

SRD5A2 gene (2p23) encodes the steroid 5-alpha-reductase 2 isoenzyme, which converts testosterone into dihydrotestosterone (DHT) mainly in target tissues.

Affected 46,XY individuals have normal or increased testosterone plasmatic levels, with decreased DHT levels and an elevated testosterone/DHT ratio in a basal blood sample on the 1st and 2nd days and at 1–3 months of age. Newborns present with ambiguous undervirilized or almost female external genitalia. However, wolffian differentiation occurs normally and they have epididymides, vas deferens and seminal vesicles. The testes are often located in the abdomen or in the inguinal region, suggesting that DHT influences gonadal migration in the scrotum. Virilization occurs at puberty and some patients, who were not submitted to orchidectomy in childhood, have undergone a male social sex change (Table 123.8). In adulthood, the prostate is small and rudimentary, the penis is small and facial and body hair is absent or decreased and balding has not been reported. Spontaneous fertility has been reported when orchidopexy has been properly performed, so that male gender should be assigned. Correct early diagnosis is mandatory.

The main differential diagnoses are described in Table 123.1 and molecular analysis of the *SRD5A2* gene is indicated during the newborn period before assigning female sex and performing gonadectomy [30, 31].

123.5.4 Disorders in Testosterone Action

An androgen receptor (AR) mediates the pleiotropic effects of testosterone. The phenotype of androgen insensitivity, an X-linked recessive disorder, depends on the degree of AR disruption. The phenotype of complete androgen insensitivity syndrome (CAIS) is that of a normal female, despite the presence of an XY karyotype. The testis is histologically normal and produces testosterone concentrations within the age-appropriate normal male range. Data on prevalence are imprecise, ranging from 1:20,400 to 1:99,000 genetic males.

Presentation may vary from the perinatal period to adulthood. In pregnancy, the diagnosis may be suspected because of a male fetal karyotype and female phenotype at antenatal ultrasound or at birth. During the perinatal period and childhood, the main presentation of CAIS is as a bilateral inguinal or labial hernia. All girls with this type of hernia should therefore be investigated for CAIS.

In partial androgen insensitivity syndrome (PAIS), the external genitalia may be ambiguous at birth, thus making immediate sex assignment difficult. The phenotype varies, depending on the degree of hormonal resistance, from perineoscrotal hypospadias, micropenis and a bifid scrotum with undescended testes, to isolated clitoridomegaly, marginally different from CAIS. The milder end of the spectrum of PAIS includes isolated hypospadias in the newborn and infertility in adulthood (minimal androgen insensitivity syndrome [MAIS]).

PAIS should be differentiated from sex chromosome DSD with 45,X0/46,XY or 46,XX/46,XY karyotype, defects in gonadal development or a defect in androgen biosynthesis. Dynamic endocrine investigations (hCG stimulating test and/or tests to assess androgen sensitivity) should be performed to select patients for genetic investigation. A number of patients, previously misclassified as PAIS without demonstrated AR mutations, have been recently diagnosed as heterozygous carriers of SF1 (NR5A1) mutations. In the majority of these cases the adrenal function was apparently normal [25].

123.5.5 Persistent Müllerian Duct Syndrome

Anti-müllerian hormone (AMH), a member of the transforming growth factor beta (TGF-beta) family, is produced by gonadal somatic cells and is mainly responsible for the regression of müllerian ducts during male sex differentiation with signaling through two serine/threonine kinase receptors. A defect of AMH causes the persistence of müllerian derivates in otherwise normally virilized males. Its inheritance is as a recessive autosomal and is due, in 84% of cases, to mutations of *AMH* and *AMH* receptor type II genes. Serum AMH is normal for age in patients with *AMH* type II mutations and low or undetectable in those with AMH mutations (although some exceptions have been recently described [32]). In 14% of cases the origin of the condition is unknown [33].

Table 123.8 Comparison of main clinical and laboratory findings among Leydig cell hypoplasia/aplasia, 17β-HSD3 deficiency, 5α-reductase deficiency and complete androgen insensitivity syndrome (AIS) [29]

	Leydig cell hypoplasia	17β-HSD3 deficiency	5α–Reductase deficiency	Complete AIS
Eponymous	–	17-Ketosteroid reductase deficiency	Pesudovaginal perinoscrotal hypoplasia	Testicular feminization syndrome
Karyotype	46,XY	46,XY	46,XY	46,XY
Inheritance	Autosomal recessive	Autosomal recessive	Autosomal recessive	X-linked recessive
External phenotype	Female or ambiguous	Female or ambiguous	Ambiguous or female	Female

123.5.6 Endocrine Disruptors in Pregnancy

Timing of hormone secretion is critical for normal organogenesis, and any external disruption is therefore time-dependent. Androgen action is most critical since it causes masculinization of the external genitalia early in pregnancy (from week 7–8). Androgen exposure of the female fetus during this period will cause masculinization, whereas impaired androgen action in a male fetus will result in under-masculinization [34].

Endocrine disruptors with androgenic or antiandrogenic potency or estrogenic chemicals (i.e., diethylstilbestrol) may therefore interfere with sexual differentiation. Hypospadias and cryptorchidism can be caused by antiandrogens. Phthalate esters, ubiquitous in the past and still widely used as plasticizers, disturb androgen biosynthesis and exposure to these chemicals causing antiandrogenic effects has been related to inhibition of Leydig cell function [35]. Exposure to phthalates occurs via skin, airways, intravenous transfusion, food, and drink [36] and absorption through the skin is very rapid [37].

The first step to prevent environmental causes of disorders of sexual differentiation is the effective recognition of endocrine disrupting properties of chemicals on developing fetuses and children. However, although great effort as been put into the development of robust testing methods of endocrine disruptors in industrialized countries, progress is slow.

123.6 Ethics and Sex Assignment

Initial management of DSD depends on establishing an early diagnosis. A precise diagnosis may, however, be difficult in many cases of 46,XY DSD and in more than 50% of the cases no conclusive diagnosis is made. Nevertheless, there are also legal reasons for assigning a gender to all newborns with ambiguous genitalia, even though it is possible to postpone assignment when expert assessment is needed. At this critical early stage, discussion with the parents must be open, and parents' participation in decision-making should be encouraged.

A multidisciplinary team should be established at the time of the the first communication of the diagnosis of DSD with the aim of helping professionals and parents to evaluate the pros and the cons of all medical and surgical options. The multidisciplinary team should help with anxieties both in physicians and parents that may lead to premature and irreversible decisions [38–40]. According to the 5th World Congress on Family Law and Children Rights (Halifax, August 2009), the principles of ethical guidelines for the management of infants with DSD should be: 1) minimising physical risk to child, 2) minimising psychosocial risk to child, 3) preserving potential for fertility, 4) preserving or promoting capacity to have satisfying sexual relations, 5) leaving options open for the future if necessary, and 6) respecting the parents' wishes and beliefs if it is possible [41].

There is general agreement that 46,XY DSD due to complete testicular dysgenesis, severe testosterone biosynthesis defect or Leydig cell aplasia should be assigned to the female sex.

In CAIS, gender assignment and sex of rearing is female. Inguinal hernias need repair. There is no uniformity of practice for early versus late gonadectomy: parents require appropriate information to enable them to reach a joint decision with the professional health care team. Two important points for discussion are the merits of spontaneous puberty with gonads in situ versus induction of puberty by oestrogen replacement therapy, and the possible risk of gonadal tumor development (usually seminoma) if gonadectomy is delayed until adulthood.

In 46,XX CAH with genital virilization, gender assignment is female, even when there is complete virilization at birth. Steroid replacement is mandatory. In salt-wasting forms, it is necessary to start this therapy as soon as possible in order to prevent electrolytes imbalance or to treat hypovolemic shock.

In 5-α-reductase deficiency, male assignment is the first choice. Possible assignment to the male sex should be seriously discussed in cases of 17-β-OH-steroid-dehydrogenase deficiency and 46,XY DSD due to PAIS or partial testicular dysgenesis. Many authors suggest that gender assignment should also be based on prenatal androgen brain exposure [42, 43].

Social and cultural factors, as well as hormonal effects, appear to influence gender role and gender role change. DSD may carry a stigma. In some societies, female infertility precludes marriage, which also affects employment prospects and creates economic dependence. Religious and philosophical views may influence how parents respond to the birth of an infant affected by this medical condition. There may also be fatalism and guilt feelings related to congenital malformations or genetic conditions, and poverty and illiteracy impair access to health care [44]. Support groups integrate the work of the health care team. Peer and parent support groups may provide a context in which intimate issues of concern can be approached safely with someone who has been there, even though parents may be more amenable to these discussions than adolescent patients. Support groups can also help families and consumers to find the best quality care (www.dsd.guidelines.org).

Long-term outcome should be studied in every treatment center, paying special attention to different cultural settings [43, 45]. So far, studies have shown that while many patients fare well and are leading productive lives, gender dysphoria has been underestimated in the past and gender counseling as well as sexual counseling should be part of the multi-disciplinary service concerning DSD patients. More emphasis is also needed on strategies to prevent the development of germ cell cancers (i.e., seminoma in CAIS and dysgerminoma in gonadal dysgenesis DSD) or unnecessary gonadectomy. Urological problems in both males and females with DSD should not be underestimated [46].

In cases of genetic defects carried by both parents as heterozygous, genetic counseling should be planned and offered to families (risk of recurrence).

123.7 Medical Management of DSD in the Newborn

The evaluation of a newborn with abnormalities of genitalia should be carried out by an experienced multidisciplinary team. A careful history should take account of any family history of unexplained neonatal death, siblings with virilization or precocious puberty or female sexual infantilism, maternal drug assumption or androgen changes during pregnancy. There should also be a complete physical examination (external genitalia appearance including the presence or absence of palpable gonads, measurement of phallus length, urethral opening identification, presence or absence of a vagina), laboratory and radiological investigations.

A diagnostic schedule is proposed in Fig. 123.3. At 24–48 hours and 72–96 hours of life, blood samples should be collected and a serum sample should be stored to decide on the most appropriate diagnostic test after the results of karyotyping.

Timing is important because of the physiological changes which occur in the hormonal profile shortly after birth [47]. If hormonal tests (i.e., hCG stimulation test) and imaging investigations do not lead to a definite diagnosis, laparoscopy should be performed. During surgery, skin biopsy may be used for functional studies on intracellular mechanisms induced by androgen receptor activation.

The standard treatment of CAH is hydrocortisone 10–20 mg/m^2/day (3.0–5.0 mg/day) usually in three divided doses (10 mg tablets can be dissolved in 2 mL water). For sick infants, 2 mg/kg of hydrocortisone hemisuccinate by i.v. bolus, followed by 20–30 mg/m^2/day by constant i.v. infusion may be a more appropriate initial treatment. Blood electrolytes should be monitored daily from day 3 and if K^+ raises or Na^+ falls (salt loss may occur between 6 and 21 days of life) 9α-fludrocortisone should be started at 0.05 mg/day in two divided doses. The latter dose may be increased to 0.2 mg/day in two divided doses in resistant cases. Salt supplementation (5 mEq/kg/day; 5 mL sol 20% NaCl =1 g = 17 mEq) complements mineralocorticoid treatment during the first 6 months of life. For the management of acute adrenal insufficiency, see § 123.4 on 46,XX DSD.

123.8 Surgical Management of DSD: an Approach

There is an increasing tendency to recommend that any decision about genital surgery should be made by the parents and, when appropriate, the patient, in discussion with the medical team [48]. Of course, patient involvement in decision making, implies the delay of all the interventions not primarily directed to functional repair or to remove malignant tissue.

The goal is to construct genitalia that are compatible with the assigned gender sex, prevent urinary infections or incontinence, and provide good adult sexual and reproductive

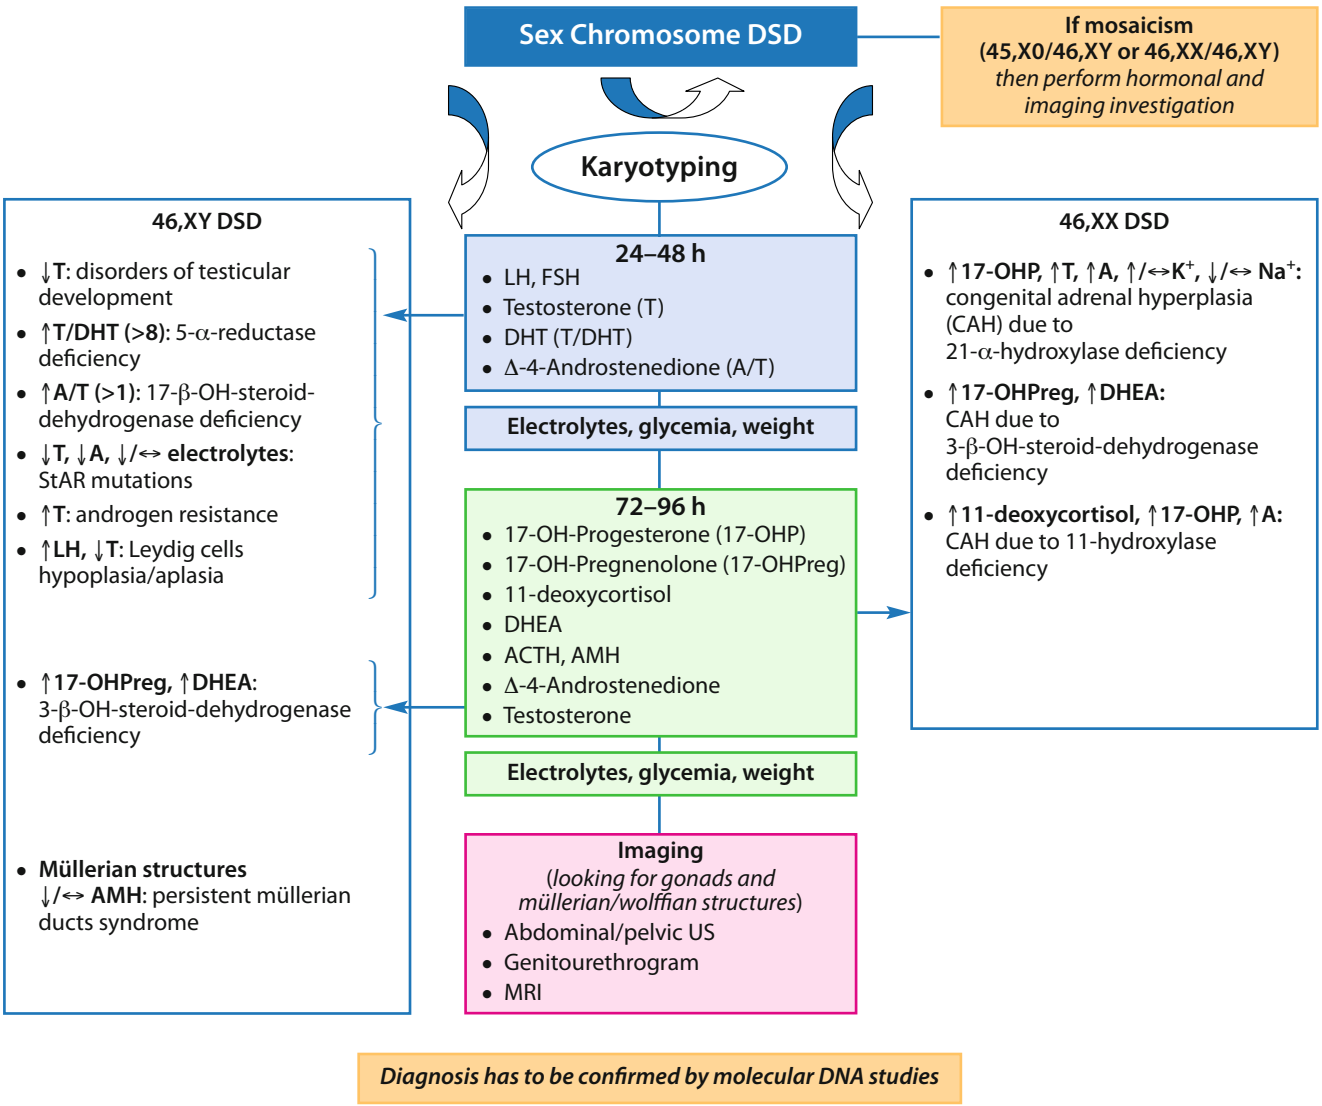

Fig. 123.3 A diagnostic schedule for early diagnosis of DSD in the newborn

function [49]. Surgeons with expertise in DSD management, together with the DSD team, need to explain the surgical sequences and the transition from infancy to adulthood.

There is controversy about the timing of feminizing genitoplasty (FG) in girls with virilising CAH. Many pediatric urologists and endocrinologists continue to recommend early FG in agreement with the guidelines of American Academy of Pediatrics (recommended period between 2 and 6 months of age). However, intersex advocacy groups would delay genital surgery. When possible, FG should be a one stage repair. Clitoroplasty should only be considered in cases of severe virilization (Prader III–V) with emphasis on functional outcome rather than cosmetic appearance. Vaginoplasty should be performed in infancy only if the persistence of a urogenital sinus causes complications. Generally, surgical refinement needs to be done at puberty. Vaginal dilation is not recommended during childhood, while its use during young adulthood may be useful in avoiding the need for bowel vaginoplasty, especially in women with CAH or CAIS.

In patients raised as males, the repair of hypospadias with correction of chordee, urethral construction and orchidopexy for undescended testes are recommended. Because of limitations in penile reconstruction, the complexity of phalloplasty should be explained to the parents during initial counseling, especially if gender assignment depends on it.

The risk of gonadal malignancy should inform the timing of gonadectomy, although there is some controversy about this. Testes in individuals with 46,XY gonadal dysgenesis or fragments of Y-chromosome material raised as female should be removed early if there is no possibility of realistically controlling gonadal development. Among those with gonadal dysgenesis and a scrotal testis, the current

recommendation is to perform testicular biopsy at puberty looking for malignancy.

For female patients with ovotesticular DSD and functional ovarian tissue, separation and removal of the testicular component in early life is advised in an attempt to preserve fertility. Gonadectomy should be performed before puberty in PAIS, 17β-HSD, and 5α RD deficiencies and in 45,X/46,XY mixed gonadal dysgenesis raised as females.

123.9 Cryptorchidism and Hypospadias

Cryptorchidism, failure of the testis to descend from its intra-abdominal location into the scrotum, has a prevalence of approximately 3% in newborns at term, but is 10 times higher in preterms. If there is late spontaneous descent during the first 6–9 months of life, the prevalence of cryptochidism declines to 1% in infants born at term but it is still three fold higher in infants born preterm or low birth weight [50].

Using a two-handed technique, testes may be palpable (inguinal or prescrotal) or impalpable (abdominal). If cryptorchidism is unilateral, the consistency and size of the undescended testis should be noted, in comparison with the opposite one.

A family history should be investigated for cases where there is doubt about the diagnosis of DSD and for other cases of undescended testes. If cryptorchidism is bilateral (impalpable testes in an otherwise normal boy), urgent karyotype is mandatory as well as in cases of cryptorchidism associated with an ambiguous appearance of external genitalia (see Medical Management).

The testosterone response to hCG stimulation can clarify normal Leydig cell function, and elevated gonadotropin levels suggest primary gonadal failure. The evaluation of AMH and inhibin B levels, secreted by Sertoli cells, may be a sensitive marker for the presence of functioning testicular tissue. Imaging (ultrasound [US], magnetic resonance imaging [MRI]) may be useful for identifying inguinal or abdominal testes, but there is a high false-negative rate.

If one or both testes are palpable and the genitalia are normal male, the newborn should be referred to a pediatric surgeon. Hormonal treatment (intramuscular hCG or intranasal GnRH) was largely used in the past, but there are many different protocols. Hormonal therapy induced permanent testicular descent in a minority of young cryptorchid boys with either unilateral or bilateral palpable testis [51, 52].

These days, surgical treatment is preferred and orchidopexy is performed during the 1–2nd year of life, both to preserve fertility and to monitor testicular cancer lesions (20–48 fold increased risk in undescended testes; the incidence of malignant transformation related to testicular dysgenesis syndrome is also increased in the unaffected testis [53, 54].

Hypospadias is a congenital displacement of the urethral meatus in male newborns. The exact position of the meatus determines whether the form of hypospadias is glandular or coronal (mild), penile (moderate), scrotal or perineal (severe). While most cases of mild forms usually occur as isolated defects, severe forms may be a sign of DSD. The prevalence is about 3–4 per 1000 live births. The pathogenesis of isolated hypospadias is multifactorial (genetic, endocrine and environmental factors) [55]: however, the prevalenceof hypospadias is higher in infants born small for gestational age than in newborns of normal birth weight.

Patients need surgical repair, since they may have urological disorders and subfertility [56].

Cryptorchidism and hypospadias may be part of the clinical spectrum of complex genetic syndromes, e.g., Opitz GBB syndrome, Robinow syndrome and CHARGE association.

Opitz syndrome (22q11.2 del) is marked by hypertelorism or telecanthus, laryngotracheoesophageal cleft, clefts of lip, palate, and uvula, swallowing difficulty and hoarse cry, genitourinary defects (hypospadias in males and splayed labia majora in females), mental retardation; developmental delay, congenital heart defects.

Robinow syndrome (autosomal dominant or autosomal recessive due to a mutation of receptor tyrosine kinase-like orphan receptor gene-2, *ROR2* in 9q22) may present with mesomelic limb shortening, facial and genital anomalies.

The CHARGE association, possibly due to a mutation of 7q21.11 (semaphorin-3E gene, *SEMA3E*) or 8q12.1 (chromodomain helicase DNA-binding protein-7, CHD7), is characterized by coloboma of the eye, heart anomalies, choanal atresia, delayed mental and somatic development, microphallus, ear abnormalities and/or deafness. Facial palsy, cleft palate, and dysphagia are commonly associated.

Pathophysiology of Fetal and Neonatal Kidneys

Farid Boubred, Isabelle Grandvuillemin and Umberto Simeoni

124.1 Kidney Development

The definitive kidney, the methanephros, is formed by two processes, nephrogenesis (the formation of glomerulus and tubules) and branching morphogenesis (the formation of collecting ducts, calyces, pelvis and ureters). The metanephric kidney takes place after the formation and involution of two embryonic kidneys, the pronephros (non functional organ) and the mesonephros (first functional kidney), that in turn evolves into the ureteric bud (UB). The metanephros appears during the fifth gestational week, and develops from the specific interaction between the epithelial ureteric bud and the undifferentiated metanephric mesenchyme (MM). This interaction is crucial for the differentiation of the mesenchyme and the induction of UB branching division (Fig. 124.1). The UB arises in response to signals elaborated by the mesenchyme and then undergoes branching morphogenesis following the invasion of the MM by the UB. This process gives a 15 branch generation. At 20–22 weeks of gestation, branching morphogenesis is completed and results in the collecting system. Mesenchymal cells that are in close contact with the invading UB undergo an epithelial transformation. The induced metanephric mesenchyme (MM) gives the nephrons, through the consecutive stages of condensation, renal vesicule, vascular cleft, and S-shaped body. The glomerular capillary tuft is formed via recruitment and proliferation of endothelial and mesangial cells precursors. The nephrons develop in successive stages from the inner to the outer area of the fetal kidney in parallel with the vascular system. In the human, the primitive glomerulus appears at approximately 9–10 weeks of gestation. The nephrogenesis is completed by 34–36th weeks of gestation [1]. About 60% of the nephrons develop during the third trimester of gestation, while nephrogenesis may continue ex-utero in preterm infants [2]. Once nephrogenesis is complete, stroma cells differentiate into fibroblasts, pericytes and lymphocytes-like cells. At birth the final nephron number varies from 800,000 and 1 million per kidney. Such variation in nephron number is due to genetic factors and to the fetal environment [3]. Several genes and molecular pathways control the formation of the renal collecting system and nephrogenesis, such as transcriptional factors (PAX-2, WT1), growth factors (IGF, EGF, TGF), oncogenes, the extracellular matrix, and vascular factors (Table 124.1) [4]. These factors act at a specific time of kidney development especially when the UB interacts with the adjacent MM. Blockade of vascular endothelial growth factor receptor (VEGF-R), inhibition of the

Glutaric aciduria type II	*Glutaryl CoA dehydrogenase*	Cystic dysplasia

renin angiotensin system (RAS) and knock-out for cyclooxigenase (COX)-2 gene expression are associated with impaired nephrogenesis including glomerular cysts, dysplasic tubules and tubular dysgenesis [5–7].

124.2 Renal Physiology

124.2.1 The Fetus

During intrauterine life, the homeostasis of the fetus is assigned to the placenta. Glomerular filtration rate, renal blood flow and tubular functions progress with renal growth and nephrogenesis. The kidney is involved in urine production, which is essential in fetal well-being, and in hormonal production (1,25 OH vitD_3 and erythropoietin). In the near-term period, the fetal kidney shows sufficient glomerular and tubular development to allow the adaptation to extrauterine life [8].

124.2.1.1 Glomerular Function and Renal Blood Flow

During fetal life, nephrogenesis plays an important role in maturation of the glomerular filtration rate (GFR). GFR in the fetus is low, even at the end of gestation, and depends on various factors especially on renal blood flow.

In the fetus, the systemic arterial blood pressure, around 40–60 mmHg, and renal blood flow are low in comparison with the newborn or the adult. In the sheep, the fetal kidneys receive 3% of cardiac output compared to 15% in the neonatal period. Such low renal blood flow (RBF) is related to elevated renal vascular resistances. This state is mainly due to a subtle equilibrium between vasoconstrictive factors, including the RAS and the renal sympathic nervous system, and vasorelaxing factors such as the prostaglandins, nitric oxide, and other factors (Fig. 124.2). In the fetal kidney, the RAS is up-regulated. The fetus is able to release renin into the fetal circulation. Renin does not cross the placenta and the fetal plasma renin levels are higher than maternal levels. Angiotensin II increases mainly the glomerular efferent tone, which is highly sensitive to angiotensin. Up-regulation of the RAS maintains renal blood flow and renal perfusion pressure.

The renal sympathetic nervous system increases renal vascular tone in afferent and efferent arterioles. The fetal renal vasculature is more sensitive to alpha-2 adrenoreceptor stimulation than the neonatal one. Up-regulation of alpha-2 receptors is associated with a down-regulation of beta-2 adrenoreceptors. Adenosine vasodilates glomerular arterioles in the physiologic state, but reduces GFR in stress conditions (increasing tone in afferent glomerular arteriole).

Vasoconstrictive forces are counterbalanced by vasodilating factors that act on the glomerular afferent arteriole to maintain a sufficient renal blood flow. Theses factors are mainly prostaglandins, nitric oxide (NO), and the kallikrein-kinin system. Prostaglandins, in particular prostanglandins E2 and I2, are of major importance. These prostaglandins are produced by the placenta, the membranes and the fetus, from the action of two enzyme isoforms, the type-1 and type 2 cyclooxigenases (COX-1 and COX-2). COX-2 is constitutive in the fetal

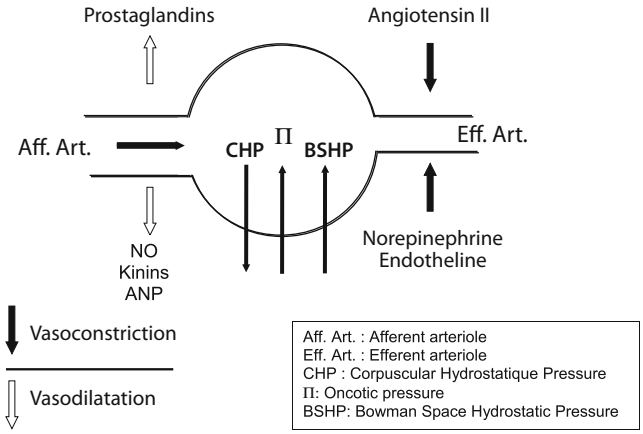

Fig. 124.2 Determinants of glomerular filtration with preglomerular and postglomerular vasoactive forces

kidney and appears essential for the development and function of the kidney [9]. Administration of COX inhibitors during pregnancy decreases renal blood flow, impairs renal function and induces oligohydramnios. Nitric oxide is synthesized by endothelial cells, and vasodilates the afferent arteriole. In the sheep, inhibition of NO leads to increased renal vascular resistance, impaired renal function and reduced sodium excretion. Other factors including endothelin and atrial natriuretic factors can modulate renal hemodynamics.

The expression of vasoactive factors is related to the development of the nephrons. In the rat, as nephrogenesis continues after birth, COX-2, endothelial nitric oxide synthase (eNOS) and angiotensin receptors are highly expressed in immature nephrons and then down-regulated at the end of nephrogenesis. Vasoactive factors participate in the nephrogenesis and in the regulation of intrarenal vascular renal blood flow repartition.

124.2.1.2 Tubular Function

In the adult, the kidney plays an important role in the homeostasis, especially through the function of the tubules. The tubular system is composed of proximal tubules, which are mainly responsible for the regulation of fluid and electrolytes, and of distal tubules and collecting ducts, responsible for fluid and tonicity regulation.

During intrauterine life, the placenta assumes the fetal homeostasis. The maturation of tubular functions follows the development of nephrons. The formation of urine, the main constituent of amniotic fluid in the third trimester, begins by 12 weeks of gestation. The urinary flow rate increases 10 fold from 6 mL/h at 20 weeks to 60 mL/h at 40 weeks of gestation. Fetal urine is hypotonic (100–250 mOsm/kg H_2O). In comparison with maternal plasma, potassium and phosphorus plasmatic levels are higher in fetus suggesting a specific maturation of tubular channels and transporters [8].

The excretion of sodium is higher during fetal life than in the newborn and the adult. Such a high rate of sodium excretion may be related to various factors, including high circulating concentrations and high sensitivity to natriuretic factors; large extracellular fluid volume; relative insensitivity to aldosterone; and dysmaturity of tubular sodium reabsorption. In contrast to the adult physiology, the sodium is mainly reabsorbed in the distal portion of the immature tubules. The sodium/hydrogen exchangers (NHE, four different isoforms) play an important role. These exchangers mediate the exchange of one sodium for one hydrogen ion and contribute to the acidification of urine. The NHE 3 channel, located at the apical or luminal membrane of tubular cells, is thought to be responsible for the bulk of tubular reabsorption of sodium. It is down regulated in the proximal portion of the immature tubules when it is markedly up-regulated after birth. Its expression and activity is dependent on the tubular Na^+, K^+ ATPase, which is down-regulated in the immature kidney [10].

Potassium is important for cell growth and cell function. The balance of potassium is positive in the fetus, due in part to active transplacental transport. Renal excretion of potassium is low and tends to increase towards term. Potassium excretion increases with glomerular and tubular surface area, with maturation of tubular Na^+/K^+ ATPase activity, and with the progressive development of tubular sensitivity to aldosterone.

As for potassium, the fetus is characterized by a positive phosphorus balance resulting from a transplacental transport, a high rate of tubular reabsorption of phosphorus via a sodium-phophorus co-transporter, and a relative parathyroid insufficiency. Calcium is important for the adequate mineralization and growth of the fetal skeleton. Vitamin D-dependent calcium binding proteins, involved in transepithelial calcium transfer, are present in the fetal kidney. The major role of the kidney in fetal calcium homeostasis is the production of $1,25(OH)_2D_3$, rather than the renal regulation of calcium excretion.

During fetal development, the placenta regulates the fetal acid-base balance. The reabsorption of bicarbonates and chloride in the proximal tubule increases with gestational age, which allows the kidney to participate in acid-base homeostasis, near term. This function is mainly related to the maturation of the carbonic anhydrase activity.

The fetus produces hypotonic urine at an elevated rate of 1.5 litres every day. The urine concentration capacity is blunted in the immature kidney. This defect is related to various factors including a low sensitivity of the collecting duct to arginin vasopressin (AVP), a structural immaturity of the loop of Henle with preferential distribution of blood flow to the inner cortex, a low gradient concentration in the medulla due to limited protein intake to generate significant amounts of urea, and a low expression of aquaporin 2 (AQ2). AQ2, a water channel, is located in the apical membrane of collecting duct cells and is involved in water reabsorption. Humans who lack aquaporins have a urine concentrating defect. Expression

of AQs is regulated by the AVP via the V2-receptor. AVP is highly synthesized during the last trimester in pregnancy [11].

Tubular function is dependent on structural maturation of the nephron and on various mediators including the RAS, aldosterone, prostaglandins, atrial natriuretic peptide and cortisol. Cortisol in particular has a potent maturational effect. The sensitivity of renal tubules to such hormonal factors increases along gestation and continues after birth. Such relative tubular immaturity allows the production of amniotic fluid at a sufficient rate and prepares the fetus to the postnatal adaptation [8].

124.2.2 The Newborn

124.2.2.1 Glomerular Function and Renal Blood Flow

GFR is influenced by various factors including blood pressure, renal blood flow and structural determinants. In the neonate, nephrogenesis is completed at birth and the postnatal maturation of glomerular structure consists of an increase in glomerular membrane permeability, in filtration surface area, in corpuscular glomerular diameter (especially in glomeruli from the outer area of cortex), and in intrarenal redistribution of blood flow. Glomerular size reaches adult values at the age of 3 years.

Clearance of endogenous creatinine is widely used to assess GFR in neonates. Creatinine is a metabolite of creatine located in skeletal muscle. Serum levels are correlated with muscle mass. Creatinine is filtered and secreted in part by renal tubular cells. Other markers of GFR including inulin clearance and cystatin C are not used routinely in neonates. Inulin is inert, being not metabolized and neither reabsorbed nor secreted by the renal tubules. Clearance of inulin is the gold standard to evaluate GFR, however it has limited applications in clinical practice. Cystatin C is produced by all nucleated cells and is independent of muscle mass. It is freely filtered, reabsorbed and catabolized in the kidney, which prevents clearance measurement. Serum levels are higher during the neonatal period and stabilize at 12 months of age.

Transition of fetal circulation to extrauterine life is characterized by a rapid increase in systemic blood pressure. In sheep, renal blood flow is low and increases markedly in the first 24 hours after birth rapidly. Renal vascular resistances are elevated immediately after birth and decrease during the first postnatal days. The rapid change in RBF is due to a postnatal decrease in glomerular vascoconstriction, mainly dependent on the RAS. Such hemodynamic changes are associated with increased glomerular capillary hydrostatic pressure, which is still lower than in the adult [12].

At birth, GFR is low compared to adult values, and is correlated with gestational age: 20 mL/min/1.73 m^2 in term and less than 15 mL/min/1.73 m^2 in very low birth weight infants. GFR rapidly increases during the first of month of life (2.5–3 fold increase) (Fig. 124.3) [13]. Postnatal maturation depends on gestational age with a delayed maturation being possibly observed in low birth weight infants (Fig. 124.4). In term neonates plasma creatinine concentration is elevated at birth (60–70 mcmol/L) and stabilizes at the end of the first week (30–40 mcmol/L). In preterms infants, creatinine level at birth is elevated (90–110 mcmol/L), increasing transiently within days 3 to 5 (reaching 130–150 mcmol/L) and then decreases progressively (Fig. 124.5) [14].

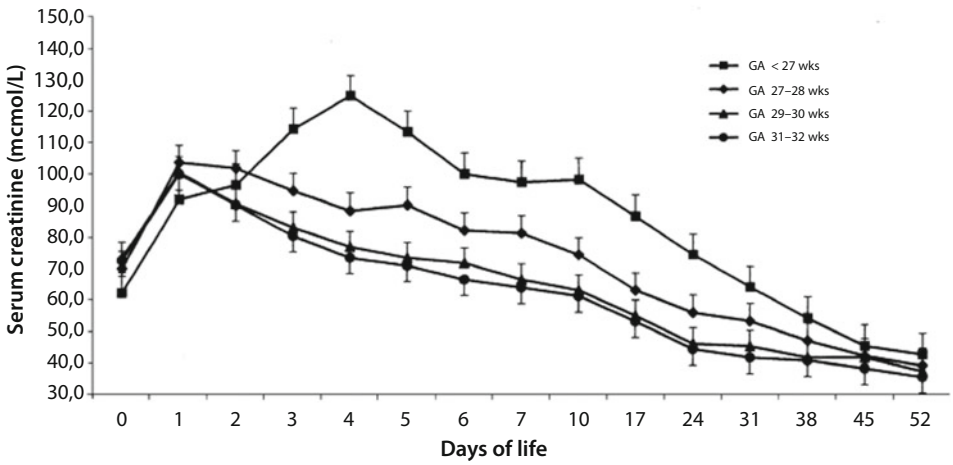

Fig. 124.5 Postnatal maturation of glomerular filtration rate in extremely low gestational age neonates. Reproduced from [14] with permission

GFR is maintained by a delicate balance of vasoconstrictor and vasodilatator forces. Neonates and especially preterm infants are in a state of physiological renal insufficiency. They are at higher risk to develop renal function impairment causes by hypotension, hypovolemia, perinatal asphyxia and nephrotoxic drugs.

124.2.2.2 Tubular Function

The postnatal maturation of renal tubules follows the maturation of GFR. Postnatal maturation is characterized by a 10-fold increase in proximal tubular length and diameter within the weaning period.

After birth, the regulation of homeostasis is transferred from the placenta to the kidney. After birth, postnatal fluid and electrolytic adaptation is characterized by a transient increase in urine output during the first week of life, due to the contraction of the extracellular volume. Commonly, neonates lose around 5–10% of their birth weight. Very low birth weight infants may undergo even a higher weight loss, of up to 15% of birth weight. Fractional excretion of sodium in neonates is around 1%. After birth, maturation of proximal tubules is rapid. In the rat, Na^+/K^+-ATPase activity increases markedly in the first 2 weeks with enhanced expression of proximal NHE exchangers. Fetal and maternal production of endogen glucocorticoids during the neonatal period favours such maturation [8].

The neonate is able to achieve a maximal dilution of urine with urine osmolarity as low as 40–60 mOsm/L. Diluting capacity tends to mature rapidly in the newborn and preterm infants who, at 36th postconceptional age, have a urine dilution capacity comparable to that of adults. Within the limits allowed by GFR, neonates, even preterm infants, tolerate a large range of fluid intake (150 mL/kg/day) without major alterations in water and electrolytes parameters. Diluting capacity is greater than concentrating capacity, which is limited to 400–600 mOsm/L. Children reach the adult maximal urine concentration ability (1300–1400 mOsm/kg) by 2 years of age. This characteristic may be explained by reduced tonicity of the medullary interstitium, low expression of water channels (aquaporins), and a relative tubular insensitivity to ADH. Higher production of prostaglandins E2 in neonates may inhibit the tubular effect of ADH. Low neonatal concentrating capacity is of limited importance in healthy neonates. However neonates and especially preterm infants are more vulnerable to insufficient water intakes and extrarenal water loss (skin loss, diarrhea, etc.), with the risk of osmotic diuresis and hypernatremic dehydration, favored by a lower threshold for renal glucose excretion.

The newborn infant has a diminished threshold for renal bicarbonates excretion. The large expansion of extracellular volume may result in depressed proximal tubular bicarbonate reabsorption. When extracellular fluid is contracted, renal reabsorption increases and urinary pH becomes more acidic. In preterm infants, immaturity of carbonic anhydrase may favour prolonged depressed tubular bicarbonates reabsorption. The normal range for plasma bicarbonates concentration is lower in preterm infants (16–20 mmol/L) than in term infants (21–24 mmol/L).

124.3 Pathophysiology

124.3.1 The Immature Kidney

Nephrogenesis is incomplete in preterm infants. However, recent data have suggested that preterm birth affects postnatal nephrogensis with altered glomerular structure and possibly reduced nephron endowment [15]. Impairment of mesenchymal cell differentiation has been suggested. In comparison with term neonates, GFR is lower in preterm infants and increases progressively after birth [16]. Structural maturation may explain the progressive maturation of GFR in very preterm infants in whom postnatal nephrogenesis continues

after birth. Blood pressure and renal blood flow are low in preterm infants. The immature kidney is particularly dependent on vasodilator forces to maintain a sufficient GFR, allowed by elevated renal vascular resistances from RAS up-regulation. Administration of prostaglandins synthesis inhibitors (indomethacin) for the closure of a patent ductus arteriosus impairs renal function with oliguria, reduced RBF and GFR. Such adverse effect disappears after discontinuation of the drug. Ibuprofen, another COX-inhibitor, is less likely to reduce GFR [17].

Preterm infants are more likely to receive drugs in neonatal intensive care. Most drugs are eliminated by the kidney and undergo glomerular filtration or tubular metabolism, both being immature in preterm infants. Circulating levels of drugs such as vancomycin or aminoglycosids need to be monitor to optimize dosing and reduce toxicity.

Postnatal fluid and electrolytic adaptation is characterized by high water and sodium losses during the first 10 days after birth. Fractional excretion of sodium is elevated in preterm infants (5 *vs* < 1% in term infants) and reach term values progressively after days 15–21. Fluid and electrolytes intakes have to be adapted. Preterm infants are prone to renal water and salt wasting. However, a postnatal contraction of the extracellular fluid volume occurs during the first postnatal days of life and translates into a 2–3% daily, 10–15% total weight loss that should be respected. Moreover the kidney of preterm infants cannot efficiently excrete excessive water and sodium loads, which increases the risk of bronchopulmonary dysplasia, intracerebral hemorrhage and necrotizing enterocolitis. It is thus recommended to introduce sodium, potassium and phosphorus only by postnatal day 2 or 3 and then, when postnatal weight loss is completed, to adapt individually electrolytes intake (especially sodium intake), to maintain a positive balance. Sodium is essential for postnatal growth [18]. Glomerular and tubular consequences of renal immaturity are shown in Table 124.2.

Such glomerular and tubular consequences have been blunted by maternal administration of synthetic glucocorticoids (GC) (betamethasone and dexamethasone). Prenatal administration of GC improves systemic blood pressure, RBF and GFR, and accelerates the maturation of tubular function with enhanced proximal reabsoprtion of sodium and excretion of potassium. Such effects are due to increased expression and activity of sodium exchangers, of Na^+/K^+-ATPase, and to increased renal sympathetic nerve activity [19].

124.3.2 Congenital Renal Tubular Disease

Congenital tubular diseases are rare and include various diseases according to defects in epithelial tubular channels [20]. Bartter syndrome corresponds to a group of tubulopathies involving the regulation and expression of various tubular transporter located in the ascending limb of Henle and the corresponding genes (up-regulation of NKCC2 and ROMK, and down-regulation of Barttin and ClC-Kb). Bartter syndrome is characterized by salt-wasting, by hypovolemia with a low or a preserved arterial blood pressure that activates the RAS, and by metabolic alkalosis. Polyhydramios and hypercalciuria are often observed in fetal and neonatal forms. Treatment consists of adaptation of salt, water and potassium intakes, amiloride and/or indomethacin.

Primary pseudo-hypoaldosteronism is an autosomal recessive disease due to defective epithelial ENaC channel (in collecting ducts). This syndrome is characterized by life threatening salt-wasting, risk of dehydratation and arterial hypotension, severe hyperkaliemia, distal tubular acidosis and hyperaldosteronism. This disease is treated by sodium supplementation. When ENac activity is increased, sodium is exaggeratedly reabsorbed with hypertension, and metabolic hypokaliemia. Renin activity and aldosterone levels are decreased. Liddle syndrome, an autosomal dominant disease, displays such features. Treatment consists in salt restriction and amiloride.

Nephrogenic diabetes insipidus, an X-linked or autosomal transmitted disease, is characterized by polyuria-polydipsia, dehydratation, irritability and failure to thrive. These symptoms are due to a defect in the arginin vasopressin-V2 receptor or in AQ2.

Table 124.2 Glomerular and tubular consequences of immature kidney

Fluid-electrolytes therapy in preterm infants	Glomerular immaturity: consequences	Tubular immaturity: consequences
D1-D2: Volume: 80–100 mL/kg/d Na: 0 K: 0 (except if < 3.5 mmol/L) D3-D5: Volume: 120–140 mL/kg/d Na: 2–4 mmol/kg/d K: 1–2 mmol/kg/d > D5: Volume: 140–170 mL/kg/d Na: 4–6 mmol/kg/d K: 1–3 mmol/kg/d	– Reduced ability to salt/water overload excretion – Hyperkaliemia – High sensitivity to vasoactives drugs – Increased risk of renal failure – Reduced clearance of drugs	– Sodium wasting – Metabolic acidosis – Reduced urine concentration capacity with preserved urine dilution capacity – Glucosuria – Elevated urinary calcium excretion – High sensitivity to diuretics

124.3.3 Parenchymal Consequences of Urinary Tract Anomalies

Congenital abnormalities of the kidney and urinary tract (CAKUT) are a wide range spectrum of anomalies including malformations of uretero-pelvic junction, of vesico-ureteric junction, of vesico-urethral area, and dysplasic kidneys.

124.3.3.1 Renal Structure Changes

The relation between urinary tract obstruction and renal dysplasia is controversial. Renal dysplasia would be the consequence of an induction failure of the metanephrogenic blastema related to urinary obstruction. Obstruction of the collecting system is associated with increase urinary pressure and muscular hypertrophy after an early compliance stage. Early and complete ureteral obstruction in fetal lamb impairs renal architecture with abnormal tubular differentiation, inflammation and reduction of nephron endowment. Changes in renal expression of transcription factors involved in early stage of nephrogensis have been demonstrated in experimental models of fetal ureteral obstruction (Pax2, Wnt). In human, congenital ureteropelvic junction obstruction is associated with renal histologic changes associated with glomerular density, interstitial fibrosis and tubular dilatation [21].

Such complex malformations linking the kidney and urinary tract have been suggested to share common causes. Various defects in specific genes involved in renal development affect kidney parenchyma and urinary tract development (Table 124.1). The quality of the ureteric bud-mesenchyme interaction, the position at which the UB arises from the pronephros, and the pattern of branching morphogenesis are critical for the kidney development. Failure to induce UB outgrowth leads to renal agenesis. An aberrant outgrowth of more than one UB may result in double collecting system and duplication of the ureter. An ectopic positioning of the UB is associated with renal tissue malformation, abnormalities of the uretero-vesical junction, and a defect in the number of branches formed are considered to reduce nephron number endowment at birth (Fig. 124.1).

124.3.3.2 Renal Function Changes

The outcome of CAKUT depends on defects in other organs, on the importance of urinary obstruction and of the alteration of the kidney structure. Early occurrence of urinary tract obstruction, bilateral renal dysplasia, olygohydramnios (with severe fetal renal insufficiency), and reduction of the kidney size across pregnancy are associated with poor prognosis. Biomarkers of renal function in fetal urine have proven of limited interest for the prenatal establishment of prognosis in intermediate cases. Infants with severe abnormalities often die in the perinatal period as a consequence of the Potter's sequence (pulmonary hypoplasia resulting from olygohydramnios and fetal renal function impairement). Survivors may develop renal failure during childhood. Dialysis during the neonatal period, followed by renal transplantation should be discussed with parents and the multidisciplinary nephrology team before and after birth.

Infants with severe obstructive nephropathy are prone to acid-base and hydroelectrolytic balance abnormalities, and to glomerular function impairment. Complete and prolonged fetal uereteral obstruction is associated with decreased RBF and GFR, in proportion to the loss of parenchyma. The RAS is up-regulated in such situations. Infants are prone to type IV renal tubular acidosis (hyperchloremic metabolic acidosis) with hyperkaliemia, salt wasting and defects in urine concentration which are responsible for water wasting and nephrogenic diabetes insipidus. Such tubular dysfunction has been related to changes in tubular channel exchangers characteristics including decreased Na^+/K^+-ATPase activity, unresponsiveness of the damaged distal nephron to aldosterone, with secondary hyperaldosteronism, loss of H^+-ATPase on the surface of intercalated cells, and down-regulation of aquaporins. Treatment of renal infection, adapted protein intake, and limited use or close monitoring of nephrotoxic drugs aim to preserve renal function.

124.3.4 Pharmacological Interactions

The number of pregnant women and women of childbearing age receiving drugs is constant increasing. These drugs can cross the placenta and can impair potentially the function and structure of the fetal kidney. The newborn infant may in turn express renal failure leading to severe renal insufficiency and neonatal death. Selective COX-2 inhibitors and non-selective non steroidal anti-inflammatory drugs (NSAIDs), angiotensin converting enzyme inhibitors ACE-Is and angiotensin type 1 receptor (AT1-R) antagonists are the main drugs affecting the development and the function of perinatal kidney [22].

NSAIDs are used as antalgic or as tocolytic agents (indomethacin) in pregnant women. The renal side effects of in utero exposure to NSAIDs vary from transient fetal oligohydramnios, to severe and lethal renal failure in babies. Quickly after the initiation of indomethacin therapy, a reduction of fetal urine production and oligohydramnios occur. This effect, frequent and transient in many cases, has been the basis of the treatment of polyhydramnios with NSAIDs. The available information originates principally from retrospective and descriptive studies and indicates a rate of incidence from 1.5–20%. Experimental and human studies show that NSAIDs decrease fetal GFR (consequence of renal blood flow reduction) and increase urinary osmolality (enhanced activity of arginin vasopressin). The risk of neonatal renal failure seems increased with prolonged and cumulate doses,

a short time-period between treatment and delivery, pre-existing fetal distress, and low birth weight. In addition to the changes of renal function, a singular renal nephrotoxic dysplasia attributable to chronic antenatal exposure to NSAIDs has been described: the renal mass is reduced, while histologic examination reveals abnormal glomerular and tubular changes including various degrees of ischemic injury and of fibrosis in the medullary area, cortical necrosis, focal tubular and glomerular microcysts of developing nephrons, and loss of differentiation between proximal and distal tubules. Such lesions are associated with increased expression of renin in the juxtaglomerular apparatus. The severity of the renal hypoperfusion induced by NSAIDs may lead to irreversible renal injury involving glomerular and tubular segments, and may distract the development of fetal kidney. Such effects have been noted recently after prenatal exposure to the selective inhibitors of COX-2, a new generation of NSAIDs proposed as an alternative to non specific NSAIDs with the aim of preventing adverse effects.

When administered during pregnancy, inhibitors of the RAS including ACE-Is and AT1-R antagonists, can induce a variety of serious fetal complications, with a high mortality rate. These complications named angiotensin-converting enzyme inhibitor fetopathy include intrauterine growth restriction, profound fetal and neonatal hypotension refractory to any treatment, renal failure, oligohydramnios with limb deformities and pulmonary hypoplasia, hypocalvaria, and increased rate fetal loss. Renal histology shows typically proximal tubular dysgenesia. Numerous cases have been reported with a wide range of adverse fetal and neonatal renal effects varying from transient oligohydramnios (when treatment was arrested rapidly), to severe (requiring peritoneal dialysis) and lethal renal failure. The magnitude of these adverse renal effects cannot be quantified precisely but the risk increases with chronic administration and stage of fetal exposure, especially during the second and third trimester. In contrast, elective exposure during the first trimester of gestation is not associated with an enhanced risk of teratogenicity. When therapy is interrupted rapidly before the 2nd trimester, poor or no adverse renal effects are noted.

Experimental studies have shown that maternal antenatal administration of various drugs can affect nephrogenesis in the absence of clinical renal function impairment in the fetus and newborn infants. In rodents and sheep, antenatal maternal administration glucocorticoids (GCs) at a specific time of pregnancy reduces nephron number and induces hypertension in adult offspring. The mechanism by which GCs alter the fetal kidney structure is unclear. Several pathways are suspected. In utero exposure to GC may 1) disturb the cell differentiation/proliferation ratio at the expense of reduced proliferation, 2) reduce ureteric bud branching, 3) alter gene expression of specific genes involved in kidney development (GNDF), or 4) reduce renal AT1-R and renin gene expression.

Antenatal maternal administration of cyclosporine A (CsA) during gestation (E14–18, and E20–24) affects fetal growth and nephrogenesis leading to a permanent nephron deficit in rat offspring (average of 25–30%). CsA may act through blockage of the conversion of metanephric mesenchyme to epithelium. In humans, outcome of infants exposed in utero to CsA has not shown any changes of renal function and morphology in childhood. But data are too scarce, and long-term follow-up (the maximal age of follow-up was 7 years) is insufficient to conclude definitely in occurrence of side effects in adulthood.

Antenatal maternal administration of ampicillin and aminoglycosides reduces nephron number (20–30%) and induces hypertension in adult rat offspring. Reduced nephron number results from a defect in ureteric bud branching morphogenesis affecting the first branching division. This toxic effect corresponds, in fact, to the first stage of renal development: gentamicin exposure during late stages of nephrogenesis does not induce a nephron deficit. Other aminoglycosides, such amikacin and netilmicin, have less adverse renal effects. Antenatal maternal administration of ampicillin is associated with a 20% reduction of nephron number in rat offspring. An increased rate of apoptosis reaction in mesenchyme area is the suspected leading event of oligonephronia. Such experimental observations have not been found in human.

Other drugs, such as chlorambucil and antineoplasic drugs can impair renal development with urinary tract malformation and renal agenesia.

In most cases, newborn infants do not express clinical renal failure postnatally. However, experimental studies suggest that prenatal exposure to certain drugs may lead to reduced nephron number, followed by hypertension and renal function at adulthood. However, one must be careful in extrapolating data from animals to humans, since major interspecies differences in renal sensitivity to drugs exist, so long-term follow-up of infants exposed in utero to drugs are needed.

124.3.5 Long-Term Consequences of Nephron Number Reduction

It has been suspected for a long time, since the works of Brenner et al in the 80s, that a reduced nephron number is associated with an enhanced risk of hypertension and renal deficiency in adulthood [23]. Reduced nephron number is associated with renal changes including increase in single nephron glomerular filtration rate (SNGFR) and glomerular and tubular hypertrophy. Such hemodynamic changes are responsible for glomerular injury through increase in glomerular capillary hypertension. Over a long time a vicious circle takes place leading to glomerular sclerosis, chronic renal insufficiency and hypertension (Fig. 124.6). Such a hypothesis has been confirmed by experimental studies and human data. Recent data have supported an inverse relationship between reduced nephron number and essential hypertension [24]. An adult born with congenital agenesia is at higher risk of

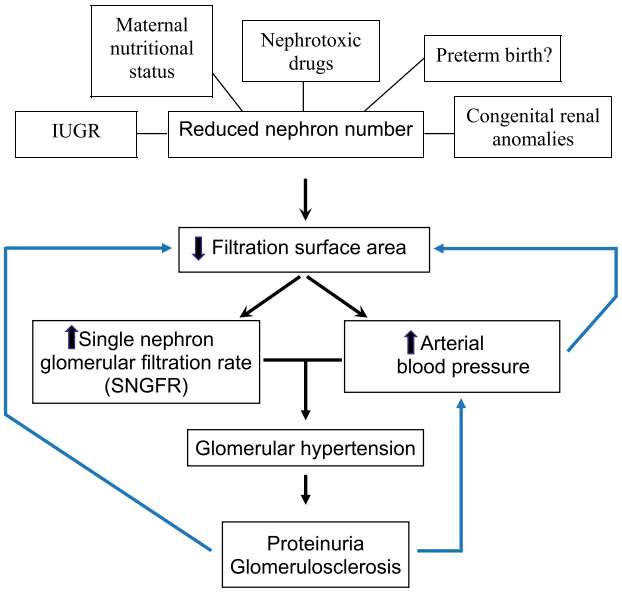

Fig. 124.6 Renal mechanism of systemic hypertension and renal damage, the Brenner hypothesis

developing systemic hypertension and early chronic renal insufficiency [23].

At birth the final nephron number varies from 800,000 to 1 million per kidney. Such variation in nephron number is due to genetic factors and mostly to fetal environment. Various perinatal factors have been shown to induce reduced nephron number including intrauterine growth restriction (IUGR), maternal nutrient deficiency (vitamin A, iron depletion), maternal protein or global nutrition deficit, drugs (see above), maternal and fetal stress, maternal gestational diabetes [2]. In other hand, preterm birth with postnatal adverse environment (postnatal denutrition, stress, nephrotoxic drugs), renal and urinary tract malformations, are associated with impaired nephrogenesis which may lead to reduced nephron endowment.

Such perinatal events are less likely to affect renal functions during the neonatal period but are associated with high risk of hypertension and renal disease at adulthood. Long-term follow-up is needed, with close assessment of blood pressure and renal parameters (creatinine, proteinuria) to prevent adverse evolutive cardiovascular and renal diseases.

Acute and Chronic Renal Failure in the Newborn Infant

Jean-Pierre Guignard and Uma S. Ali

125.1 Introduction

Acute renal failure (ARF) is the consequence of a sudden decrease in glomerular filtration rate with consequent retention of nitrogen waste products and disturbances in water, electrolyte and acid-base balance. Because of its physiological specifics, the premature fetal and neonatal kidneys are particularly vulnerable to common endogenous and exogenous stresses occuring before birth, during delivery or after birth. Clinical studies have shown that 8–24% of all neonates hospitalized in intensive neonatal care units may present with ARF [1–4]. The causes of ARF (Table 125.1) are divided into prerenal (functional), renal (intrinsic) and postrenal (obstructive) causes. Functional pre-renal insufficiency is the most frequent form of ARF. It is preventable if treated early and adequately.

125.1.1 The Fetal Kidney

The fetal kidney lives in a protected environment without real homeostatic responsibilities. Perfusion is limited, the fetal kidney receiving only 3–4% of the cardiac output. Glomerular filtration rate (GFR) is also extremely low in the fetus. Nephrogenesis is complete by 35 weeks of gestation. At birth, the immature kidney is abruptly thrust into an independent extrauterine existence where it has to assume the responsibility of safeguarding the life and well-being of the neonate by providing the moment to moment fine tuning required for body homeostasis [5].

Table 125.1 Normal mean arterial blood pressure in the newborn infant*

Age	< 1.0 kg	1.0–1.5 kg	> 2.5 kg
Birth	33 ± 15	39 ± 18	49 ± 19
1 week	41 ± 15	47 ± 18	60 ± 19
2 weeks	45 ± 15	50 ± 18	64 ± 19
4 weeks	48 ± 15	53 ± 18	68 ± 19

* Mean ± 95% confidence limits for single measurements; measurement via umbilical artery catheterization or by Dynamap. Adapted from [22].

125.1.2 The Neonatal Kidney

Glomerular filtration rate at birth is close to 20 mL/min per 1.73 m^2 in term neonates [5]. It doubles within 2 weeks and reaches 50 mL/min per 1.73 m^2 at 4 weeks of life (Fig. 125.1) [5, 6]. The neonatal kidney is thus in a state of relative physiological renal insufficiency during the first postnatal month and is ill-equipped to handle major homeostatic challenges. The driving force for producing the glomerular filtrate is the systemic arterial pressure which is quite low in the newborn period (Table 125.1).

The two major vasoactive forces that optimize the driving force for filtration are the prostaglandins that relax the afferent arteriolar tone and angiotensin II (ATII) that constricts the efferent arteriole, thus increasing the effective transglomerular pressure gradient (Fig. 125.2). This hydrostatic pressure is opposed by the intratubular pressure as well as by the oncotic pressure, resulting in a net driving force of only a few mmHg [2]. GFR shows a progressive direct correlation with both gestational and postnatal ages [5, 6].

Premature birth increases the renal vulnerability. In healthy premature neonates, nephrogenesis continues after birth, but for only 40 days [7]. Nephrogenesis stops at birth in growth-retarded neonates. Low birthweight infants have consequently a lower number of nephrons as compared to term infants. GFR is lower in low birthweight infants and increases more slowly than in full-term neonates.

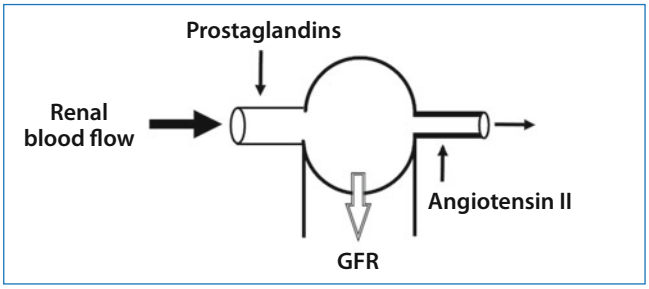

Fig. 125.2 The glomerulus: intrarenal regulation of GFR

125.1.3 Definition

Acute renal failure can be oliguric or non-oliguric, so that urine flow rate cannot define ARF, the diagnosis of which is based on the follow-up of plasma creatinine concentration. ARF is suspected when the plasma creatinine is above 130 µmol/L (15 mg/L) for at least 24–48 h while maternal renal function is normal. In very premature neonates, the elevated plasma creatinine present at birth increases in the first 3–4 days of life because of tubular reabsorption of creatinine across leaky tubules [8]. In clinical practice, repeated measurements of plasma creatinine are used to confirm the presence of ARF.

Oliguria is defined by an urine output less than 1.0 mL/kg per h in preterm and less than 0.5 mL/kg per h in term neonates.

125.2 Etiology and Pathogenesis

125.2.1 Etiology

Risk factors for the development of ARF include perinatal asphyxia, antepartum hemorrhage, sepsis, hyaline membrane disease, administration of non-steroidal anti-inflammatory drugs (NSAIDs) pre- or post-natally and hypernatremic dehydration (Table 125.2) [9]. The primary disease may manifest clinically as respiratory distress in hyaline membrane disease or as lethargy, apnea, poor feeding, prolonged capillary refill and hypotension in sepsis. More than 75% of cases of neonatal renal failure are prerenal in nature. Intrinsic renal failure accounts for less than 10% of the cases and may occur due to drug-induced nephrotoxicity or when the hypoxic-ischemic insults are prolonged or severe [4].

125.2.1.1 Prerenal Causes

All factors that decrease cardiac output can lead to ARF. Some insults to the kidney begin in prenatal life. Fetal hypovolemia as a result of feto-fetal transfusions, feto-maternal transfusions and ante-partum hemorrhage can lead to renal ischemia in utero with or without fetal hypotension resulting in fetal oliguria, oligohydramnios and postnatal renal failure. Hypotension, hypoxemia, metabolic acidosis, metabolic alkalosis, small changes in body temperature, as well as the administration of vasoconstrictive agents are common stresses that increase renal vascular resistance [2]. Cardiac diseases, the persistence of patent ductus arteriosus and hyperviscosity states can also impair cardiac output [1].

Table 125.2 Causes of acute renal failure in neonates

Prerenal
- Hypovolemia or renal hypoperfusion
- Asphyxia
- Respiratory distress syndrome (RDS)
- Dehydration
- Hemorrhage (maternal antepartum, twin-to-twin transfusion, intraventricular bleeding, hemolytic disease)
- Sepsis
- Cardiac disease (patent ductus arteriosus, aortic coarctation)
- Polycythemia (hyperviscosity)

Renal
- Acute tubular necrosis (ATN)
- Persistent prerenal disturbances
- Nephrotoxins (nephrotoxic antibiotics, e.g., aminoglycosides, contrast agents, angiotensin-converting enzyme [ACE] inhibitors and angiotensin II AT1 receptor blockers)
- Myoglobinuria, hemoglobinuria, hyperuricemia
- Vascular disorders (renal vein thrombosis, renal artery thrombosis, aortic thrombosis, disseminated intravascular coagulation)
- Congenital renal anomaly (dysplasia, hypoplasia, polycystic kidney, agenesis)
- Pyelonephritis
- Transient acute renal failure of the neonate
- Maternal etiology (gentamicin, indomethacin, ACE inhibitors, paraproteinemia)

Postrenal
- Congenital anomaly (ureteral or urethral obstruction, neurogenic bladder, magacystis-megaureter)
- Obstruction secondary to circumcision
- Renal candidiasis
- Calculi
- Neurogenic bladder

125.2.1.2 Intrinsic Causes

Persistent prerenal disturbances can lead to acute renal necrosis and severely impaired renal function [3, 4]. The renal parenchyma can also be injured by vascular disorders, renal thrombosis, nephrotoxins, acute pyelonephritis, myoglobinuria and hemoglobinuria. Cortical necrosis may result from severe ischemia and microthrombi formation. Congenital renal anomalies, including hypodysplasia and cystic diseases can favor the occurrence of both ARF and chronic renal failure.

125.2.1.3 Postrenal Causes

Obstruction on the urinary tract, whatever the cause, can lead to ARF. The obstruction can occur at the level of the ureters, the bladder or the urethra. When not relieved immediately, the obstruction can induce permanent damage to the kidney [10].

125.2.1.4 Nephrotoxic Drugs

Nephrotoxicity of drugs may play an important role in producing renal injury [11]. They can affect the fetus when administered to the pregnant mother, or the neonate when administered post-natally. Aminoglycosides may cause renal injury even with normal blood levels due to the high tissue concentrations of the drugs that can be achieved. All cephalosporins are potentially nephrotoxic though clinically the third generation cephalosporins appear to be reasonably safe. Vancomycin needs to be used in appropriate dosages and monitored closely. The use of two simultaneous nephrotoxic drugs should preferably be avoided. Vasoactive drugs interfering with the synthesis of prostaglandins as well as with the renin-angiotensin system are particularly deleterious to the immature kidney [2, 4].

Non-Steroidal Anti-Inflammatory Drugs (NSAIDs)

The maintenance of prenatal as well as postnatal GFR is highly dependent upon prostaglandin-mediated afferent arteriolar dilatation [2]. Inhibition of prostaglandins can decrease renal perfusion and GFR [12], and even lead to severe fetal or neonatal failure that can even be irreversible [13]. In utero exposure to the non-selective NSAIDs inhibitors such as aspirin, indomethacin and ibuprofen have indeed been associated with adverse fetal outcomes such as fetal olguria and neonatal renal failure. Administration of NSAIDs early in pregnancy carries a high-risk of inducing renal tubular dysgenesis in the fetus, with fetal oliguria and oligohydramnios. COX-2 is indeed also expressed in the proximal tubular cells and is believed to play an important role in the differentiation of the renal tubules.

The NSAIDs are cyclo-oxygenase (COX) inhibitors, some of which non-selectively inhibit COX-1 and COX-2, while others selectively inhibit COX-2. Because COX-1 is constitutively expressed in several cell types in the gastrointestinal tract, liver, platelets and kidney, toxicities are fairly commonly encountered when it is inhibited. COX-2 is an inducible enzyme and is not expressed in the gastrointestinal tract and liver. COX-2 inhibitors were thus expected to have a better safety profile. Experimental and clinical studies on nimesulide, a COX-2 selective inhibitor, have shown that the drug can also produce renal tubular dysgenesis and failure when administered pre- or postnatally [14]. When really needed, all NSAIDs must be used with great caution, be it before or after birth [2].

Angiotensin Inhibitors Converting Enzyme Inhibitors (ACEIs) and Angiotensin II AT1 Receptor Blockers (ARBs)

The renin-angiotensin system is highly activated in fetal and neonatal life and the maintenance of a normal GFR in the face of physiologically low arterial pressures is dependent on efferent arteriolar vasoconstriction mediated by angiotensin II [2]. Interfering with the action of angiotensin II by maternal ingestion of ACEIs or ARBs can result in a dramatic fall in GFR leading to fetal oliguria, oligohydramnios and postnatal oliguric renal failure that can be irreversible. Angiotensin II receptors type 2 are expressed prominently during fetal life in the proximal tubules and play an important role in tubular differentiation. Maternal ingestion of ACEIs and ARBs produces a classical fetopathy with renal tubular dysgenesis [15]. Postnatal administration of drugs interfering with the action of angiotensin II can also depress GFR and lead to renal failure. Drugs interfering with angiotensin II must definitively be avoided during pregnancy and used with caution after birth.

Miscellaneous Drugs and Iatrogenic Intervention

Tolazoline, an alpha-adrenergic blocking agent used in the past as a pulmonary vasodilator, as well as D-tubocurarine or pancuronium can increase renal vascular resistance [2].

Ventilation with continuous positive airway-pressure has deleterious effects on renal function due to decreased venous return and low cardiac output, increased renal sympathetic nervous activity and very elevated serum vasopressin levels [2].

125.2.2 Specific Pathogenesis

The hemodynamic effects of stresses such as preterm birth, asphyxia, respiratory distress and sepsis lead to decreased systemic arterial pressure, diminished renal blood flow and a marked increase in the renovascular resistance (Fig. 125.3). These changes further reduce the already small net effective filtration pressure, leading to a clinically deleterious fall in GFR [2].

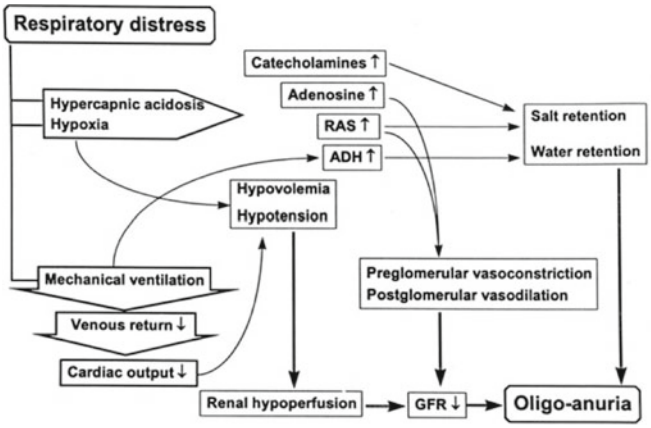

Fig. 125.3 Pathogenesis of hypoxic renal failure. Mechanical ventilation as well as the hypoxemia-induced activation of vasoactive factors contribute to the development of renal hypoperfusion, renal insufficiency, and oligoanuria. Reproduced from [2] with permission

125.2.2.1 Hypoxemic-Hypoxic Insults

Hypoxia is one of the commonest stresses faced by the neonate and it leads to the activation of various potent intrarenal vasoconstrictors such as the catecholamines, angiotensin II, adenosine and endothelin, which play a role in the pathogenesis of ARF. Hypoxic-ischemic insults also activate the intracellular hydrolysis of ATP that generates adenosine. Studies in newborn rabbits have shown that adenosine causes constriction of the afferent arterioles and relaxation of the efferent arterioles leading to a profound drop in GFR. Pretreatment with theophylline, a non-specific adenosine antagonist, prevents the development of ARF in hypoxic animals and asphyxic neonates [16]. Endothelin is a potent vasoconstrictor but its role in the pathogenesis of vasomotor nephropathy is still inconclusive [13]. The occurrence of renal failure in severely asphyxiated neonates is extremely frequent, in up to two-thirds of patients [1–4].

125.2.2.2 Sepsis

ARF in sepsis is part of multiorgan dysfunction and is mediated by both hemodynamic and non-hemodynamic factors. Sepsis-mediated cardiorespiratory depression results in renal hypoperfusion and a decline in GFR that is sustained by various vasoactive substances such as angiotensin II, the catecholamines, adenosine, endothelin and thromboxane A2 [17]. Renal failure can occur in septic states in the absence of altered global hemodynamics. Bacterial lipopolysaccharides (LPS) along with proinflammatory cytokines, free-oxygen radicals, procoagulant and immunological factors generated by the host both intra- and extrarenally contribute to the development of ARF.

Platelet activating factor (PAF) produced by LPS-stimulated resident renal cells as well as by polymorphonuclear leucocytes, plays an important role in the pathogenesis of ARF, producing a fall in renal blood flow and GFR when infused in animals. Intrarenal production of endothelin-1 (ET-1) stimulated by tumor necrosis factor produces a marked fall in renal blood flow and GFR that is ameliorated by administration of ET-1 antibodies or receptor blockers. Endotoxemia also increases the renal expression of inducible nitric oxide synthase mRNA that leads to a fall in blood pressure and decrease in GFR [18, 19]. The intermediate host response to the inciting agent thus results in the sequential production of several inflammatory cytokines and chemical mediators that facilitate the progression of the inflammatory cascade resulting in multiorgan dysfunction and renal failure.

125.3 Clinical Events

Clues to the presence of renal dysfunction may manifest in prenatal life as oligohydramnios. As fetal urine is the major contributor to the amniotic fluid volume, the occurrence of olighydramnios may suggest fetal oliguria and the presence of severely affected kidneys in utero. Bilateral renal agenesis, multicystic dysplastic kidneys, autosomal recessive polycystic kidneys (ARPKD) and obstructive uropathies can all lead to olighydramnios. Late onset olighydramnios is a characteristic finding in renal tubular dysgenesis and warrants a thorough evaluation for exposure to drugs such as NSAIDs, ACEIs and ARBs. The technological and pharmacological interventions used to improve the outcome of sick neonates may themselves contribute to the occurrence of ARF.

Mechanical ventilation reduces the preload by increasing the intrathoracic pressure and results in decreased cardiac output and renal perfusion. Mechanical ventilation *per se* may generate cytokines and chemical mediators that lead to multiorgan dysfunction [20]. Vasoactive infusions used to maintain normotension may lead to excessive splanchnic vasoconstriction, renal ischemia and ARF. Umbilical artery and vein catheterization can lead to renal artery or renal vein thrombosis. Indwelling urinary catheters favor the occurrence of urinary tract infections and the use of broad-spectrum antibiotics may result in the development of fungal urinary tract infections (UTIs) and fungal bezoars [1].

125.3.1 Physical Features

The presence of external features such as Potter's facies, preauricular tags, polydactyly, single umbilical artery or sacral abnormalities may indicate the presence of an underlying developmental renal anomaly. Enlarged kidneys may indicate autosomal polycystic renal disease or obstructive uropathy. Palpable bladder and a poor stream of urine in a male child

suggest the presence of posterior urethral valves. Although these congenital uropathies may present as acute renal failure they are chronic problems that tend to be persistent or progressive in nature [21].

Edema due to fluid overload, hypoproteinemia or capillary leak may complicate the clinical course. Hypotension due to hypovolemia, sepsis or cardiac dysfunction may coexist. Hypertension due to renal failure may be encountered during the course of illness as a result of volume overload or a high renin state. Recognition of hypertension requires reference to appropriate charts as the normal range of blood pressure in neonates would vary depending on gestational age, weight and postnatal age (Table 125.1) [22].

125.3.2 Oliguric ARF

Thirty percent of normal newborns void soon after birth; 92% will void within the first 24 h and 99% by 48 h. Oliguria is observed in the majority of neonates presenting with ARF. Oliguria can also result from poor fluid intake or be due to inappropriate ADH secretion in sick neonates.

125.3.3 Non-Oliguric ARF

One fourth to one third of neonates with ARF may have non-oliguric failure and the renal failure can only be recognized by the finding of elevated urea and serum creatinine concentrations. Birth asphyxia, aminoglycoside therapy and methoxyflurane anesthesia are some of the conditions leading to non-oliguric renal failure [23].

125.4 Laboratory Evaluation

125.4.1 Urinalysis

Urinalysis in vasomotor nephropathy may show normal urine, epithelial cells and coarse granular casts, normal urine, or mild proteinuria, microscopic hematuria, epithelial cells and coarse granular casts. Gross or microscopic hematuria is usually seen in renal vein thrombosis and sometimes in urinary tract infections. Pus cells or pus cell casts reflect severe UTI.

125.4.2 Blood Count

Anemia is present in neonates with ARF, in whom it may also reflect bleeding or dilution by fluid retention. Eosinophilia suggests an allergic reaction to drugs.

125.4.3 Plasma Urea

Azotemia refers to the retention of nitrogenous waste products and is detected by the finding of elevated levels of plasma urea and creatinine. Plasma urea is a poor marker of renal function as it is influenced by multiple factors such as protein intake, urine output, gastrointestinal bleeding and a hypercatabolic state. It may be deceptively low in sick neonates as a result of poor protein intake.

125.4.4 Plasma Creatinine

Creatinine is the most widely used surrogate marker for GFR albeit not a perfect one as it is not only filtered by the glomeruli but also secreted by the renal tubules in term neonates. The serum creatinine in the first few days of life reflects maternal creatinine levels and gradually comes down to normal neonatal levels close to 4 mg/L (35 μmol/L) by one week of age in term infants. In preterm babies the creatinine may actually rise further before falling slowly to normal neonatal levels over 2–3 weeks (Fig. 125.4). [24, 25]. This increase occurs because of back-leak of filtered creatinine through leaky immature tubules [8]. Failure of plasma creatinine to decrease below maternal levels after the first few days of life or a rise in serum creatinine greater than 25–30 μmol/L (3 mg/L) per day is indicative of acute renal failure [1].

Creatinine levels may also be artefactually elevated depending on the associated co-morbid conditions as well as the methodology employed for its estimation. In the commonly used Jaffe's method that also measures non-creatinine chromogens, creatinine levels may be spuriously high in the presence of hyperbilirubinemia or treatment with cephalosporins. However, the use of newer techniques such as the kinetic or

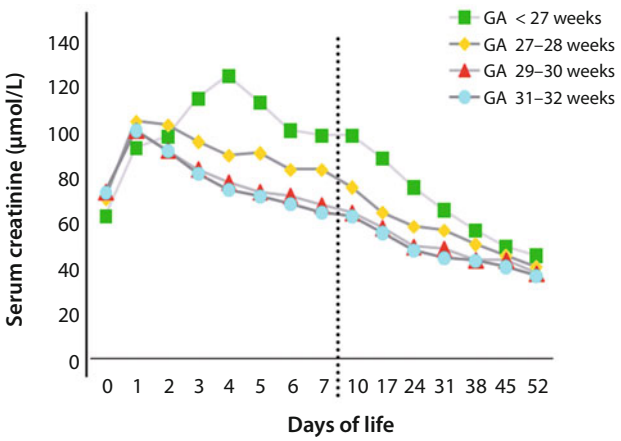

Fig. 125.4 Plasma creatinine in the first weeks of life of premature neonates. Reproduced from [24] with permission

enzymatic assays does not measure these chromogens and give truer values of creatinine. Further improvement in measuring creatinine has recently been achieved by the use of newer techniques such as the high-performance liquid chromatography and the gas chromatography-isotope dilution mass spectrometry [26].

125.4.5 Plasma Cystatin C

Cystatin C, a non-glycosated 13-kDa basic protein produced by all nucleated cells has been claimed to be a better glomerular marker than creatinine. Cystatin C is freely filtered, almost completely reabsorbed and catabolized by proximal tubular cells. However, the clinical use of this marker suffers important drawbacks:

a. the handling of this product by the immature tubular cells, in particular when they are injured is not known;
b. its production and concentration is influenced by factors independent of GFR, such as rises in serum protein C-reactive levels, thyroid dysfunction or corticosteroid administration; and
c. its measurement is considerably more expensive than that of creatinine, by a factor of at least 12 [26].

125.4.6 Urinary Indices

Chemical analysis of urine may help in distinguishing prerenal from intrinsic ARF. Previously healthy kidneys respond to acute hypoperfusion by maximally conserving water and electrolyte, thus excreting concentrated urine with low sodium concentration (U_{Na}). By contrast an intrinsically damaged kidney is not able to concentrate urine and retain sodium. Therefore a urinary osmolality (U_{osm}) above 400 mosm per kg H_20, a U_{Na} below 40 mmol/L and a fractional excretion of sodium (FE_{Na}) below 2% suggest the presence of a prerenal functional problem. The assessment of FE_{Na} is more reliable than the U_{Na} only. It should be noted that these urinary indices are only valid when measured before the administration of volume expanders or diuretics, and that they cannot be used in very premature salt-wasting neonates who may normally present with FE_{Na} above 5% [1–4].

125.5 Imaging

Imaging of the genitourinary tract by ultrasound is useful for assessing the size, the shape and the echogenicity of the kidneys; for diagnosing pelvicalyceal dilatation; and for examining the ureters and the bladder. Imaging is almost an extension of the clinical examination and gives highly valuable diagnostic information. Evaluation of the renal vessels by color Doppler gives important information regarding the presence of renal vein or renal arterial thrombosis. Radionuclear scan may be useful in suspected cases of obstructive uropathy.

125.6 Conservative Management

125.6.1 Management of Suspected Prerenal Oliguric ARF

Acute renal failure should be proactively detected in the neonatal intensive care unit by regular monitoring of urine output and serial measurements of serum creatinine. As the cause of ARF is generally multifactorial, reassessment of both the primary problem and all the therapeutic interventions needs to be done in order to identify the contributory factors. When feasible, nephrotoxic drugs should be substituted by non-nephrotoxic agents. Drug dosages should to be adjusted to the presupposed level of GFR [27] (see Table 125.3).

125.6.1.1 Fluid Challenge and Rehydration

In the prerenal types of ARF, restoration of volume by the administration of 20 mL/kg of normal saline over 1–2 h usually improves urine output (see Fig. 125.4). Such administration should not be given when there is clinical evidence of fluid overload or strong suspicion of a cardiac cause for the prerenal failure. In neonates with fluid refractory hypotension, dopamine infusion should be started to improve blood pressure and renal perfusion. Low-dose hydrocortisone may be useful in fluid and dopamine refractory hypotension [28].

128.6.1.2 Low-Dose Dopamine

The use of low, non-pressor doses of dopamine in preterm babies with hyaline membrane disease has been claimed to im-

Table 125.3 Drugs requiring dose adjustment when GFR is compromized

Antibiotics
– Aminoglycoides (amikacin, gentamicin, totramycin)
– Amoxycillin, amoxycillin-clavulanic acid
– Cephalosporin (cefixime, cefotaxime, ceftazidime)
– Cotrimoxazole
– Ticarcillin
– Vancomycin
Antifungial agents
– Fluconazole
Cardiac drugs
– Digoxin

prove renal blood flow, natriuresis and diuresis, and produce a modest improvement in renal function [29]. The renal vasodilatory and diuretic response presumably results from stimulation of dopaminergic receptors that occurs with low-dose dopamine. Higher doses lead to alpha-receptor stimulation that causes systemic vasoconstriction as well as an increase in renal vascular resistance. What constitutes a renal vasodilator dose in a given patient is not always clear and has varied from 2.5–6 μg /kg per min. Variations in the dopaminergic receptor density, increase in half-life of dopamine, decreased adrenoreceptor sensitivity mediated by extreme prematurity, systemic hypoperfusion and other pathological states may be responsible for the variations in the renal vasodilatory dose. What may be a vasodilator dose in one baby may be a pressor dose in another. Dopamine can have several adverse effects such as tachycardia, cardiac arrhythmia and increase in pulmonary vascular resistance. The modest benefits that may be obtained in some babies with low-dose dopamine have to be weighed against the possible adverse effects of the drug. Noteworthy is the fact that all neonatal studies in favor of the renal doses of dopamine were uncontrolled, and that a placebo-controlled randomized study in adult patients failed to demonstrate that low-dose dopamine could protect the stressed kidney [30].

125.6.1.3 Furosemide

When urine output fails to improve after fluid repletion, a trial of diuretics can be given. Intravenous furosemide at 1–3 mg/kg may improve the diuresis. The natriuretic and diuretic responses to furosemide are highly variable and depend on the level of GFR. When a diuretic response is present, it carries the risk of inducing hyponatremia, with consequent vasoconstriction of the kidney. Torasemide, a loop diuretic with close similarities to furosemide, is sometimes used instead of furosemide. When given to immature rabbits undergoing hypoxemic vasomotor nephropathy, torasemide has been shown to increase sodium excretion and urine output without improving renal perfusion and GFR [31]. Clearly, loop diuretics should basically not be used to treat oliguric neonates, but primarily those presenting with edematous states and congestive heart failure. When given together, dopamine and furosemide have been claimed to have a synergetic effect in increasing urine output. It remains questionable whether this would also improve renal function.

125.6.1.4 Mannitol

Mannitol is best avoided in the neonate as it can increase intravascular volume and produce fluid overload in the absence of diuresis. Being hyperosmolar it should be especially avoided in premature babies as it may give rise to intracranial hemorrhage. Mannitol itself can cause or exacerbate ARF.

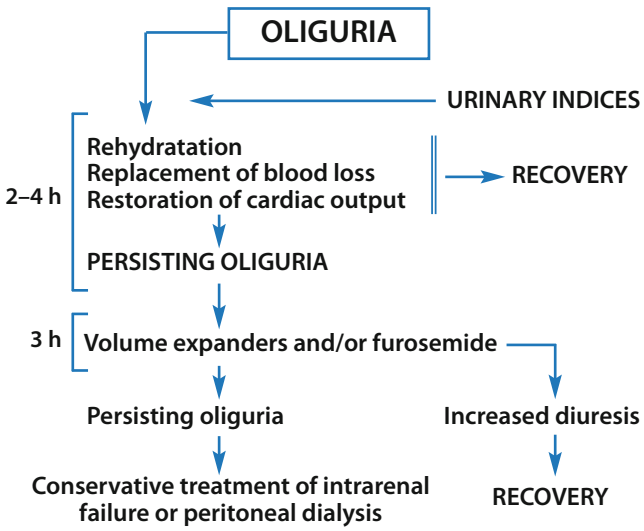

Fig. 125.5 Management of acute renal failure

125.6.2 Fluid Management in Neonates with Intrinsic ARF

Oliguric neonates who fail to respond to the above maneuvers (Fig. 125.5) should be considered to have intrinsic renal failure and require additional measures to prevent major homeostatic disturbances [32]. In those neonates responding to the above measures by an increase in urine output, a progressive fall in the serum creatinine is observed. Persistence of elevated creatinine, or increases in creatinine levels in the face of a good urine output suggests the presence of non-oliguric renal failure. In a normal neonate with intact renal function urine output contributes to 50–80% of the total fluids administered and varies with the amount of solute needed to be excreted. In oliguric neonates, fluid administration should be restricted to insensible water losses plus the ongoing renal and extrarenal losses. The insensible water losses in full-term neonates amounts to 35 mL/kg per day whereas in preterms this may vary from 60–70 mL/kg per day. The fluid administered should be electrolyte-free and the concentration of glucose adjusted to deliver the adequate amount of glucose. Daily weight is the best parameter to judge adequacy of fluid management. In oligo-anuric neonates a daily weight loss of 0.5% is expected and reflects appropriate fluid balance.

125.6.3 Electrolyte Disorders

125.6.3.1 Hyponatremia

Hyponatremia when present is dilutional in nature and should not be treated by giving sodium chloride. Free-water admin-

istration should be restricted instead to produce a gradual increase in the serum sodium concentration. However, when the serum sodium level is less than 120 mmol/L, it can give rise to cerebral edema that may manifest as lethargy, seizures and apnea. In such situations 3% NaCl may be given iv at a slow rate of 5–6 mL/kg over 2–4 hours. The amount of sodium required to correct the hyponatremia can also be estimated by the formula:

$$\text{Na (mmol)} = [\text{desired Na-actual Na (mmol/L)}] \times (0.8 \times \text{BW})$$

where BW represents body weight (in kg) and 0.8 × BW represents total body water.

125.6.3.2 Hyperkalemia

Elevated potassium levels are fairly common in ARF. Care should be taken to confirm that potassium has been eliminated from the iv infusions and that medications containing potassium are not administered. Mild to moderate hyperkalemia of 6–6.5 mmol/L without electrocardiographic (ECG) changes may require nothing more than the correction of co-existing metabolic acidosis. Higher levels of potassium or the presence of ECG changes require active cardio-protective measures that include intravenous calcium administration (0.5–1.0 mL/kg of 10% calcium gluconate, over 5 min under ECG surveillance), and glucose-insulin infusions. The benefit of adding inhaled albuterol to the infusion of glucose-insulin awaits confirmation. When the neonate is still passing urine, diuretics such as furosemide (1 mg/kg) can be tried. The use of potassium binding resins is not without risk in infants. It may cause gastric erosions when given orally and colonic ulcerations and impaction when given rectally. They are best avoided in a sick neonate [33]. Severe hyperkalemia (> 7.5 mmol/L) and/or major ECG changes represent an indication for dialysis.

125.6.3.3 Hypocalcemia

Hypocalcemia is common but the ionic fraction may not be very low because of concomitant hypoalbuminemia and metabolic acidosis. When the hypocalcemia is symptomatic intravenous calcium gluconate (10% calcium gluconate at a dose of 0.5–1.0 mL/kg in 5 min under cardiac monitoring) needs to be given and repeated every 6–8 h. Caution is required in the administration of iv calcium in the presence of hyperphosphatemia, as it may lead to soft tissue calcification and nephrocalcinosis.

125.6.3.4 Hyperphosphatemia

Hyperphosphatemia is common in neonates with renal failure. Calcium-containing phosphate binders such as calcium carbonate may be used although severe hyperphosphatemia is best treated with dialysis. Aluminum containing phosphate binders are best avoided.

125.6.3.5 Acidosis

Mild metabolic acidosis is common in renal failure. When the plasma bicarbonate concentration falls below 12 mmol/L and/or the plasma pH below 7.20, correction of the acidosis is best achieved by adding sodium bicarbonate to the maintenance fluid.

125.6.4 Convulsions

Convulsions are the consequence of electrolyte imbalance or arterial hypertension. Symptomatic therapy is achieved by giving diazepam (0.2 mg/kg iv or rectally), iv lorazepam (0.05–0,1 mg/kg), or iv phenobarbital (15–20 mg/kg).

125.6.5 Hypertension

Hypertension may occur as a result of volume overload as well as hyperreninemia.

Severe or symptomatic hypertension is best treated with continuous iv infusion of nicardipine. Esmolol, enalaprilat, or sodium nitroprusside can be used with caution (Table 125.4) [1, 4]. The optimal oral therapy for newborns is not clearly known. ACE inhibitors notably captopril has been used in neonatal hypertension. However its use in the context of neonatal renal failure is risky. If necessary it should be used cautiously in small doses. Calcium channel blockers can be used as first line drugs. Beta blockers should be used with caution and are best avoided in babies with coexisting respiratory problems. In these babies diuretics may form a good adjunct.

125.6.6 Sepsis

Severe infection is a common cause of death in neonates with ARF. Adequate intravenous antibiotherapy is essential. The dosage of drugs excreted mainly by the kidney (aminoglycosides, vancomycin) must be adapted to the severity of renal failure. When possible, monitoring of plasma concentrations is recommended.

Table 125.4 Antihypertensive drugs in the neonate

Agent	Starting dosage	Intervals	Maximum recommended	Route of administration
Furosemide	1 mg/kg	q 4–6 h	5 mg/kg/day	O/IV
Hydrochlorothiazide	1 mg/kg	q 8 h	3 mg/kg/day	O
Propranolol	0.25 mg/kg/dose	q 6-8 h	5 mg/kg/day	O/IV
Atenolol	0.5 mg/kg/dose	q 12–24 h	4 mg/kg/day	O
Labetalol	0.5 mg/kg/dose	q 1–4 h	2 mg/kg/day	IV
Sodium nitroprusside	0.5 µg/kg/min	–	6 µg/kg/min	IV
Captopril	0.1 mg/kg/dose	q 8–12h	0.5 mg/kg/day	O
Enalapril	5 µg/kg/dose	q 8–24 h	20 µg/kg/day	IV
Nifedipine	0.5 mg/kg/dose	q 4–6 h	2 mg/kg/day	O

125.6.7 Nutrition

Unless aggressively managed, neonatal renal failure invariably results in nutritional failure. Nutritional inadequacy is an important contributor to neonatal mortality. Enteral nutrition when feasible should consist of appropriate formulae that are calorically dense with a low electrolyte content. Neonates require 120 kcal/kg per day. Protein restriction should be avoided in neonates. When enteral nutrition is not feasible, it may be necessary to resort to parenteral nutrition. High concentrations of glucose need to be given to provide the required non-protein calories in the limited permissible volume necessitating central venous access.

125.7 Acute Renal Replacement Therapy

Acute renal replacement therapy (RRT) is indicated when the renal failure produces serious disturbances such as fluid overload, severe hyperkalemia, uncontrolled metabolic acidosis, hyperphosphatemia or hyponatremia unresponsive to fluid restriction [1, 3, 4]. Even in the absence of these indications, RRT may be required to create enough fluid space by ultrafiltration to enable administration of the necessary medications, blood products and nutrition that the child may need.

125.7.1 Peritoneal Dialysis

Peritoneal dialysis is the most common and widely used option for RRT in this age group [3, 4]. It is easily instituted even in the very low birthweight infant with either percutaneous bedside placement of a stiff catheter or surgical placement of a soft Tenchkoff catheter. Acutely ill babies on ventilator may not tolerate large intraperitoneal volumes. Small volumes with short dwelling-times may suffice to tackle the acute life threatening problems. Bicarbonate dialysis is needed in children with liver dysfunction or advanced sepsis as use of lactate-based dialysis fluid may lead to worsening of acidosis in these babies. The presence of intra-abdominal pathology may preclude the use of the peritoneum for dialysis.

125.7.2 Hemodialysis

Hemodialysis is infrequently used in this age group and can be considered only in hemodynamically stable babies. In neonates it requires the availability of suitably small dialysers and tubings. Blood or albumin priming of the lines and filter is usually needed. It can only be done in units where sufficient technical expertise is available.

125.7.3 Continuous Venovenous Hemofiltration

Continuous venovenous hemofiltration is a modality that can be used in sick neonates requiring renal replacement. It allows greater fluid removal, better hemodynamic stability and better nutrition. Its use in critically-ill children with renal failure is increasing steadily and 30% of centers surveyed in North America considered it as the preferential mode of treatment irrespective of age [34].

125.8 Outcome

Despite major advances in both neonatology and nephrology the mortality in neonates with ARF is fairly high and ranges from 45 to 60% [35]. Neonates with prerenal failure have a much better outcome than those with intrinsic renal failure. The worst outcome is seen in babies with intrinsic renal failure in the context of multiple organ dysfunction. As the de-

velopment of renal failure is a reflection of the severity of illness, it is not surprising that the mortality is so high. Babies with non-oliguric renal failure have a much better outcome than those with oligo-anuric renal failure [35].

Following recovery from the ARF, residual renal dysfunction may be seen in more than half the babies without an underlying congenital uropathy [21]. Incomplete recovery is invariable in those neonates who have suffered cortical necrosis. Although numerically not a large group, babies with *in utero* exposure to NSAIDs, ACEIs or ARB have a poor renal outcome and are likely to have persistent irreversible renal failure. Long-term follow-up of ELBW infants with neonatal renal failure has shown that nearly 45% of the children show a decrease in GFR over time. Urine proteins/creatine ratio > 70 g/mol creatinine (0.6 mg/mg creatinine) and serum creatinine > 55 μmol/L (6 mg/L) at 1 year of age were predictors of a poor prognosis for long-term renal function [36].

125.9 Present and Future Challenges

The challenges that lies before us are the following: a) to find markers that could detect renal injury much before it develops into renal failure; b) to find pharmacological measures that could prevent the development of renal failure in babies faced with stressful renal situations; c) to identify measures that would ameliorate renal failure and hasten renal recovery.

125.9.1 Early Diagnosis

Creatinine is an insensitive biomarker for GFR especially in the neonatal period and is blind to the early fall in GFR. More sensitive biomarkers are required that will facilitate early identification of renal injury. The hope that cystatin C could play such a role appears illusory [26]. The appearance of markers of renal tubular injury in the urine may precede the changes in GFR and may help in the diagnosis of acute kidney injury even before failure sets in. Biomarkers of renal injury such as NGAL, KIM-1 and IL-18 have been shown to appear in the urine more than 24 hours before the rise in serum creatinine and may serve as early diagnostic tools in the recognition of renal injury.

125.9.2 Prevention and Amelioration of Renal Failure

125.9.2.1 Animal Studies

Several pharmacological measures have shown varying degrees of success in preventing or ameliorating renal failure in experimental animals. Agents that favorably modulate renal hemodynamics as well as agents that counteract the mechanisms mediating cellular injury have been studied.

Protection of the renal hemodyamics has been attempted by the use of selective antagonists to endogenously produced vasoconstrictors or by the use of renal vasodilators. Selective antagonists that have been used with success include theophylline in hypoxia-induced renal failure and endothelin antagonists in sepsis. Atrial natriuretic peptide, a potent renal vasodilator, has also shown some promising results. Hypoxic ischemic insults to the kidney lead to renal tubular injury by cellular depletion of ATP as well as intracellular accumulations of calcium. Measures to restore cellular ATP by administration of ATP-$MgCl_2$ appear to ameliorate the hypoxemia- induced ARF in animals. Thyroxine also hastens cellular repair and renal recovery by restoration of cellular ATP and may prevent reoxygenation injury [2, 4]. Pretreatment with calcium channel blockers prevents the intracellular accumulation of calcium and the intense vasoconstriction that occurs with various renal insults such as ischemia and cyclosporine administration.

125.9.2.2 Human Studies

Many of the vasoactive agents have pronounced systemic effects or could potentially affect extrarenal organs and systems that preclude their routine clinical use until validated by human studies. Low-dose theophylline has shown promises when used to prevent renal failure in neonates undergoing perinatal asphyxia or respiratory distress syndrome [4, 26, 37–39]. In two small studies thyroxine has been used in neonates with hypoxemic renal failure with recovery of renal function. The possibility of using pharmacological measures to prevent renal failure needs to be systematically studied in humans before it can translate into standard clinical practice. The most important measures to prevent acute neonatal renal failure is to pay attention to general measures that include adequate hydration and maintenance of electrolyte and acid-base balance, and to limit the use of nephrotoxic drugs including NSAIDs in the hemodynamically-vulnerable perinatal period.

125.10 Chronic Renal Failure

125.10.1 Causes of Chronic Renal Failure in Newborn Infants

In certain circumstances, infants presenting with ARF do not recover completely and enter a state of chronic renal failure (CRF). Other babies present from the start with a chronic state of renal failure. The main neonatal causes leading to CRF are listed in Table 125.5. Prolonged ischemia can lead to irreversible tubular necrosis and cortical necrosis.

Table 125.5 Causes of chronic renal failure in the first year of life *

Cause	No of patients
Renal dysplasia	18 (37%)
Obstructive uropathy	16 (33%)
Polycystic kidney disease	5 (10%)
Congenital nephrotic syndrome	5 (10%)
VACTERL association	3 (6%)
Denys-Drash syndrome	1 (2%)
Unknown origin	1 (2%)
Antifungal agents (Fluconazole)	–
Cardiac drugs (Digoxin)	–

* Data from 49 infants. Reproduced from [40] with permission.

Congenital abnormalities of the kidneys and urinary tract are the most common causes of CRF, and include renal hypoplasia and cystic dysplasia, polycystic disease of the kidney, severe obstructive uropathy or reflux nephropathy, and posterior urethral valves [10, 21]. Vascular disorders such as renal vein or artery thrombosis, prolonged ischemia with subsequent irreversible tubular or cortical necrosis, disseminated intravascular coagulation and hemolytic disease with massive myoglobinuria represent acquired causes of CRF. Congenital forms (finnish type) of nephrotic syndrome can also induce early onset CRF.

125.10.2 Presentation

125.10.2.1 Malformative Uropathies

Antenatal ultrasound may reveal anomalies of the kidney, bladder and urinary tract that can permanently compromise postnatal renal function. Obstruction to urine flow by posterior urethral valves results in bilateral hydronephrosis and hydroureter, distended thick-walled bladder, dilated urethra and renal dysplasia [41]. The associated oligo-anuria and oligohydramnios may be the cause of marked pulmonary hypoplasia. Optimal management of posterior urethral valves requires a multidisciplinary approach by obstetricians, neonatologists, pediatric nephrologists and urologists.

After birth, the presence of a palpable abdominal mass or bladder may be the first clue to underlying CRF. Ultrasound examination usually leads to the diagnosis. The occurence of urinary tract infection is often the first clinical manifestation of congenital uropathies [10].

125.10.2.2 Failure to Thrive and Anemia

Failure to thrive, usually associated with poor and difficult feeding, is almost always present in infants with chronic renal failure [42]. Normochromic-normocytic anemia, secondary to the uremic state, is a manifestation of a decrease in erythropoietin formation by the sick kidneys.

125.10.2.3 Hypertension and Congestive Heart Failure

Arterial hypertension may have a renovascular origin, or be secondary to salt and water overload with or without congestive heart failure. Loop diuretics are indicated.

125.10.2.4 Nephrotic Syndrome

The presence of edema, heavy proteinuria and hypoalbuminemia at birth indicates the presence of a nephrotic syndrome, usually of the finnish type. The prognosis is extremely poor, the infants dying from sepsis or developing chronic renal failure in the first weeks of life.

125.10.3 Management of Chronic Renal Failure

125.10.3.1 Nutrition

Adequate nutritional therapy is essential to preserve the growth of the infant. An energy intake of 115 kcal/kg is necessary to sustain growth during the first 3 months of life, with appropriate calcium, phosphorus and sodium intakes. Many anorexic infants require calorie supplements (glucose polymers or fat emulsions) that often can only be administered by naso-gastric or gastrostomy tubings. The help of a skilled pediatric dietetician is mandatory to provide optimal nutrition in infants with CRF. When nutritional intervention fails to improve growth, treatment with growth hormone must be considered [43].

125.10.3.2 Fluid, Electrolyte and Acid-Base Balance

Most infants with CRF present with metabolic acidosis, hypocalcemia, hyperphosphatemia. These factors all inhibit growth. The acidosis must thus be compensated by the administration of sodium bicarbonate (2–3 mmol/kg per day), with the risk of inducing arterial hypertension; the hypocalcemia and the hyperphosphatemia by the administration of calcium carbonate (starting dose: 100 mg/kg per day). The levels of parathormone (PTH) may be increased in response to both hypocalcemia and hyperphosphatemia, the administration of calcium not being sufficient to prevent the occurrence of hyperparathyroidism and renal osteodystrophy. In this case, the administration of calcitriol (1,25-dihydroxycholecalciferol), orally or intraperitoneally, may be necessary [44].

125.10.3.3 Anemia

The anemia associated with CRF is due to inadequate production of erythropoietin by the kidney. Recombinant alpha or beta erythropoietin, given weekly or twice monthly by sc or iv injection, will correct the anemia.

125.10.3.4 Arterial Hypertension

When hypervolemia contributes to the hypertension, loop diuretics (furosemide, torasemide) or metozalone can be administered. ACE inhibitors or ARBs are particularly effective in renin-dependent hypertension. But drugs interfering with angiotensin II can induce a sharp decrease in GFR in volume-depleted patients because of an acute decrease in intraglomerular pressure. Calcium channel blockers are usually well-tolerated. The use of beta-blockers is limited because of the risk of symptomatic bradycardia [22].

125.10.4 Renal Replacement Therapy

Failure to normalize growth or to control the electrolyte disturbances is an indication to start dialysis. In neonates and infants, peritoneal dialysis is the method of choice [45]. It is easy to perform, and has been shown to be effective. It can be used until the child can undergo renal transplantation. Peritoneal dialysis can be performed manually with 4–5 dialysis fluid exchanges a day. When available it is best performed using an automated cycling machine that can deliver 8–10 exchanges over 8–10 hours. Although providing effective renal replacement therapy [46], peritoneal dialysis in infants carries a significant risk of infection and death, with repeated episodes of peritonitis. For parents, the burden of long-term peritoneal treatment in infants is substantial [32, 47].

No neonate with CRF should be started on RRT unless there is a hope for later kidney transplantation. Full immunization should be completed before considering transplantation, usually only after a body weight of 8–10 kg, and an age of 2–3 years are attained.

125.11 Conclusions

The morbidity rate of ARF in newborn infants is elevated. In those developing CRF, RRT is possible with relative success. Decisions concerning RRT must be discussed with the family and an expert ethical committee, keeping in mind the long-term outcome of severe CRF in very young children. In developed countries this outcome is globally as follows: one third of the infants die, half have a functioning renal graft and the rest will have returned to dialysis in the first years of life [32].

Diagnosis and Treatment of Renal and Urinary Tract Malformations

Vassilios Fanos, Marco Zaffanello and Michele Mussap

126.1 Introduction

Renal and urinary tract malformations in newborns are mostly congenital anomalies with genetic bases. The routine of antenatal ultrasound (US) scans has resulted in the early detection of these conditions and in selected cases has leaded to the development of prenatal management strategies including fetal intervention and/or the organization of the diagnostic procedures, postnatal surgical intervention and/or clinical follow-up. In minor cases, where diagnosis is not allowed during prenatal life, it may be obtained after a postnatal routine follow-up or subsequently a clinical complication, generally urinary tract infection (UTI).

126.2 Etiology and Pathogenesis

The development of the kidney results from the interaction between the ureteral bud and the metanephrogenic mesoderm in the intermediate mesodermal layer. At the fifth week of embryonic development, the ureteral bud grows and comes in close contact with mesodermal elements. The ureteral bud undergoes a series of divisions, which give rise to the pelvicalyceal system. At the same time, mesoderm differentiates to form the nephrons, a process that is completed by 36 weeks of gestation. During intrauterine life, the placenta provides the main source of fluid and electrolyte regulation. Therefore, urine secreted by the fetal kidney provides the main volume of the amniotic fluid [1].

Several genes may have roles in multiple stages of kidney and lower urinary tract morphogenesis. Specific mutations of genes involved in renal tract development have been found in individuals with familial occurrence.

and Neonatal Section, University of Cagliari, Cagliari, Italy

126.2.1 Genetic Factors

A spectrum of renal tract malformations is part of the genetically defined syndromes with Mendelian distribution of inheritance that could be classified as syndromic and nonsyndromic urinary tract malformations.

126.2.1.1 Syndromic Renal and Urinary Tract Malformations

Edith Potter subdivided cystic dysplastic kidney (CDKs) into those with little normal tissue, which she considered to arise from a primary defect in interaction and induction between the ureteric bud and metanephric mesenchyme versus others, in which nephrogenesis had begun, but then become interrupted. Many corresponding genes are known to be expressed in development of the human renal tract, with some of these genes recently found to be mutated in individuals with either isolated (non-syndromic) kidney malformations or renal tract

Table 126.1 Syndromes associated with renal and urinary tract malformations

Autosomal dominant syndromes
1. Branchio-oto-renal [4]
2. Hypoparathyroidism, sensorineural deafness, and renal dysplasia [5]
3. Mayer–Rokitansky–Küster–Hauser [6]
4. Renal coloboma [7]
5. Renal cysts and diabetes [8]
6. Townes–Brocks [9]

Autosomal recessive syndromes
1. Bardet–Biedl [10, 11]
2. Fraser [12, 13]
3. Jeune [14]
4. Meckel–Gruber [15]
5. Prune belly syndrome [16]

X-linked syndromes
1. Kallmann [17]
2. Simpson–Golabi–Behmel [18]

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

malformations associated (syndromic) with defects in other organ systems [2]. Thus, multiorgan syndromes associating with a renal tract malformation may be autosomal dominant, autosomal recessive or X-linked [3]. Each syndrome may associate a large spectrum of renal tract malformations with the involvement of different organs (Table 126.1).

126.2.1.2 Nonsyndromic Renal and Urinary Tract Malformations

Common renal malformations encountered in the fetal period are hydronephrosis associated with primary vesicoureteral reflux (VUR) and duplex kidneys. These malformations may have genetic bases because they sometimes affect more than one family member, perhaps with two or more abnormal genes necessary in any one person to produce the anatomical change [19]. Analysis of data from humans and mice suggests that some of the renal damage associated with VUR is congenital and is due to a kidney malformation, not to secondary VUR/UTI related damage [20]. Human nonsyndromic renal tract malformations may be of both sporadic pattern and inherited fashion, dominant and recessive inheritance.

Half a decade ago the key anatomical differences between cystic dysplastic kidney (CDK) malformations and congenital polycystic kidney disease (PKD) were defined for the first time, with the identification of genes inherited with dominant (ADPKD) or recessive (ARPKD) fashion. However, dominant inheritance has been described for primary vesicoureteral reflux (VUR) [21], dysplastic or hypoplastic kidneys [22] and pyeloureteral junction obstruction (PUJO) [22]. Primary VUR and nephropathy have been described in few patients with *UPKIIIA* [23] and *ROBO2* genes mutations [19].

Dominant mutations of the paired box 2 (*PAX2*) gene, which is expressed in developing fetal kidney tubules, should be considered in individuals with renal hypoplasia or dysplasia, who have either visual impairment, from associated optic nerve coloboma and/or a similarly affected first degree relative [7, 24]. A polymorphism of the transcription factor *PAX2* is associated with reduced neonatal kidney size [25, 26]. Moreover, the *PAX2* gene, which is expressed in developing fetal kidney tubules, should be considered in individuals with renal hypoplasia or dysplasia, who have either visual impairment (from associated optic nerve coloboma) and/or a similarly affected first-degree relative in Renal-coloboma syndrome (RCS), an autosomal dominant disorder [2].

The main cause of fetal bilateral hyperechogenic kidneys is associated with hepatocyte nuclear factor 1-β (*HNF1B*) gene mutations [27]. Mutations of the gene that encodes the transcription factor *HNF1B* are associated with renal cysts and diabetes (RCAD) syndrome. Moreover, *HNF1B* mutations lead to different types of renal tract malformations, including multicystic dysplastic kidney (MDK), congenital solitary functioning kidneys (CSFK), cystic dysplastic kidneys, hypoplastic kidneys and glomerulocystic kidneys [8, 24, 27, 28]. *HNF1B* mutations or variants may be found in 8% of children who have dysplastic/hypoplastic kidneys and renal failure and in 22% who have cysts [24, 28, 29]. However, intronic regulatory expression sequences have been identified in the *HNF1B* gene [30] named retinoic acid regulatory element (*RARE*) and *T-MARE* (MafB Responsive Element) which links retinoic acid (RA) and *MafB* pathways with *HNF1B* gene regulation. Both *MafB*, a member of the large Maf family of transcription factors, and the RA signaling pathway have been implicated in renal development. In particular, *MafB* is specifically expressed in glomerular epithelial cells (podocytes) and is essential for podocyte differentiation and renal tubule survival [31]. However, RA signaling modulates the expression of renal transcription factors and components of signaling pathways that are known to direct segment fates during mammalian nephrogenesis.

Several other genes are identified since involved in aberrant renal and urinary tract morphogenesis. The *c-ret* gene encodes an epithelial cell, trans-membrane tyrosine kinase receptor protein. In *c-ret* mutants, renal agenesis, severe hypodysplasia and blind-ending ureters are observed [25]. Two X-linked gene mutations, angiotensin type II receptor gene (*Agtr2*) [32, 33] and L1-cell adhesion molecule (*L1-CAM*) are involved in PUJO or MDK, and in the process of kidney and urogenital tract organogenesis [25]. Bone morphogenic protein 4 (BMP4) has also been shown to interact with proteins in systems outside of the kidney and urinary tract that have been identified as regulators of kidney and urinary tract organogenesis. WNT11 is a target molecule of glial cell line-derived neurotrophic factor (GDNF) and down regulation by BMP4 results in the inhibition of ectopic ureteric bud formation from the Wolffian duct. The *Foxc1 C*/*Foxc2 C* compound heterozygotes have hypoplastic kidneys and single ureters. However, *Uroplakin* genes may be critical for development of both the upper and lower urinary tract in humans. De-novo heterozygous mutations in *Uroplakin IIIA* are associated with severe renal adysplasia and hypodysplasia with kidney failure in childhood [34]. Furthermore, mutations of genes encoding Renin-Angiotensin System (RAS) components are associated with perinatal kidney disease. The renal phenotype usually comprises slightly large kidneys, appearing bright on fetal ultrasound, together with a profound decrease in amniotic fluid volume [35]. Finally, evidence is emerging that posterior urethral valves (PUVs) may have a genetic basis, possibly a male-limited autosomal recessive condition: the exact genes involved, however, are currently unknown [2].

Considerable recent progress has been made in unraveling the rather complex genetic bases of the spectrum of diseases known as the Bardete-Biedl, Meckele-Gruber and Joubert syndromes. These syndromes show considerable phenotypic overlap, with all featuring perinatal kidney disease with dysplasia and cysts [2].

126.2.2 Environmental Factors

Some observational studies linked the environmental factors with the development of malformation in renal and urinary tract in the fetus and newborn. Renal tract malformations are more common in fetuses of mothers with high alcohol intake or diabetes mellitus [3]. However, gross gestational insults, such as twin–twin transfusion syndrome and heavy prematurity, may perturb human kidney differentiation [36, 37]. Moreover, the discovery of mutations in genes coding for the RAS cascade in patients with renal tubular dysgenesis [35] are associated with the increased incidence of renal anomalies in fetuses exposed to drugs that block angiotensin II signaling [38].

126.3 Clinical Aspects

126.3.1 Prevalence

Prenatal ultrasound (US) screening programs assessing the diagnostic prevalence of renal anomalies in 20 registries of 12 European countries identified unilateral MDK in 1:7100 of fetuses, unilateral renal agenesis in 1:12,500, bilateral renal agenesis or dysplastic kidneys in 1:7700 and PUVs in 1:33,300. Terminations of pregnancies were performed in 67% of the detected bilateral renal agenesis/dysgenesis, but only 4% of the unilateral MDK malformations [39].

The US screening of fetuses in the last trimester showed that 7.7% had transient upper renal tract dilatation [40, 41]. From a multicenter study, prenatal hydronephrosis had an overall prevalence of 11.5 cases per 10,000 births. The large majority of cases were live births (96% of total), only a minority were terminations of pregnancy or fetal deaths. Boys accounted for 72% of all cases. A high proportion of the cases (86%) had an isolated renal tract malformation [42]. Hydronephrosis may be bilateral in 37–57% of cases [43]. Among hydronephrosis, PUJO was the most common cause of prenatal pelvis dilatation, accounting for 33% of infant cases, followed by primary VUR (28%), megaureter (18%) and complicated renal duplex kidney (12%). Less frequent conditions of prenatal renal pelvis dilatation were MDK, PUVs, hydronephrotic horseshoe kidneys, and hereditary renal adysplasia [44]. MDK, although not classified as hydronephrosis, may be mistaken for hydronephrosis [45].

Sometimes the hyperechogenic kidney, detected with prenatal US, may pose problems of differential diagnosis. The prevalence of renal pathology associated with kidney hyperechogenicity at US detected after 17 weeks' gestation has been assessed in a retrospective multicenter study. The conditions more frequently associated with fetal hyperechogenic kidneys were ADPKD and ARPKD. Less frequent conditions were Bardet-Biedl syndrome, Meckel-Gruber syndrome and Ivemark II syndrome. Jarcho-Levin syndrome, Beemer syndrome and Meckel-like syndrome were rare. Lastly, one third of the fetuses with hyperechogenic kidneys had renal cysts [46].

126.3.2 Classification of Renal Anomalies

An abnormal human renal tract may develop from the beginning of the metanephros to the end of nephron formation, which occurs at about 34 weeks of gestation [47]. The acronym CAKUT means congenital anomalies of the kidney and urinary tract, a syndrome that includes a wide spectrum of anomalies affecting the formation of the kidney and bladder. In the kidney, these anomalies include hypoplasia, dysplasia or a complete lack of kidney formation (agenesis). Proximally the ureter can be obstructed (PUJO) or grossly dilated (megaureter). Distally the ureter can be blocked at its insertion into the bladder (vesicoureteral junction obstruction [VUJO]). Alternatively, the ureter may be incompetent (VUR) or insert outside the bladder (ectopic). Bladder and urethral anomalies include abnormal hemitrigone formation as well as urethral valves (PUVs) and urethral atresia [25].

The anomalies that affect the renal system may be classified according to the renal and urinary tract district involved (Table 126.2) [1].

Table 126.2 Classification of main anomalies affecting the renal system

- Renal agenesis
  - Unilateral
  - Bilateral (Potter's syndrome)
- Abnormalities of position (ectopia)
- Kidney fusion
  - Horseshoe kidney
  - Crossed fused ectopia
- Dysplasia/cystic renal disease
  - Aplastic or tiny dysplastic remnant kidney
  - Hypoplastic kidney
  - Simple renal cysts
  - Multilocular cysts
  - Multicystic dysplastic kidney (MDK)
  - Polycystic kidney disease (ADPKD and ARPKD)
- Obstructive uropathy
  - Posterior urethral valves (PUVs)
  - Pelviureteric junction obstruction (PUJO)
  - Vesicoureteric junction obstruction (VUJO)
- Vesicoureteral reflux (VUR)
- Ureteral alterations, duplications and ectopia
  - Ectopic ureter
  - Ureterocele
  - Ureteral duplications
- Anomalies of the bladder
  - Epispadias
  - Classical bladder exstrophy
  - Bladder exstrophy complex
- Anomalies of the penis

Modified from [1].

126.3.3 Renal Agenesis

Embryologically, renal agenesis occurs because the ureteric bud has not interacted with the metanephric mesenchyme. The bud fails to form the ureter, renal pelvis and collecting ducts. The mesenchyme fails to form nephrons. On occasion, unilateral renal agenesis is accompanied by genital tract anomalies on the same side [48]. The most profound and severe renal tract malformation is the complete bilateral kidney development, called renal agenesis, oligohydramnios sequence or Potter's syndrome, often accompanied by absent ureters. Prenatal diagnosis of oligohydramnios in the second trimester is dependent on US scanning and often a full post mortem examination is necessary to identify any underlying fetal cause [49]. Bilateral renal agenesis or hypoplasia was associated with a mother's risk factors such as adiposity prior to pregnancy, smoking during the periconceptional period, and binge drinking during the second month of pregnancy [50].

126.3.3.1 Diagnosis

Renal agenesis is suspected when US does not identify the renal parenchyma and a postnatal scintigraphic scan does not show any renal function in a given side of the body. A nonfunctional kidney is diagnosed when US identifies residual renal parenchyma, without valuable scintigraphic renal function (Fig. 126.1).

126.3.3.2 Management of Bilateral Renal Agenesis

The diagnosis of bilateral renal agenesis is made during pregnancy by US scan, which show the absence of the kidneys and non-visualization of the bladder. Since this syndrome (Potter's syndrome) is frequently associated with poorer life expectancy, termination of the pregnancy is the most frequent outcome.

126.3.3.3 Management of Unilateral Renal Agenesis

Diagnosis of unilateral renal agenesis is generally performed by prenatal US. Controlateral compensatory renal hypertrophy can be detected in the third trimester and occasionally in the latter part of second trimester [51].

Postnatal radionuclide scan (DMSA) may confirm the diagnosis and establish the functional state of the CSFK. After the diagnosis of unilateral renal agenesis, postnatal screening is mandatory to rule out other associated renal anomalies. Early diagnosis and treatment of urological anomalies associated with CSFK is imperative to decrease the long-term risk of renal damage [52]. The early identification of risk factors for renal damage is essential because CSFK may further exhibit growth failure even if it was initially normal [53]. The management of VUR in CSFK follows the same strategies used to manage unilateral VUR in children with two normally functioning kidneys [54]. On the other hand, infants with PUJO in CSFK who have severe pelvis dilatation and decreased renal function require early surgical therapy or selective internal ureteric stenting [55]. Severe renal hypodysplasia, mistaken for renal aplasia, may evolve into renal malignancy and may cause hypertension.

126.3.3.4 Prognosis

CSFK may progressively lead to persistent hyperfiltration, microalbuminuria and increasing proteinuria, with focal and segmentary hyalinization of the renal glomeruli requiring periodical long-term follow-up.

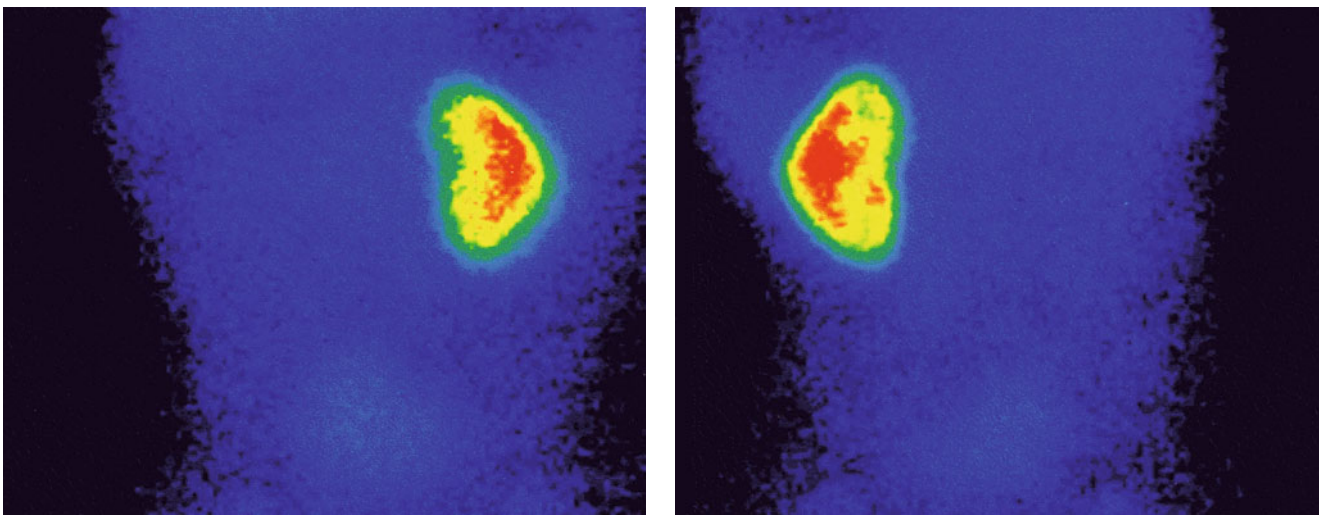

Fig. 126.1 Renal DMSA scintigraphy performed in a male-baby with left solitary hypertrophic functioning kidney and right iliac-sided ectopic not-functioning kidney. Reproduced from [53] with permission

126.3.4 Abnormalities of Position

During embryological development, the kidney undergoes rotation as well as cranial migration taking its blood supply from the middle sacral artery, iliac artery and the aorta. Malrotation may occur as result of incomplete, excessive or reversed rotation. In these situations, the renal hilum faces in an abnormal direction and gives rise to obstruction. Anomalies of ascent may result in abnormal positions of the kidney of which the most common is the pelvic kidney. The abnormal location frequently predisposes to UTI and VUR [1].

126.3.4.1 Management

Asymptomatic patients, with adequate renal function, require inclusion into follow-up protocols. Imaging with US and radionuclide scan (DMSA) is required to identify location and associated abnormalities. Overall, a radionuclide scans is advisable when the pelvic position makes the kidney difficult to identify by US. Computed tomography/magnetic resonance imaging (CT/MRI) scan is advisable in cases where renal function is poor. Voiding cystoureterogram (VCUG) or scintigraphic screening may rule out a concomitant VUR.

Adequate renal function associated with clinical and radiological evidence of obstruction or VUR may require surgical consideration. Not functioning, poorly functioning, and MDK associating obstruction or recurrent infections are normally treated by nephrectomy.

126.3.5 Kidney Fusion

In crossed fused ectopia, the upper pole of one kidney is fused with the lower pole of the opposite kidney. Crossed renal ectopia is most frequently associated with VUR and UTI. Fusion of renal elements may occur across the midline to produce a horseshoe kidney (Fig. 126.2), which is one of the most frequent genitourinary abnormalities with an overall incidence of 1/666 [56]. Renal fusion anomalies may be asymptomatic but are frequently associated with obstruction and infection. In a horseshoe kidney, the most common clinical problem is obstruction at the pelviureteric junction. Horseshoe kidney may be part of the spectrum of well-known syndromes associated anomalies affecting multiple organs such as Turner's, Frasier's, Renal Coloboma and Mayer-Rokitanski.

A recent survey reports that concomitant urogenital and non-urogenital malformations were equally frequent for horseshoe kidney and crossed fused ectopia. Severe anomalies or malformations were found in 23% of patients, less frequent than previously reported [57].

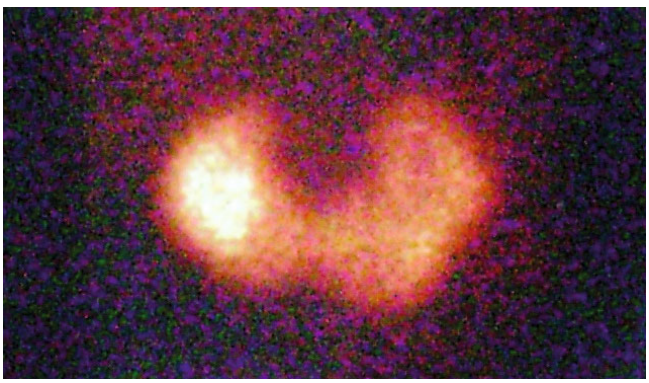

Fig. 126.2 Anterior view of DMSA scintigraphy in a baby with horseshoe kidney

126.3.5.1 Management

The diagnosis of fusion abnormalities can be made with the commonly used imaging modalities, such as US and scintigraphy. In cases of obstruction confirmed by radionuclide scan (MAG3), a pyeloplasty is commonly required. Patients with VUR, demonstrated by VCUG, requires surgery if UTIs are frequent. Individual cases of complex anatomical situations require special examination strategies, and CT appears to be the most reliable imaging method [57]. Finally, parenchyma with poor renal function or dysplasia associated with recurrent infections may need partial nephroureterectomy.

126.3.6 Renal Dysplasia

Dysplastic kidneys are so-called because the both organs are present but development is abnormal and incomplete. These organs contain incompletely branched ducts derived from cells of the ureteric bud and collecting duct line, surrounded by undifferentiated and metaplastic stroma. The classic antenatal presentation of dysplastic kidneys is of large bright kidneys, with or without cystic spaces, occurring within the cortex at the routine 20-week scan [34].

126.3.6.1 Aplastic or Dysplastic Kidney

The dysplastic kidney may be either aplastic (a few millimeters long) or large and distended by multiple cysts. Ureters attached to MDKs are scarcely formed and with non-patent sections. These severe types of dysplastic kidneys generally have no excretory function.

126.3.6.2 Hypoplastic Kidney

Hypoplastic kidneys contain fully formed nephrons but have a deficit in nephron number. Kidney hypoplasia is defined as

kidney mass below 2 standard deviations of that of age-matched normal individuals or a combined estimated kidney mass of less than half of normal for the patient's age. Oligomeganephronia represents a severe variant of hypoplasia in which both kidneys are one-eighth to one-half normal weight. Nephron number is reduced by 80% and nephrons are markedly hypertrophied, with glomerular diameter more than twice normal. Premature babies and/or infants small for gestational age due to intrauterine malnutrition will be born with relatively small kidneys and a certain nephron deficit, a condition called congenital oligonephropathy [58].

126.3.6.3 Cystic Dysplastic Kidney

In dysplastic kidneys, cysts arise in the context of abnormal renal development. Cystic dysplastic kidney contains primitive tubules and cysts alongside normal nephrons and generally may have excretory function. Renal tubular dysgenesis is related to incomplete differentiation of proximal tubular nephron segments, often associated with fetal anuria and oligohydramnios. In the variant of kidney malformation associated with obstruction, the first filtering nephrons develop normally, but nephrogenesis subsequently halts developing subcapsular cysts from nephron precursors [59, 60]. Moreover, dysplasia is sometimes limited to the medulla and, in the presence of a duplex ureter, only the upper moiety is generally dysplastic.

126.3.6.4 Multicystic Dysplastic Kidney

Histology of fetal MDK showed that few nephrons, containing relatively normal glomeruli and proximal tubules, are present in these kidneys [61]. MDK result from complete obstruction early in embryonic development. Abnormal structures seem to be destroyed later in gestation or postnatally [62]. In unilateral MDK, the presence of minimal function is rare (3–7%), occurring in 4% cases of patients [63].

Management and Prognosis

In asymptomatic patients, a follow-up with serial US scans is mandatory. US screening may detect spontaneous involution in the most severely affected kidney. All MDK patients on conservative management will need regular scans until at least 5 years of age.

Symptomatic patients with increasing abdominal distension and poor feeding may require nephrectomy [64]. Surgeons advocated prophylactic removal of these asymptomatic lesions for possible risks of hypertension and malignancy. The risk of hypertension is less than 1%. If severe hypertension is detected it will be necessary to carry out curative nephrectomy [65]. However, malignancy has not been found [64]. If neoplasms occur, they usually present as Wilms' tumor. If any increase in size or unusual features appears this will be an indication to proceed to nephrectomy.

Bilateral involvement leads to lethal pulmonary hypopasia from anhydramnios.

126.3.6.5 Polycystic Kidney Disease

Polycystic kidney disease (PKD) is a genetic disorder presenting diverse forms:

- Autosomal recessive polycystic kidney disease (ARPKD)
- Autosomal dominant polycystic kidney disease (ADPKD)
- Nephronophthisis/medullary cystic kidney disease

PKD is a disease of the nephron with multiple renal tubular cysts that leads ultimately to end stage renal failure (ESRF) [66]. It has been estimated that there are approximately 6.5 million people in the world with inherited PKD [67]. Inherited PKD may have either dominant or recessive inherited fashion. The dominant form (ADPKD) is due to mutations in two different genes, *PKD1* or *PKD2*. The protein products of the PKD genes, polycystin-1 and polycystin-2, regulate renal tubule epithelial cell division and differentiation. The recessive form (ARPKD) and nephronophthisis/medullary cystic kidney disease are associated with the *PKHD1* and *NPH1* genes and their protein products are fibrocystin and nephrocystin, respectively.

Nephronophthisis or medullary cystic kidney disease was associated in one fourth of cases with Joubert syndrome, an autosomal recessive disorder that is described in patients with cerebellar ataxia, mental retardation, hypotonia, and neonatal respiratory dysregulation [68].

ARPKD is an inherited recessive disorder in which both kidneys are affected by cysts developing from dilated collecting ducts. The condition is associated with congenital hepatic fibrosis leading to the development of portal hypertension. The renal cystic changes appear in utero, and are associated with poor renal function leading to oligohydramnios. Neonates with severe disease have a high mortality up to 50%. Severe kidney disease tends to be associated with milder liver involvement, whereas milder renal disease applies when liver manifestations are predominant. Differential diagnosis is made on the history, clinical examination, prenatal and postnatal imaging by US. In some cases, biopsy of the kidney and liver may be necessary to confirm the diagnosis. Many families who lost a child with severe ARPKD desire an early and reliable prenatal diagnosis. Given the limitations of antenatal US, this is only feasible by molecular genetics that became possible from 1994 when *PKHD1* was mapped [69].

Management

Patients require evaluation of renal function providing appropriate supportive measures if renal failure occurs, treating hypertension and metabolic disturbances. If kidneys are massively enlarged causing respiratory difficulty a nephrectomy may be required with either unilateral or bilateral and dialysis.

126.3.7 Obstructive Uropathy

Prenatal suspicious of obstructive uropathy at US may be made as marked dilatation of the urinary tract. Antenatal pelvicalyceal dilatation has been reported in ~0.6% of pregnancies. Fetal lower urinary tract obstruction affects 2.2 per 10,000 births [70].

Many different causes are involved in the pelvicalyceal dilatation, including transient hydronephrosis, physiological hydronephrosis, PUJO and PUVs [71]. Obstructive uropathy can be classified as lower or higher urinary tract obstruction. High urinary tract obstruction is suggested when there is hydronephrosis or pelvicalyceal dilatation in the absence of visible ureteral bladder pathology, either at prenatal or postnatal assessment. The most common lower anomaly is PUVs, which accounts for approximately half of cases, followed by urethral obstruction/atresia [70]. Congenital megaloureter is a poorly defined entity in which ureterectasias is associated with no reflux and normal bladder [72]. Many newborns with pelvicalyceal dilatation can be safely treated non-operatively and obstruction occurs in only small number of patients. In a series of patients, 54% of cases the hydronephrosis improve or resolved spontaneously during the first 3 years of life [73].

126.3.7.1 Posterior Urethral Valves

PUVs is a congenital disease of high mortality and morbidity, starting in the uterus and leading to progressive renal dysfunction. PUVs are recognized as the most common cause of bladder outlet obstruction in boys with an incidence of 1 in 2,000–4,000 live male births [1]. Commonly, PUVs consist of two folds arising from the urethra at the level of the veru montanum and fusing anteriorly in the midline. A much rarer form is a diaphragm extending across the lumen of the urethra just beyond the veru montanum. The degree of obstruction can vary from minimal with associated symptoms of dysfunctional voiding to severe with dilated posterior urethra, trabeculated bladder and severely hydronephrotic kidneys.

Antenatal Diagnosis

The antenatal diagnosis is made on the finding of dilated upper tracts associated with a thick-walled bladder and oligohydramnios. The bladder appears thick-walled and tense in cases of obstruction whereas in prune belly syndrome the bladder appears floppy [74]. A detailed sonographic evaluation of the fetus is carried out to exclude extrarenal abnormalities. MRI is reported of benefit when used in addition to US if the resolution of US is impaired by oligohydramnios [75].

Antenatal Management

Prenatal diagnosis provides the opportunity to improve functional outcome by either decompression of the obstructed bladder in intrauterine life or prompt postnatal intervention to relieve obstruction, minimize the risk of sepsis and optimize management of the valves [65]. Fetal intervention is not without risk of complications and should be avoided where renal function is poor with little possibility of survival. However, fetal intervention is not indicated in patients detected prior to 24 weeks because the renal changes are not reversible. Where the diagnosis is made after 24 weeks, the outcome in terms of renal function is generally favorable [76]. Thus, fetal intervention should not be performed if the US indicates marked renal dysplasia or in cases with adequate renal function with stable amniotic fluid volume. Fetal intervention has conventionally been restricted to male fetuses with suspected PUVs, good renal prognosis and oligohydramnios. The procedure most commonly performed is percutaneous vesico-amniotic shunt [74]. In utero percutaneous vesico-amniotic drainage possibly improves overall perinatal survival as compared to the non-drainage group [77]. On the other hand, open fetal vesicostomy has a high risk of complications since risk for preterm labour, maternal morbidity, premature ruptures of the membranes and fetal death.

Postnatal Management

Open or endoscopic procedures would provide a definitive treatment of obstruction, although limitations are the uncertainty whether renal function can be significantly improved [78]. Anyway, some cases of PUVs may benefit from timely identification and surgical intervention, although prenatal diagnosis has little impact on mortality or ESRF in the first 10 years of life ,reflecting the crucial role of renal dysplasia as a determinant of early renal impairment [65].

Surgical Treatment

The initial management is to pass a urethral catheter into the bladder and establish drainage. If a urethral catheter cannot be passed because the bladder may contract around the urethral catheter, suprapubic drainage is required. Moreover, if contrast study of bladder and urethra visualizes the urethra adequately, the diagnosis of PUV will be confirmed and VUR if present will also be identified.

Primary valve ablation is performed transurethrally with miniature endoscopes and under direct vision; the coagulating electrode fulgurates the valve leaflets. There is good evidence that early valve ablation can lead to recovery of bladder function and improvement in the upper tracts [79]. Vesicostomy is generally reserved for neonates with severe upper tract changes and poor renal function especially if associated VUR. The temporary decompression of the bladder may help to improve upper tract function. Closure of the vesicostomy is carried out after valve ablation and when upper tract surgical intervention has been completed [80, 81]. In a long-term study, primary valve ablation gave the best results

with good capacity, compliant bladders similar to those with ureterostomy, while the vesicostomy group had small-capacity and hyperreflexic bladders [82]. From another study, the long-term results of prenatally detected PUVs confirm that early valve ablation can be considered as the primary treatment in the majority of patients, without the need for preoperative drainage or diversion [83].

Prognosis

Cases where the US features of PUVs appear early (before 20 weeks of gestational age) and upper tract dilatation is moderate to severe have a poor prognosis [84]. The kidneys are often dysplastic and have poor function. Many of these fetuses would either abort or be stillborn. In appropriately selected fetuses, intervention may improve perinatal survival, but long-term renal morbidity amongst survivors remains problematic. An important prognostic feature on US is the presence of significant oligohydramnios, which if present prior to 24 weeks is associated with a higher prevalence of pulmonary hypoplasia [76]. Moreover, both gestational age at diagnosis and oligohydramnios were statistically significant predictors of final renal outcome [83]. Finally, poor renal function associated with renal dysplasia could not improve even after relief of obstruction. Thus, a high percentage of cases progress to renal failure regardless of prenatal diagnosis [65].

126.3.7.2 Pelviureteric Junction Obstruction

Hydronephrosis secondary to PUJO is the commonest anomaly affecting the renal collecting system. On total of the antenatally diagnosed renal pelvis dilatation, PUJO occurred in 13% of cases [44]. Of total fetal hydronephrosis, PUJO accounted for 0.2–0.4% of cases, of which 20–25% of cases were bilateral [71].

Pathogenesis

The condition results from an intrinsic stenosis of the ureter at the point where it joins the pelvis. PUJO is characterized by aberrant pyeloureteric smooth muscle, which typically exhibits hypertrophy and perifascicular fibrosis and abnormal innervation [85]. The abnormal ureteric segment has decreased peristaltic activity resulting in failure of transport of urine from pelvis down to the ureter.

Clinical Presentation

Renal pelvis dilatations are frequently detected with prenatal US. Pelvicalyceal dilatation in the fetus must be interpreted with caution as many of these resolve spontaneously in the postnatal period. A system of grading based on the anteroposterior diameter (APD) of the renal pelvis is used to evaluate the severity of the hydronephrosis. Measurements of 3 mm or less are considered normal at any gestational age. Beyond 30 weeks' gestation, thresholds for diagnosis of mild, moderate, and severe hydronephrosis were defined as 5–8 mm, 9–15 mm, and greater than 15 mm, respectively. Most agree that postnatal evaluation is prudent if the renal pelvis APD reaches 10 mm at any point in gestation, or if calyceal dilation is noted. Recent prospective studies have found that even mild hydronephrosis that is stable or resolves over a pregnancy may redevelop, progress, and necessitate surgery after birth [72].

Management

The management of hydronephrosis secondary to PUJO is aimed at preserving long-term renal function. In infants, asymptomatic unilateral hydronephrosis with stable differential renal function can be managed conservatively while obstructive dilatation requires serial assessments and early surgical correction [86]. Ensuring a sufficient follow-up interval, especially during the first 3 years of life, is essential to prevent permanent loss of renal function in kidneys that do develop signs of obstruction [73].

All patients with prenatally detected hydronephrosis should have US scans, MAG-3 renograms and VCUG (to rule out VUR). On the US scan, APD of the renal pelvis, degree of caliectasis, renal length, and thickness of the renal cortex, echogenicity and cortico-medullary differentiation should be assessed.

The concept of measuring renal pelvic dilatation on US allows children to be categorized into a conservatively managed group (APD below 12 mm) and an early surgical intervention group (APDN 40 mm). If APD is below 12 mm these patients are not at risk and are followed up with US scans at 3 months and 1 year. When APD is from 12 to 20 mm these patients require US scans at 3 months and 1 year and MAG-3 scan at 3 months. If APD is from 20 to 40 mm these patients requires MAG-3 scan at age 1 month [87]. MAG-3 renogram provides a more accurate assessment of obstruction. On diuretic MAG3 scintigraphy, infants show renal pelvis dilatation with delayed drainage and relatively reduced renal function [88].

Fetal Intervention

Hydronephrosis with normal renal parenchyma is generally associated with good renal function and hence does not require fetal intervention. Fetal intervention should be considered in cases of severe bilateral hydronephrosis associated with oligohydramnios, bilateral hydronephrosis with dysplastic renal parenchyma and solitary kidney with severe hydronephrosis. Therefore, the risk of chronic or ESRF posed by upper tract obstruction is exceptionally low, except in the rare instances when it affects a solitary kidney [65].

Postnatal Management and Prognosis

Close follow-up is required in the first 2 years of life to identify the subgroup (35%) of children with obstruction that requires prompt surgery. Nonoperative management with close follow-up during the first 2 years is a safe and recommended approach for neonates with primary bilateral PUJO type hydronephrosis [73]. Large numbers of children have been submitted to an unnecessary pyeloplasty for asymptomatic PUJO, which was otherwise destined to resolve spontaneously [65]. However, from 20 to 40 mm with function near 40% these patients need close follow-up, by US and MAG-3 scan at 3 months, 6 months and 1 year. If the APD is near 40 mm, surgical intervention is required. Treatment and follow-up protocol for UPJO hydronephrosis was proposed by Onen et al [73] (Table 126.3).

Pyeloplasty of renal units with PUJO and decline of kidney function is widely suggested to improve renal outcome or delay long-term morbidity [89]. Such an approach prevented permanent loss of renal function. Actually, unilateral PUJO is less indicated for surgery, especially if renal function is unaffected. During follow-up, the main indications for surgery are deterioration of renal function of 5% or more, glomerular filtration rate drop to 40% or less, bilateral hydronephrosis or solitary kidney [90]. Generally, amelioration has been related to kidney maturation rather than a result of surgery [91]. If renal function is already reduced, the operation is made even if there is no proof of improving final renal outcome, as usually split renal function does not change. When renal function is poor at the beginning despite the pyeloplasty, the functional amelioration of the operated kidney is frequently absent or minimal [92]. In terms of relieving obstruction, a pyeloplasty has a success rate in excess of 95%. In the small percentage of patients requiring repeat pyeloplasty, the failure of the original procedure is usually apparent within a year or two of the original procedure [65].

Prenatal diagnosis and surgical intervention have contributed to a reduction in long-term morbidity in children with PUJO. Therefore, many children have almost certainly undergone unnecessary early pyeloplasty for an obstruction that would have resolved spontaneously [65].

Table 126.3 Treatment and follow-up protocol for ureteropelvic junction hydronephrosis

Grade 1
- Follow-up with serial ultrasound starting at 1 month
- No prophylactic antimicrobial
- No renal scintigraphy
- Follow-up for development of urinary symptoms

Grade 2
- Follow-up with ultrasound plus renal scintigraphy starting at 1 month
- Antibacterial prophylaxis may be beneficial
- Renal scintigraphy at every other control

Grade 3
- Close follow-up with ultrasound plus scintigraphy
- Antibacterial prophylaxis could be necessary
- Renal scintigraphy at every other control as far as renal function > 35%
- Surgical (pyelography) indications if significant increase* in hydronephrosis, decrease in renal function

Grade 4
- Early intervention, after short period of follow-up, is safe for prevention of renal function. Delay in prompt treatment may cause irreversible renal deterioration

* Control if the echography is comparable (i.e. empty or full bladder)
Modified from [73].

Differential Diagnosis

The less common mid ureteral tricture accounts for 4% of prenatal hydronephrosis [93].

126.3.7.3 Vesicoureteric Junction Obstruction

Causes of pediatric obstructive hydroureteronephrosis may include primary or congenital vesicoureteric junction obstruction (VUJO) and a secondary form of VUJO (i.e., ureterocele, retroperitoneal fibrosis, calculus).

Diagnosis

An US screening during pregnancy enables the physician to make an early diagnosis of primary VUJO, which involves 4% of the total fetal hydronephrosis [94]. Prenatal diagnosis of VUJO requires postnatal US confirmation and follow-up. Most series have reported an operation rate, predominantly performed because of reduced renal function, in the range 10 to 20%. Prenatally detected VUJO follows an even more benign course than PUJO with a high tendency to spontaneous resolution [95]. However, MRI techniques make it possible to see the anatomical details of the obstruction level from the third trimester of pregnancy to postnatal life [96]. Primary obstruction may become symptomatic late in infancy, especially in patients with normal prenatal US screening [97].

Management

Surgical treatment consists of excision of the distal ureteric segment, tapering of the ureter and reimplantation or insertion of a JJ stent [98].

126.3.8 Vesicoureteral Reflux

VUR is the retrograde flow of urine into the upper urinary tract. The estimated prevalence of VUR affects about 1% of

the general infant population [99]. Mild fetal renal dilatation (fetal renal pelvis 4–10 mm) was associated with VUR ranges between 13 and 30% [99], with an increasing risk in children of parents with VUR. Infants with a family history of VUR, persistent fetal renal dilatation after 30 weeks of gestation should be investigated [100].

Generally, in newborns a reflux is primary. Primary reflux can be associated with dysplastic kidneys, especially in boys [101]. There is growing evidence that congenital renal dysplasia rather than acquired infective scarring is the most important determinant of reflux nephropathy in males with high-grade VUR, who are the infants most commonly identified by prenatal US [65]. The mean overall relative risk of kidney damage is higher in renal units with VUR, particularly in those carrying high-grade VUR, than in not-refluxing kidney [97].

Some cases of VUR are associated with duplicated renal tracts: the lower ureter may be refluxing since it inserts laterally into the bladder. The upper moiety might be associated with an obstructed ureter that inserts into the bladder in a more distal position than normal, or inserts ectopically, for example into the urethra. Finally, some cases of VUR are secondary to other conditions, such as fetal bladder outflow obstruction from PUVs [102].

126.3.8.1 Postnatal Management

Three methods are currently used to identify VUR in children: X-ray voiding cystourethrography (VCUG), radionuclide voiding cystography, and echo-enhanced voiding urosonography [103]. Diagnosis of VUR is traditional performed with serial VCUG scans. In young patients, US showed higher diagnostic accuracy than radionuclide cystography in assessing the grade of VUR [104].

Treatment goals include the prevention of pyelonephritis, reflux nephropathy, and other complications of reflux. Treatment alternatives include antibiotic prophylaxis and surgical correction (open, injection therapy, or laparoscopic) performed after the neonatal period [105], although the additional benefit of surgery over antibiotics alone is small at best [106]. The treatment of choice, with antibiotic prophylaxis and/or with surgery, needs to be discussed on an individual basis.

126.3.8.2 Prognosis

Surgery procedure (ureteral reimplantation or endoscopic correction) leads to similar renal outcomes as medical or supportive treatment. Generally, a congenitally damaged kidney does not ameliorate after each treatment. However, prenatal detection of VUR does not seem to modify the outcome of the kidney significantly [29]. Despite treatment of affected children for the past 40 years, the incidence of end-stage renal disease secondary to VUR has not decreased [107]. Thus, the association of VUR and renal failure may be caused by a genetic defect affecting both the formation of the kidney and the urinary tract [20].

126.3.9 Ureteral Duplications and Ectopia

Ureteral duplications arise from one of two embryological anomalies: a single ureteral bud branching into two before reaching the metanephric mesoderm or two ureteral buds arising from the mesonephric duct and each individually reaching the metanephros to induce formation of two renal moieties.

Ectopia occurs when the ureteral bud arises from an abnormal position on the mesonephric duct. The site of origin of the ureteral bud determines whether the ectopic ureter opens into or outside the bladder. The latter occurs in females and the ectopic orifice is frequently associated with the genital tract.

Ureteroceles represent cystic dilatation of the submucosal part of the ureter. Ureteroceles may be associated with single systems but are more commonly seen in duplex systems [1].

126.3.9.1 Clinical Presentation

Prenatal US scans are capable of identifying most urinary tract abnormalities including duplications, ectopic ureters and ureteroceles. Postnatally many infants may be completely asymptomatic and the diagnosis may be missed in the perinatal period if routine US scans are not available. They may also be associated with obstruction of the upper tracts causing hydronephrosis.

The common postnatal presentation includes UTIs, bladder outlet obstruction and incontinence. Ureteroceles may prolapse through the urethra and present as a mass causing obstruction. Such cases may present with abdominal distension and palpable masses due to the dilated ureter and pelvicalyceal system. Ectopic ureters in males always insert proximal to the sphincter.

126.3.9.2 Diagnosis

US scan is usually the first line of investigation and will show up hydronephrosis, renal dysplasia, dilated ureters, ureteroceles and indicate duplex systems. VCUG will demonstrate the presence of ureteroceles. Moreover, it will show reflux and dilated ureter or part of the duplex system. Radionuclide scan (DMSA) is the most useful for detecting duplex systems and providing an assessment of renal function. Endoscopy provides direct visualisation of ureteroceles and some ectopic ureters. Contrast studies in retrograde fashion improve the delineation of the anatomy.

126.3.9.3 Management

Ectopic ureters

If renal function is adequate, the procedure of choice is reimplantation of the ureter with single system ureters. In duplex systems, either reimplantation of both ureters or anastomosis to the lower moiety ureter as an uretero-ureterostomy may be required. Nephroureterectomy is advisable with absent or poor renal function in duplex system. Removal of the ureteric remnant can be mandatory when there is reflux into the ectopic ureter [108].

Ureterocele

The initial management in the neonate is cystoscopic incision to provide drainage. Subsequently, the renal morphology and function can be assessed with follow-up US and DMSA scans. If these remain satisfactory and no UTIs occur, the patients do not require further surgical intervention [109]. Incomplete excision can leave a cuff of ureterocele at the bladder outlet that acts as a valve obstruction when the patient voids. Finally, complications are infections, obstruction and non-function of the renal moiety requiring treatment by nephrectomy with complete excision of the ureterocele.

Ureteral Duplication

The most common congenital abnormality of the urinary tract is ureteric duplication. Many children with renal tract duplications remain asymptomatic and do not require surgical intervention. Therefore, ureteric duplication is frequently associated with other urinary tract anomalies. Duplex systems are prone to UTIs because of VUR or obstruction. Hydronephrosis in complete duplicated systems usually affects the upper pole, and is mostly secondary to obstruction at the lower end of its ureter by an ureterocele or due to an ectopic ureteric insertion. Hydronephrosis of the lower segment is most often a result of VUR. Obstruction at the level of the PUJ in duplex kidneys is rare [110].

When symptoms occur in duplex system, surgical management is required [111]. Duplications associated with poorly functioning renal moiety and complicated by UTIs should be treated by heminephroureterectomy. Duplications with preserved renal function but complicated by obstruction or infection should be treated by reimplantation of the ureter/ureters. All of the surgical procedures can be done laparoscopically with equally good results compared to open surgery. The ultimate goal of surgical intervention remains the elimination of complications associated with urinary tract abnormalities in the perinatal period and the preservation of renal function.

126.3.10 Anomalies of the Bladder

Bladder exstrophy is a complex anomaly involving the urinary, genital, and intestinal tracts and the musculoskeletal system. The severity ranges from simple epispadias to complete exstrophy of the cloaca involving exposure of the entire hindgut and the bladder. The diagnosis is made typically at the newborn examination or on fetal US that is performed by an experienced observer [112]. Exstrophy of the urinary bladder occurs about once in every 30,000–50,000 births, with male preponderance [113].

126.3.10.1 Clinical Manifestations

Anomalies of the bladder are hypothesized to result when the mesoderm fails to invade the cephalad extension of the cloacal membrane; the extent of this failure determines the degree of the anomaly. In classic bladder exstrophy, the bladder protrudes from the abdominal wall and its mucosa is exposed. The umbilicus is displaced downward, the pubic rami are widely separated in the midline, and the rectus muscles are separated. In males, there is complete epispadias with dorsal chordee, and the overall penile length is approximately half that of unaffected boys [114]. Undescended testes and inguinal hernias are common. Females also have epispadias, with separation of the two halves of the clitoris and wide separation of the labia. The anus is displaced anteriorly in both sexes, and there may be rectal prolapse. The pubic rami are widely separated.

Children with more complex cases of cloacal exstrophy associating with omphalocele, exstrophy of the cloaca and imperforate anus had a prevalence of 1:200,000 live births. The real incidence is unknown since many cases are incorrectly diagnosed prenatally or these pregnancies are prematurely terminated [115]. However, other severe abnormalities of the colon and the rectum are present such as short bowel syndrome [116], upper urinary tract anomaly and spina bifida. Current reconstructive techniques result in a satisfactory outcome in most patients.

Epispadias is in the spectrum of exstrophy anomalies, affecting approximately 1 in 117,000 boys and 1 in 480,000 girls. Epispadias, classic bladder exstrophy and cloacal exstrophy are causally related, representing a spectrum of the same developmental defect, with a small risk of recurrence within families [117]. In boys, the diagnosis is obvious because the prepuce is distributed primarily on the ventral aspect of the penile shaft and the urethral meatus is on the dorsum of the penis. In girls, the clitoris is bifid and the urethra is split dorsally.

126.3.10.2 Treatment and Prognosis

Initially, the bladder should be covered with plastic wrap to keep the bladder mucosa moist. These individuals are prone to

latex allergy, so latex precautions should be practiced in their care. Early bladder closure with reconstructive surgery can be applied to almost all neonates with classic bladder exstrophy. Conventional therapy has included a series of staged reconstructive procedures, but a single-stage complete reconstruction in the neonatal infant has gained popularity [118]. Treatment should be deferred in selected situations when surgical therapy would be excessively risky or complex, such as in a premature baby or when it would have to be performed by inexperienced surgeons. Postoperatively, the infant's upper urinary tract is monitored closely for the possible development of hydronephrosis and infection. Most infants with bladder exstrophy have VUR and should receive antibiotic prophylaxis.

Children who undergo reconstructive surgery as newborns have a greater chance of obtaining a normally functioning bladder.

126.3.11 Anomalies of the Penis

Hypospadias is one of the most frequent genital malformations in the male newborn and results from an abnormal penile and urethral development; estimates of its prevalence range from 3–8 cases per 1000 male births [119]. Hypospadias referring to an incomplete development of the prepuce, called a dorsal hood, in which the foreskin is on the sides and dorsal aspect of the penile shaft and absent ventrally. Hypospadias shows a genetic pattern especially in familial and syndromic forms and in forms due to abnormal genital development or associated with a defect of the androgens pathway [120].

126.3.11.1 Clinical Manifestations

Hypospadias is classified according to the position of the urethral meatus after taking into account whether chordee is present. The deformity is described as glanular (on the glans penis), coronal, subcoronal, midpenile, penoscrotal, scrotal, or perineal. In the most severe cases, the scrotum is bifid and sometimes extends to the dorsal base of the penis [121]. Approximately 10% of boys with hypospadias have an undescended testis; inguinal hernias also are common [122]. In the newborn, the differential diagnosis of proximal hypospadias associated with an undescended testis should include forms of ambiguous genitalia, particularly female virilization (congenital adrenal hyperplasia) and mixed gonadal dysgenesis. A karyotype should be obtained in patients with midpenile or proximal hypospadias and cryptorchidism.

126.3.11.2 Treatment

Management begins in the newborn period. This malformation is usually corrected surgically when the infant is between 6 and 24 months. Whereas hypospadias repair is recommended for boys with midpenile and proximal hypospadias, some boys with distal hypospadias will have no functional abnormality and do not need any surgical correction.

126.4 Differential Diagnosis

Although histology provides the purest way of classifying renal tract malformations, renal biopsies are rarely performed in suspected cases of dysplastic or hypoplastic kidneys. Consequently, in clinical practice, most diagnoses of renal tract malformations are made on the basis of radiological investigations [123].

126.4.1 Fetal Radiology

Prenatal diagnosis can identify either specific pathologies (MDK, duplex collecting system, renal agenesis, PKD) or non-specific pathologies (hydronephrosis, ureteral dilatation, bladder enlargement and oligohydramnios, hyperechogenicity, enlarged kidneys, hypoplastic kidneys). US screening for fetal anomalies is becoming routine and abnormally shaped bladders from midway through gestation [39]. The finding of a renal tract malformation during antenatal screening leads to careful evaluation of the rest of the fetus. In some cases, other organ systems are found to be malformed, which can indicate the presence of a particular syndrome [124].

MRI contribution to the analysis of urinary tract abnormalities is far less well-developed, although this method has proven useful in small series [75, 96, 125]. With regard to nephropathy, the potential contribution of MRI is not currently well-defined and US examination is still the major imaging tool, despite its usefulness in cases with inconclusive sonographic findings (maternal obesity and/or oligohydramnios).

126.4.1.1 Fetal Renal Pelvis Dilatation

Fetal renal pelvis dilatation is a frequent abnormality that has been observed in 4.5% of pregnancies [126]. The fetal kidneys can be easily visualized on US scans at 12 weeks. After 16 weeks, fetal urine production becomes the primary source of amniotic fluid [72]. US provides the opportunity to diagnose upper tract obstruction based on measurements of the renal pelvic APD. Measurements of 3 mm or less are considered normal at any gestational age. It is generally accepted that a fetal renal pelvic diameter greater than 10 mm at 26 weeks gestation is indicative of significant dilatation. In particular, fetal renal dilatation after 23 weeks can be used to predict obstructive uropathy, especially if the renal pelvic diameter continues to increase throughout pregnancy [127]. The

threshold for the diagnosis of abnormal fetal renal pelvis dilatation is significantly higher among pediatric urologists than nephrologists.

Postnatal renal pelvis dilatation is considered abnormal if the APD was 11 ± 1.9 mm by the pediatric urologists and 9 ± 2.9 mm by the pediatric nephrologists [93]. The third-trimester threshold value for renal pelvis APD of 7 mm is beyond any doubt the best prenatal criterion both for the screening of urinary tract dilatation and for the selection of patients needing postnatal investigation. In cases where only a second-trimester fetal examination is performed, a 4 mm threshold value for pelvis APD should be used as a warning sign because this finding may reveal a significant urologic abnormality in 12% of cases [44]. Hydronephrosis has an association with aneuploidy and is a component of several well-described syndromes if associated with other organ system (VACTERL association). The risk for trisomy 21 is approximately 1.5 times the patient's background risk [128].

VUR is diagnosed in 9–15% of infants with prenatally detected hydronephrosis and persistent postnatal hydronephrosis with VCUG performed during the first week of life. Prenatally detected VUR is more frequent in boys and is associated with poorly functioning kidneys in 15–30% of infants without a previous history of UTI [129].

126.4.1.2 Renal Agenesis

Diagnosis of renal agenesis can be complicated when the fetal adrenal gland occupies the empty renal bed, since the adrenal gland can mimic a kidney in US scans.

126.4.1.3 Dysplastic Kidney

MDK and severely hydronephrotic kidneys appear as collections of hypoechogenic spaces. These spaces are noncommunicating with the renal pelvis in multicystic disease and communicate in hydronephrotic ones. Moreover, increased echogenicity in variably enlarged fetal or neonatal kidneys is a nonspecific finding associated with polycystic and cystic dysplastic kidneys [130].

126.4.1.4 Posterior Urethral Valves

PUVs are characterized by variably enlarged, thick-walled urinary bladders and a dilated anterior urethra, both of which findings are highly variable and not specific for the condition [131]. Other entities, such as urethral atresia and prune belly syndrome, can mimic the radiological appearance of PUVs. Prune belly syndrome involves severe dilatation of the lower renal tract in the absence of overt anatomical obstruction, in association with deficiency of the abdominal wall musculature and cryptorchidism [132].

126.4.1.5 Polycystic Kidney Disease

In PKD, the US prenatal screening report unspecific hyperechogenic kidneys. Therefore, fetal MRI is not disadvantaged by a lack of amniotic fluid and, in addition to renal analysis, can be used to look for pulmonary hypoplasia or associated brain malformations. Fetal MRI images with high resolution allow the visualization of cysts in cases of ARPKD [96, 133]. In particular, fetal MRI appearance of ARPKD has been described as increased renal signal intensity on T2-weighted images [134], whereas low renal signal intensity is observed on T1-weighted images because of high water content in the renal parenchyma, consistent with tiny renal cysts. RARE-MR urography can be used to show directly the microcystic dilatation of collecting ducts [135].

126.4.2 Postnatal Radiology

Generally, postnatal neonatal radiology includes US, CT and MRI. Considering the immaturity of nephrons in newborns, the usual recommendation is that renography would be delayed until the age of 4 weeks [43].

Scintigraphy helps establish correct and accurate diagnosis in most congenital renal anomalies, indicates the current functional state of the individual kidneys, provides prognostic information, and can be used for decisions about intervention [136].

126.4.2.1 Hydronephrosis

The objectives of postnatal evaluation are to confirm hydronephrosis and then to determine its cause and to assess renal function. Neonatal urine generation can take a few days to be fully established. Hydronephrosis can be missed in cases of urinary flow obstruction if US scanning is performed too soon. Remarkably, the first postnatal US study is usually performed during the first week after birth, depending on the severity of the prenatal findings, but not during the first 72 h because of reduced urine output after delivery. Hydronephrosis does not generally represent a surgical emergency in the newborn. Most infants probably do not need surgery. The decision should be taken only on the basis of at least two evaluations demonstrating either a progressive increase in dilatation or a progressive reduction in glomerular filtrate. Normal appearing urinary tracts on two successive neonatal US rarely coexist with abnormal findings at VCUG [137]. Unilateral hydronephrosis is generally considered a benign condition that rarely leads to renal failure. Follow-up would appear to be mandatory in all patients, even over lengthy periods. Prenatal renal pelvic dilatation correlates with obstruction, and 15 mm maximum dilatation appears to be the most accurate predictor of postnatal

obstruction [138]. Bilateral hydronephrosis requires prompt evaluation by US and VCUG, especially in boys, in order not to miss PUVs [71, 139].

126.4.2.2 Dysplastic Kidneys

MDKs often regress at US in the first few postnatal years [140]. Therefore, it is infrequent that kidney remnant remain below the limit of radiological detection. Moreover, involution of noncystic dysplastic kidneys can also occur [62, 141]. In a child with a CSFK, it is difficult to distinguish either unilateral renal agenesis or aplasia from a regressed dysplastic kidney unless prenatal data are available. Large cysts replacing kidney parenchyma and lack of central pelvis or tiny remnant kidney characterize MDK. Cystic dysplastic kidneys have echobright kidney, echobright kidney with cysts and poor corticomedullary differentiation [142]. Renal agenesis and MDK commonly affect only one renal tract, although the contralateral tracts have an increased incidence of PUJO and primary VUR [143, 144]. ARPKD have bright kidney, echobright, large kidney with small cysts. ADPKD have large, bright kidney, sometimes with cysts that increase in size and number with age.

126.4.2.3 Renal Agenesis and Hypoplasia

Renal agenesis or aplasia is characterized by absent kidney at fetal US (adrenal gland might be mistaken for kidney). In CSFK, the kidney might be larger than normal, whereas it is hypoplasic when small kidney at US [145]. Some excretory functional compensation occurs postnatally in humans with bilateral dysplastic or hypoplastic kidneys. Distinguishing between dysplastic remnants and aplastic kidneys can be clinically relevant, because dysplastic remnants can sometimes drive hypertension [146]. Not all small kidneys, detectable by US and DMSA scintigraphy, may be caused by developmental malformations. Moreover, neonatal renal vein thrombosis [147] or severe renal artery stenosis can all damage a normal kidney, resulting in a small organ [148].

126.4.2.4 Vesicoureteral Reflux

VUR is the main risk factor for nephropathy [149]. The histological finding of dysplastic changes was reported in some poorly functioning kidneys attached to ureters with primary VUR [101]. Some of the babies with VUR, especially the boys, showed parenchymal defects, without history of UTIs [150]. In these subjects, the scarring associated with primary VUR were related as congenital kidney malformations. On the other hand, in girls, renal parenchymal changes associated with primary VUR were more commonly associated with a history of UTIs [151].

Fig. 126.3 Voiding cystoureterogram in a baby with posterior urethral valves

Scintigraphy with DMSA scan is currently used to detect nephropathy from VUR since concentrates only in functioning tubules. The DMSA scintigraphy may detect focal parenchymal defects that in most cases occur transiently after acute pyelonephritis but that resolve over 3–12 months [152].

126.4.2.5 Posterior Urethral Valves

PUVs are diagnosed by VCUG or cystoscopy revealing an obstruction at the urethral level in males (Fig. 126.3). VCUG can reveal the presence, grade and position of the VUR. In addition, dynamic radioisotope renography MAG3 can provide information about the flow of urine. Drainage from a very-dilated upper tract might be slower than normal even if there is no anatomical obstruction.

126.5 Prognosis

126.5.1 Antenatal Hydronephrosis

Children with any degree of antenatal hydronephrosis are at greater risk of postnatal pathology as compared with the normal population. Favorable prognosis in children with

antenatal hydronephrosis is related with monolateral pathology, such as such as renal agenesis or MDK, late obstruction and renal pelvis dilation. These forms are associated with normal amniotic fluid and normal lung development and the risk of renal failure in childhood is minimal [47, 143]. Although prenatal hydronephrosis has good prognosis, it raises the risk of hospitalization for pyelonephritis in infancy [153]. There was a significant increase in risk of pathology per increasing degree of hydronephrosis. The risk of any postnatal pathology per degree of antenatal hydronephrosis was 11.9% for mild, 45.1% for moderate, and 88.3% for severe [154]. Spontaneous resolution of idiopathic prenatal hydronephrosis occurs in most cases when the renal pelvic APD is less than 12 mm, but is less frequent when dilatation is greater than 12 mm [155].

126.5.2 Renal Agenesis and Dysplasia

Non-favorable renal prognosis is related to bilateral pathology, such as bilateral agenesis, bilateral MDK, early urethral obstruction (PUVs). Generally, these forms are associated with oligohydramnios and abnormal lung development. The renal functional outcomes in children with bilateral renal pathology are worse than those in children with uncomplicated unilateral disease [156], and decreased glomerular filtration rate (GFR) at presentation predicts progression to renal failure during childhood [142]. On follow-up, unobstructed and obstructed dysplastic or hypoplastic kidneys together account for about 40% of all children on renal replacement therapy. Dysplastic or hypoplastic kidneys are 10 times more common than PKD in children with renal replacement therapy [3].

126.5.3 Vesicoureteral Reflux

The risk of VUR was similar for all degrees of antenatal hydronephrosis [154]. In most infants with VUR, the reflux is of low grade and resolves rapidly. Reflux resolved spontaneously in 56% of cases at the 12-month follow-up and 72% at the 24-month follow-up. In those children with high-grade VUR, spontaneous resolution is rare at age 2 years. High-grade VUR had complete resolution of reflux in 9% at 12 months and 18% at 24 months [157]. The outcome of severely refluxing renal units was similar after medical treatment or surgical correction. Finally, prenatal and postnatal diagnosis of hydronephrosis from VUR did not seem to modify the renal outcome at follow-up [29].

126.5.4 Pyeloureteral Junction Obstruction

A prospective study on unilateral congenital PUJO showed that in kidneys with good function, followed conservatively, about a quarter underwent pyeloplasty because of an observed decrease in function [158]. Obstructed kidneys may undergo to stabilization or a relative reduction of the scintigraphic renal function than the unaffected contralateral kidney [159]. In this latter case, failure of the pyeloplasty could be due to underlying concomitant congenital renal dysplasia.

126.5.5 Posterior Urethral Valves

For several decades in newborns with PUVs it has been technically feasible to decompress fetal bladders affected by outflow obstruction by use of vesico–amniotic shunts. Unfortunately, no clear improvement in renal outcomes with such interventions has been shown, but only weak evidence that perinatal survival increased [77]. Although fetal intervention has the capacity to reduce neonatal mortality from pulmonary hypoplasia, increased survival of infants with severe renal dysplasia are destined to progress rapidly into ESRF.

126.6 Overview of Treatment Options

The most severe types of malformations, such as bilateral renal agenesis or dysplasia, although rare, lead to renal failure. With advances in dialysis and transplantation for young children, it is now possible to prevent the early death of at least some individuals with severe malformations. Now intervention could be either prenatal or postnatal for some disease. Treatment options for specific diseases are discussed in the related sections.

126.6.1 Fetal Intervention

Therapeutic termination of pregnancy is often undertaken if a fetus has severe renal tract malformations [39]. The main factor that leads to the decision to terminate is poor renal function and/or severe bladder outflow obstruction, which is manifested by reduced amniotic fluid, sometimes leading to impaired lung growth (oligohydramnios sequence or Potter's syndrome). However, some fetuses are found to have anomalies in other organ systems (e.g., brain, heart or gut), which are sometimes accompanied by gross chromosomal aberrations, such as trisomies [160]. With advances in dialysis for young babies and renal transplantation for young children [161], termination might not always be necessary [162].

The long-term outcomes for children born with PUVs remains poor, with some dying perinatally for lung hypoplasia and respiratory failure, and a significant subset of survivors going into severe renal failure within the next two decades of life [77, 163]. Even if infants with PUVs undergo bladder decompression, the risk of developing ESRF rises

with increasing age [164]. The long-term protection of kidney function from PUVs with prenatal surgical decompression aimed to slow the progression of renal failure needs to be established as well [2].

Therefore, prenatal diagnosis may have made an important, although numerically small, contribution to reducing the risk of renal failure in significant obstruction or high-grade reflux in a solitary functioning kidney.

126.6.2 Postnatal Therapies

The association between chronic pyelonephritis and VUR in childhood suggested an active treatment of individuals born with primary VUR to minimize kidney damage. The treatment options for specific disease are discussed in each section. The postnatal therapeutic options include surgery for obstructed kidneys and severely refluxing kidneys that are rarely performed before the first month of life and antimicrobial prophylaxis to treat and prevent infective complications.

126.6.3 Non Obstructed Hydronephrosis

Early correction of VUR in neonatal period is not performed since most of VUR resolve spontaneously. Few data support the primacy of either long-term antibiotic therapy or antireflux surgery for renoprotection [105, 165]. The era of active therapy has not reduced the incidence of end stage renal disease (ESRD) that occurs as a result of reflux nephropathy, which accords with the concept that reflux nephropathy is often caused by dysplasia or hypoplasia rather than by pyelonephritic damage [106]. Finally, after postnatal ages the initiation of therapies such as with prophylactic antibiotics, to prevent UTIs [166] or angiotensin blockade for reflux nephropathy [167], may be indicated in selected cases to improve the long-term renal outcomes.

126.6.4 Urinary Tract Obstruction

Rapid decline of the renal function related to severe obstruction, such as in newborns with solitary kidney, needs to be discussed for early surgical intervention with an expert pediatric urologist, as well as for early postnatal ablation of the urethral valves in newborns since early ablation and bladder management gave a better outcome [168]. Long-term results of prenatally detected PUVs confirm that early valve ablation can be considered as the primary treatment in the majority of patients, without the need for preoperative drainage or diversion. Gestational age at diagnosis and volume of amniotic fluid are significant predictors of postnatal renal outcome [83]. Moreover, in low birth weight neonates, primary valve ablation by a visually guided Fogarty catheter gave effective disruption of the valvular obstructive mechanism [169].

126.7 Laboratory Management of Kidney Diseases

Laboratory management of renal function is usually performed by urinalysis as well as by determining blood urea nitrogen (BUN) and serum creatinine for the estimation of the glomerular filtration rate (GFR). This traditional strategy, which has existed for more than one hundred years, seems no longer to meet the demands to detect and exclude renal lesions in early and treatable states, especially in the neonatal age [170]. The most important factor appears to be the renal functional reserve that masks renal degeneration, as assessed by GFR, BUN, and creatinine, up to the point where over 75% of the functioning nephrons have been lost. It should be stressed that these factors measure incipient renal failure and in most cases, the finding of normal results does not mean the absence of renal dysfunction. In addition, tubular proteinuria, which reflects tubulotoxic and tubulointerstitial diseases, is likewise not detected by the protein test strip [171]. Therefore, there is a growing demand for a clinically convenient and reliable markers of renal function.

126.7.1 Biomarkers in Pediatric and Neonatal Nephrology

The widespread availability of enabling technologies such as functional genomics and proteomics has accelerated the rate of novel biomarker discovery and therapeutic targets for kidney diseases [172]. The advent of the microarray, or cDNA chip, allows investigators to search through thousands of genes simultaneously, making the process very efficient. Such gene expression profiling studies have identified several genes whose protein products have emerged as chronic kidney disease (CKD) and acute kidney injury (AKI) biomarkers. However, microarray-based methods cannot be used for the direct analysis of biological fluids, and usually require downstream confirmation by proteomic techniques prior to clinical use. Proteomics is the study of both the structure and function of proteins by a variety of methods, such as gel electrophoresis, immunoblotting, mass spectrometry, and enzymatic or metabolic assays. Each method is used to determine different types of information and has its own set of strengths and limitations. Advancing technologies have radically improved the speed and precision of identifying and measuring proteins in biological fluids, and proteomic approaches are also beginning to yield novel and non-invasive biomarkers for assessing kidney damage. Urinary proteins include soluble

Table 126.4 Sources of urinary proteins

Sources of urinary proteins	Comments
1. Soluble proteins	
a. Glomerular filtration of plasma proteins	– Normally present (< 150 mg/day) – Defects in glomerular filter increase high molecular weight protein (e.g., albumin) excretion – Defects in proximal tubule reabsorption or abnormal production of low molecular weight plasma proteins increase low molecular weight protein (e.g., 2-microglobulin, immunoglobulin light chains, retinol-binding protein, and amino acids) excretion
b. Epithelial cell secretion of soluble proteins	Via exocytosis (e.g., epidermal growth factor) or glycosylphosphatidylinositol-anchored protein detachment (e.g., Tamm-Horsfall protein)
2. Solid phase components	
a. Epithelial cells	
– Whole cell shedding	Increased cell number compatible with several diseases including acute tubular necrosis (e.g., renal tubule cell shedding) and glomerular diseases (e.g., podocyte shedding)
– Plasma membrane and intracellular component shedding	Could be due to nonspecific, nephrotoxic, or apoptotic processes
– Exosome secretion	Normal process

proteins and protein components of solid phase elements of urine (Table 126.4). Solid phase elements consist of sediments that can be precipitated at low centrifugation speeds and exosomes that are of very low density and sediment only with ultracentrifugation. Prefractionation of these components can be useful as a means of enriching for markers of particular types of disease. A study of urine collected from normal human adult subjects indicated that, of the total urinary protein excreted, ~48% was container in sediments, 49% was soluble, and the remaining 3% was in exosomes [173].

Some of the soluble proteins in urine originate as membrane-bound proteins that are proteolytically cleaved from their membrane attachments. One of these is Tamm-Horsfall protein (uromodulin), an abundant soluble urinary protein that is secreted by the thick ascending limb of Henle loop, a nephron segment downstream from the proximal tubule [174]. It originates as a glycosylphosphatidylinositol-linked protein present in the apical plasma membrane that can be cleaved from its cell attachment proteolytically.

126.7.2 Markers for Assessing Glomerular Filtration Rate

Serum creatinine concentration and endogenous creatinine clearance have been used for such a long time to assess glomerular filtration rate (GFR); nevertheless, serum creatinine has a limited diagnostic value, because this marker shows no response until the GFR is reduced by approximately 40% [175]. Creatinine clearance is affected by inaccuracies in quantitatively collecting urine and by the renal tubular secretion of creatinine, which would falsely elevate the apparent GFR [176]. Moreover, proteins and substances with a ketone group are known to interfere in the Jaffe (alkaline picrate) reaction for the measurement of creatinine in serum and urine; this prevents the measurement of the true concentration of creatinine [177]. Finally there is a lack of availability of pediatric creatinine serum standards referenced to an isotope dilution mass spectrometry method [178].

Because serum creatinine concentration is influenced by both the production rate and the excretion rate, the nephrology community concluded that results should be interpreted in light of the expected rate of production of creatinine. Thus, equations based on serum creatinine are more accurate and precise than serum creatinine alone for estimating GFR (*e*GFR), as recommended by the clinical practice guidelines for CKD in children [179]. Estimating equations include variables such as sex, age, body size, and ethnicity in addition to serum creatinine, as surrogates for muscle mass. Equations have the advantage of providing an estimate of GFR which empirically combines all of these average effects while allowing for the marked differences in creatinine production between individuals [180]. Clinical laboratories should report an estimate of GFR using a prediction equation, in addition to reporting the serum creatinine measurement [181]. Two of the common formulas used for adults are the Cockcroft–Gault and the Modification of Diet in Renal Disease (MDRD) formulas, but these are not appropriate for use in children and babies [182]. In the newborn and in the early infancy, the most widely used estimate of GFR is the original Schwartz equation [183]; based on serum creatinine (SCr), height, and an empirical age-related constant k, this equation was firstly devised in the mid-1970s. It has been successful because it relates GFR to (patient's height)/(SCr) rather than to 1/(SCr). Although simple to use, the Schwartz formula may give biased and imprecise *e*GFR, unless the values of k are derived from local estimates of mean height,

GFR, and SCr. When locally derived estimates of *k* are used, the bias decreases substantially but the precision of *e*GFR remains poor. In addition, the Schwartz equation assumes that there is no intercept associated with the relationship of GFR versus height/SCr which, if incorrect, could lead to more biased *e*GFR and to incorrect values for the slope, *k*. It remains unknown whether a less biased and more precise estimation of GFR can be achieved using regression to determine the relation between GFR and height/SCr in a local population, rather than substituting variables and computing mean *k* [184]. Finally, pediatricians need to recognize that the formula requires updating when analytically specific methods of measuring serum creatinine, such as enzymatic assays, are used in their institutions [185].

The accuracy of the *e*GFR is important for the early detection of CKD in adults, children, and newborns, as has been recognized in the recent awareness campaigns in the European Union and in the US (www.NKDEP.nih.gov). An early detection of changes in GFR leads to an early appropriate treatment options, such as weight loss, exercise, or blood pressure control, especially with angiotensin-converting enzyme (ACE) inhibitors, slowing or even halting progression of renal injury and/or dysfunction. Because serum creatinine concentration and the *e*GFR are interrelated, the performance of the creatinine analysis affects GFR estimates [186]. The Laboratory Working Group of the National Kidney Disease Education Program (NKDEP), in collaboration with international professional organizations, has developed a plan that enables standardization and improved accuracy (trueness) of serum creatinine measurements in clinical laboratories worldwide. The Working Group developed a report in the US, reviewing the information on the non-specificity of routine creatinine methods and recommended that manufacturers of *in vitro* diagnostics address and reduce the influence of interfering substances in patient samples [187].Two serum pools with creatinine concentrations within the pediatric reference interval were spiked with albumin, IgG, unconjugated bilirubin, adult hemoglobin (Hb A), and fetal hemoglobin (Hb F) to produce one unspiked and five spiked samples per pool. Albumin, IgG, and Fetal Hemoglobin (HbF) interfered with Jaffe creatinine assays, leading to inaccuracies in *e*GFRs that are clinically important, especially in children and neonates. In particular, albumin interference leads to a GFR underestimation ranging from 17 to 27%, while HbF interference to a GFR overestimation ranging from 24 to 60%. Because protein error and HbF interference do not occur with any of the enzymatic methods tested, the authors conclude that enzymatic creatinine methods are preferred for evaluation of kidney function in pediatric cases. The more recent enzymatic creatinine method results in lower determinations compared with the older Jaffe method, even when the latter was improved with a dialysis step and elimination of interfering samples [188].

In 2009, Schwartz proposed a new formula for calculating *e*GFR in children with CKD [189]. The new equation includes serum creatinine, measured by an enzymatic analytical method, cystatin C, and BUN together with an accurate height measurement. Based on a carefully described, prospectively recruited cohort of children with various types of kidney diseases that have compromised function, the results seem to provide a more accurate, noninvasive method of estimating the GFR in the pediatric and neonatal age. This formula yielded 87.7% of *e*GFR within 30% of the GFR assessed by iohexol plasma disappearance and 45.6% within 10%. This new equation permits to improve the adjustment of drug dosing and can be used as a research tool. But it can also be used clinically as a confirmatory screening tool for children with impaired renal function and to determine whether CKD in children is stable or progressing. Unfortunately, it cannot yet be used as a general screening tool, since it has not yet been verified in a cohort of children with normal renal function.

Taking into account the extreme importance of the accuracy in the measurement of serum creatinine when creatinine-based equation are used to estimate GFR [190], the National Disease Education Program (NKDEP) has developed several recommendations for the improvement and development of creatinine assays [187]. These recommendations include optimizing creatinine assays to provide accurate (traceable to MS-IDMS) and precise measurements (imprecision goal of approximately 8% to meet the maximum 10% impact on *e*GFR) particularly at a concentration of 1.00 mg/dL, revising GFR-estimating equations based on more accurate methods, and introducing proficiency testing programs that use commutable serum materials with target values traceable to MS-IDMS procedure [191]. The National Institute for Standards and Technology has developed a reference material at concentrations of approximately 0.80 and 4.00 mg/dL to help manufacturers in the standardization of creatinine assays [192].

126.7.3 Low Molecular Mass Proteins

Over the past 20 years, interest has been shown in the diagnostic power of low molecular mass proteins (low-M_r proteins) in serum and urine for the evaluation of renal function. These proteins are freely filtered through the capillary wall, then reabsorbed and catabolized in the proximal tubular cells. Thus, if the GFR in the kidney is reduced, the serum concentrations of low-M_r proteins increase and may be taken as suitable markers of GFR [193]. On the other hand, if the tubular reabsorption capacity is reduced, or if tubular cells have been damaged by nephrotoxic drugs or agents, the urinary excretion of these proteins increase and may be taken as suitable index of renal tubular impairment and dysfunction [194]. In the normal kidney, the reabsorption of low-M_r proteins by proximal tubular cells is nearly complete so that only trace amounts of these proteins are excreted in urine (approximately 0.1 mg/24 h). As a corollary, low-M_r proteins in urine are very sensitive markers of impaired proximal tubular function. The urinary excretion of low-M_r proteins reflects

the reabsorptive capacity of proximal tubules when the GFR is normal or only slightly abnormal. Herget-Rosenthal have measured urinary excretion of a number of candidate low-M_r-proteins, such as α_1-microglobulin (protein HC), β_2-microglobulin, cystatin C, retinol-binding protein, α-glutathione *S*-transferase, lactate dehydrogenase, and *N*-acetyl-β-(D)-glucosaminidase, early in the course of non-oliguric acute renal failure in humans [195]. In this cohort of patients with established acute renal failure (ARF) from a variety of causes, urinary excretion of α_1-microglobulin and cystatin C were found to be predictive of severe ARF requiring renal replacement therapy, with an area under characteristic curve (AUC) of 0.86 and 0.92 respectively. α_1-microglobulin is a tubular protein that belongs to the lipocalin superfamily, while cystatin C is a cysteine protease inhibitor that is synthesized and released into the blood at a relatively constant rate by all nucleated cells. Both α_1-microglobulin and cystatin C are stable in the urine [196], and can be easily measured by immunonephelometric methods in most standard clinical chemistry laboratories. The predictive role of these urinary proteins in early AKI remains to be determined.

126.7.4 Cystatin C

Cystatin C is a non-glycosylated 13 kDa basic protein that acts as a cysteine proteinase inhibitor and is produced at a relatively constant rate. This constancy is apparently not influenced by the presence of inflammatory conditions, muscle mass, gender, body composition, and age after 12 months [197]. Blood cystatin C level is approximately 1 mg/L in healthy individuals of age > 1y, while in the neonatal age and in the early infancy blood cystatin C is significantly higher [198]. Cystatin C is catabolized and almost completely reabsorbed by renal proximal tubular cells, so that a very small amount is excreted in the urine [199] and cannot be used to calculate a clearance GFR. Inter-individual variation of cystatin C level is significantly less (25%) than that of creatinine (93%) [200]. The upper limit of the population reference interval for cystatin C is seldom more than 3–4 standard deviations (SD) from the mean value of any healthy individual (compared with 13 SD for creatinine). These findings suggest that cystatin C is potentially a better marker than creatinine for detecting impaired renal function. From a number of clinical studies on cystatin C, two key findings are evident. First, the concentration of serum cystatin C correlated better with directly measured values for GFR than did serum creatinine. Second, subtle decrements in GFR are more readily detected by the determination of serum cystatin C than by creatinine concentration [201]. Thus, while cystatin C is not a conventional marker of GFR, reciprocal values of serum cystatin C levels are reasonably well correlated with GFR in adults [202] and in children [203]. Some studies have suggested that the serum concentration of cystatin C might be superior to serum creatinine in distinguishing normal from abnormal GFR [204]. However, because it is metabolized and not excreted, cystatin C cannot be used to measure GFR by standard urinary clearance techniques [205]. Nevertheless, serum cystatin can be used to estimate GFR in milliliters per minute per 1.73 square meters according to the following formula: $\log_{10}(\text{GFR}) = 1.962 + [1.123 * \log_{10}(1/\text{cysC})]$, where cysC is cystatin C [206]. Additional formulae using both cystatin C and creatinine to estimate GFR have recently been reported. Such studies have shown that plasma cystatin C is slightly better than plasma creatinine in diagnosing renal insufficiency but is less sensitive than creatinine clearance or *e*GFR (from $k * \text{L/Pcr}$) [207].

126.7.5 Albumin in Urine and Kidney Disease

The appearance of albumin in the urine has long been recognized as a cardinal feature of kidney disease and more recently has been shown to also be an independent cardiovascular risk factor associated with insulin resistance. Normal human urine contains only very small quantities of albumin, less than 30 mg/d. In a position statement published in 2003, the National Kidney Foundation and the National Institute of Diabetes and Digestive and Kidney Diseases recommend a spot, untimed urine specimen be used for measurement of urinary albumin [208]. Using the ratio of urine albumin to urine creatinine, microalbuminuria is defined as a level of 30–300 mg albumin/g creatinine [209].

Urine albumin has traditionally been screened in the office setting by use of a variety of semiquantitative dipsticks. These tests involve wetting a chemically impregnated test strip with urine. Some commercial dipsticks detect microalbuminuria by albumin binding to a sulfonephthalein dye, which produces a color reaction that is read reflectometrically in a portable urine chemistry analyzer. Comparisons of this dipstick to reference laboratory tests have shown that the sensitivity ranges from 79 to 95.4% and that the specificity ranges from 73 to 81% [210]. Other commercial dipsticks detect albumin by a different chemical method: albumin passes via a wick fleece into a conjugate fleece, where it binds to specific, gold-labeled antibodies, and then flows to a detection pad [211]. A chemical reaction in the detection pad produces a color that is compared visually with color blocks. Comparisons of this test to reference laboratory results have shown that the sensitivity ranges from 93 to 97.1%, and the specificity ranges from 33.3 to 81% [212].

Quantitative measurement of urine albumin are traditionally based on three laboratory methods: immunonephelometry, immunoturbidimetry, and radioimmunoassay (RIA). The performance characteristics of these methods are listed in Table 126.5. Conventional immunoassays suggest that normal humans would only excrete less than 30 mg/d of albumin, whereas the amount of albumin-derived material excreted may range from 1 to 3 g/d [213]. These studies demonstrate that a considerable amount of peptide-derived

Table 126.5 Performances of the most common analytical methods for the measurement of microalbuminuria

Analytical method reproducibility (CV, %)	Interassay	Detection limit
Radioimmunoassay (RIA)	9.2% at 12.2 mg/L 4.8% at 33.0 mg/L	16 µg/L (0.016 mg/L)
Immunonephelometry (Beckman Array Analyser)	4.2% at 12.1 mg/L 5.3% at 45.0 mg/L	2 mg/L
Immunoturbidimetry (Siemens Turbitimer)	4.1% at 10.6 mg/L 2.2% at 43.2 mg/L 4.2% at 77.9 mg/L	6 mg/L
Immunoturbidimetry (Siemens Dimension RxL)	8.5% at 8.0 mg/L 3.4% at 35.0 mg/L	6 mg/L
HPLC	2.4% at 95.8 mg/L	2 mg/L

Modified from [245].

low-molecular-weight fragments is commonly excreted in urine of healthy subjects. The degradation process occurs in tubular epithelial cells, where albumin is endocytosed and trafficked to lysosomes. Once degraded, albumin is exocytosed into the tubular lumen and excreted in urine. The degradation products are exclusively found in urine and they never return in blood stream. This technique is likely to provide new information as a diagnostic tool because changes in the peptide profile, or fingerprint, can reflect renal disease and possibly other diseases, such as cancer.

126.7.6 Novel Markers for Kidney Ischemia, Hypoxia, and Drug-Induced Toxicity

Proteomic approaches have recently yielded additional biomarkers for acute kidney injury (AKI). AKI is a term proposed to reflect the entire spectrum of acute renal failure, a complex disorder that occurs in a wide variety of settings with clinical manifestations ranging from a minimal elevation in serum creatinine to anuric renal failure [214]. In current clinical practice, AKI is typically diagnosed by measuring serum creatinine. Unfortunately, during acute changes in glomerular filtration, serum creatinine does not accurately depict kidney function until steady state equilibrium has been reached, which may require several days.

Conventional urinary biomarkers such as casts and fractional excretion of sodium have been insensitive and non-specific for the early recognition of AKI. Other traditional urinary biomarkers such as filtered high molecular weight proteins and tubular proteins or enzymes have also suffered from lack of specificity and dearth of standardized assays.

Identification of novel AKI biomarkers has been designated as a top priority by the American Society of Nephrology [215]. The concept of developing a new toolbox for earlier diagnosis of disease states is also prominently featured in the NIH Road Map for biomedical research [216]. The application of innovative technologies such as functional genomics and proteomics to human and animal models of kidney disease has uncovered several novel candidates that are emerging as biomarkers and therapeutic targets [217]. Several human models of AKI have consistently demonstrated the presence of apoptotic changes in tubule cells [218]. Importantly, proteomic studies have now identified a multitude of apoptotic pathways, including the intrinsic (Bcl-2 family, cytochrome c, caspase 9), extrinsic (Fas, FADD, caspase 8), and regulatory (p53) factors, that are activated in tubule cells following human AKI [219]. As a consequence of these studies, inhibition of apoptosis has emerged as a promising approach in human AKI [220]. Cell-permeable caspase inhibitors have provided particularly attractive targets for study. In this regard, an orally active small molecule pan-caspase inhibitor (IDN-6556, Pfizer) has been shown to be effective in preventing injury after lung and liver transplantation in animals [221].

126.7.7 Neutrophil Gelatinase-associated Lipocalin (NGAL)

Supavekin also identified neutrophil gelatinase-associated lipocalin (NGAL, also known as *lcn2*) as one of the most upregulated transcripts in the early post-ischemic mouse kidney [222], a finding that has now been confirmed in several other transcriptome profiling studies. Downstream proteomic studies have also revealed NGAL to be one of the earliest and most robustly induced proteins in the kidney after ischemic or nephrotoxic AKI in animal models, and NGAL protein is easily detected in the blood and urine soon after AKI [223]. These findings have spawned a number of translational proteomic studies to evaluate NGAL as a novel biomarker in human AKI.

In a cross-sectional study, subjects in the intensive care unit with established ARF displayed a greater than 10-fold increase in plasma NGAL and more than a 100-fold increase in urine NGAL by Western blotting when compared to normal controls [223]. Both plasma and urine NGAL correlated highly with serum creatinine levels. Kidney biopsies in these patients showed intense accumulation of immuno-reactive NGAL in 50% of the cortical tubules. These results identified NGAL as a widespread and sensitive response to established AKI in humans. Urine NGAL has been shown to predict the severity of AKI and dialysis requirement in a multicenter study of children with diarrhea-associated hemolytic uremic syndrome [224]. Preliminary results also suggest that plasma and urine NGAL measurements represent predictive biomarkers of AKI following contrast administration [225] and in the intensive care setting [226]. In summary, NGAL is emerging as a center-stage player in the AKI field, as a novel predictive biomarker. However, it is acknowledged that the studies published thus far are small, in which NGAL appears to be most sensitive and specific in relatively uncomplicated patient populations with AKI. NGAL measurements may be

influenced by a number of coexisting variables such as pre-existing renal disease [227] and systemic or urinary tract infections [228]. Large multicenter studies to further define the predictive role of plasma and urine NGAL as a member of the putative AKI panel have been initiated; simultaneously, a new chemiluminescent microparticle method, optimized on a fully-automated analytical platform (ARCHITECT, Abbott Diagnostics Inc, Abbott Park, IL, USA) has been developed for the measurement of urine NGAL in the clinical practice and, specifically, in the emergency setting [229]. This new simple method permits to measure urine NGAL in all the clinical laboratories in a time closely comparable with that occurring for measuring creatinine. Thus, both NGAL and cystatin C may represent promising tandem biomarker candidates for inclusion in the blood AKI panel [230].

126.7.8 Kidney Injury Molecule 1 (KIM-1)

Kidney injury molecule 1 (KIM-1) is a type-1 transmembrane protein with glycosylated mucin and IgG-like domains in the ectodomain of the protein and a relatively short intracellular domain that is tyrosine phosphorylated. Downstream proteomic studies have also shown KIM-1 to be one of the most highly induced proteins in the kidney after AKI in animal models, and a proteolytically processed domain of KIM-1 is easily detected in the urine soon after AKI. In a small human cross-sectional study, KIM-1 was found to be markedly induced in proximal tubules in kidney biopsies from patients with established AKI (primarily ischemic), and urinary KIM-1 measured by ELISA distinguished ischemic AKI from prerenal azotemia and chronic renal disease [231]. Patients with AKI induced by contrast did not have increased urinary KIM-1.

Recent preliminary studies have expanded the potential clinical utility of KIM-1 as a predictive AKI biomarker [232]. KIM-1 represents a promising candidate for inclusion in the urinary AKI panel. An advantage of KIM-1 over NGAL is that it appears to be more specific to ischemic or nephrotoxic AKI, and not significantly affected by prerenal azotemia, urinary tract infections, or chronic kidney disease. It is likely that NGAL and KIM-1 will emerge as tandem biomarkers of AKI, with NGAL being most sensitive at the earliest time points and KIM-1 adding significant specificity at slightly later time points.

126.7.9 Additional Protein Markers: CYR61, SSAT, Zf9, TSP-1, IL-18

Gene expression studies have provided several additional clues regarding the AKI proteome, but human data are hitherto lacking. For example, Muramatsu et al have utilized a subtractive hybridization approach to identify *Cyr61* (also known as *CCN1*) as a markedly upregulated gene in the rat kidney very early after ischemic injury [233]. CYR61 protein was induced in the kidney within one hour and detectable in the urine at 3–6 hours after ischemic injury, but not after volume depletion. However, this detection required a complex bioaffinity purification step with heparin-Sepharose beads, and even after such purification, several crossreacting peptides were apparent. A more convenient platform for the evaluation of CYR61 as a urinary biomarker in humans has not been available to date. Zahedi et al described spermidine/spermine N1-acetyltransferase (SSAT), the rate-limiting enzyme in polyamine catabolism, as a novel early biomarker of tubular cell damage after ischemic injury in rats [234]. SSAT protein appears to play a role in the initiation of oxidant-mediated injury to tubules, raising the possibility of inhibition of polyamine catabolism as a future therapeutic approach [235].

Tarabishi et al showed that another maximally induced gene identified very early after ischemic injury in animal models is Zf9, a Kruppel-like transcription factor involved in the regulation of a number of downstream targets [236]. Zf9 protein is markedly upregulated in the postischemic tubule cells, along with its major trans-activating factor, TGF-β1. Gene silencing of Zf9 abrogated TGF-β1 protein expression and mitigated the apoptotic response to ischemic injury *in vitro* [236]. These studies have thus identified a novel pathway that may play a critical role in the early tubule cell death that accompanies ischemic renal injury. Thakar et al have employed transcriptome profiling in rat models to identify thrombospondin 1 (TSP-1), a previously known p53-dependent pro-apoptotic and anti-angiogenic molecule, as another maximally induced gene early after ischemic AKI [237]. The TSP-1 protein product is upregulated in the post-ischemic proximal tubule cells, where it colocalizes with activated caspase-3. TSP-1 null mice were partially protected from ischemic injury, with striking structural preservation of kidney tissue [237]. These results have thus identified yet another previously unknown apoptotic protein that is activated in proximal tubule cells early after ischemic AKI in animals. Transcripts that have been consistently reported to be either upregulated or downregulated in animal models of AKI are listed in Tables 126.4 and 126.5, respectively. While many of them have now been confirmed by downstream proteomic analysis, the majority of these studies remain in the pre-clinical research realm, and convincing data attesting to their utility in human AKI are currently unavailable.

IL-18 is a pro-inflammatory cytokine that is known to be induced and cleaved in the proximal tubule, and subsequently easily detected in the urine following ischemic AKI in animal models [238]. In a cross-sectional study, urine IL-18 levels measured by ELISA were markedly increased in patients with established AKI, but not in subjects with urinary tract infection, chronic kidney disease, nephritic syndrome, or prerenal failure [239]. Urinary IL-18 was significantly upregulated up to 48 hours prior to the increase

in serum creatinine in patients with acute respiratory distress syndrome who develop AKI, with an AUC of 0.73, and represented an independent predictor of mortality in this cohort [240]. Both urinary IL-18 and NGAL were recently shown to represent early, predictive, sequential AKI biomarkers in children undergoing cardiac surgery [241]. In patients who developed AKI 2-3 days after surgery, urinary NGAL was induced within 2 hours and peaked at 6 hours whereas urine IL-18 levels increased around 6 hours and peaked at over 25-fold at 12 hours post surgery (AUC 0.75). Both IL-18 and NGAL were independently associated with duration of AKI among cases.

Urine NGAL and IL-18 have also emerged as predictive biomarkers for delayed graft function following kidney transplantation [242]. In a prospective multicenter study of children and adults, both NGAL and IL-18 in urine samples collected on the day of transplant predicted delayed graft function and dialysis requirement with AUC of 0.9. Thus, IL-18 may also represent a promising candidate for inclusion in the urinary "AKI panel". IL-18 is more specific to ischemic AKI, and not affected by nephrotoxins, chronic kidney disease or urinary tract infections. It is likely that NGAL, IL-18 and KIM-1 will emerge as sequential urinary biomarkers of AKI [243].

Brain Development and Perinatal Vulnerability to Cerebral Damage

Luca A. Ramenghi, Monica Fumagalli and Veena Supramaniam

127.1 Introduction

The recent exponential rise in detailed magnetic resonance (MR) imaging studies has emphasized the concept of gestationally determined regional vulnerability in the brain: the site and nature of the injury sustained being determined by a combination of the characteristics of the insult, the specific tissue and cell vulnerability and the gestation of the infant. The type of insult may also be partly dependent on gestation. However, it is now known that acute perinatal hypoxic ischemic events, previously considered characteristic for the term born neonate presenting with hypoxic-ischemic encephalopathy (HIE), may occur at earlier points in gestation [1, 2]. Nevertheless, such events occur less often in the infant born preterm where lesions develop in similar brain regions and in other areas characteristically more vulnerable in more premature babies (Fig. 127.1). Similarly, white matter (WM) lesions, which are considered the hallmark of injury to the preterm brain because they are characteristic of perinatal injury relating to inflammation, infection or hypoglycemia in the term brain, may also occur in a small percentage of neonates with an encephalopathy (Fig. 127.2) [3].

The regional tissue vulnerability at a given gestation will be determined by the local metabolic requirements in combination with specific cell characteristics, e.g., density of glutamate receptors [4]. Regional tissue vulnerability at different gestational ages has been demonstrated by numerous *in vivo* brain imaging studies, as well as by conventional postmortem examinations. However, animal studies have highlighted the concept of a specific vulnerability by certain cell types, e.g. the subplate neurons [5] and oligodendrocyte precursors [6] are most vulnerable in the preterm brain. In the term brain, excitatory pyramidal projection neurons especially in the deep grey nuclei are at greatest risk during ischemic insults (Fig. 127.1). The vulnerability of a specific cell type at a given gestation relates to characteristics such as the expression of different glutamatergic receptor subtypes that favor calcium

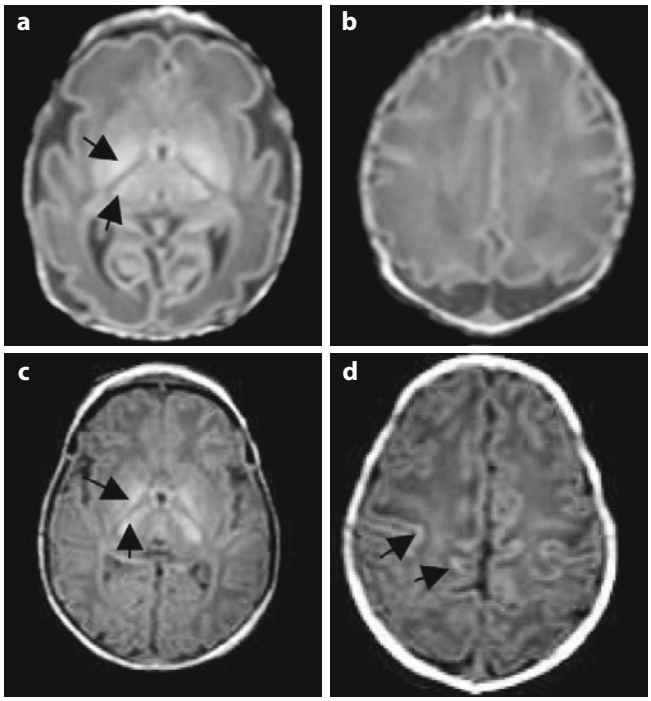

Fig. 127.1 Basal ganglia and thalamic (BGT) injury. BGT lesions are the hallmark of an acute hypoxic-ischemic event regardless of gestational age. **a**, **b** Preterm infant born at 32 weeks gestation by emergency cesarean section (EMCS) for abnormal fetal heart rate. There is abnormal high signal intensity (SI) either side (*arrows*) of the low SI posterior limb of the internal capsule (PLIC) (unmyelinated at this age). There is no obvious abnormality in or adjacent to the developing central sulcus or interhemispheric fissure (**b**). **c**, **d** Term born neonate born by EMCS for fetal distress. There is bilateral abnormal high signal intensity in the globus pallidus and thalamus (*arrows*). There is no myelin in the PLIC, which is abnormal at this age (**c**). Superiorly there is some increased SI in the central sulci and cortex along the interhemispheric fissure (*arrows*). The subcortical white matter adjacent to these regions is abnormally low SI (**d**)

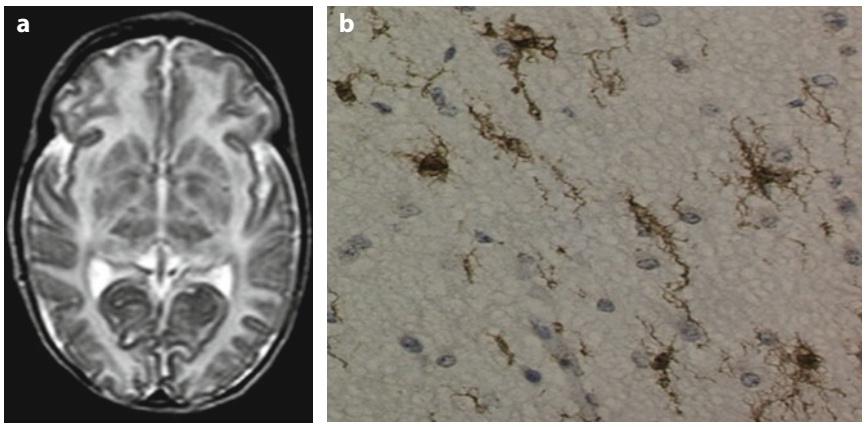

Fig. 127.2 T2 weighted scan (**a**) obtained at 9 days of age in a neonate with severe perinatal basal ganglia and thalamic injury showing diffuse high signal intensity in the white matter. Marked microglial activation (**b**) was seen in the white matter at post mortem ten weeks later

entry and excitability, and endogenous antioxidant mechanisms [7]. In addition, the neonatal neuron is programmed for cell death to allow for essential pruning and optimal connectivity, but this characteristic increases the vulnerability of such cells to injury. However, while research has focussed on WM vulnerability in preterm infants and gray matter vulnerability in term infants, the nature of the insult is also important in dictating lesion site.

In this chapter we will discuss the vulnerability of tissue and cell types in relation to gestational age and examine how these relate to patterns of injury seen on brain MR imaging and the clinical history and presentation of the infant.

127.2 Brain Development

In order to understand the vulnerability of the immature brain to injury, it is essential to consider the stages of brain development from early fetal life until term at around 40 weeks' postmenstrual age (PMA). A full description of brain development is beyond the scope of this chapter so we will concentrate on regions of the preterm brain that are known to be particularly vulnerable; the immature white matter and the germinal matrix. In the more mature term brain we will focus on the deep gray matter and myelinating white matter with different cell types that may contribute to this changing vulnerability.

The first half of gestation is characterized by neuronal proliferation and migration. During the second half, glial cell proliferation and programmed cell death predominate [8–10]. The last trimester of gestation is characterized by developing connectivity. There is axonal and dendritic sprouting and synapse formation. These processes, which involve programmed cell death, continue throughout childhood and into adolescence. Whilst early myelination in central brain structures, such as the brainstem and thalami, is present by 26 weeks, further

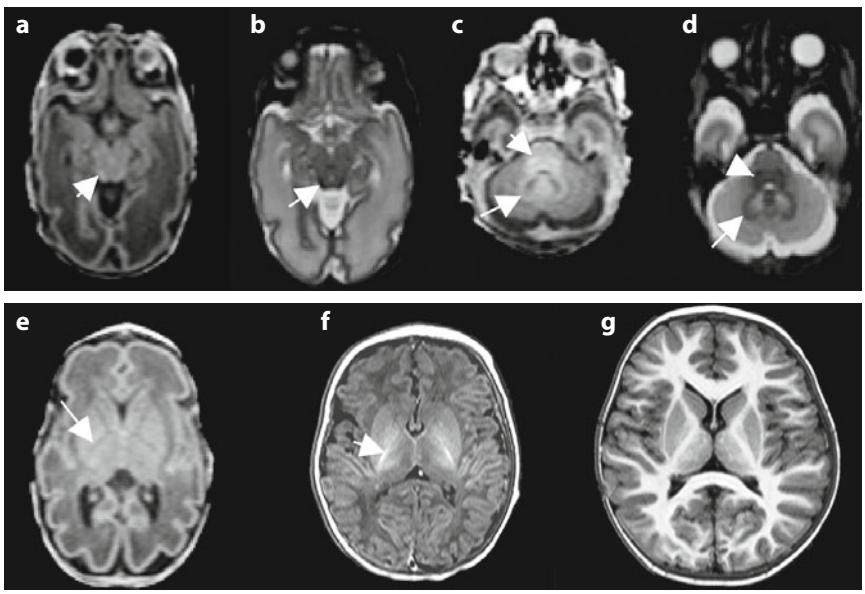

Fig. 127.3 Myelination. Preterm infant born at 26+5 weeks gestation and imaged at 29 weeks (**a**–**e**). Term born neonate (**f**). Two year old child (**g**). Myelination is seen as high signal intensity on T1 weighted images (**a**, **c**, **e**, **f**, **g**) and low signal intensity on T2 weighted images (**b**, **d**). At 29 weeks postmenstrual age myelination is detected in many central brain areas such as in brainstem regions e.g., lateral lemnisci (*arrows*) (**a**, **b**) and the medial lemnisci (*short arrows*) (**c**, **d**) and in the dentate nuclei (*long arrow*) (**c**, **d**). Myelination is easier to detect on T2 weighted images in the preterm brain. Myelination in the PLIC is visible from around 37 weeks postmenstrual age (*arrow*) (**f**). Prior to myelination the PLIC may look low signal intensity on T1 weighted images (*arrow*) (**e**). The majority of brain myelination occurs during the first two years of postnatal life (**g**)

myelination in the posterior limb of the internal capsule is then not detected until the end of gestation [11]. The majority of brain myelination occurs in the first 2 years after birth (Fig. 127.3). There is, however, extensive premyelination occurring within hemispheric white matter during late gestation and the abundance of oligodendrocyte precursors are particularly vulnerable to damage [6]. This pre-myelination is in part responsible for the anisotropy of WM tracts documented in diffusion tensor images of the preterm brain before the appearance of myelination. Measures of anisotropy can therefore be used as an indirect measure of oligodendrocyte injury in the immature brain prior to myelination [11, 12].

Knowledge of the timing of events, such as myelination, allows us to understand the vulnerability of tissue types. *In vivo* methodology to assess such injuring processes provides an insight into the neurological sequelae that may result from lesions sustained at a given gestation.

127.3 Regional Vulnerability

127.3.1 Neuronal Migration

From the fifth week PMA, the neural tube starts to develop and differentiate. Specific proliferation areas can be identified in the ventricular and subventricular zones from where excitatory pyramidal neurons migrate to their final destination, mostly following specialized radial glial fibers. This radial migration process is closely regulated by complex molecular interactions between neurons and glial cells mediated by glycoproteins, membrane lipids and neurotransmitters [13].

More recently it has been appreciated that, in addition to this radial migration, there are two further modes of migration, tangential and multipolar migration [14, 15]. The latter occurs independently of radial glia. It was originally thought that all neuronal migration ceased by 20 weeks PMA, but this referred to radially migrating pyramidal neurons. Gabaminergic inhibitory interneurons generated in the ganglionic eminences migrate in a tangential manner initially and then along the radial glia into the cortex in an inside-out manner. This process continues until past term [8, 16]. Later, the medial and lateral ganglionic eminences appear and give rise to different populations of interneuron; those from the lateral or caudal eminence migrate and occupy superficial layers of the cortex [17]. Thus neuronal migration continues during a period when an infant born preterm may be exposed to a variety of potentially damaging factors. Many recognized disturbances in neuronal migration result from genetic defects [18], giving rise to profound abnormalities of cortical development such as the lissencephalies. Acquired injuries to the immature brain such as ischemia, viral infection [19, 20] or maternal drug abuse [21] may target replicating neuroblasts and disrupt neuronal migration. Acquired injuries result in more focal cortical dysplasias such as polymicrogyria, which is frequently associated with cytomegalovirus infection (Fig. 127.4) [19, 20]. Earlier insults (Fig. 127.4) cause more severe disruption of cortical development, and later insults may result in subtle abnormalities in cortical development that may not be visually obvious but that could be investigated using more advanced imaging techniques such as diffusion tensor imaging.

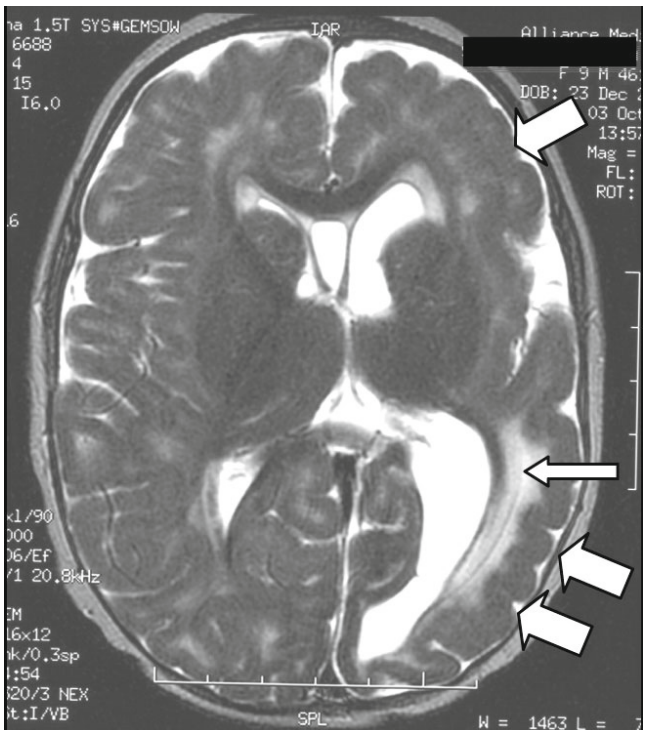

Fig. 127.4 Congenital CMV. Axial T2 scan of a term baby with CMV infection acquired around the 12th week of intrauterine life. The early fetal infection has determined cortical malformations such as polymicrogyria (*white arrows*) more evident in the right hemisphere and diffuse and severe white matter abnormalities (*thin arrow*)

127.3.2 The Cortical Subplate

The cortical subplate is an important anatomical and functional structure, which is present at all phases of intrauterine brain development from early gestation to near term. The first populations of migrating neurons occupy the transient cortical subplate from approximately 7–8 weeks post conception. The subplate is essential for normal cortical development and subplate neurons develop both intracortical and subcortical projections [22]. The subplate zone becomes visible in the human brain at around 14-15 post-conceptional weeks (PCW), the beginning of the second trimester of human gestation. This coincides with the invasion of the subplate region by thalamocortical afferents as well as basal forebrain afferents, leading to rapid expansion of the subplate so that it comprises 35% of the cerebral wall by 16 PCW. From 14 to 25 PCW in the human, a large number neurons are continuously added to the

subplate compartment, which increases in width concurrent with the growth of the cortical plate. The highest density of cells is always found at the border between cortical plate and subplate. At its peak of development, the human subplate zone is four times the width of the cortical plate [23], reaching its maximum thickness in the late second and early third trimester, more or less between 25 and 29 weeks. This is a period of high vulnerability for WM injury. Thereafter it gradually decreases in size and becomes unrecognizable by the sixth month post-term [23].

Early thalamo-cortical afferents remain within the subplate until approximately 28 weeks when they progress into the cortex to form the earliest functional neurocircuits of the neocortex. The subplate layer contains a hydrophilic extracellular matrix that enables visualization of the subplate *in vivo* using MR imaging of the fetal or preterm infant brain. It can be quantified using volumetric scanning or diffusion tensor imaging [24, 25]. On MR imaging the subplate layer is thicker than the cortex until approximately 24 weeks, equivalent to the cortex until about 28 weeks, and then starts to involute, being visible only at the tops of gyri throughout the third trimester (Figs. 127.5, 127.6). A normal term infant usually only displays a few regions of residual subplate on imaging, and, in infants with overt lesions, the subplate may disappear prematurely. In contrast, in preterm infants imaged at term equivalence, the subplate may persist abnormally when compared to term born controls. This alteration in subplate involution associated with preterm birth may be due to more subtle forms of injury. The consequences of these alterations in subplate evolution on cortical development are unknown. However cortical gyration is reduced in the preterm brain at term equivalence, in comparison with normal term born control brains. However, MR cortical maturation at term corrected age is delayed in preterm babies with mild white matter abnormalities compared to those without (Fig. 127.7) [26–28].

In a rodent animal model of perinatal HI, the subplate neurons appear to be selectively vulnerable and their loss corresponds to the severity of the insult [29]. Investigators speculated that the glutamate receptor played a role in the pathogenesis, although the problem seems further complicated by more recent observations, suggesting a novel mechanism for subplate vulnerability.

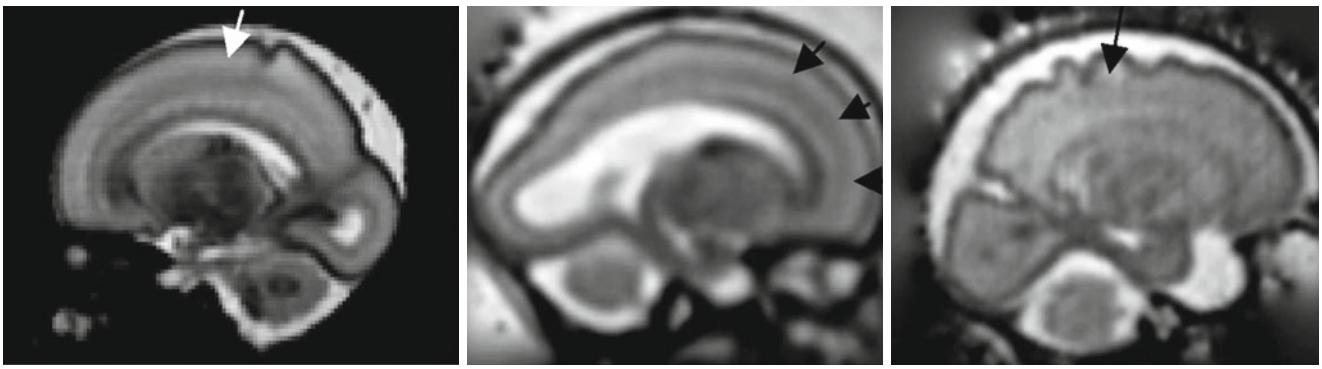

Fig. 127.5 Subplate visualization. T2 weighted images. Preterm infant 26+2 imaged at 28+1 weeks post-menstrual age. The subplate can be seen as a band of high signal intensity adjacent to the cortex (*arrows*)

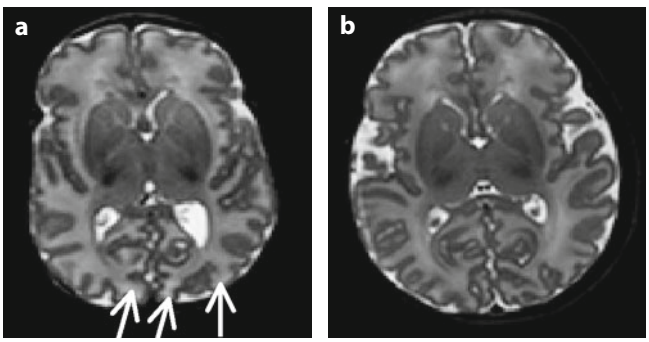

Fig. 127.6 Subplate involution. Preterm infant born at 26+3 and imaged at term (**a**). Term born control infant (**b**). Preterm infants at term have more subplate remnants, seen as regions of high SI adjacent to the gyral cortex (*arrows*) than term born controls, suggesting abnormal or delayed involution of the subplate layer

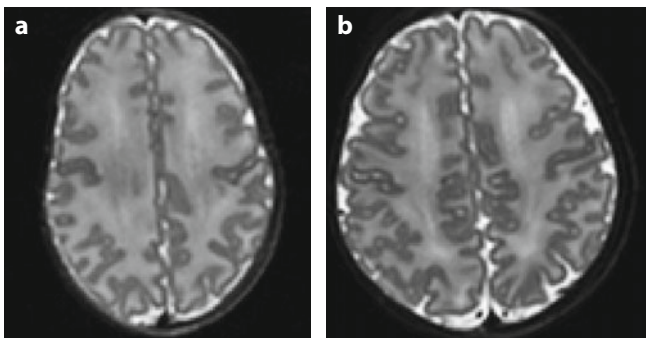

Fig. 127.7 Cortical development in the preterm. **a** Preterm infant born at 26+3 weeks gestation and imaged at term age. **b** Term born control infant T2 weighted images acquired in the transverse plane, at the level of the centrum semiovale. Preterm infants imaged at term age have less complex cortical folding than the term born controls [26, 27]

It is, however, well known that selective ablation of subplate neurons at critical time periods in development may cause altered cortical organisation [29, 30]. Thus, isolated injury to the subplate neurons, which play a fundamental role in axonal routing to and from the developing cortex, may result in abnormal thalamocortical connectivity. It has been speculated that this may explain the visual and somatosensory impairment seen in prematurely born humans [31]. Seventy-one percent of premature infants with moderate periventricular leukomalacia (PVL) during the neonatal period were found to have at least one abnormality of visual testing at 1 year of age, and yet 66% of these children had normal optic radiations, and all had a visual cortex that appeared normal [32]. Primary abnormalities within the visual cortex of subcortical white matter have not generally been demonstrated by imaging studies of infants with PVL, although the accelerated disappearance of the subplate may be a sign of injury. Cortical abnormalities in terms of loss of volume have been documented following PVL [33], but no studies to date have looked specifically at the visual cortex. The neurobiological basis for their visual impairment is therefore not well understood and abnormalities in the visual cortical function may occur as a secondary phenomenon due to injury elsewhere. In more recent studies, Ricci [34] and colleagues reported an association with poor visual function and thalamic atrophy. However, others [35] have suggested a plausible explanation for failing visual test during the neonatal age period is that an unspecific parenchymal lesion may damage the complex connectivity network as [34–36].

The cortical subplate continues to be related to brain development even late in gestation. In newborn babies at term with HIE, potential WM involvement may occur due to subcortical laminar necrosis in the subcortical subplate, as shown by highlighting in areas close to the cortex, which is particularly evident at the depths of sulci. The predilection of cortical necrosis at the bottom of sulci remains unexplained, although the fact that the subplate first disappears at the depths of sulci as the cortex folds may indicate an increasing vulnerability of the local resident neurons as they are more mature than those at the tops of gyri.

The role of subplate neuronal injury as a neurological basis for later impairments needs to be further investigated. A more sophisticated *in vivo* imaging approach such as serial diffusion tensor imaging studies is needed [24, 37].

127.3.3 The Developing White Matter

The association of preterm delivery and white matter injury in the form of periventricular leucomalacia (PVL) has been recognised since the 1960s [38]. Imaging studies have emphasised that injury to the developing white matter is associated with secondary abnormalities involving the entire thalamo-cortical circuit, giving rise to thalamic atrophy and a decrease in cortical volume [33]. Recent MR studies have also identified a spectrum of WM abnormalities in the preterm brain. PVL represents the most severe, with new findings of punctuate WM lesions and the diffuse appearance of DEHSI being reported more recently [3].

127.3.4 Oligodendrocytes

The vulnerability of preterm white matter appears to be multifactorial, relating to vessel anatomy with arterial end and border zone regions of relatively poor perfusion, low baseline blood flow, impaired regulation of blood flow in the sick infant and inherent susceptibilities of pre-oligodendrocytes (preOLs) to injury [6, 39]. The current theory is that both hypoxia-ischemia and infection lead to microglia activation that in turn leads to cytokine release, production of free radicals with both reactive oxygen and reactive nitrogen species and glutamate release, all of which contribute to death of the immature oligodendrocyte which demonstrate a vulnerability to oxidative stress [40] and glutamate receptor immaturity [41].

The ultimate result of either event would be a deficit of mature oligodendroglia, and a consequent impairment of myelination, the hallmark of PVL. Early white matter injury may result in a combination of delayed preOL degeneration and preOL maturation arrest. The persistence of susceptible populations of preOLs renders chronic white matter lesions markedly more vulnerable to recurrent hypoxia-ischemia. PreOL maturation arrest may predispose to more severe white matter injury in preterm survivors that sustain recurrent hypoxia-ischemia [42].

127.3.5 Axons

Axonal injury has been recognized for many years to be a feature of the focal necrotic component of PVL. Perhaps more important quantitatively, axonal degeneration, detected by the apoptotic marker fractin, has been recently found to be a feature of the diffuse component of human PVL. Whether the axonal degeneration observed in diffuse PVL is a primary injury or a secondary effect remains unclear. However, if primary axonal injury did occur, the expected results would be hypomyelination via failure of axonal-oligodendroglial interactions and decreased cortical [33] and thalamic/basal ganglia volumes [43, 44].

127.3.6 Thalami

We have included thalami in this section due to direct links with white matter. Recent human neuropathological data have demonstrated a high incidence of damage to specifically mediodorsal and reticular nuclei of the thalami in infants with PVL. Four patterns may be considered: diffuse gliosis, status marmoratus, micro-infarcts, and macro-infarcts. Irrespective

of the pattern and/or mechanism, it has been suggested that the reduced thalamic volumes revealed by neuroimaging are caused by neuronal loss [45]. Thalamic neuronal loss would be consistent with either primary injury and/or secondary anterograde and retrograde trophic effects. If there is primary neuronal injury, secondary effects would involve white matter axons, with subsequent hypomyelination and impaired development of the cerebral cortex, and such changes would be expected to compound the effects of the initial WM injury characteristic of PVL.

The role of the cerebral cortex in the cognitive deficits in preterm survivors is poorly understood. Periventricular leukomalacia (PVL), the key feature of the encephalopathy of prematurity, is characterized by periventricular necrotic foci and diffuse gliosis in the surrounding cerebral white matter. A recent study tested the hypothesis that reductions in the density of layer I neurons and/or pyramidal neurons in layers III and/or V are associated with PVL, indicating cortical pathology potentially associated with cognitive deficits in long-term survivors. In 15 controls (23 gestational weeks to 18 postnatal months), there was no difference in pyramidal density among incipient Brodmann areas, suggesting that cytoarchitectonic differences across functional areas are not fully mature during the fetal and infant periods. There was a marked reduction (38%) in the density of layer V neurons in all areas sampled in children with PVL cases compared with controls, in whom the six-layer cortex was visually distinct ($P < 0.024$). This may reflect a dying-back loss of somata complicating transection of layer V axons projecting through the necrosis in the underlying white matter. This study emphasised the potential role of secondary cortical injury in the encephalopathy of prematurity [46].

127.3.7 The Role of Microglia in WM Injury

Microglia are the main cell type implicated in injuries to the developing WM. Microglia are hemopoietic in origin and migrate into the brain from approximately 6 weeks' gestation. There are at least three morphological forms (amoeboidal, activated and ramified), which are distinguished by staining with markers such as tomato lectin and Iba. In the normal adult brain, the majority of microglia are ramified or resting, and activated microglia are assumed to be pathological. The normal immature brain contains all recognized morphological forms of microglia (ramified, activated and amoeboidal), although the exact site and numbers of the different forms alters with increasing gestation. Normal developmental or resident microglia perform many essential roles. These include the phagocytosis of unwanted tissue from programmed cell death as shown by labelling of microglia and apoptotic cells in regions of synaptogenesis and neuronal differentiation [47]. Resident activated microglia are also involved in brain modelling by secreting growth factors such as nerve growth factor (NGF), basic fibroblast growth factor (bFGF) and neurotrophin-3 [48], which provide trophic support for neurons and glia cells.

There is a maturation dependent concentration of microglia in apparently normal cerebral white matter during the third trimester of human gestation [49]. A few of these microglia are MHC II immunopositive cells, further evidence that they are developmentally activated resident cells and not immune induced. It has been suggested that the presence of numerous resident microglia in the immature brain increases its susceptibility to WM injury. Microglia co-exist during this developmental period with pre-oligodendrocytes which, as discussed, are also particularly susceptible to ischemic and inflammatory injury. Microglia are known to play a pivotal role in diffuse white matter injuries in the immature brain such as PVL.

Microglia are a potent source of both inflammatory cytokines and free radicals. Reactive oxygen and nitrogen species (ROS/RNS) release is mediated via Toll-like receptors known to be present on microglia. Interferon γ expression has been demonstrated in astrocytes in diffuse PVL. Interferon γ toxicity is greater for pre-OLs than for mature cells and is potentiated by tumor necrosis factor alpha (TNFα), which is produced by microglia. Evidence for the contribution of inflammation to preterm white matter injury emanates from studies of pregnant and neonatal animal models, where responses to exogenous lipopolysaccharide (LPS) are particularly involved. These studies have identified striking upregulation of inflammatory cytokines and microglial activation. LPS activates the innate immune system through an interaction with a specific toll-like receptor (TLR4) on immune cells, including microglia. Further evidence supporting the role of microglia in WM injury is provided by many studies using animal models of WM injury which demonstrate a decrease in injury in the presence of inhibitors of microglial activation such as chloroquine, minocycline and melatonin. Strategies for decreasing immune activated microglial activity in response to injurious processes should ideally not interfere with the function of normal developmentally active resident microglia.

In vivo and *in vitro* imaging studies of the immature brain have attributed regions of altered signal intensity within the developing white matter to the presence of dense clusters of microglia [50]. An increase in activated microglia in all periventricular white matter areas (sometimes called WM crossroads) compared to the deep white matter and subplate has been demonstrated in a cohort of 23 human brains with gestational ages of 22 to 40 weeks (Fig. 127.8). In addition, these authors demonstrated increased numbers of periventricular microglia in association with germinal matrix/intraventricular hemorrhage [51]. Although the morphological appearances of Iba positive cells do not differentiate normal developmentally activated microglia from abnormal immunoactivated microglia, some differentiation between developmentally activated microglia and immune/injury activated microglia may be made based on their site and number and the presence of overt tissue injury. However, functional differentiation may require more specific

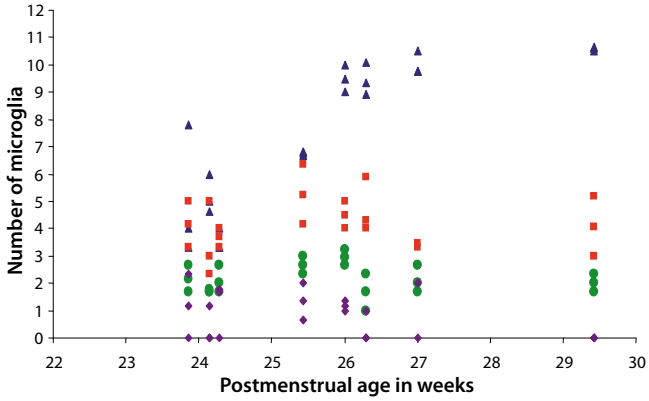

Fig. 127.8 Distribution of Iba 1 immunopositive microglia in the frontal, occipital and parietal lobes of the extremely preterm normal brain. Microglia numbers at the PVWM (*blue*) were significantly higher than deep white matter ($p = 0.0251$; *red*), subplate ($p < 0.0001$; *green*) and cortex ($p < 0.0001$; *purple*). This difference was most marked over the gestational age range in which PVL is most common

immunological markers. For example, mouse models have shown that in response to ibotenate, early microglial activation was CD45 negative, i.e., these cells are likely to have originated from the normal resident population [52].

In vitro studies of animal models have shown that the LPS-induced inflammatory response initiated by microglia was mediated via the TLR4 *My*D88-dependent pathway [53, 54]. This activation of microglia causes neuronal death, whilst *My*D88-deficient microglia do not. Manipulation of this activation may provide an opportunity for neuroprotective intervention. In a separate rodent model, LPS preconditioning was shown to have an altered protective response to subsequent ischemic injury via the TRIF-IRF3-IFNβ TLR4 cascade [55], which may have a beneficial effect on microglia. Investigation of these TLR4 activation pathways would enable functional characterization of different microglial phenotypes in the immature human brain, especially in association with lesions detected by MR imaging. In addition, co-labelling for apoptosis and for axonal injury would determine any deleterious effect by immune activated microglia.

127.3.8 The Germinal Matrix

The term germinal matrix is used by neonatologists to describe dense regions of tissue seen primarily within the caudothalamic notch on cranial ultrasound. On MR imaging scans of younger babies similar areas are also seen in the roof of the temporal horn and in the frontal areas externally adjacent to the frontal horns. These areas correspond to the ganglionic eminences referred to by neurobiologists. The germinal layer lining the entire ventricle may be identified on MR imaging of the fetal or very preterm brain but is not seen on ultrasound. In the fetal brain this layer is very prominent, but in infants born preterm, involution is already evident. On MR imaging of postmortem specimens, the germinal layer increases exponentially; it reaches a maximum at around 23 weeks' PMA and then decreases dramatically [56].

The germinal and subventricular layers are sites of neuronal and glial cell proliferation and migration. The characteristic vulnerabilities of early migrating neurons and preoligodendrocytes to injury have already been discussed, but their site of origin, the germinal matrix itself, is a common site of injury in the preterm brain. It is vulnerable to both hemorrhagic injury, as a result of the dense vascular network, and to injury from infection, e.g. by cytomegalovirus, which results in necrosis and cyst formation.

Germinal matrix intraventricular hemorrhage (GMH/IVH) has decreased in incidence because of improvements in intensive care, specifically in respiratory morbidity with the introduction of antenatal steroids for threatened preterm labor and artificial surfactant at the time of delivery. However, with the survival of the most extremely preterm infants who remain very vulnerable, germinal matrix hemorrhage remains a major cause of morbidity and mortality. The incidence in those born at 24–26 weeks' gestation or below 750 g birthweight is approximately 20–30%. The inverse relationship with gestational age indicates that the larger the matrix, the more susceptible it is to hemorrhage. In the term born neonate in contrast, intraventricular hemorrhage is thought to originate from the choroid plexus and is recognized as being a complication of sinus thrombosis particularly when associated with thalamic hemorrhage [57]. A germinal matrix hemorrhage can also derive from sinus thrombosis in late-preterm babies [58]. The site of hemorrhage in the preterm is usually from the ganglionic eminence of the caudothalamic notch or less frequently in the temporal horn [59]. These regions have a rich capillary network, which is vulnerable to rupture and hemorrhage because of the poor vascular integrity of involuting immature vessels and inadequate connective tissue support with a deficiency in mesenchymal and glial elements. Furthermore, a pressure passive circulation, compliant skull and disturbances in coagulation in the sick preterm exacerbate the fragility of the matrix. Hemorrhagic lesions are thought to be secondary to venous congestion with distortion and tearing of local small venous tributaries by the presence of blood in the perivenous space [60–62]. The hemorrhage originates and destroys the germinal matrix and this may impair proliferation and late migration of GABAergic interneurons to upper cortical layers, and the thalamus could contribute to defective cortical and thalamic development. There is some neuropathological data to support this [63], although it is difficult to determine the independent effect of progenitor cell loss on subsequent brain development because infants that die are likely to have additional brain lesions. Such complications of GMH/IVH include venous infarction and ventricular dilation, both of which will additionally injure developing white matter and

possibly thalamic tissue and therefore disrupt thalamo-cortical connectivity and cortical development. So, whilst there is likely to be a disturbance of the late GABAergic neuronal proliferation and migration from the subventricular zone (SVZ) and the ganglionic eminence (GE) to upper layers of the cerebral cortex and from the GE to the thalamus, venous infarction will cause additional destruction of both axons and pre-OLs, resulting in the formation of a porencephalic cyst. Thalamocortical connections will be disrupted, resulting in thalamic atrophy and overlying cortical development may be impaired. Thalamo-cortical disconnection may be demonstrated at a distance from the site of infarction.

The neurodevelopmental consequences of this are evident in follow-up studies such as the DRIFT trial, which enrolled neonates with marked ventricular dilation complicating GMH/IVH. The majority also had evidence of venous infarction. While the trial demonstrated some improvement in neurodevelopmental outcome following specific intervention, as a study group these infants with complications showed severe neurodevelopmental impairments at 2 years corrected age [64]. A secondary imaging study of total brain tissue volume and cerebellar volume highlighted the need to preserve supratentorial tissue and avoid cerebellar compression by a dilated fourth ventricle [65]. Reduced cerebellar size following GMH/IVH may be multifactorial and related to a primary cerebellar hemorrhage or to secondary atrophy as a consequence of supratentorial lesions [43, 44].

127.3.9 The Cerebellum in Extremely Preterm Babies

Primary cerebellar hemorrhage arising from the external granular layer and associated tissue infarction is relatively common in very preterm infants. There is a well documented association between intraventricular and cerebellar hemorrhage. In one large ultrasound study of 1242 preterm infants with intraventricular hemorrhage, 77% of infants also had cerebellar hemorrhages [66]. MR imaging studies seem to confirm this high vulnerability of the most premature babies to develop cerebellar hemorrhage [67].

A study using the mastoid window for better visualization of the posterior fossa demonstrated an incidence of cerebellar hemorrhage in 3% of preterm infants <1500 g, with nearly 60% of these occurring in infants less than 750 g [66]. In the very preterm infant, the hemorrhage originates within the hemisphere with involvement initially of the subpial and subependymal layers sites of the germinal matrices and subventricular zones respectively. The more extensive lesions extend and involve both the cerebellar cortex and white matter. In contrast, in the term infant the site of origin is more frequently the vermis. Pathogenesis in the preterm infant shares many similarities with the causes of intraventricular hemorrhage. In the term infant, trauma is a more important factor. Injury to the developing cerebellum will result in disruption of neuronal migration, which continues into infancy in the cerebellum with consequent cerebellar disconnectivity.

The role of the cerebellum in cognitive function is being increasingly recognized. It is not surprising therefore that 40% survivors of preterm cerebellar hemorrhage demonstrate cognitive deficits and 37% have autistic spectrum disorders [68]. In term infants, subsequent motor impairments are described more frequently, particularly in association with larger lesions [69, 70].

127.3.10 Effects of Germinal Matrix Intraventricular Hemorrhage

There is evidence to suggest that less severe forms of GMH/IVH may be associated with periventricular WM injury. This may result in milder degrees of ventricular dilation and studies have reported an association with later cognitive function in such infants [71, 72]. In addition, two studies have reported worse outcomes in survivors of preterm birth where subsequent ventricular dilation was associated with an original GMH/IVH [73, 74]. In the rabbit kit, IVH was associated with an increase in periventricular white matter (PVWM) microglial activation and axonal disruption and apoptosis [52]. An increase in activated microglia has also been demonstrated in human PVWM in the presence of uncomplicated IVH (Fig. 127.9). Tissue injury may occur secondary to free radical release, secondary to the presence of free iron from the blood and the presence of resident activated microglia may exacerbate this process.

It is unclear whether as the germinal matrix involutes it becomes less susceptible to the effects of infection. The development of subependymal cysts in the persisting germinal matrix of the caudothalamic groove postnatally suggests that the tissue remains vulnerable to viral infection in more mature infants, but the consequences for progenitor cell destruction may be less severe as the infant matures.

127.4 The Late Preterm Infant

In recent years the vulnerability of late preterm infants of gestation between 34 and 37 weeks has become recognized. Reports demonstrate increased short-term neonatal morbidity in low risk late preterm pregnancies [75, 76] with a 12-fold increase in mortality compared with term born controls and a mortality rate of 0.8% [77]. Studies of surviving late preterm infants have conflicting results, with no significant differences in childhood outcome [78]. A study at school entry showed that the risk for developmental delay or disability was 36% higher among late preterm infants compared with term infants [79]. However, outcome studies at 12 and 18 months stress the importance of correcting for gestational age when interpreting results [80].

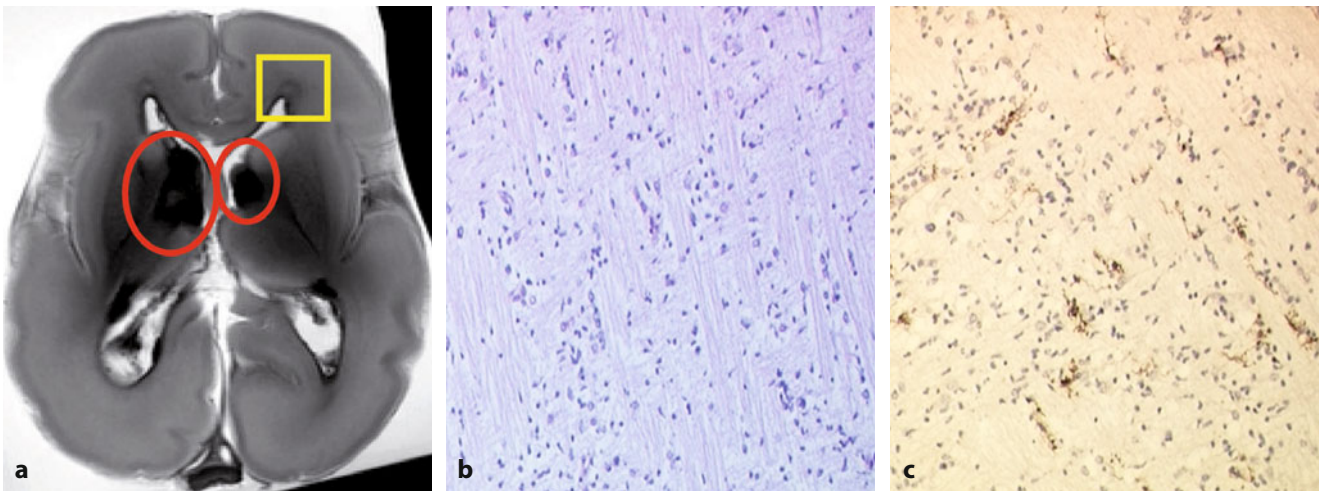

Fig. 127.9 T2 weighted MRI image (**a**) of a preterm infant born at 26 weeks and imaged postmortem at 28 weeks. There is bilateral germinal matrix/intraventricular hemorrhage seen as foci of low signal intensity (red circles). PAS (**b**) and Iba (**c**) staining through anterior periventricular white matter, (in the region of the yellow rectangle) showing intersecting axons, so called WM crossroads (**b**). Many of the cells in this region are microglia (**c**), which have roles associated with axonal guidance and WM modeling. Their presence may enhance the susceptibility of these regions to injury

Neuromorbidity in this group has been attributed to many factors. The cellular pathology of PVL and the developmental characteristics of oligodendrocytes and neurons put the late preterm brain at risk of injury. The cortical volume in the very preterm infant at 28 gestational weeks is 13% of term volume [11]. The cortical volume in the late preterm infant is only 53% of the term volume, with approximately half the volume being attained in the last 6 weeks before 40 gestational weeks. In addition, minimal myelinated white matter is present in the very preterm infant (around 29 weeks), but increases dramatically in volume as term is approached, with a five-fold increase between 35 and 41 weeks [81].

Studies of HIE in the preterm usually only include mature preterms and demonstrate that whilst mature preterms sustain injury to the central gray matter, the sites may differ to the more mature term brain. Mature preterm infants are more likely to show thalamic and globus pallidum lesions. In addition, they are more likely to sustain brainstem lesions [2]. This may be because of more severe injury or indicate a particular susceptibility of the brain stem at these slightly younger gestations [82].

It is of interest that the late preterm infant does not demonstrate cortical abnormalities around the central sulcus, which is a frequent abnormality n the term infant. This region is probably vulnerable due to the presence of myelination, which does not occur until approximately term [2].

127.5 The Term Brain

Studies of injury to the more mature term brain have concentrated on the vulnerability of the neuronal population. Imaging studies of neonates with perinatal injury complicating an acute hypoxic ischemic event demonstrate involvement of the cortex, central gray matter and brainstem. Vulnerability to specific neuronal populations in the term brain is due to multiple factors but, like white matter vulnerability in the preterm brain, excitotoxicity and oxidative stress play major roles in term injury. Vulnerability may be related to the maturational state of the neurons. There is over-expression of certain glutamate receptors in selective regions like the basal ganglia.

The N-methyl-D-aspartate (NMDA) glutamate receptor subtype is the predominant mediator of this type of injury because of its coupling to neuronal nitric oxide synthase-containing neurons in the postsynaptic density complex. The NMDA receptor can change subunit compositions with development of the NR2B subunit predominating early, followed by increasing expression of NR2A. NMDA receptors with NR2B seem to have a slower deactivation and higher conductance. Following an hypoxic insult, there are differential effects on NMDA receptor subunit composition and these effects differ by age. This interaction may result in the production of both nitrogen and oxygen free radicals that in turn injure nearby cells [83]. The vulnerability to neurons in the basal nuclei also appears to be related also to the local environment as neuronal nitric oxide synthase-containing neurons make neurons relatively resistant to severe hypoxic ischemia [84]. There is also an overabundance of NMDA receptors in this region at term allowing for the robust glutamatergic synapses necessary for long-term potentiation and connectivity but also allowing the neuron to be more vulnerable to glutamate attack. It has been suggested that these neurons may be protected either pharmacologically or by gene

knockout to render the region less vulnerable and prevent neuronal loss [85, 86].

Regions of vulnerability following acute hypoxic ischemia at term are recognized as being those that are metabolically active with increased energy requirements such as the basal ganglia and thalami [87]. Regions that are actively myelinating also appear to be more vulnerable. In the term infant, regions around the myelinating corticospinal tracts arising from the cortex at the central sulcus are frequently involved. However, in less mature infants these areas are often spared the metabolic demands of myelination, which may compound the additional vulnerability of cortical neurons, which express a high number of Ca^{2+} permeable glutamate receptors at term. This contrasts with the peak period for overexpression of these receptors in oligodendrocytes and subplate neurons, which is in the late second and early third trimesters.

127.6 Focal Infarction

White matter injury is often seen in the mature term brain, presumed either to be due to a vascular event relating to vessel obstruction by an embolus or by vessel spasm. Affected areas are as middle cerebral artery infarction or more global hypoperfusion such as in parasagittal or watershed injury. Bilateral injury is often associated with a history that suggests chronic hypoxia, e.g.decreased fetal movements, infection or hypoglycemia. Injury usually involves both the WM and the cortex. Thalamic involvement is common but may occur as a secondary phenomenon. Posterior WM may be involved more frequently than anterior WM regions, particularly in association with hypoglycemia. This may be explained in terms of watershed injury, with posterior regions representing the watershed areas for all three cerebral arteries. However posterior involvement with hypoglycemia does not always selectively involve borderzones between arterial territories.

The hypothesis of a chronic or repeated event priming the WM suggests that the WM is made progressively more vulnerable so that it can be injured by a relatively mild hypoxic-ischemic event. The additional role for infection in such term infants may again relate to a cascade of injurious events precipitated by a fetal inflammatory response. The underlying mechanism for this acquired increased vulnerability remains unclear, but it may involve altered mitochondrial function. When mature oligodendrocytes die after exposure to kainate, (1) AMPA receptors are the most important mediators, (2) kainate receptors play a smaller role, and (3) death occurs predominantly by necrosis, not apoptosis. [88].

127.7 Programmed Cell Death

Apoptosis is a critical component of normal brain development but, as the brain is poised to initiate programmed cell death around human birth, it becomes more susceptible to the initiation of a cell death pathway. Although necrosis plays a major role in early neuronal death in both the immature and mature brains after injury, there is a spectrum of cell death that includes apoptosis within the first 24 h following perinatal hypoxic ischemia [89]. Programmed cell death is a crucial mechanism in the control of the final number of neurons and glial cells. This process, commonly referred to as apoptosis, can be observed from the earliest gestational ages with different times of cell death peaks in different brain regions [90]. In addition to refining normal brain development and connectivity, the plasticity it provides may be important in repair mechanisms following injury. However, a predisposition to programmed cell death may be exploited following injury and result in an increase in cellular apoptosis in injured regions as a consequence of disturbances disrupted connectivity.

The concept of priming of a brain region to injury is an important one, although a region such as the white matter is not traditionally considered to be vulnerable. There is, however, animal evidence to suggest that such priming occurs with preinjury insults (i.e., delivery related events) such as hypoglycemia, intrauterine growth restriction (IUGR) and infection. The biological mechanisms by which such events increase the susceptibility of WM to injury are poorly understood but investigations of preconditioning may explain the acceleration of such events due to birth.

Inflammation and Perinatal Brain Injury

Henrik Hagberg, Carina Mallard and Karin Sävman

128.1 Introduction

Inflammation is a systemic and local immune reaction to injury secondary to microbial invasion or other damaging events like trauma and hypoxia-ischemia (Fig. 128.1). This response aids in identifying extrinsic pathogens and kills microbes (and affected cells) if the injury is caused by infection [1]. Irrespective of the primary triggering event, inflammation often causes brain damage during its acute stage (collateral damage) followed by a secondary phase that in most cases promotes tissue repair and regeneration [2].

Historically, several findings support a link between brain injury and antenatal/postnatal inflammation [3]. In the 70s it was discovered that postnatal sepsis was strongly associated with brain injury in spite of the lack of microbial invasion in the brain parenchyma [4]. Induction of sterile systemic inflammation in newborn kittens with lipopolysaccharide (LPS, fragment of the gram-negative bacterial cell wall) induced white matter injury [5]. These studies suggested that infection triggers a systemic inflammatory response that inflicts brain injury under some conditions. During the 60–70ties it was discovered that cytokines, a family of ubiquitous and pleiotropic immune molecules with pro-, anti- or immunomodulatory properties orchestrate the inflammatory response [6]. Indeed, cytokines were shown to play a critical role in preterm delivery [7] and initiation of a fetal inflammatory response with subsequent development of brain injury and cerebral palsy [8, 9].

In parallel, experimental work demonstrated that non-infectious insults like hypoxia-ischemia and excitotoxicity elicited cytokine expression [10] and activation of immunoinflammatory microglia/macrophages [11, 12] in the immature brain that seemed to play a role for development of brain injury [13–15]. Epidemiological studies found that chorioamnionitis was associated with cerebral palsy in term infants [16] and there was a remarkable correlation between cytokine levels 2.5 days after birth and cerebral palsy in mostly term infants [17].

These early studies indicated that cytokine-mediated inflammation is an important factor for development of brain injury irrespective of whether the inflammatory response was caused by infection, hypoxia-ischemia or excitotoxicity. However, since these early reports the complexity, diversity and sometimes contradictory (Jekyll-Hyde) properties of the inflammatory reaction have become increasingly clear. Furthermore, cytokines have been discovered to have other roles, e.g., in brain development and in the setting of CNS vulnerability as well as in neuronal and oligodendroglial regeneration [18]. In this short review we will summarize some of the recent pertinent experimental and clinical findings.

128.2 Immune Molecules and Brain Development

Molecules classically involved in immune responses are pleiotropic and have critical non-immune functions during normal CNS development, including neuronal and glial cell migration, cell differentiation, axonal path finding and synaptic plasticity. These molecules include classical pro-inflammatory cytokines and chemokines as well as proteins of both the innate and adaptive immune system.

Cytokines are of importance during all stages of neural development. Members of the transforming growth factor beta (TGFβ) cytokine superfamily, including bone morphogenetic proteins (BMPs), are critical for neural induction and normal CNS development requires active inhibition of BMPs [19]. Later in CNS development, maintenance of the progenitor cell population is dependent on several members of the gp130 cytokine family, including leukemia inhibitory factor (LIF) and ciliary neurotrophic factor (CNTF) [20]. Also classical pro-inflammatory cytokines, such as interleukin-1 beta

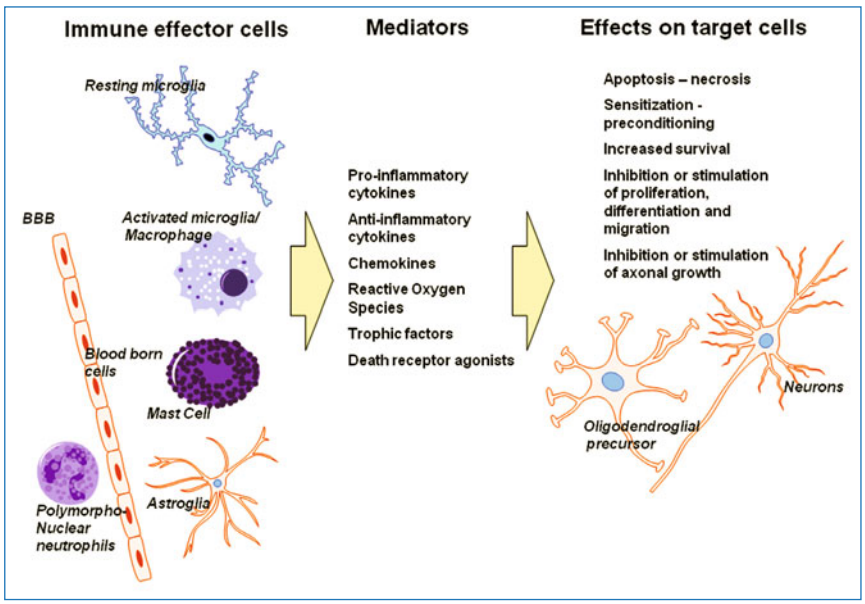

Fig. 128.1 Inflammation and perinatal brain injury. Infection, hypoxia-ischemia or other insults activate immune effector cells in the vascular compartment as well as in the brain parenchyma. These cells produce a plethora of mediators that exert protective as well as toxic effects in the immature CNS

(IL-1β), have been reported to modulate neuronal and glial cell survival during development [21] and to regulate progenitor proliferation [22]. There is also evidence to suggest that IL-1β promotes differentiation of oligodendrocyte progenitors as well as maturation and survival of differentiating oligodendrocytes [23].

Chemokines are traditionally considered as secreted leukocyte chemoattractants. However, several chemokines and their respective receptors are constitutively expressed in the CNS and significant evidence supports chemokines, such as CXCL12, as key regulators of early brain development, including survival and migration of neural and oligodendrocyte precursors [24–26]. CXCL12, via activation of its receptor CXCR4, is also crucial for tangential migration of Cajal-Retzius cells and thereby the normal development of the cerebral cortex [27].

Innate immune responses have been implicated in normal CNS development. Both C1q and C3, components of the classical complement cascade, are expressed in neurons in the developing brain and play an important role in synapse pruning in the visual system during development [28] and complement-derived C3a regulates differentiation and migration of neural progenitor cells [29]. Toll-like receptors (TLRs) belong to a recently discovered family of innate immune receptors [30]. TLRs are expressed in the developing brain and stimulation of TLR3 negatively regulates both axonal growth in sensory neurons [31] and embryonic neural progenitor cell proliferation [32]. Furthermore, TLR8 is expressed in neurons and axons during mouse development and stimulation of TLR8 in cultured cortical neurons causes inhibition of neurite outgrowth and induces apoptosis [33]. In addition, TLRs are expressed in adult neural progenitor cells and may influence their proliferation and differentiation as TLR2 deficiency impaired hippocampal neurogenesis, whereas the absence of TLR4 resulted in enhanced proliferation and neuronal differentiation [34]. Also the adaptive immune system, including the class I MHC molecules has been shown to play a role during normal development and plasticity [35].

128.3 Inflammation and Brain Injury in Preterm Infants

Infection/inflammation is strongly associated with preterm delivery and accounts for 20–40% of all cases with preterm birth [36] including the majority of cases with spontaneous preterm birth before 30 weeks of gestation, i.e., those at highest risk of neurological morbidity [37, 36]. Hypothetically, ascending microbes activate TLRs leading to increased accumulation of polymorphonuclear neutrophils and expression of pro-inflammatory cytokines (IL-6, IL-8, IL-1β, TNF-α) in the decidua and chorioamniotic membranes histological chorioamnionitis (HCA). The inflammatory response elicits myometrial contractions, cervical ripening and preterm prelabor rupture of the membranes (PPROM) subsequently resulting in preterm delivery [38]. In most cases, chorioamnionitis (CA) is subclinical and manifests rarely as clinical chorioamnionitis (CCA) (maternal fever, tachycardia, uterine tenderness, malodorous amniotic fluid and leukocytosis/raised C-reactive protein). CA is a predominately fetal infection and spread of the inflammation and/or microbial invasion from the membranes to amniotic fluid to umbilical cord to fetal blood (fetal inflammatory response syndrome) increases, not unexpectedly, the risks of fetal morbidity and mortality see below [39, 36]. The degree of

fetal inflammation (defined as e.g. IL-6 elevation in amniotic fluid or blood) determines at least acute neonatal morbidity, whereas detection of microbial invasion does not seem to aggravate outcome further [39].

Some data indicate that intrauterine inflammation is associated with neurological injury. Severe brain lesions were 10 times more common after spontaneous onset of labor (with high occurrence of CA) than in physician-initiated delivery (with a low occurrence of CA) at a comparable gestational age offering support of the inflammatory hypothesis [40]. A similar, but not as marked, correlation was found between diplegic cerebral palsy (CP) and type of delivery onset [41], whereas no such association was found by Jacobsson et al [42]. In a very important study, the presence of umbilical cord inflammation (funisitis) or high amniotic IL-6 and IL-8 levels conferred an increased risk of CP in the offspring at 3 years of age even after adjustment for differences in gestational age [9].The proposal that fetal rather than maternal involvement predicts neurological outcome is supported also by a large study (1078 infants, 500–1500g, 47 with sonographic echolucency) showing that fetal vasculitis was associated with an increased risk of late echolucent white matter injury in cases born shortly after PPROM (OR 10.1, CI 1.03–114) [43]. Furthermore, cytokines and CD45RO(+) T lymphocytes in fetal blood predicted cerebral white matter injury detected by magnetic resonance imaging soon after birth [44].

According to a meta-analysis, CCA is associated with CP (RR 1.9, CI 1.4–2.5) and cystic periventricular leukomalacia (PVL) (3.0; 2.2–4.0), whereas CA constitutes a risk factor for PVL (2.1; 1.5–2.9) but not CP (1.6; 0.9–2.7) [45]. However, a strong association was found between polymicrogyria (a migratory disturbance of the cortical plate/cerebral cortex) and CA [46]. The brains of fetuses at gestational age 15–26 weeks in the context of CA were compared with those aborted for other reasons. Polymicrogyria was found in 25/32 cases (78%) with infection compared with none in the control group. These remarkable results suggest that inflammation inflicts on brain development (see above), which agree with experimental studies in adult rodents [47] and with a recently published review suggesting that microglial activation may disturb cortical migration and stem cell survival [48].

Moreover, several investigators have shown that intravenous administration of LPS to fetal sheep [49–52] or into the amniotic fluid [53, 54] results in white matter damage. Early studies suggested that the LPS caused brain damage by reducing cerebral blood flow [55, 56], however more recent evidence, using lower doses of LPS, do not find that perfusion deficits contribute to injury [57, 58].

It is important to mention that not all studies support the inflammatory hypothesis. For example, no association between white matter injury/neurological outcome and HCA or umbilical blood IL-6 were found by Kaukola et al [59]. Reiman et al [60] found no correlation between fetal or maternal HCA and brain injury defined by ultrasound or magnetic resonance imaging (MRI), which agree with Chau et al [61], who found no association between fetal or maternal HCA and MRI-defined brain abnormalities in preterm infants at 24–32 weeks of gestation. Furthermore, Kumazaki et al [62] detected no difference in ultrasound-defined PVL in cases with versus without fetal or maternal HCA.

These discrepancies cannot easily be explained but generally there is a lack of statistical power in many studies (both those pro and con the inflammatory hypothesis), inconsistencies in the definition of CA (see above), differences in cases included, study design or the fact that inflammation has many different phenotypes (toxic, beneficial, no effect) depending on timing and other circumstances (Fig. 128.1).

There are several clinical and experimental studies indicating that CA may be a stronger risk factor if combined with another exposure, the so-called multiple-hit hypothesis [63]. For example, HCA alone was not a risk factor but if combined with signs of a placental perfusion defect the risk of abnormal neurological outcome was increased (3/10 with HCA versus 3/43 without HCA) [59]. In another study, culture positive postnatal infection increased the risk of MRI-defined brain injury if occurring in combination with hypotension [61]. Indeed, chorioamnionitis (with or without funisitis) increases the risk of hypotension in very low birth infants [64].

128.4 Inflammation in Term Brain Injury

Inflammation has been extensively studied as part of the secondary response to experimental hypoxic-ischemic (HI) injury and the presence of an inflammatory response has been demonstrated also after clinical HI. There are, however, also studies that suggest that infection/inflammation may precede brain injury or sensitize to subsequent HI. In addition, the inflammatory response and its involvement in injury and repair in the immature brain is dependent on timing as well as context and differs substantially from that seen in the adult brain.

128.4.1 Clinical Findings of Inflammatory Factors in Term Brain Injury

Several studies demonstrate that an inflammatory response is elicited in CSF from term infants fulfilling criteria for acute intrapartum asphyxia. Elevated levels of pro-inflammatory cytokines IL-6 and IL-8 in CSF are correlated with severity of encephalopathy as well as neurodevelopmental outcome [65, 66]. In samples obtained within 24h after birth IL-1β and TNF-α show similar correlations [67, 68] and comparisons with serum levels suggest that the cytokines are produced within the brain [69, 68]. Support of cytokines contributing to brain injury rather than just being biomarkers of inflammation is presented in a study showing increased risk for CP in infants with specific IL-6 genotype [70].

The correlation between brain injury and systemic inflammation is less well documented, but at least one study show that asphyxiated infants with adverse outcome had elevated pro-inflammatory cytokines in serum [71]. An intriguing study of dried blood spots from term infants who later developed spastic CP demonstrates, however, elevated levels of multiple cytokines in virtually all affected infants in comparison with term matched controls even if HI is likely to be the cause of only a minor fraction of the CP cases in that study [17].

The suggestion that exposure to infection or inflammation in itself or together with HI may lead to term brain injury is further supported by individual studies [16] as well as a large meta-analysis showing that clinical chorioamnionitis is an independent risk factor (OR 4.1) for term/near-term CP [72]. In the same analysis, chorioamnionitis in the mother was also associated (OR around 5) with signs of neonatal depression (APGAR at 5 min <7, clinical diagnosis of birth asphyxia) as well as signs of neonatal encephalopathy (seizures) [72]. Since data on metabolic acidosis and from neuroimaging were not available it cannot be excluded that these findings were secondary to exposure to chorioamnionitis only. Extensive MRI studies show, however, that a large majority of term infants with the combination of neonatal depression and neonatal encephalopathy have acutely evolving injuries suggesting intrapartum asphyxia [73]. It is thus likely that at least some of the infants with subsequent CP were exposed to chorioamnionitis as well as HI, giving additional support to the multiple-hit hypothesis. Further evidence of the detrimental effect of fetal inflammation in combination with HI is provided by a study of term spastic CP showing relatively low OR for exposure to chorioamnionitis as well as potentially asphyxiating factors (placental and cord complication) while the combination of both increased the risk for severe spastic CP hundred-fold [74]. In addition, neonatal serum cytokines are elevated after exposure to chorioamnionitis but the increase is most pronounced in infants who also fulfil very strict criteria for hypoxic-ischemic encephalopathy (including metabolic acidosis, moderate-severe encephalopathy and multiorgan failure), illustrating the close relationship between exposure to infection and clinical HI [75].

128.4.2 Experimental Studies Supporting Inflammatory Factors in Post HI Injury

The inflammatory response after experimental HI includes an early but restricted accumulation of neutrophil cells, mainly in blood vessels adjacent to injury [76, 77]. Resident microglia and/or invading macrophages are, however, the predominant inflammatory cell type after neonatal HI and infiltration of activated cells is detected as early as 2–3 hours after injury, followed by a marked increase in the following days that persists for weeks [11, 77]. Inflammatory cells may contribute to injury by release of excitatory amino acids, pro-inflammatory cytokines, degrading enzymes and reactive oxygen species (ROS), but microglia can also produce neurotrophic or neuronal survival factors upon activation [78]. In the neonatal setting HI is accompanied by a massive change in the expression of inflammation-related genes with close to 150 genes differentially regulated at 2–72 hours after the insult including up-regulation of cytokines, chemokines, proteases and ROS-forming enzymes [79].

A number of experimental studies show that inflammatory cells and inflammatory mediators may contribute to injury, but the complexity of the inflammatory response is illustrated by conflicting data or results limited to certain contexts. In addition, several studies indicate that the inflammatory mechanisms related to the development of brain injury are substantially different in the immature compared with the adult brain and that inflammatory cells may also have protective properties.

Factors that may influence the results of anti-inflammatory interventions include means and timing of inhibition and degree of injury. As an example, the pro-inflammatory cytokine IL-1β is up-regulated at the mRNA as well as protein level after HI and soluble IL-1 receptor antagonist protects from HI injury in newborn rats [80, 14] while genetic inhibition of IL-1β or IL-1α/β combined confers no protection in newborn mice [81]. IL-18 is another cytokine that is up-regulated after HI in newborn mice and transgenic mice lacking functional IL-18 are protected from injury [82]. Genetic inhibition of interleukin-1 converting enzyme (ICE) that converts IL-1β as well as IL-18 to their active forms is, however, protective only after moderate but not severe HI [83]. A similar restriction is found for matrix metalloproteinase-9 (MMP-9), a tissue-degrading enzyme expressed by activated microglia, where genetic knock-out attenuates injury after moderate HI only [84].

The difference between the adult and immature brain is illustrated by findings after neutrophil depletion and inhibition of the enzyme NADPH-oxidase that is responsible for ROS formation in inflammatory cells. Neutrophil inhibition is protective after adult [85] as well as neonatal HI injury [76] but neutrophil infiltration is limited in the immature brain [77] and protection is only seen if the depletion is induced well before injury suggesting early effects on brain microcirculation [86]. Neutrophil depletion also results in reduced free radical formation in the adult brain [87] and mice lacking functional NADPH-oxidase have 40% reduction of infarction volume after adult stroke [88]. This is in stark contrast to the immature brain where genetic or pharmacological inhibition of NADPH-oxidase results in un-altered or even aggravated brain injury [89]. These findings imply maturity-related differences in the inflammatory response to injury and suggest that ROS may have protective properties in the developing brain.

Recently, the possible protective properties of inflammation and in particular microglia cells have come into focus. Exogenous microglia cells are protective in adult models of ischemic injury [90, 91] but studies of microglia inhibition with minocyclin after neonatal HI are contradictory

with reports of strong protective effect after HI in neonatal rats [92], worsening of injury after HI in newborn mice [93] and transient protection after neonatal stroke [94]. It has thus been suggested that intervention aimed at protecting the brain from inflammatory injury should modulate microglia phenotype rather than merely inhibit the inflammatory response or single inflammatory mediators.

In adult brain different microglia populations have been identified after stroke and resident proliferating microglia expressing insulin-like growth factor-1 (IGF-1) and galectin-3 are protective [95]. Such sub-populations of microglia are yet to be identified in the neonatal brain, but a recent study of the novel inflammatory marker galectin-3 illustrates the possibility of modulating the inflammatory response after HI [96]. Previous studies show that galectin-3 activates NADPH-oxidase [97] and augments inflammation by increased chemotaxis and decreased apoptosis in inflammatory cells [98, 99]. In the neonatal setting genetic inhibition of galectin-3 resulted in attenuated HI injury with no effect on apoptosis or growth factor expression. Instead galectin-3 deficient mice had increased microglia infiltration but decreased oxidative stress and MMP-9 expression, suggesting changes in microglia phenotype [96].

In addition, the protection and the changes in inflammatory response in galectin-3 deficient mice were more pronounced in male pups, suggesting that gender may also influence the immune response in the immature brain [96]. The gender differences at this early age are more likely to depend on genetic differences than hormonal factors [100] and opens new intriguing avenues of research.

128.5 Inflammation and CNS Vulnerability

As pointed out above, there is strong experimental evidence to show that infection/inflammation may act in synergy with other insults and aggravate brain injury. Studies in both rats and mice have shown that exposure to LPS, sensitizes the immature brain to subsequent HI [101–104] and results in extended cerebral damage and long-lasting memory and learning impairment [105]. Similar sensitizing effects are seen with excitotoxicity [15], where pro-inflammatory cytokines and IL-9 exacerbate excitotoxic lesions of the newborn murine neopallium [15]. The underlying mechanisms of sensitization are not well understood, however at least LPS-induced aggravation of injury is known to act in a TLR-4 and MyD88 dependent manner [106, 107]. Microglia cells appear to play an important role in the injury process as LPS-stimulated microglia are able to kill neurons and oligodendrocytes, at least when grown in culture [108, 109]. Oxidative stress may also be involved in LPS-induced sensitization as the free radical scavenger N-acetylcysteine (NAC) provided marked neuroprotection following LPS/HI insult in neonatal rats [110]. As mentioned above, inflammatory stimuli can under certain circumstances also protect the brain from further events, so called preconditioning or tolerance [111]. Although the mechanisms that are responsible for the switch from protection to injury are not well understood, it has been suggested that endotoxin-induced tolerance may be mediated by up-regulation of corticosterone in neonatal rats [112] and interestingly, the synthetic corticosteroid anti-inflammatory drug dexamethasone was able to prevent both structural brain damage and subsequent learning and memory deficits in neonatal rats exposed to LPS-induced HI injury [113].

128.6 Conclusions

There is today ample support to show that inflammation is involved in perinatal brain injury. Early studies provided support for the hypothesis that inflammation can aggravate brain injury during the acute phase both in the setting of infection and sterile insults like hypoxia-ischemia. Subsequent clinical and experimental work support the concept that the immunoinflammatory molecular network is complex and multifaceted with important roles in brain development as well as setting of CNS vulnerability, and during the acute and repair phases of injury. There is potential for neuroprotective immunomodulatory therapies to be developed, but we still need a more detailed knowledge about the basic mechanisms. Hence, the net effect of immune responses – protective versus beneficial – are often difficult to predict and depends on many factors, for example, which cells and mediators are activated, time point in relation to insult, molecular context, gender and developmental age.

Normal and Abnormal Neurodevelopmental and Behavioral Outcomes of Very Low Birth Weight Infants

Betty R. Vohr and Bonnie E. Stephens

129.1 Introduction

Advances over the past ten years in perinatal and neonatal management of very low birth weight (VLBW) infants (<1500 grams and <30 weeks' gestation) have resulted in a significant increase in survival of fragile high risk infants, including those with extremely low birth weight (ELBW) (<1000 grams) [1–10]. Therapeutic advances including the use of antenatal steroids [3, 4], surfactant for respiratory distress syndrome [11, 12], prophylactic indomethacin for prevention of intra ventricular hemorrhage [13], improved nutritional management, and new ventilatory techniques [14] have all contributed to improved survival especially for infants with birth weights less than 1000 grams [5–10]. These high risk preterm survivors have increased complex neonatal medical morbidities affecting all organ systems including lungs, gastrointestinal tract, kidneys and brain, and post-discharge morbidities including increased growth failure, neurologic, developmental, cognitive, neuropsychological, functional and behavioral sequelae [15–25].

Most tertiary care programs in the United States and all neonatal training programs currently include a requirement for fellow participation in the care and evaluation of discharged infants in a structured follow-up program. A workshop on the Follow-up Care of high risk infants sponsored by the National Institute of Child Health and Human Development (NICHD), the National Institute of Neurologic Disorders and Stroke and the Centers for Disease Control and Prevention held in 2002 established guidelines for the provision of Follow-up Services [21]. The workshop concluded that two primary areas of responsibility for Neonatal Follow-up Programs are surveillance and research.

Surveillance is indicated so that centers can systematically monitor and report on the care of high-risk infants during their hospitalization and their outcomes after discharge from the neonatal intensive care unit (NICU). The availability of a data management surveillance system for the NICU facilitates the ability to annually audit the safety and efficacy of interventions, monitor identified quality indicators for the individual NICU, summarize annual data on neonatal morbidities and summarize annual post-discharge outcomes such as rates of cerebral palsy (CP), mental retardation, developmental delay, blindness, hearing impairment, behavioral abnormalities, autism, learning disabilities, growth failure and medical morbidities. Information about center outcomes for specific conditions and by gestational age categories also allows staff caring for high-risk infants to counsel parents with regards to prognosis [26]. A follow-up clinic may also provide a mechanism for the provision of seamless comprehensive medical, psychosocial, and intervention services to NICU graduates [27]. Outcome data can be shared with the Departments of Health and Education to aid in planning for adequate service provision for high risk NICU graduates.

Research is an integral part of academic neonatal programs. An advantage of having a structured follow-up program is that it provides a mechanism to carry out research ranging from observational studies to randomized control trials, which include post-discharge outcomes. Currently, post-discharge neurodevelopmental impairment (NDI) is a common primary outcome for randomized control trials of NICU infants. NDI is defined as the presence of any of the following: moderate to severe CP, blind in both eyes, bilateral hearing impairment requiring amplification, and a Bayley mental developmental index or psychomotor developmental index score < 70. The use of NDI as a standard outcome for intervention trials evolved with the recognition of the frequent disconnect between perinatal outcomes and long-term outcomes. Examples include: 1) the aggressive administration of oxygen for relief of respiratory distress syndrome and subsequent retinopathy of prematurity/blind infants and 2) administration of postnatal steroids for weaning infants with broncho pulmonary dysplasia from a ventilator and subsequent CP [28–30]. The combined outcome of NDI or death

B.R. Vohr (✉)
Department of Pediatrics, Women and Infants Hospital, Warren Alpert Medical School of Brown University, Providence, Rhode Island, USA

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

is often a choice for primary outcome since it is well recognized that death is a competing outcome with NDI. Utilization of the same definition for outcome among studies allows one to more readily compare the findings.

129.2 Methodological Issues and Follow-up Techniques

Differences in the reported incidence of neonatal morbidities (i.e., bronchopulmonary dysplasia [BPD]) or post-discharge outcomes (i.e., CP) may not be secondary to a specific intervention, but may be related to the specific characteristics of the center's NICU population (race, health insurance, poverty rates) and differences in management style [25, 31, 32]. Examples of medical management confounders include a center's policies for antenatal and obstetric care, variability of use of ventilators, medications, enteral and parenteral nutrition, and approaches to care for infants at the limits of viability. Neonatal factors affecting outcome include multiple versus singleton, inborn versus outborn, gestational age at birth and male versus female [33]. Social and environmental characteristics with significant heterogeneity include poverty level, public versus private insurance, level of parent education, single parent, English speaking versus bilingual or non-English speaking, cultural and religious differences, and availability of post-discharge medical, therapeutic, early intervention and educational services [34]. One of the challenges of follow-up studies which can contribute to bias in interpreting NDI rates is that poor and less educated families are less likely to return for follow-up.

129.2.1 Assessment in the Follow-up Program

Age of follow-up assessment impacts on the findings that can be reliably identified. In the first 2–3 years of life valid primary outcomes include moderate to severe CP, mental retardation, bilateral blindness, and bilateral hearing impairment. Current studies in the first 3 years often use the composite outcome of NDI as the primary outcome. At school age, however, a broad spectrum of subtle cognitive and neuropsychological deficits including impaired language skills, perceptual-motor skills, executive function, memory skills and attention problems become apparent and can be identified with standardized test administration.

The question that is often raised is at what age one can identify the real impact of a neonatal intervention. It is clear that neurologic status at the time of discharge has limited predictive value. There is consensus that major neurologic and sensory impairments can be identified at 18–24 months of age. Do the findings at 18–24 months predict school age findings? Longitudinal studies of preterm children have demonstrated variability in the progression of neurologic and developmental findings and include: stability [35], improvement [22], and worsening [36, 37] of neuropsychological findings. Limitations in the predictive value of early assessments may be secondary to differences in the follow-up rates, the inclusion or exclusion of children with major neurologic or sensory impairments, and the post-discharge environment. To minimize bias a follow-up rate of 90% is optimal. The validity of outcome data is always enhanced by utilization of a gender and age matched comparison group. Because of the exorbitant costs of tracking families to school age, the majority of trials and observational studies report outcomes at 18–24 months, an age at which major sequelae can be identified.

129.3 Assessments

One approach of outcome studies is to report comprehensive neurological, developmental, functional and health care status, which permits a total view of the child within the context of the family. Table 129.1 lists assessments suitable for follow-up studies of children up to 36 months of age divided into seven major categories: neurologic/neurosensory, cognitive, visual-motor/fine motor, speech and language, motor function/coordination, functional skills for daily living, and behavior.

129.3.1 Neurologic/Neurosensory

Because of its significant impact on the child and family, neurologic status, especially CP is an important quality indicator for a NICU. A diagnosis of CP is obtained by performing a systematic neurologic assessment [38]. CP is defined as a non-progressive central nervous system disorder with abnormal muscle tone in at least one extremity and abnormal control of movement and posture which interfere with age appropriate activities [38]. CP is a challenging diagnosis to make on infants less than a year of age because of the prevalence of hypertonicity among premature infants in the first year of life [39]. A definitive diagnosis of moderate to severe CP can be made by 18 months of age. CP is classified as moderate if the child can sit independently or with support, but an assistive device is required for ambulation, and severe if the child is unable to sit or walk even with support. Other neurologic findings identified in preterm children include hypertonicity, hypotonicity, seizures, dyspraxia, absent pincer, or facial palsy without a specific diagnosis of CP. Explicit criteria for describing hand function, sitting ability, and self-mobility have recently been developed [40]. Moderate to severe CP is a component of NDI.

Vision abnormalities are common among former preterm infants. The standard of care within tertiary care centers

Table 129.1 Assessments for neurodevelopmental and behavioral outcomes of VLBW infants

Tests		Ages
1. Neurologic and Sensory		
– Vision	Ophthalmologic examination	All ages
– Hearing	Auditory Brainstem Test	All ages
	Otoacoustic emissions	All ages
	Tympanometry	>6 months
	Vision reinforcement audiometry	>6 months
– Neurologic	Standard Neurologic Examination	All ages
categorize child as: Normal/Suspect/Abnormal		
Cerebral Palsy: Mild, Moderate, Severe		
2. Developmental/Intelligence and Developmental Tests		
– Bayley Scales of Infant Development II (BSID II) [42]		1–42 months
– Bayley III Scales of Infant and Toddler Development [160]		1–42 months
– Stanford Binet Intelligence Test, 4th edition (SB-4) [44]		2–18 years
– Differential Ability Scales [45]		2.5 to 18 years
– McCarthy Scales [46]		2.5 to 8.5 years
3. Vision Motor		
– Beery Developmental Test of Vision Motor Integration (VMI) [161]		Short form 3–8 years
4. Speech/Language/Vocabulary		
– Preschool Language Scale 3 [51]		Birth – 6 years
– Peabody Picture Vocabulary Test-Revised (PPVT-R) [162]		2 years 6 months – adult
– Early Language Milestone 2 (ELM2) [48]		Birth – 36 months
– Sequenced Inventory of Communicative Development-Revise (SICDR) [50]		4 mo – 4 years
5. Motor Function		
– Peabody Developmental Motor Scales [55]		0–7 years
– AGS Early Screening - Motor Profile [56]		2–11 years
– Palisano Gross Motor Classification Scale [67]		12 months – 12 years
6. Functional Status		
– WeeFim [62]		6 months – 8 years
– Vineland Adaptive Behavior Scale (VABS) [163]		Birth – 18 years 11 months
– Battelle Developmental Inventory (BDI) [164]		Birth – 8 years
– Pediatric Evaluation of Disability Inventory (PEDI) [74]		6 months – 7.5 years
7. Behavioral Outcomes		
– Child Behavior Checklist (CBCL 1.5-5) [165]		1.5 to 5 years

determines that VLBW infants have ophthalmologic examinations for retinopathy of prematurity prior to discharge with appropriate follow-up and intervention where appropriate. This has facilitated the identification of both severe and milder degrees of vision impairment. In addition, ongoing monitoring for the detection of strabismus and myopia are indicated. Bilateral blindness is included in the composite outcome of NDI.

Since NICU infants are at increased risk of all types of permanent hearing loss (HL) including neural (auditory neuropathy/auditory dyssynchrony) HL, the Joint Committee on Infant Hearing (JCIH) 2007 [41] has recommended automated auditory brainstem response (ABR) screening for all infants that require NICU care for > 5 days. Infants who fail the screen should have a comprehensive audiology assessment by 3 months of age. An audiology diagnostic assessment for infants less than 6 months at a minimum consists of a diagnostic auditory brainstem response (ABR) and otoacoustic emissions. Children who are at least 6 months of developmental age should also have a behavioral assessment, vision reinforcement audiometry, completed. Bilateral HL that requires amplification is included in the composite outcome of NDI.

129.3.2 Cognitive

The Bayley Scales of Infant Development (Bayley II) [42] has been the most commonly reported assessment of development from 4 months to 36 months of age and provides information for both cognitive (the mental developmental index [MDI]) and motor (the psychomotor developmental index [PDI]) domains. Bayley scores of 100 ± 15 represent the mean ± 1 standard deviation (SD) of a population of normal infants born at term. A score < 70 (2 SDs below the mean) is interpreted as evidence of developmental delay. The Bayley Scales of Infant Development III (BSID-III) is currently available for assessments from 1 month to 42 months of age [43]. In contrast to the Bayley II, the BSID-III consists of three domains: Cognitive, Language and Motor. In addition

there are subscores for receptive communication, expressive communication, fine motor and gross motor. The Bayley III was developed, in part, to separate cognitive from language domains to eliminate the bias imposed for children residing in a bilingual or non-English speaking household.

The Stanford Binet Intelligence Scale, 4th edition (SB-4) [44], the Differential Ability Scales [45] and the McCarthy Scales of Children's Abilities [46] are all tests of early cognitive/developmental ability. For studying populations of children, outcome data can be used to compare groups with one another (intervention *vs* control) or with normative data. Children's overall performance is often evaluated on a battery of tests which include visual perceptual skills [47], speech and language skills [48–52], cognition [44–46, 53, 54] fine and gross motor function [55–57] behavior [58–61] functional skills and health care status [62].

For an individual child early test results have limited predictive validity of cognitive status. First, tests administered at younger ages may not tap into the same psychological capacities as those present in older children, and the child resides within a changing environment with a spectrum of influences on development. School age outcomes have the most validity for final status of cognitive function.

At school age, cognitive functioning is assessed using a variety of different measures including the Stanford Binet Intelligence Scale – 4th edition, the Wechsler Preschool and Primary Scales of Intelligence – 3rd edition (WPPSI), the Wechsler Intelligence Scale for Children (WISC-III), the Woodcock-Johnson Psycho-Educational Battery – Revised, the Differential Abilities Scales, the McCarthy Scales of Children's Abilities, the British Abilities Scale, and the Kaufman Assessment Battery of Childhood. Each of these assessments provides an intelligence quotient (IQ) and subtest scores that allow for a limited assessment of specific areas of strengths and weaknesses. These tests, like the Bayley, have a mean of 100 with a standard deviation of 15 in the general population.

129.3.3 Visual Motor/Fine Motor Skills

The third category is visual motor and fine motor skills [47]. The most commonly used test for visual motor skills is the Beery-Buktenica Developmental Test of Visual-Motor Integration 4th edn (Beery VMI) [47]. The VMI assesses the degree to which visual-perception and motor behavior is integrated. It can help identify visual-motor problems before they develop into more serious difficulties. The VMI consists of geometric figures arranged in order of increasing difficulty. The child copies the figures as accurately as possible with pencil and paper. Fine motor skills can be assessed using the Peabody Developmental Motor Scales (PDMS) [55]. This test presents the child with a variety of fine motor tasks including block design, shape copying, cutting, folding, and manual dexterity tasks. A developmental motor quotient is calculated for each child's performance based on age. Mean developmental quotient is 100 ± 15.

129.3.4 Speech and Language

Speech language delays are common among preterms and a variety of tests are available. The Preschool Language Scale – 3rd edition (PLS-3) [51] is a standardized assessment which includes two subscales-auditory comprehension and expressive communication – to assess attention, vocal development, social communication, semantics, language structure, and integrative thinking skills. The Peabody Picture Vocabulary Test (PPVT-R) [49] is a non-verbal, multiple-choice test that measures receptive vocabulary. The Early Language Milestone Scale, 2nd edn (ELM Scale-2) [48] assesses speech and language development in three areas: Auditory Expressive, Auditory Receptive, and Visual. The Sequenced Inventory of Communication Development Revised edition (SICDR) [50] is a diagnostic test that evaluates the communication abilities of children who are between 4 months and 4 years of age. It has been used successfully with children with sensory impairments and varying degrees of retardation [63–66].

129.3.5 Motor Function/Coordination

The PDMS [55] are a test of gross and fine motor skills of children aged birth through 83 months. The Early Screening Profiles (ESP) [56] measures motor, cognitive/language, and developmental skills in children. The ESP consists of three profiles: Motor Profile, Cognitive/Language Profile, and Self-Help/Social Profile. A Gross Motor Function Classification System (GMFCS) skill level derived from the work of Russell et al and Palisano et al [67–69] is used in outcome studies to assess gross motor function. A scoring system consisting of skill levels ranging from 0 to 5 was developed by Palisano and colleagues [67–69]. This system was developed as a method for assessment of a child's motor function by direct observation of the child's gross motor performance. It describes a child's function, not the fluidity of their movements. Palisano's system classifies gross motor function on a 5 point scale. Normal function at 18–24 months is defined as Level 0 and involves the ability to walk at least 10 steps independently. An infant at Level 1 can sit with hands free, creep or crawl on hands and knees, pull to stand and cruise or walk with hands held. Those at Level 2 use their hands for sitting support, creep on their stomach and may pull to stand; at Level 3 require external support to sit, roll and may creep; at Level 4 maintain head control in a supported sitting position and can roll prone to supine. Level 5 is the inability to maintain antigravity movements of the head and trunk [67, 70]. The GMFCS does not assess fine motor skills.

129.3.6 Functional Measures

The sixth area of assessment includes functional measures of daily living skills. Functional assessment is the process of determining as accurately as possible an individual's ability to perform the tasks of daily living and to fulfill the social roles expected of a physically and emotionally healthy person of the same age and culture [71]. In children, the key tasks include feeding, dressing, bathing, maintaining consistency, mobility, communication, play, and social interaction [72]. The social roles expected include involvement with peers and attending school. Four functional outcome measures are currently available [62, 73, 74]. The Pediatric Evaluation of Disability Inventory (PEDI) assesses developmental skills in self-care, mobility, and social function, care giver assistance and modification of environment in children 6 months to 7.5 years [74]. The Vineland Adaptive Behavior Scale (VABS) measures communication, daily living, socialization, and motor skills in children birth to 18 years. The Vineland has been used with children with motor, cognitive, and sensory disabilities. Rosenbaum et al have advocated its use for describing degrees of disability in children who were very low birth weight [75]. The Battelle Developmental Inventory (BDI) is a developmental educational assessment battery for children age 0–8 years with or without developmental delays. The Battelle consists of five domains: personal-social, adaptive, motor, communicative and cognitive. It is widely used in early intervention. The Functional Independence Measure for Children (WeeFIM) [62] can be used in children with and without disabilities through age 8 years. After age 8 years, individuals with developmental skills less than 8 years can continue to be assessed with the WeeFIM [76] through adolescence.

129.3.7 Behavior and Psychology

Evaluations of behavior are routinely obtained in infancy and childhood by parent, teacher, or subject interviews with standardized measures of behavior, attention, adaptive skills and depression. The Child Behaviour Checklist [77] is a parent-report questionnaire designed to describe social competencies and emotional/behavioral issues of children and is commonly used in follow-up studies. It has a version for 1½ to 5 year olds and a version for ages 4–18. It provides scores for internalizing (i.e., anxious, depressive, and overcontrolled) and externalizing (i.e., aggressive, hyperactive, noncompliant, and under-controlled) behaviors, and has scores that were derived for withdrawn, somatic complaints, anxious/depressed, social problems, thought problems, attention problems, delinquent behavior, aggressive behavior, and the presence of any behavior problem. The Conners Rating Scales [78] are questionnaires designed for parents or teachers to describe symptoms of inattention, hyperactivity, and oppositionality in school age children. Multiple different measures of childhood depression exist and have been studied in this population. The Modified Checklist for Autism in Toddlers (M-CHAT) [79, 80] and the Pervasive Developmental Disorders Screening Test II (PDDST II) [81] are currently available as screeners for autism spectrum disorder.

129.4 Definitions of Normal and Abnormal Outcome

Although the traditional outcome described for infants is an abnormal outcome defined as NDI, more recent investigators have attempted to define a normal outcome. A recent study by Gargus et al [82] defined a normal outcome at 18–22 months corrected age as infants who were unimpaired; they had both Bayley-II [42] MDI and PDI scores within 1 standard deviation of the mean, normal neurological findings, normal vision, hearing, normal functional ability for swallowing by parent report, and normal ambulation. In addition, infants were classified as having mild impairments if they had any of the following: Bayley MDI or PDI between 70 and 84, CP, mild other neurological findings, or minor sensory impairments (glasses, transient conductive hearing loss, unilateral hearing loss, or unilateral blindness). Severe NDI was defined as any of the following: Bayley MDI < 70, Bayley PDI < 70, moderate to severe CP, bilateral blindness or bilateral hearing loss requiring amplification. The last definition is the traditional NDI.

129.5 VLBW Outcomes

The majority of published reports of neurodevelopmental outcome in infancy focus primarily on the incidence of moderate to severe disability [83]. This has been the neurodevelopmental outcome of interest due to the severity of the developmental impact of these severe and often combined morbidities. Unlike mortality rates which have dramatically improved [1, 6, 8, 83–87], the incidence of moderate to severe disabilities has not changed significantly over the past 20 years [1, 8, 83–91]. Rates are highest in ELBW populations, and like mortality rates, rates of disability generally increase with decreasing gestational age and birth weight [83, 87, 90, 92–94]. Worldwide rates of severe disability in infants of 24–25 weeks' gestation range from 22 to 45% in infants born at 24 weeks, 12 to 35% in infants born at 25 weeks, and 9 to 37% in infants born < 800 grams birthweight [83, 88].

In the NICHD Neonatal Research Network, rates of NDI in the 1990s ranged from 28 to 40% in infants born 27–32 weeks and 45 to 50% in infants born 22–26 weeks [90]. Only 21% of all ELBW infants were unimpaired (no CP, normal

cognitive and motor scores, no visual or hearing impairment) at 18 months [8]. Regional and local studies in the 1990s report similar wide ranges of major NDI rates, from 20 to 48% [1, 84, 85, 87, 91, 93, 95].

129.5.1 Neurologic/Neurosensory

Extremely preterm infants are born during a period of active brain development and maturation, placing them at extremely high risk for brain injury from hypoxia, ischemia, undernutrition, and infection, which are associated with both intraventricular hemorrhage (IVH) and periventricular leukomalacia (PVL). PVL is injury to the periventricular white matter as a result of hypoperfusion and infarction. It is visualized radiographically as echolucency, echodensity, or cystic degeneration. Although IVH, ventriculomegaly at term and cystic PVL are all associated with CP, cystic PVL is the strongest predictor [70].

Rates of CP in ELBW vary from 5 to 30% [8, 20, 70, 83–85, 87–94, 96–101] but are most commonly sited at 15 to 23% [8, 70, 90, 93, 94, 98–100]. The most common form of CP in this population is spastic diplegia, accounting for 40 to 50% of all cases, followed by spastic quadriplegia, and hemiplegia [70, 93, 100]. This is not surprising as PVL lesions involve injury to the white matter that contains the descending motor tracts for the lower extremities. More extensive lesions also involve upper extremity motor tracts.

While CP is the most well known and potentially most disabling motor abnormality associated with prematurity, infants born preterm often demonstrate less severe differences in their neurologic development. During the first year of life transient dystonia is a common deviation in the motor development of VLBW infants [39, 102, 103]. Transient dystonia was first described in 1972 by Drillien as transient abnormalities on neurologic examination in close to half of all low birth weight infants (< 2000 grams) in the first year of life. More recently these transient findings have been re-described as occurring in 21 to 36% of preterm infants with a peak incidence at 7 months corrected age [102–104]. The motor features described include increased extensor tone of the trunk and lower extremities and increased adductor tone in the lower extremities leading to shoulder retraction and hip rotation, persistent primitive reflexes, head lag on pull to sit and delayed supportive responses [39]. The presence of findings consistent with dystonia increases the risk of later cognitive and motor problems including CP but have a low specificity as they are transient in 80% of the infants in which they occur, disappearing gradually between 8 and 12 months of age. The other 20% often go on to be diagnosed with CP.

While much less common than motor disabilities, rates of neurosensory disabilities are higher in ELBW infants than the general population. Unilateral or bilateral blindness occurs in 1–10% of ELBW infants [8, 20, 83–85, 87–89, 91, 93, 94, 97, 100, 105]. Milder visual impairments including myopia, strabismus, and lack of stereopsis (depth perception) occur at rates of 9–25% [92, 94, 97, 100, 106].

Hearing impairment requiring amplification is reported in 1–9% of ELBW infants [8, 20, 83, 84, 87, 89–94, 97, 100]. Milder hearing impairment has been reported in 11–13% [94, 100]. When transient conductive or unilateral hearing loss is included, rates of milder impairment are as high as 28% [97]. These rates of neurosensory impairment persist at school age [98, 99, 107, 108].

129.5.2 Cognitive

The most common severe impairment seen in VLBW and ELBW infants at 18 and 30 months is cognitive impairment, defined as scores that are more than 2 standard deviations below the mean on standardized cognitive testing. Most published follow-up studies of ELBW infants to date have used the Bayley Scales of Infant Development II (Bayley II) as the measure of cognitive functioning between 6 months to 3 years [42]. Average score for ELBW infants at 18–22 months corrected age on the Bayley II in the NICHD is 76 [94] but varies from center to center with a range of 70 to 83 [97]. Center and regional reports site higher average MDIs. In a cohort of <1000 gram infants born from 1982 to 2002, Wilson-Costello and Hack report average MDIs of 84–86 (and 83–89 in a subset of < 750 gram infants) at 20 month follow-up [84, 87, 91]. Wood et al reported similar results at 30 months corrected age in a cohort of 20–25 week infants in the United Kingdom whose average MDI was 84 [100].

Like rates of NDI and CP, rates of cognitive impairment, defined as a score < 70 on cognitive assessment, vary worldwide, and are inversely proportional to gestational age and birth weight. Rates of cognitive impairment range from 14 to 39% at 24 weeks, 10 to 30% at 25 weeks [83], 4 to 24% at < 26 weeks, and 11% to 18% at < 29 weeks worldwide [89, 92]. In infants born < 800 grams, rates of cognitive impairment range from 13 to 50% [20, 83, 85, 88, 89] and at < 1250 grams 26% [89]. Rates of cognitive impairment are reported at 37–47% in 22–26 week infants [8, 90] 23–30% in 27–32 week infants [90] and 34–37% in all infants < 1000 grams in the NICHD [94, 109]. Wilson-Costello and Hack site 20–26% rates of cognitive impairment in their cohort of ELBW infants at 18 months [84, 87, 91] and at 30 months, 30% of Wood's cohort had cognitive impairment [100].

While cognitive functioning can by measured in infancy, it may not be predictive of cognitive functioning later in life. The assessment of an infant's cognitive function is highly dependent on their motor, language, and social-emotional development. Hack et al found that MDI at 20 months corrected age was not predictive of cognitive functioning at 8 years of age. In their cohort of 330 ELBW infants, mean MDI at 20 months was 76 compared to a mean cognitive score of 88 at 8 years, and rate of cognitive impairment dropped from 39% at 20 months to 16% at 8 years. The positive predictive value

Table 129.2 Cognitive outcomes at 12–36 months corrected age for ELBW infants

Year of birth	Sample size	BW/GA	Subgroups	Group (Mean MDI)	Group (MDI <70)	Age months	Location	Author

of having a low cognitive score at 8 years (< 70) given a low cognitive score at 20 months (< 70) was only 0.37 [108]. Ment et al reported recovery of test scores in a cohort of VLBW infant [110]. Mean expressive language scores increased from 88 at 3 years to 99 at 8 years of age and full scale IQ increased from 90 to 96.

Mean IQ for VLBW and ELBW infants at school age (5 to 14 years) ranges from 82 to 105 [99, 108, 110–117].

Although the mean IQ is within the average or low average range for children born ELBW or VLBW, they have significantly lower IQ scores than their normal birth weight peers (0.5 to 1.0 SD lower) [98, 111–118] and significantly higher rates of cognitive impairment [98, 99, 119]. Cognitive scores at school age remain significantly correlated with gestational age and birth weight [37, 111, 112, 116]. While environmental factors such as type of health insurance, bilingual household, income level, single parent, teen-age mother and level of maternal education are known to impact on intelligence, differences in IQ between preterm and term controls persist after adjustment for these confounders [120].

In addition to impairments in global cognitive functioning, more subtle cognitive impairments are often detected in school age. These higher prevalence, lower severity dysfunctions reportedly occur in 50–70% of children born VLBW [95]. Children born VLBW or ELBW have relative impairments of executive functioning [116, 121–123], visual-motor skills [123], memory [116, 122], especially verbal memory [124]. They score lower on tests of academic achievement [108, 113, 122], perceptual-organizational skills [116, 118], visual processing tasks [116, 118] and adaptive functioning [116, 122] compared to their normal birth weight peers. Even ELBW infants without neurosensory or cognitive impairment have higher rates of learning disabilities [111, 117] especially in math [115, 116, 118, 125], ranging from 25 to 40% [111, 118].

So it is not surprising that ELBW infants have higher rates of academic underachievement and need for special education services [111, 114, 119]. Like their cognitive scores, mean scores on formal tests of academic achievement fall within the normal range (94–105), but are lower than scores of normal birth weight peers [111, 114]. Teachers of VLBW infants report rates of below average school performance in all academic areas, ranging from 24 to 41% [111, 113, 119, 126]. Approximately 25% of VLBW infants and up to 62% of ELBW infants receive special education services [107, 114, 116, 119, 127, 128]. Between 15 and 34% required grade repetition [115, 116, 128, 129].

An increasing number of investigators have reported on cognitive and academic abilities of former VLBW and ELBW teenagers and young adults [37, 99, 116, 122–124, 128, 130]. ELBW teens continue to have mean cognitive scores in the average to low average range but persist in having significantly lower cognitive and academic scores than teens born normal birth weight [127, 131, 132] and significantly higher rates of cognitive impairment [127, 132]. Cognitive differences are greatest in areas of visual-perceptual tasks [131]. Academic differences are seen in reading and mathematics [131]. As a result, only 56–74% of preterm children, significantly fewer than normal birth weight teens, graduate from high school [127, 132]. Hack's report on a single center cohort of VLBW infants showed significant gender differences in graduation rates: 66% of VLBW males compared to 75% for term males and 81% for VLBW females compared to 90% for term females [132].

129.5.3 Visual Motor/Fine Motor

Difficulties with fine motor skills and with visual-motor skills, described as problems with visual perception, visual motor control, hand-eye coordination, or visual-motor integration, are common in children born VLBW or ELBW. These difficulties can impact on academic performance and functional abilities. Fine motor difficulties have been described in as many as 70% and fine motor difficulties resulting in impairment in 23% at 5 years of age [133]. Average scores on the Beery VMI are significantly lower in ELBW infants than term controls at age 7–8 (91 *vs* 97, $p < 0.001$) [134] and age 12 (82 *vs* 92) [135] and visual motor integration deficits (VMI < 70) are found in 16–24% of ELBW infants at school age [134, 135].

129.5.4 Speech and Language

Speech and language develop atypically during early childhood in previously ELBW infants, with delays in the acquisition of expressive language, receptive language, and articulation [136–138]. Children born at or before 25 weeks gestation have significantly lower total scores on the PLS (90 *vs* 104) and significantly higher rates of language impairment (16 *vs* 2%) at 6 years of age. Scores on auditory comprehension, expressive communication and articulation subtests of the PLS are uniformly lower [139]. In addition, rates of language impairment, defined as standard scores of < 70 on language assessment, are higher. Former ELBW infants have significantly lower scores (92 *vs* 105) and higher rates of impairment (13 *vs* 4%) on the PPVT, as well as lower expressive, receptive, and total scores (85–87 *vs* 100–103) and higher rates of impairment (22–24% *vs* 3–4%) on Clinical Evaluation of Language Fundamentals (CELF) at age 12 [135]. While language development in infancy and early childhood is often an early proxy for overall cognitive development, specific language deficits have been described including phonological short-term memory [140] and prosodic processing [141]. At 12 years of age, children who are born <1250 grams have less pronounced differences on tests of lower level language skills (phonological processing, phonemic decoding and sight word reading) compared to term controls, but exhibit significantly more difficulty with higher level skills (syntax, semantics, verbal language memory and reading comprehension) [135]. In addition, when given a semantic processing task, preterm children have abnormal patterns of brain activity on functional MRI, resembling the brain activity of term controls during phonologic processing [66].

129.5.5 Motor Function/Coordination

Arguably more important than the type or location of impairment is the functional level of the affected infant. Level of

gross motor function is most commonly assessed and categorized using Palisano's GMFCS [67]. In an NICHD Neonatal Network study, though 27% of a cohort of ELBW infants diagnosed with CP at 18–22 months had moderate to severe gross motor function (Level 3–5), 28% had gross motor function consistent with level 0 or 1 and were ambulatory [70]. It is important to remember that a diagnosis of CP includes a wide spectrum of motor performance.

More subtle motor abnormalities are also seen more commonly in former preterm infants and children born preterm are more likely to have difficulty with motor coordination. In the past these children were often labeled as clumsy but in recent years the diagnosis of developmental coordination disorder (DCD) has been used. DCD is defined as an impairment in motor performance sufficient to produce functional impairment that cannot be otherwise explained by the child's age, cognitive ability, or neurologic or psychiatric diagnosis. Scores of less than the 5th to 10th percentile on the Movement Assessment Battery for Children (MABC) are considered diagnostic. DCD is found in 31–34% of VLBW and 50% of ELBW infants [134, 142].

129.6 Functional Outcomes

As a result of the high rates of associated cognitive, motor, neurosensory, and behavioral difficulties seen in children who were born preterm, these children have higher rates of functional limitations than children who were born at term [107]. These functional delays are observed in VLBW infants with and without severe impairments. While 93% of ELBW infants achieve sitting balance, 83% walk, and 86% feed themselves independently by 18–22 months corrected age, more subtle functional deficits become apparent later in life [94]. At 10–14 years of age, 27% of children who were VLBW and 32% of those who were ELBW report restricted physical activity; and 24% of VLBW and 29% of ELBW report they are unable to participate in sports [107]. Functional outcomes are considered particularly important by parents.

129.7 Behavioral and Psychological

Very low birth weight has been associated with a wide variety of behavioral and psychological diagnoses and disabilities. Recent concern has arisen that rates of Autism Spectrum Disorder (ASD) may be higher in ELBW infants than previously thought. Though low birth weight (< 2500 grams) may result in a 2–3 fold increase in the risk of ASD [143, 144], true risk of ASD in very preterm infants is unknown. Two prior studies have investigated rates of autistic characteristics in children born very low birth weight (VLBW, <1500 grams). Indredavik et al [145] demonstrated a trend toward higher scores on the Autism Spectrum Screening Questionnaire in a population of 56 VLBWs at 14 years of age compared to full-term controls. Limperopoulos et al [146] recently reported 25% of VLBW infants screen positive on the M-CHAT at 18 months. However the M-CHAT was developed for use in the general population and not for a high risk population such as VLBW infants where false positive screening rates are likely high due to associated cognitive, language and motor delays. In addition, no diagnostic confirmation was performed [146]. Further studies are needed to determine the true risk of autism in this population.

At school age (8–12 years old), parents and teachers of VLBW/ELBW infants report higher rates of inattention and hyperactivity [111, 112, 116, 117, 119, 129, 145, 147, 148] with rates of 23–27% in VLBW and 33–37% in ELBW infants [117, 119, 145, 147]. At 12–14 years of age one quarter to one half of VLBW/ELBW infants have symptoms of anxiety and/or social withdrawal [117, 119] 8–14% meet criteria for generalized anxiety disorder (compared to 1–4% of peers) [145, 147] and 25–28% meet criteria for a psychiatric disorder (compared to 7–10% of peers) [145, 147]. At 17 and 20 years of age, ELBWs score higher on measures of inattention, anxiety/depression, withdrawn behavior, and social problems at 17 years of age [131, 149]. In addition, VLBW teens score significantly lower on measures of self esteem [115, 131]. They report less confidence in their athletic, school, romantic, and job related abilities [131]. In contrast, VLBW adults report lower rates of alcohol and drug use, sexual activity, and pregnancy than adults born normal birth weight [132, 149].

129.8 Late Preterm

While the majority of neonatal outcomes research has focused on the ELBW infant, more recent studies have brought a long neglected population of infants to our attention, the late preterm population. During the 1990s the rates of delivery at 40 or more weeks gestation decreased while rates of deliveries between 34 and 36 weeks increased steadily [150]. From 1990 to 2005 the rate of late preterm births increased from 7.3 to 9.1% of all births [151]. Compared to term infants, these late preterm infants have higher mortality rates [152–154]. They also have higher rates of neonatal morbidities such as respiratory distress, temperature instability, hypoglycemia, kernicteris, apnea seizures, infection, and feeding problems [151–153, 155, 156]. All of these morbidities have the potential to increase the risk of long-term neurodevelopmental sequelae. In addition, the brain of the late preterm infant is more immature than the term infants' brain. At 34 weeks there are significantly fewer gyri and sulci, and the brain weighs an estimated 60% of that of a term infant [156]. While there is a large body of literature that addresses the neurodevelopmental outcome of VLBW and ELBW infants, there is a paucity of information published about the neurodevelopmental sequelae

of late preterm birth. Infants born 34–36 weeks are 3.39 times as likely as term infants to develop CP and 1.25 times as likely to have cognitive impairment [157]. They are more likely to qualify for special needs preschool and are more likely to have problems with school readiness [158]. In kindergarden and first grade they have lower reading scores, teachers report math skills below those of their full-term peers, and they are more likely to qualify for special education services [159].

129.9 Summary

In summary, preterm infant survivors remain at increased risk of adverse neurodevelopmental outcomes. Longitudinal assessment of outcomes is indicated to identify neurosensory, developmental, and behavioral sequelae and to ensure appropriate supports and interventions are provided. Continued randomized trials are needed to identify perinatal interventions that optimize outcomes.

Neurological Examination of the Newborn Infant

Fabrizio Ferrari, Licia Lugli, Luca Ori, Claudio Gallo and Natascia Bertoncelli

130.1 Aims of the Neurological Examination and Basic Requirements

A simple neurological screening examination should be performed on all newborn infants as part of the general medical examination. It should consist of an assessment of state of consciousness-reactivity, spontaneous motor activity, neck, trunk and limb muscle tone and some primitive reflexes (e.g. suck and grasp. Not all experts include the Moro reflex in the general examination on the basis that it is cruel to startle a person) [1].

Several schemes of neurological examinations have been developed during the last decades to document clinical neurological signs and their evolution or their disappearance [2–5]. The number and type of clinical neurological signs included in the various schemes are very heterogeneous. Some are comprehensive examinations designed essentially for research purposes, others are simpler clinical tools that aim to assess the integrity of the central nervous system (CNS).

Along with the definition of neurological signs and their evolution, the neurological examination tries to answer other questions such as the recognition of age appropriate development of the CNS, the presence of an acute or a chronic brain disorder, the central or peripheral nature of the problem and the prognosis for that infant. These questions cannot be all answered by the same protocol as each has its own peculiarities and strengths.

Preterm infants after birth and small for gestational age infants demand a neurological examination which includes a number of items, assessing the age appropriateness of neurological development (CNS maturity) throughout the preterm period and at term [4, 7]. The recognition of an acute neonatal encephalopathy in full-term (or near-term preterm) infants requires an examination specifically designed for acutely ill babies. The recognition of emotional and temperamental characteristics, as well as the response to stressors, requires the use of behaviourally oriented protocols [3, 6].

The choice of neurological examination depends on the study group and the purpose of the examination. According to Prechtl, there are a few basic requirements for the neurological assessment and for its successful use in clinical practise [8]. It should include items related to the age-specific repertoire of the CNS, which changes very rapidly during the pre-and early postnatal period.

The diagnostic procedure must be non-invasive and relatively quick to perform, as the neurological examination should be included within the routine clinical assessment and should be repeated to document the evolution of neurological abnormalities and to facilitate prognostic accuracy. Reliability and prognostic capability are two critical requirements. There should also be good inter-observer agreement should also apply.

This chapter describes the different approaches to the neurological examination of the newborn infant and neurological protocols that best fulfil the above criteria.

130.2 Available Neurological Examinations

Because each method represented an improved approach to understanding the neonatal nervous system, the methods will be considered chronologically. Few studies have compared the different protocols and it cannot be claimed that one is better than another. The French school (André Thomas and Saint-Anne Dargassies, Amiel-Tison) highlighted spontaneous posture, some neonatal reflexes and various aspects of muscle tone. Active tone considers “fonctions de redressement” and is associated with spontaneous movements. Passive tone is the capacity of muscle to be lengthened when the joints are moved passively and the tone that can be seen by allowing the extremity to swing at each joint. Saint-Anne

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

Dargassies described the ontogenesis of muscle tone in premature infants: outlining the progressive maturation of muscle tone, with development of flexor predominance in caudal-cephalic direction [2, 9].

The Amiel-Tison neurologic assessment at term (ATNAT) has recently been updated for clinical application. The complete procedure takes a few minutes. A simple 0, 1, and 2 scoring system is proposed. The ATNAT is part of a set of three different instruments based on a neuro-maturative framework. By sharing a similar methodology and scoring system, the use of these three assessments allows for the follow-up of high risk children from 32 weeks post-conception to 6 years of age [2, 10].

Prechtl and co-workers [10, 11] developed a comprehensive examination, based on the assessment of spontaneous and elicited responses. They studied the various neurological responses of normal healthy term infants and documented any abnormality in the responses. They analysed and documented trunk and limb posture, spontaneous movements of the various parts of the body and of the eyes, the power and the resistance to passive movements, invluntary activities such as skin color and respiration, skin reflexes (abdominal, cremasteric, anal reflex), osteo-tendon reflexes, evoked responses such as palmar and plantar reflex, Babinski, Moro, tonic neck asymmetric reflex, rooting, sucking, placing, Bauer reflex, crawling, automatic stepping, abnormal movements (athetoid, tremors) and crying. Each single response and behavior was evaluated in its optimal state. They demonstrated the dependency of these patterns on an infant's behavioral state. When the behavioral state was considered, normal infants responded consistently to the elicited stimuli. Non-responsiveness, despite being in the right behavioral state, was considered an abnormal neurological sign [12–14].

130.2.1 Behavioral State

Recognition of behavioral states was a major advance in the field of neonatal neurology. Behavioral states are an expression of the complexity of the nervous system; they are relatively stable over time (ranging from a few minutes to half an hour or more) and occur in particular sequential patterns. They are recognized on the basis of three to four essential physiological parameters (respiration, eyes open or closed, eye movements, body movements) that remain stable over time for at least a few minutes. Prechtl identified two states of sleep (state 1 or quiet sleep, state 2 or active sleep) and three states of wakefulness (state 3 or quiet wakefulness, state 4 or active wakefulness, state 5 or crying) [12]. Evoked reflexes and responses as well as spontaneous activity (such as body and eye movement and respiratory patterns) change according to the behavioral states.

The Groningen school showed that two sleep states are recognizable from the 36th week of gestation, while before 34 weeks' gestation, indeterminate sleep is predominant. Before 28 weeks, the newborn states of wakefulness and sleep are difficult to distinguish [12].

The recognition of different behavioral states is fundamental for the diagnosis of neurological integrity in the newborn. One of the earliest and most sensitive sign of cerebral dysfunction is disorganization of the behavioral state. Such disorganization of state can be a loose state cycle, a qualitative alteration of a single state or a physiological parameter defining states or the presence of an unstable sleep pattern [12, 13].

A useful and major innovation by Prechtl was the clustering of neurological signs into diagnostic syndromes. Using the computerized analysis of individual neurological deviations, he recognized four main syndromes: the hyper-excitable syndrome with increased responsiveness to various stimuli, the apathetic syndrome with decreased responsiveness, the hemi-syndrome with asymmetry of response, and the comatose syndrome [13, 14].

Upto this point, the Prechtl examination was the most detailed and comprehensive examination: it gave reliable information about the newborn infant neurological status and was able to differentiate central from peripheral involvement. The shortcomings of the Prechtl examination are the long time to perform the examination (about 30 minutes) and its complexity: a fairly large number of items are explored and each has to be observed in its optimal state. Furthermore it is restricted to the full-term infant in good physical health, because the degree of handling required may be unsuitable for the ill and fragile baby [8].

Prechtl also developed a shorter version of the protocol, suitable for neurological screening. It includes evaluation of head, trunk and limb posture, eye coordination, normal and abnormal limb movements, head, trunk and limb resistance to passive movement, traction test and the Moro response. The neurological screening examination cannot replace a full neurological examination: it gives more false positive results and, if abnormalities are suspected, a full examination is required. The short version of Prechtl examination is illustrated in Fig 130.1.

Brazelton [3] developed the Neonatal Behavioural Assessment Scale (NBAS), a structured scheme for term infants which combined 27 items of behavior and 20 reflex items derived from the neurological examination by Prechtl. The behavioral and neurological items can be grouped into seven major clusters of items (Fig. 130.2). The NBAS was designed to score the babies' behavioral repertoire and to document the organized responses to various environmental events. It was not originally conceived as a neurological examination but as a tool to evaluate the behavioral characteristics of the single baby. The intention was to predict temperament and emotional control, allowing the parents to perceive the baby as a person from the very first. The author suggested performing the test in front of the mother who would then recognize how bright and talented her baby was. In this context the Brazelton scale aims to reinforce early

mother infant interaction. It has also the power to evaluate cultural and ethnic differences in neonatal behavior in different settings. Despite this premise, the examination has often been used as a neurological evaluation. The Brazelton test had a great impact on pediatricians: its major contribution was towards abandoning the idea of the newborn infant as incompetent, immature and disorganized. Attention was drawn to the amazing capacities of the newborn infant for attention, with very predictable behaviors and the capacity to respond and interact with the environment. Attention was drawn to the baby's sensory capacities and visual and auditory responses: visual orientation to an inanimate stimulus (a red ball) and to the human face, auditory orientation to the sound of a rattle, bell and the human voice were introduced as integral part of the assessment. Some of these items were later adopted in other neurological schemes [3].

Based on the NBAS of Brazelton's assessment of term infant, Als et al [15] developed the Assessment of Preterm Infant Behaviour (APIB). This is a strategy to document systematically behavioral ingredients of the premature infant, from the stage when the baby can first be handled in room temperature and room air, without technological aids, to the stage when

Posture and tone

						STATE	ASYMM
POSTURE Infant supine. Look mainly at position of legs but also note arms. *Score predominant posture.*	arms & legs extended or very slightly flexed 	Legs slightly flexed 	legs well flexed but not adducted 	legs well flexed & adducted near abdomen 	abnormal posture: a) opisthotonus b) marked leg extension, strong arm flexion 		
ARM RECOIL Take both hands, quickly extend arms parallel to the body, Count to three. Release. Repeat 3 times.	arms do not flex 	arms flex slowly, not always; not completely 	arms flex slowly; more completely 	arms flex quickly and completely 	arms difficult to extend; snap back forcefully		
ARM TRACTION Hold wrist and pull arm upwards. Note flexion at elbow and resistance while shoulder lifts off table. *Test each side separately.*	arms remain straight; no resistance felt  R L	arms flex slightly or some resistance felt  R L	arms flex well till shoulder lifts, then straighten  R L	arms flex at approx 100° & maintained as shoulder lifts  R L	flexion of arms <100°; maintained when body lifts up  R L		
LEG RECOIL Take *both* ankles in one hand, flex hips + knees. Quickly extend. Release. Repeat 3 times.	No flexion 	incomplete or variable flexion 	complete but slow flexion 	complete fast flexion 	legs difficult to extend; snap back forcefully		
LEG TRACTION Grasp ankle and slowly pull leg upwards. Note flexion at knees and resistance as buttocks lift. *Test each side separately.*	legs straight - no resistance felt  R L	legs flex slightly or some resistance felt  R L	legs flex well till bottom lifts up  R L	knee flexes remains flexed when bottom up  R L	flexion stays when back+bottom up  R L		
POPLITEAL ANGLE Fix knee on abdomen, extend leg by gentle pressure with index finger behind the ankle. Note angle at knee. *Test each side separately.*	 180° R L	 ≈150° R L	 ≈110° R L	 ≈90° R L	 <90° R L		
HEAD CONTROL (1) ***(extensor tone)*** Infant sitting upright. Encircle chest with both hands holding shoulders. Let head drop forward.	no attempt to raise head 	infant tries: effort better felt than seen 	raises head but drops forward or back 	raises head: remains vertical; it may wobble 			
HEAD CONTROL (2) ***(flexor tone)*** Infant sitting upright. Encircle chest with both hands holding shoulders. Let head drop backward.	no attempt to raise head 	infant tries: effort better felt than seen 	raises head but drops forward or back 	raises head: remains vertical; it may wobble 	head upright or extended; cannot be passively flexed		
HEAD LAG Pull infant towards sitting posture by traction on both wrists & support head slightly. Also note arm flexion.	head drops & stays back 	tries to lift head but it drops back 	able to lift head slightly 	lifts head in line with body 	head in front of body		
VENTRAL SUSPENSION Hold infant in ventral suspension. Observe back, flexion of limbs, and relation of head to trunk. If it looks different, DRAW.	back curved, head & limbs hang straight	back curved, head ↓, limbs slightly flexed	back slightly curved, limbs flexed	back straight, head in line, limbs flexed	back straight, head above body

Tone patterns

FLEXOR TONE (1) **(on traction: arm versus leg)** Compare scores of arm traction with leg traction.		score for arm flexion less than leg flexion	score for arm flexion equal to leg flexion	score for arm flexion more than leg flexion but difference 1 column or less	score for arm flexion more than leg flexion but difference more than 1 column		
FLEXOR TONE (2) **(arm versus leg)** Posture in supine.			arms and legs flexed	strong arm flexion with strong leg extension *intermittent*	strong arm flexion with strong leg extension *continuous*		
LEG EXTENSOR TONE Compare scores of leg traction and popliteal angle.		score for leg traction more than score for popliteal angle	score for leg traction equal to score for popliteal angle	score for leg traction less than score for popliteal angle, by 1 column only	score for leg traction less than score for popliteal angle, by more than 1 column		
NECK EXTENSOR TONE (SITTING) Compare scores of head control 1 and 2.		score for head extension less than head flexion	score for head extension equal to head flexion	score for head extension more than head flexion. but difference 1 column or less	score for head extension more than head flexion but difference more than 1 column		
INCREASED EXTENSOR TONE (HORIZONTAL) Compare scores of head lag and ventral suspension.		score for ventral suspension less than head lag	score for ventral suspension equal to head lag	score for ventral suspension more than head lag but difference 1 column or less	score for ventral suspension more than head lag but difference more than 1 column		

Reflexes

TENDON REFLEX Test biceps, knee, and ankle jerks.	absent	felt, not seen	seen	"exaggerated" (very brisk)	clonus		
SUCK / GAG Little finger into mouth with pulp of finger upwards.	no gag / no suck	weak irregular suck only No stripping	weak regular suck Some stripping	strong suck: (a) irregular (b) regular Good stripping	no suck but strong clenching		
PALMAR GRASP Put index finger into the hand and gently press palmar surface. Do not touch dorsal surface. *Test each side separately.*	no response R L	short, weak flexion of fingers R L	strong flexion of fingers R L	strong finger flexion, shoulder ↑ R L	very strong grasp; infant can be lifted off couch R L		
PLANTAR GRASP Press thumb on the sole below the toes. *Test each side separately.*	no response R L	partial plantar flexion of toes R L	toes curve around the examiner's finger R L				
PLACING Lift infant in an upright position and stroke the dorsum of the foot against a protruding edge of a flat surface. *Test each side separately.*	no response R L	dorsiflexion of ankle only R L	full placing response with flexion of hip and knee & placing sole on surface R L				
MORO REFLEX One hand supports infant's head in midline, the other the back. Raise infant to 45° and when infant is relaxed let head fall through 10°. Note if jerky. Repeat 3 times.	no response, or opening of hands only	full abduction at shoulder and extension of the arms; no adduction	full abduction, but only delayed or partial adduction	partial abduction at shoulder, and extension of arms followed by smooth adduction	• minimal abduction or adduction • no abduction or adduction; only forward extension of arms • marked adduction only or		

Fig. 130.3 (*cont.*)

the infant's attention span is relatively independent from other subsystems and the baby can use it to regulate and control investigation of the environment, i.e., by approximately one month post-term for a healthy, full-term infant [6, 16]. The assessment is used as a starting point to plan individualized and family focused intervention strategies. The Neonatal Individualized Developmental Care Assessment Program (NIDCAP) is at present the most comprehensive and advanced method to promote individualized developmental supportive and family-centered care in neonatal intensive care units [15, 16].

Movements

SPONTANEOUS MOVEMENT (quantity) Watch infant lying supine.	no movement	sporadic and short isolated movements	frequent isolated movements	frequent generalized movements	continuous exaggerated movements		
SPONTANEOUS MOVEMENT (quality) Watch infant lying supine.	only stretches	stretches and random abrupt movements; some smooth movements	fluent movements but monotonous	fluent alternating movements of arms + legs; good variability	• cramped, synchronized; • mouthing • jerky or other abnormal movements		
HEAD RAISING PRONE Infant in prone, head in midline.	no response	infant rolls head over, chin not raised	infant raises chin, rolls head over	infant brings head and chin up	infant brings head up and keeps it up		

Abnormal signs/patterns

ABNORMAL HAND OR TOE POSTURES		hands open, toes straight most of the time	intermittent fisting or thumb adduction	continuous fisting or thumb adduction; index finger flexion, thumb opposition	continuous big toe extension or flexion of all toes		
TREMOR		no tremor, or tremor only when crying or only after Moro reflex	tremor occasionally when awake	frequent tremors when awake	continuous tremors		
STARTLE	no startle even to sudden noise	no spontaneous startle but reacts to sudden noise	2-3 spontaneous startles	more than 3 spontaneous startles	continuous startles		

Orientation and behaviour

EYE APPEARANCES	does not open eyes		full conjugated eye movements	*transient* • nystagmus • strabismus • roving eye movements • sunset sign	*persistent* • nystagmus • strabismus • roving eye movements abnormal pupils		
AUDITORY ORIENTATION Infant awake. Wrap infant. Hold rattle 10 to 15 cm from ear.	no reaction	auditory startle; brightens and stills; no true orientation	shifting of eyes, head might turn towards source	prolonged head turn to stimulus; search with eyes; smooth	turns head (jerkily, abruptly) & eyes towards noise every time		
VISUAL ORIENTATION Wrap infant, wake up with rattle if needed or rock gently. Note if baby can see and follow red ball (B) or target (T).	does not follow or focus on stimuli B T	stills, focuses, follows briefly to the side but loses stimuli B T	follows horizontally and vertically; no head turn B T	follows horizontally and vertically; turns head B T	follows in a circle B T		
ALERTNESS *Tested as response to visual stimuli* (B or T).	will not respond to stimuli	when awake, looks only briefly	when awake, looks at stimuli but loses them	keeps interest in stimuli	does not tire (hyper-reactive)		
IRRITABILITY In response to stimuli.	quiet all the time, not irritable to any stimuli	awakes, cries sometimes when handled	cries often when handled	cries always when handled	cries even when not handled		
CONSOLABILITY Ease to quiet infant.	not crying; consoling not needed	cries briefly; consoling not needed	cries; becomes quiet when talked to	cries; needs picking up to be consoled	cries; cannot be consoled		
CRY	no cry at all	whimpering cry only	cries to stimuli but normal pitch		High-pitched cry; often continuous

Fig. 130.3 (*cont.*)

Dubowitz and Dubowitz [17], and Dubowitz et al [4, 18] developed an examination that included the assessment of neurological and behavioral items, taking into account behavioral states [4, 17, 18]. The authors stated that "ideally, a meaningful neurological assessment should be part of the routine clinical examination of every newborn infant". One of the strengths of this examination is that it is suitable for preterm infants as well for full-term infants, and for both ill and healthy infants. It is a simple, objective recording system, based on drawings and diagrams, recorded on a pro-forma that includes definitions. The diagrams are easy to tick and are suitable for staff with no particular expertise or experience in neonatal neurology. The examination does not take more than 15 minutes to perform and can be used as part of the routine clinical assessment of newborn infant. It is also suitable for repeated examinations. It is therefore possible to document the normal or abnormal evolution of neurological behavior in the preterm infant after birth, to compare this behavior with that expected in newborn infants of corresponding postmenstrual age and to detect features of a neonatal encephalopathy. The examination includes assessment of behavioral states, tone, and primitive reflexes and also motility and some aspects of behavior. One advantage of this method has been the development of an optimality score that allow quantification of the deviant scores and use in different settings. Another advantage is that authors have updated the examination and have provided some general guidelines on the most common findings at each gestational age (Fig. 130.3). The examination has been validated in full-term and preterm infants [4, 18].

130.3 Spontaneous Movement Patterns and General Movement

The general movements (GMs) method was the last scheme of assessment of the nervous system to be standardized and validated. It was conceived by Prechtl and co-workers during the late eighties [11, 19–21]. It is based on the observation of spontaneous movements of the fetus and of the newborn infant, either preterm or full-term. Since the seventies, Prechtl and co-worker had focused their attention on the spontaneous movements of the fetus observed using ultrasound scans: they recognized that spontaneous movements could be distinguished as movements clearly constant in form and therefore easily recognisable. Prechtl defined these sequences as "movement patterns". With the aid of ultrasound he was able to recognize several fetal movements patterns such as startles, GMs, isolated limb movements, twitches, stretches, breathing movements, hiccups, yawns, head rotations, head flexion, sucking, swallowing and others [20]. They emerge as early as 9–12 weeks postmenstrual age (Table 130.1). It is striking that they look complex and differentiated from their first appearance. They hardly show any change in form in the first weeks after birth, despite the profound changes in the environmental conditions; thus, an intrauterine or extrauterine environment seems to influence them very little. Two of these movement patterns (stretches and yawns) are maintained throughout life without changing form. Surprisingly, local and isolated movements of the limbs appear 1–2 weeks sooner than GMs. They continue to be present during the whole preterm period and are seen until the age of 5–6 months post-term. The immature nervous system of the fetus generates these movement patterns without being stimulated: they are generated endogenously, and reflect spontaneous activity of the brain.

The chance to observe, record and eventually measure endogenously generated brain activity is one of the dreams of neurobiologists. Prechtl's idea was that spontaneous movements were markers of brain impairment and dysfunction [14].

It is likely that GMs are produced by complex nervous networks, the so-called central pattern generators (CPG) that are located in different parts of the brain and at different brain levels, especially in the higher parts of medulla and the brain stem. Breathing, sucking, chewing, eye movements, swimming, crawling and walking are other spontaneous motor activities that appear to be endogenously generated, i.e., generated

		Sucking and swallowing	Sucking and swallowing
			Eye movements

without any recognizable external stimulus. The combination of these motor activities varies depending on the ongoing behavioral state. During state 2 (irregular breathing), slow and rapid eyes movements and body movements are fired by CPG (termed "active" or "agitated" sleep). During state 1 (quiet sleep), there is regular breathing with no eye and no body movements, reflecting the different neural mechanisms that actively inhibit (or modulate in the case of respiration) these motor activities from higher cortical and sub-cortical structures. GMs as well as the other movement patters are typical of states 2, 4 and 5. Startling which appears in state 1, is an exception [19, 21].

130.4 What Are General Movements?

General movements (GMs) consist of movements that involve the whole body in a variable sequence of arm, leg, neck and trunk movements. They wax and wane in intensity, force and speed, with a gradual beginning and end. Rotation along the axis of the limbs and continuous changes in the direction of movement make them fluent and elegant and create an impression of complexity and variability. Minor changes can be seen during early develppoment: preterm, GMs are of large amplitude and often accompanied by lifting of the pelvis; at term, GMs are smaller in amplitude and show a writhing character that gradually disappears; at 6–9 weeks post-term, fidgety GMs start to appear [11, 22].

GMs are the most frequent of the various movement patterns exhibited by newborn babies, and also the most complex. It is likely that their complexity makes them vulnerable to brain dysfunction, and therefore a sensitive indicator of brain injury.

Brain lesions affect the quality rather than the quantity of GMs. The only exception to this rule is that severe perinatal asphyxia is accompanied by a transient phase of hypokinesia. Other brain lesions are associated with preterm and writhing GMs changing in character with loss of fluency, variability and complexity, with a poor repertoire and becoming cramped-synchronized or chaotic. Abnormal fidgety GMs may be either exaggerated or absent [22, 23].

Poor repertoire GMs are the most common abnormality and variability in sequence is lost or poor. When abnormal GMs are followed by normal fidgety movements, recovery from brain lesions and a normal outcome are expected. However, absence of fidgety movements is likely to herald cerebral palsy [24]. Cramped synchronized GMs also represent a severe GM abnormality and are recognized when all limbs and trunks muscle contract and relax almost simultaneously (Fig. 130.4) [23]. If this abnormal character of GMs persists for weeks and is accompanied and/or followed by no fidgety movements, the development of a spastic form of cerebral palsy is predictable (Fig. 130.5) [22–24].

130.5 The Neurological Examination in the Sick Newborn Infant

Sick infants should be have a daily neurological examination. Tthis should be with minimal handling if there is cadiorespiratory instability. The neurological examination is hampered by long lines, monitoring and sedation, in which

Fig. 130.6 Neurological assessment of the sick newborn infant

case the examination may be curtailed to a few items that can be assessed reasonably quickly. The baby's level of consciousness should be assessed. The general use of cerebral ultrasound and MRI scans enable documentation of the presence, evolution and severity of brain lesions.

New neuroprotective strategies such as brain cooling require the recognition of a severe neonatal encephalopathy (NE) soon after birth. A neurological scheme for assessing the severity and evolution of acute brain dysfunction is described in Fig. 130.6. It is based on nine items, mostly requiring observation of spontaneous movements. It includes assessing the level of consciousness (motor response to pinch of the skin of the leg, pupillary size and reaction to light), respiration, posture, spontaneous general movements and eye movements, brainstem reflexes (corneal and oculocephalic), resistance of the trunk, neck and limbs to passive movement, and abnormal movements (seizures and or limb automatisms, such brain stem release phenomena, BSRP).

130.6 Hyypoxic Ischemic Events and NE in the Full-Term Infant

NE is a clinical syndrome of disturbed neurological function. It is manifested by difficulty in the initiation and maintenance of respiration, depression of tone and reflexes, abnormal level of consciousness, and often seizures [25]. NE may be caused by perinatal asphyxia, as well as other conditions such as stroke, infection, mitochondrial disease, brain malformation, and metabolic disorders.

Volpe has provided an accurate description of the development of NE due to perinatal asphyxia (HIE) in full-term infants [1]. From birth to 12 hours, severely affected infants are stuporose or comatose (i.e., not arousable and with minimal or no response to sensation), have periodic breathing or respiratory irregularity, intact pupillary responses and spontaneous eye movements. Infants are hypotonic, and have minimal spontaneous or elicited movements and hypokinesia is common. Very few babies show signs of brain stem injury, such as pupils that are fixed and in the midposition and dilated, and eye movements, which are fixed when the doll's eye maneuver is performed.

50–60% of NE infants who ultimately convulse have seizures, which are mostly subtle, by 6–12 hours after birth. By 12–24 hours, the infant's level of consciousness may appear to improve and there are severe seizures with overt status epilepticus, apneic spells, jitteriness and weakness in a hip-shoulder distribution. Babies with basal ganglia (BG) injury may have spontaneous or evoked hypertonus. Between 24 and 72 hours, the baby with NE may be in deep stupor or coma, with irregular ataxic respirations (and even respiratory arrest), brain stem oculomotor and papillary disturbances disturbances (i.e., constricted hyporeactive pupils, fixed to light dilated pupils) [1].

Sarnat and Sarnat in 1976 [5] developed a clinical grading system for the severity and the progression of the neurological signs in HIE. Stage 1 lasted less than 24 hours, characterized by hyperalertness, uninhibited Moro and stretch reflexes, sympathetic effects, and a normal electroencephalogram. Stage 2 is chacterised by obtundation, hypotonia, strong distal flexion, and multifocal seizures. The electroencephalogram (EEG) shows a periodic pattern, sometimes preceded by continuous delta activity. Infants in stage 3 are stuporous, flaccid, with suppressed brain stem and autonomic functions. The EEG is isoelectric or with infrequent periodic discharges. Amiel-Tison [26], Finer [27], Fenichel [28], Levene [25] and others developed alternative scoring systems along similar lines. All accepted the Sarnat three grade system, from 1 (mild) to 3 (severe). In spite of some differences, they agree on the prognostic value of HIE: grade 1 correlates with a good outcome, grade 3 with poor outcome, and grade 2 with neurological sequelae affecting 25–40% of cases.

Recent MRI studies have demonstrated that in acute severe global hypoxic ischemia, the basal ganglia (BG) and thalami (T) are mainly affected. Lesions in these areas are often associated with abnormal signal intensity in the posterior limb of the internal capsule (PLIC). Concomitant injury to the cortex (C) of the central sulcus and the adjacent sub-cortical white matter (WM) is common. In severe cases, the brainstem may also be involved. When the predominant lesion involves WM and cortex but spares the BGT and PLIC, the likely cause is prolonged partial hypoxia-ischemia [1, 19, 23]. The clinical correlates of these lesions during the first hours of life are not known. Future studies based on early diffusion weighted imaging and early serial neurological examinations may provide an answer. Some signs are markers of specific brain structure involvement. Seizures with clonic focal or multifocal jerks are likely to rise from damage to the cortex and white matter. Akinesia (no eye movement), divergent eye position, unresponsive pupils, monotonous respiration and brainstem release phenomena, are markers of brain stem involv- ement and/or BGT and PLIC lesions. Coma or severe stupor, accompanied by tonic seizures, BSRP and lack of body and eye movements indicate a more severe and diffuse brain involvement as in the most serious MRI pattern seen after perinatal asphyxia with lesions in the BGT, PLIC, WM and C [1, 23].

130.7 Other Brain Injuries

130.7.1 Periventricular Leukomalacia (PVL)

The initial neurological correlates of PVL are not establish: cystic or noncystic PVL takes 2–4 weeks to become manifest after US has demonstrated increased periventricular echogenicity, which is clinically silent. Other hemorrhagic, metabolic or infective disorders may be associated. Several clinical signs have been described: in preterm infants, who

later develop cerebral palsy, signs such as irritability, abnormal posture of fingers, spontaneous Babinski reflex, popliteal angle reduction, increased extensor tone, inferior limbs weakness and marked hypotonia have been observed. Long-term correlates of PVL include spastic diplegia and intellectual deficits [1, 18].

130.7.2 Intraventricular Hemorrhage (IVH) in Preterm Infants

Three clinical syndromes are associated with IVH:

- Catastrophic clinical deterioration, which is a dramatic presentation usually in the most severe degrees of IVH. It is characterized by deep stupor and coma, respiratory abnormalities (hypoventilation and apneas), seizures, decerebrate posturing, pupils fixed to light, and eyes fixed to vestibular stimulation, and by a flaccid quadriparesis
- Saltatory syndrome, which is most subtle in presentation and evolves over many hours. Signs are: altered consciousness, decreased quantity and quality of spontaneous movement, altered of ocular position and motility.
- A clinically silent syndrome, when neurological signs are so subtle that they are not seen [1, 15].

130.7.3 Bilirubin Encephalopathy

The clinical features in infants with bilirubin injury depend on the damage topography and on the infant age. Acute bilirubin encephalopathy is characterised by three phases:

- In the first phase, stupor and hypotonia are prominent, often accompanied by poor sucking. Seizures occur in a minority of cases.
- In the second phase, the principal signs are hypertonia, particularly in the extensor muscles with backward arching of the neck (retrocollis) or of the back (opisthotonus). The increase in tone is probably of extrapyramidal origin and newborns, who show these signs, later develop features of chronic bilirubin encephalopathy.
- In the third phase, hypertonia evolves into hypotonia, usually after the first week of life [1].

130.7.4 Metabolic Disease

Metabolic disorders during the neonatal period are generally associated with: altered level of consciousness, seizures, hypotonia or hypertonia, impaired feeding, and delayed neurological development. Stupor, coma and seizures, urine with the odour of maple syrup occurs in maple syrup disease. Seizures, stupor or coma associated with myoclonus and hiccups are typical of nonketotic hyperglycinemia. Hyperammonemic states are accompanied by vomiting, poor feeding, stupor, coma. There are dysmorphic facial features in some metabolic diseases such as the mitocondriopathies, which may manifest in the neonatal period with seizures, hypotonia, stupor, coma and tachypnea due to a metabolic acidosis [1].

130.7.5 Jitteriness

Jitteriness is a disorder of movement frequently observed during the neonatal period. Movements are generalized and symmetrical, have the quality of a coarse tremor, are stimulus sensitive and can be diminished by gentle flexion of the limbs. It is frequently accompanied by brisk tendon reflex and an easily elicited Moro reflex (hyperexitability syndrome). Jitteriness is often related to neurologic al hyperirritability, as in f HIE, hypoglycemia, hypocalcemia, drug withdrawal syndrome,. In some cases, no cause can be found [1, 13].

130.7.6 Stiff Baby Syndrome

Stiff baby syndrome or hyperexplexia is a familiar disorder (autosomic dominant). It is characterised by marked hypertonia, which is accentuated by minor sensory stimulation. An episode of hypertonia may involve respiratory muscles, causing apnea. Hypertonia is accompanied by an exaggerated startle response, which may mimic seizures [1].

130.7.7 Neuromuscolar Disorders or Spinal Cord Disease: the Floppy Infant

The term floppy baby or infant is used to denote an infant with poor muscle tone affecting the limbs, trunk and the cranio-facial musculature. Hypotonia may be caused by congenital or acquired disorders, as a consequence of central or peripheral nervous system involvement. Lower motor neuron lesions result in a loss of muscle tone and flaccidity. Lesions affecting the upper motor neurons result in reduced supraspinal inhibitory influences, leading during early infancy to flaccidity and ldiminished muscle tone with preserved or hyperactive reflexes, and later evolving into spasticity. Thus hypotonia with no obvious weakness and normal or increased reflexes suggests CNS involvement. In neuromuscolar disorders, hypotonia is usually associated with weakness and/or contractures. Contractures, skin dimpling and poor dermatoglyphic patterns are indicators of poor fetal movements and are highly suggestive of a neuromuscular disorder. In myasthenia gravis and infantile botulism, diffuse hypotonia and weakness are present, often in conjunction with CNS involvement. In congenital myopathies, proximal extremity weakness is prominent and there are limb deformities if the onset was *in utero*.

Spinal cord trauma with a tear in the cervical dura can be caused by a difficult breech delivery. This results in symmetric lower extremity paralysis with sparing of the face and cranial nerves and involvement of the sphincters. The most common injury involving the peripheral nerves is the proximal cervical roots of C5, C6, and C7, usually caused by a traumatic delivery with shoulder dystocia. In Erb's palsy, there is paralysis of shoulder abduction, elbow flexion, and finger extension, so that the arm is held extended, externally rotated with flexion at the wrist. There is no biceps reflex,although the triceps reflex may be present [1].

130.8 Conclusions

Advances in neuroimaging and other diagnostic techniques do not reduce the importance of performing a neurological examination, which may highlight the presence of neurological abnormalities and help to select those infants who need investigation, neuroprotection and follow-up.

A full neurological examination will show if the development of the baby is appropriate for postmenstrual age.

Sick newborn infants require a simple non-invasive test to evaluate the state of consciousness, and the severity of the brain damage. If there is coma or stupor, brainstem involvement should be considered and the neurological test should be repeated every few hours.

Seizures are the most important sign of an acute brain disorder. They may be difficult to recognize without concomitant EEG recording. Only clonic jerks are easily recognizable, indicating acute cortical involvement. Spontaneous movements and GMs in particular are reliable and effective tools for the diagnosis of brain dysfunction and may predict the motor outcome.

Neonatal Electroencephalography

Lena K. Hellström-Westas

131.1 The Neonatal Electroencephalogram

The electroencephalogram (EEG) reflects brain function and is an important diagnostic tool for infants requiring neonatal intensive care, not least since neurological symptoms may be very vague, or entirely absent. The EEG can be used for early detection of general or focal cerebral abnormalities, and also to give important predictive information on later neurodevelopmental outcome.

The standard EEG is recorded from electrodes placed over the scalp according to the International 10–20 system which uses the nasion and the inion as anatomical landmarks on the skull to identify electrode positions. The inter-electrode distance is usually 10 or 20% of the total distance between these positions. The electrode positions are defined by capital letters followed by a number, e.g., F for frontal, C for central, T for temporal, O for occipital, with even numbers indicating the right side and odd numbers the left side. Additionally, respiration, electrocardiogram, eye movement and electromyogram are recorded, which together with the EEG give supplementary information such as sleep states, movements, seizures, and possible artefacts. EEG development occurs mainly in parallel in the fetus and in the preterm infant with comparable maturation. The terms postconceptional age (PCA), or postmenstrual age (PMA), represent a summary of gestational age and postnatal age and are used when assessing EEG maturation.

131.1.1 Normal EEG Maturation

The recorded EEG can be described according to amplitude, frequency, topographic distribution of activity and temporal (time) evolution. The normal EEG background in very preterm infants is mainly discontinuous, a pattern that is called *tracé discontinu* which is characterized by high-amplitude bursts of activity alternating with periods of low-voltage activity, interburst intervals (IBI). With increasing maturation the duration of the bursts increase while their amplitude decreases, and simultaneously the IBIs become shorter, resulting in an increasingly continuous EEG background. The mean IBI duration is around 18–26 seconds at 21–24 weeks PCA and decreases to 10–12 seconds at 25–30 weeks PCA, and down to 6–8 seconds at 34–36 weeks. The topographic organization of the developing EEG occurs in an occipital-frontal direction. Interhemispheric synchrony of electrocortical activity changes during maturation: at extremely low PCA the EEG activity is usually synchronous, between 26 and 30 weeks PCA there is increased desynchronization, which again is followed by increasing synchronization at PCAs above 30 weeks [1–3].

Sleep wake cycling can be identified in the EEG from around 30 weeks' PCA, but already from around 24–25 weeks PCA immature cycling can be seen although specific sleep states cannot be distinguished. Active sleep, or rapid eye movement (REM) sleep, can usually not be distinguished from wakefulness in the EEG without other measures, i.e., direct observation or evaluation of eye movements, respiration and muscular activity. Quiet sleep, or non-REM, sleep is characterized by increased discontinuity. The EEG during quiet sleep in term infants is either discontinuous (*tracé alternant*), or contains high voltage slow activity (HVS).

The distribution of the main EEG frequencies, i.e., delta (< 4 Hz), theta (4–8 Hz), alpha (8–12 Hz), beta (13–20 Hz), also change with maturation, although there is usually a mix of frequencies at all PCA. In preterm infants, high voltage delta activity, and to some extent, theta activity is predominant while theta and alpha activity can be identified in term infants [1–3]. Recently, the presence of very slow EEG activity (< 0.5 Hz) has been demonstrated both in term and preterm infants. Experimental data indicate that this activity may be essential for development of brain wiring processes [4]. High frequency oscillation ventilation (HFOV) in the

NICU is often performed with frequencies between 10 and 15 Hz, i.e., frequencies that are parts of the normal EEG, and care has to be taken to avoid such interference. When EEG-trend monitoring (see below) is performed during HFOV, it is important to avoid contact between the electrodes and the bedding, and to evaluate the raw-EEG signal.

During normal EEG maturation, several distinctive waveforms and patterns are expected to appear and disappear at certain PCA: these can be used for evaluation of maturation although their functional and anatomical correlates are not known. Delta brush pattern is characterized by runs of fast activity (alpha-beta) superimposed on delta waves; this pattern is typical of the very preterm EEG. Temporal theta bursts (temporal saw-tooth) are brief, rhythmic, 4–6 Hz transients that first appear around 26 weeks PCA and reach a maximum at 30–32 weeks before they disappear. Temporal sharp waves may appear during the first weeks of life in infants born at 31–32 weeks gestation. However, if abundant, or persisting, they are associated with brain injury. Frontal sharp wave transients appear from 34–35 weeks PCA and disappear around 10 weeks later [1–3].

The accuracy of estimation of PCA from various EEG measures is usually 2 weeks. An interesting observation in a few publications is that the EEG activity in very preterm infants seems to exhibit a progressive increase during the first days of life: whether this is due to postnatal adaptation or recovery is not known [5].

131.1.2 Abnormal EEG

Severe hypoxic-ischemic or metabolic insults such as perinatal asphyxia, hypoglycemia or severe hypotension are associated with transient EEG depression. The electrocortical activity usually recovers after an insult during a time-period that may last from minutes to weeks. Seizures of varying intensity often develop during the recovery phase [6]. Sleep-wake cycling is usually depressed or entirely absent during the acute stage. Chronic EEG changes may persist as markers of permanent damage. The consistent way by which the electrocortical activity behaves after an insult, and the relation between the severity of the EEG activity and the brain damage, makes EEG sensitive for diagnosis of brain damage and early prediction of outcome.

Acute changes during and after an insult are characterized by slowing of the EEG, amplitude depression and increasing discontinuity of varying degree and duration, which correlates with the severity of the insult. A severe insult may result in an entirely flat (inactive, isoelectric) EEG, while mild insults may only results in subtle slowing of the EEG or increased discontinuity. Burst-suppression (BS) and undifferentiated extremely low voltage patterns may also be present after severe insults. These EEG patterns are both associated with increased risk for adverse outcome in asphyxiated term infants.

In the very preterm infant, the IBIs may become prolonged, and the background may also change to a BS pattern. Burst-suppression is characterized by bursts of activity with flat (inactive) or very low amplitude interburst intervals, as compared to the normal discontinuous background of the preterm infant in which the IBIs contain more activity. The BS pattern is abnormal at all maturational stages; it is associated with presence of brain damage, administration of sedative medications, and some rare encephalopathies (mainly non-ketotic hyperglycinemia and Ohtahara syndrome). In term infants, a recording with predominant IBI duration of more than 30 seconds, is highly predictive of death or poor neurological outcome [7].

Chronic stage EEG changes appear within a few weeks after an insult and are markers of persisting brain injury. Chronic stage background abnormalities can be categorized as being either dysmature or disorganized. Dysmature EEG patterns are characterized by delayed development (> 2 weeks) and are associated with cognitive impairment. Disorganized EEG patterns develop after severe acute insults, and are characterized by deformity of delta waves and brushes, as well as presence of abnormal sharp waves; they are closely associated with white matter damage and development of cerebral palsy [8]. Some waveforms, especially positive rolandic sharp waves (PSRW) are markers of white matter damage. PRSW are predictive of later cerebral palsy when appearing with a frequency of more than two per minute in the neonatal EEG [9].

131.1.3 Effects of Medications

Administration of several antiepileptic or sedative medications, including benzodiazepines (diazepam, midazolam), phenobarbital, opioids (morphine, fentanyl), and lidocaine is associated with transient depression of the EEG background for minutes to hours. Surfactant treatment has also been associated with a 10 minute profound aEEG depression immediately after administration in some infants, the reason for which is not known. The most common response to a loading dose of sedative or anticonvulsant medication in a term infant with normal continuous EEG background is a change to a moderately discontinuous EEG pattern.

Preterm infants and infants with severely compromised brain function tend to respond with more profound discontinuity, including burst-suppression. The EEG background activity will usually recover within 2–2.5 hours after a single dose of sedative medications in term infants [10, 11]. Repeated doses and continuous infusion of such medications may, of course, be associated with prolonged and more marked discontinuity.

131.1.4 Seizures

The electrographic appearance of neonatal seizures can be very variable as regards waveform morphology, frequency, localization and temporal evolution. A seizure pattern in the EEG is often defined as "a sudden, repetitive, evolving and stereotyped ictal pattern with a clear beginning middle and ending and a minimum duration of 10 seconds" [12].

Status epilepticus is usually defined as repetitive seizures with a duration of more than 30 minutes. Term infants tend to have a focal onset of seizures, while seizures in a preterm more often are regional [13]. Clinical seizure identification can be difficult, since ill newborn infants may have seizure-suspected movements without corresponding EEG seizure activity, but also because a majority of neonatal seizures are entirely subclinical.

In babies with electroclinical seizures, administration of antiepileptic drugs is associated with a phenomenon called electroclinical dissociation, i.e., the electroclinical seizures disappear while subclinical seizures persist.

131.2 EEG-monitoring

Video-EEG monitoring is the gold standard of EEG-monitoring. However, it is not available in all neonatal care units (NICUs), and it is often too complicated for the neonatal staff to interpret bedside on a 24 hour/7 day basis unless continuous service is provided from an EEG department. This has, so far, limited the use of video-EEG to complicated cases and research studies. In contrast, continuous EEG-monitoring with limited channels, especially the amplitude integrated EEG (aEEG), is increasingly used in many NICUs since the method is easy to apply and to interpret by the neonatal staff. Furthermore, the usefulness of the aEEG has been demonstrated in several studies in both term and preterm infants requiring intensive care. The aEEG is derived from the raw EEG; first the EEG signal is passed through an asymmetric filter which strongly attenuates low (< 2Hz) and high (> 15 Hz) EEG frequencies, then the signal undergoes rectification, semi-logarithmic display (to give better resolution within very low voltage activity), and time-compression. The resulting aEEG trend gives a good overview of changes in minimum and maximum electrocortical activity over hours and days [14] (Fig. 131.1). Maturational aEEG changes parallels the EEG development, which is expected since it is derived from the EEG. A main developmental feature in the aEEG trend is the progressive rise of the lower border (during the more discontinuous quiet sleep) with increasing gestational age. The first aEEG monitor was created in the 1960s by Prior and Maynard, and was called the Cerebral Function Monitor (CFM).

Several studies have shown that aEEG recorded within the first 3–6 hours after birth asphyxia is highly predictive of neurodevelopmental outcome [15]. Abnormal background patterns (BS, extremely low voltage, flat) are predictive of adverse outcome, while normal continuous or slightly discontinuous patterns are associated with normal outcome. Sleep wake cycling appearing before 36 postnatal hours is associated with better outcome in infants with moderate hypoxic-ischemic encephalopathy (HIE). These studies were all performed in asphyxiated non-cooled infants who did not receive treatment with hypothermia. It was recently shown that intervention with moderate hypothermia is associated with altered predictive value of the aEEG and EEG [16, 17]. A normal very early aEEG or EEG is still associated with good outcome, while delayed recovery of the aEEG or EEG background until 36–48 hours, and later appearance of sleep wake cycling may be associated with healthy recovery. Recent data also indicate that seizures may still be abundant in cooled asphyxiated infants [18].

The aEEG in preterm infants is also predictive of outcome. Several aEEG and EEG studies have shown correlations between degree of early background depression and severity of intraventricular hemorrhages (IVH). It was also shown that seizures, mainly subclinical, are not uncommon in these infants. A few studies indicate that the averaged burst counts, or IBI, during the first days of life is predictive of outcome in preterm infants with IVH [19]. However, also other factors seem to affect the aEEG/EEG background in preterm infants, e.g., cardiac output and blood pressure, and arterial carbon dioxide levels. Presence of sleep-wake cycling during the first week of life is usually indicative of good recovery.

Continuous EEG-monitoring can be very useful for early detection of seizures in high-risk infants. However, a reduced number of EEG electrodes will record fewer seizures than a full EEG. Nevertheless, it has been demonstrated that a single-channel EEG from bilateral central leads, or a two-channel aEEG/EEG will record around 75–80% of all seizures that can be detected by a full EEG [12, 13]. A reason for this is that at least 60–70% of neonatal seizures will appear in the central, temporal and parietal areas [13].

Seizure identification in the aEEG trend requires the electrographic features of the seizure to be clearly distinguishable from the overall background activity since this will produce a transient change (often a rise, rarely a brief decrease) in the aEEG pattern. Repeated seizures and status epilepticus will result in a pattern similar to a saw-tooth, while ongoing epileptic seizure activity may be difficult to distinguish since there is no major change in the aEEG trend (Fig. 131.2). Brief seizures (< 30 seconds) may be very difficult to identify in the compressed aEEG trend, and for this reason it is also important to review the raw-EEG for seizure activity. Some of the newer aEEG/EEG monitors have seizure alerts which can be useful for identification of brief seizures, although no seizure alarms have a 100% sensitivity.

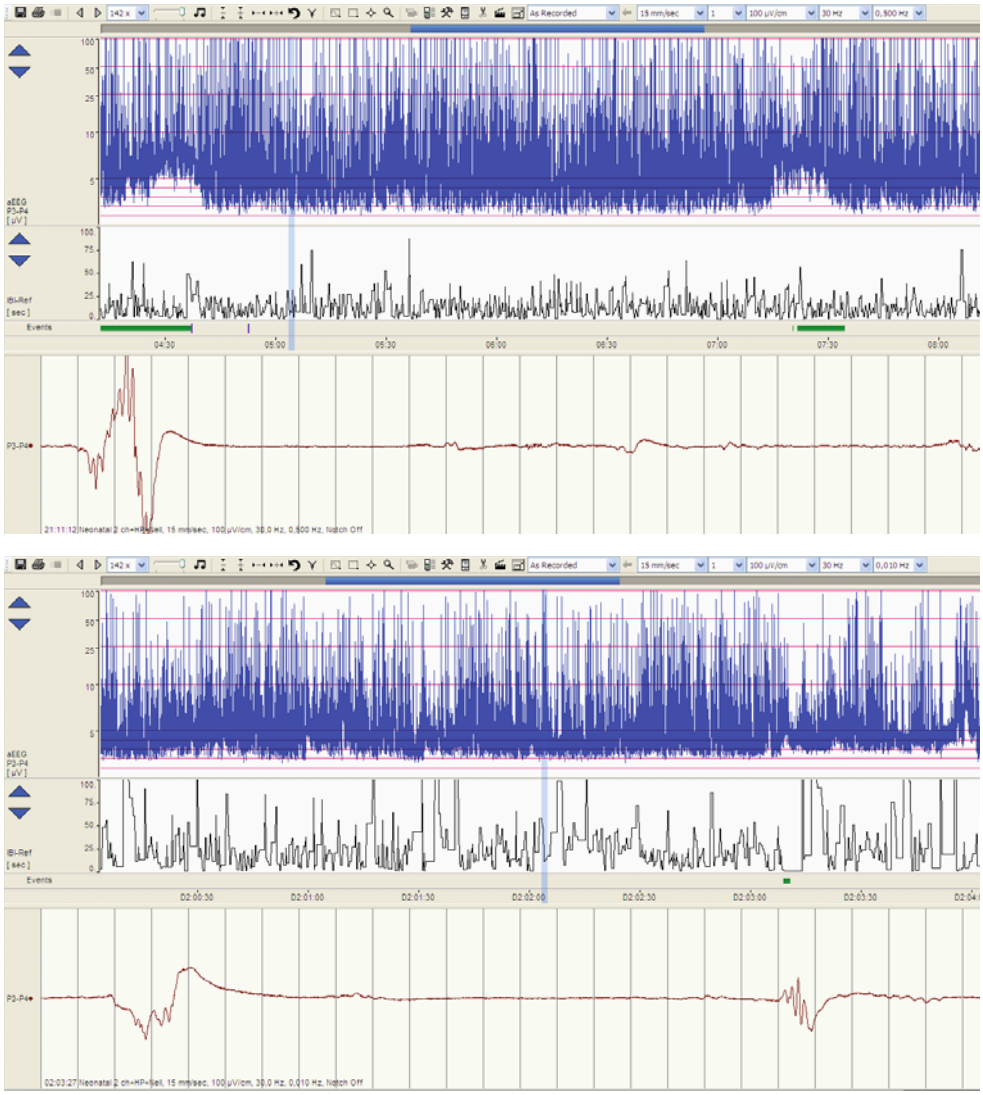

Fig. 131.1 Twins born at 24 gestational weeks, recorded during the first 2–3 days of life. Four hours of aEEG and IBI trends, below 25 seconds of corresponding EEG. The twin in the *upper panel* had a small unilateral IVH grade 1 and survived with normal outcome at 30 months (Bayley-II MDI and PDI scores >100). The twin in the *lower panel* developed bilateral IVH grade 3 and died during the first week of life. Note the differences in burst density, which are difficult to assess in the single channel EEG but visible in the aEEG trend, and better appreciated in the IBI trend. There are no seizures and no cyclicity present. The transient increases in the aEEG trend in twin a are due to care procedures

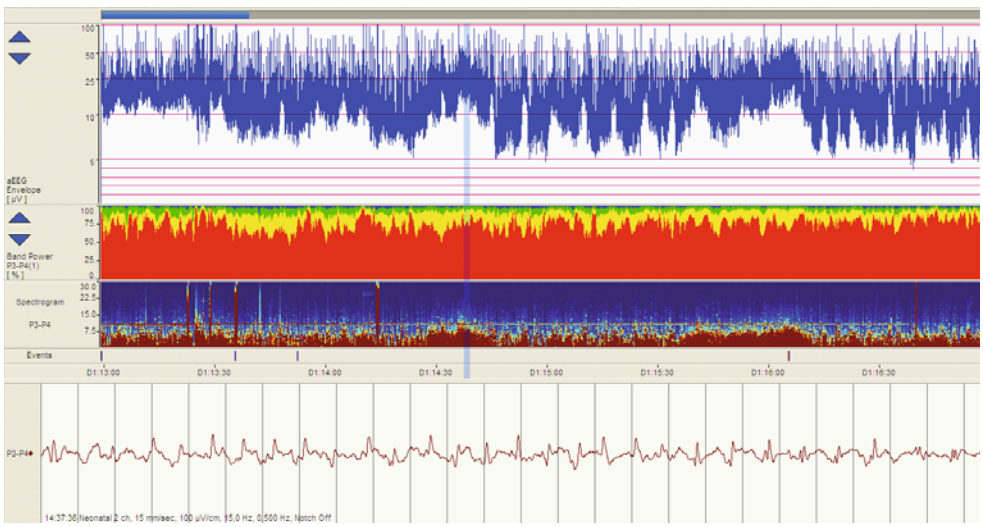

Fig. 131.2 Subclinical status epilepticus in a term infant with meconium aspiration syndrome. The repetitive seizures can be seen as a saw-tooth pattern in the aEEG trend (*top*) and in the band power and spectrogram trends below in this 4-hour recording. The unstable baseline in the aEEG is due to high frequency oscillation ventilation but the seizure activity can clearly be confirmed in the single channel EEG below (duration 25 seconds)

131.3 Conclusions

The EEG, and the aEEG, gives clinically important information on brain function. The EEG/aEEG can diagnose seizures and electrocortical background abnormalities, and the background activity shortly after an insult is highly predictive of neurological outcome. For continuous monitoring, video-EEG is the gold standard, but this method is not available for daily use in most neonatal intensive care units. Other EEG trends such as IBI or frequency-based trends may also prove to be of value in the future. When aEEG/EEG is recorded with a reduced number of electrodes, it is necessary to perform repeated EEGs and perform the monitoring in close collaboration with clinical neurophysiologists or neurologists.

Neuroimaging Studies

Luca A. Ramenghi and Petra S. Hüppi

132.1 Introduction

Many years have passed since the introduction of cranial transfontanellar ultrasound (CUS) to diagnose acquired brain lesions in neonates. CUS remains an important technique in the daily practice of neonatal units but major improvements have been obtained by combining different imaging modalities. Magnetic resonance imaging (MRI) is the modality that allows assessment of the developing brain in great detail because of its resolving power and non-invasiveness. MR techniques are unique in that they provide not only detailed structural but also metabolic and functional information without the use of ionizing radiation. Conventional MRI is therefore now widely used for identifying normal and pathologic brain morphology, and giving objective information about the structure of the neonatal brain during development and injury.

Technical advances in MR have revealed hitherto unknown aspects of brain development and have characterized patterns of injury to the developing brain. Fast diffusion-weighted imaging has provided understanding about brain white matter (WM) connectivity in health and disease. It also allows correlation of the structural development of the brain with the functional development of the child, even in the absence of overt brain lesions. This technique, together with new image postprocessing tools to assess quantitative brain volume and surface changes, have produced more accurate neuroimaging correlates for later neurocognitive disorders.

MR Spectroscopy has also provided new insights into metabolic processes in response to acute and chronic brain injury. Functional MR imaging, although still limited in the newborn, has the potential to throw light on the early functional organization of the brain and the origins of sensory, motor and cognitive functions in the newborn [1, 2].

132.2 Clinical Use of Neuroimaging Modalities in the Term Newborn

132.2.1 Ultrasound

Initial investigation with CUS in newborn babies born after the 37th week of gestation and presenting neurological symptoms is always justified. The likelihood of CUS showing a perinatally acquired brain lesion in term babies is not high, especially during the acute phase of the disease. CUS can diagnose directly specific pathology like an arterial stroke if the lesion is large, or it can help to identify a brain lesion caused by underlying disease, such as an intraventricular bleed or a posterior fossa hemorrhage caused by traumatic birth or by venous thrombosis. The value of CUS during the acute phase of an hypoxic ischemic encephalopathy is limited since it relies on the exclusion of other lesions which may mimick the clinical features of asphyxia (i.e., malformations, major subarachnoid or subdural hemorrhages, and, more rarely, stroke) (Figs. 132.1, 132.2). CUS is also useful for the identification of severe basal ganglia lesions that become visible only a few days after the asphyxic event.

132.2.2 The Role of MRI in the Symptomatic Term Newborn Baby

Seizure is a striking clinical feature of the neurologically abnormal neonate. It is useful to differentiate fitting babies born with normal Apgar scores from those who are born in a very depressed state because of perinatal asphyxia. The most common causes in the asphyxic group is focal brain injury due to arterial infarction, hemorrhage, and hypoxia-ischemia with typical lesion distribution described in detail below. Neonatal seizures may be caused by central nervous system infections, transient metabolic disturbances like hypoglycemia, congenital abnormalities of the brain including those due to chromosomal

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

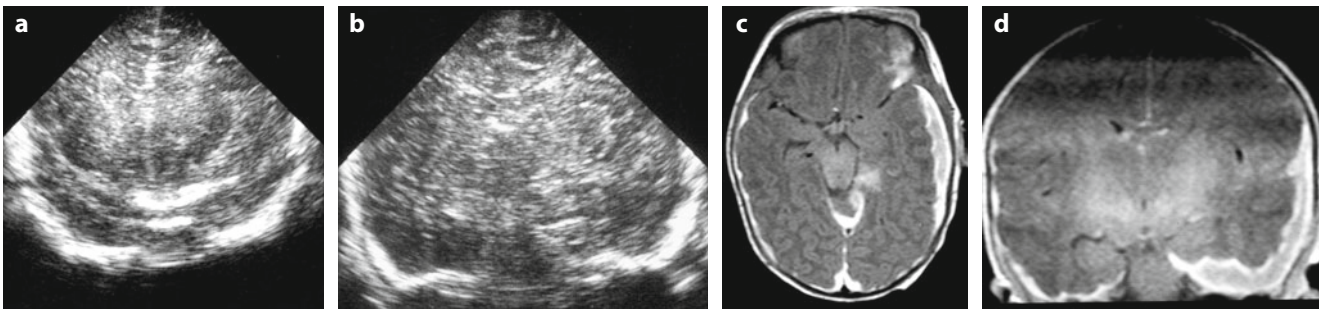

Fig. 132.1 A term baby born after ventouse application and mimicking perinatal asphyxia syndrome, with acidosis at birth and seizures at 6 h of life: CUS coronal scans (**a**, **b**), MR axial T1 (**c**) and coronal T1 (**d**) scans. Neuroimaging was performed at 24 h of life. US showed midline shift and left increased echogenicity, highly suspicious for arterial infarction. MR clearly showed a subarachnoid hemorrhage probably related to dystocia. At 5 years of age the baby was neurogically normal

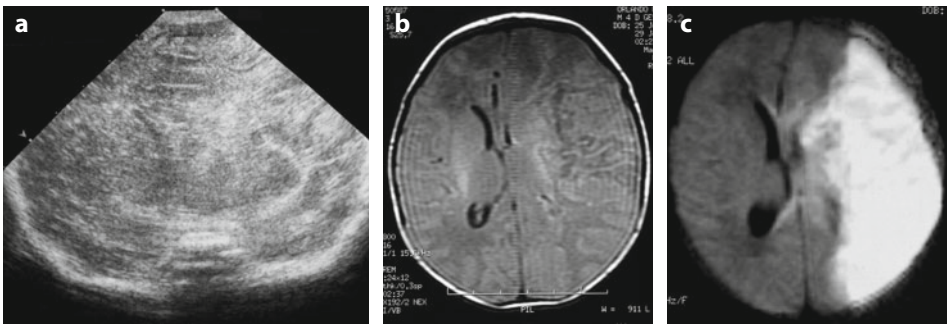

Fig. 132.2 A large perinatal arterial infarct of the left middle cerebral artery is shown on all the scans: **a** US with area of increased echogenicity, **b** conventional MR axial T1 scan with evident midline shift and **c** even better from the huge area of restriction (*white*) at DWI. The baby was macrosomic, born by vaginal delivery and depressed at birth needing resuscitation and mechanical ventilation for a few hours

anomalies, inborn errors of metabolism and benign neonatal convulsions, which may be familial or non-familial, and detailed neuroimaging is an important tool in the diagnostic work-up. Brain malformations range from highly localized focal dysplasia not diagnosable by CUS to catastrophic defects, which are partially diagnosable by CUS.

In all instances of seizures in term newborns, MRI is the ideal diagnostic neuroimaging tool. A clinical diagnosis has to rely on a careful medical history and on consideration of the most likely causes, for instance if seizures occur unexpectedly in a perfectly normal newborn, stroke and hemorrhage have to be the first disorders to be excluded [1, 3].

132.2.3 Neonatal Stroke

An acute neurological syndrome is not essential for the diagnosis of neonatal stroke [4]. The pathogenesis of neonatal stroke is discussed in detail in Chapter 139. Here emphasis is given to the neuroimaging required for the diagnosis of neonatal stroke (Fig. 132.2). As a bedside method, CUS is useful when it shows areas of asymmetrical echogenicity, usually during the first 12–36 hours following the onset of seizures. Nevertheless, MRI is the standard neuroimaging tool for the diagnosis of neonatal stroke. Conventional MRI shows loss of cortico-subcortical differentiation in both T1- and T2-weighted imaging. This is due to increased T2 signal intensity in the edematous cortex, which approaches the signal intensity of the unmyelinated white matter. This is also called the disappeared cortex sign (Fig. 132.3).

The best modality to identify a focal ischemic infarct is diffusion weighted imaging (DWI). DWI shows a striking reduction of water molecule movement (Fig. 132.2), corresponding to a decrease in the apparent diffusion coefficient (ADC) in the acute phase. There is normalization by 6–10 days followed by tissue dissolution, which results in a porencephalic cyst with T2 characteristics of cerebrospinal fluid (CSF). Areas of decreased values can be observed acutely, even a few hours after the beginning of a stroke, when conventional MR imaging remains normal until at least day 4 [5–9]. The cavitational phase of the infarction is recognizable using all techniques, and it occurs at a variable time after the initial insult. The pattern of signal intensity changes seems to be remarkably consistent among patients, suggesting that perinatal arterial ischemic stroke in symptomatic term infants occurs within a very limited timeframe around birth.

The majority of these focal lesions affect term babies and seem to be less common after birth by cesarean section performed in the absence of labor [10]. Premature infants seem

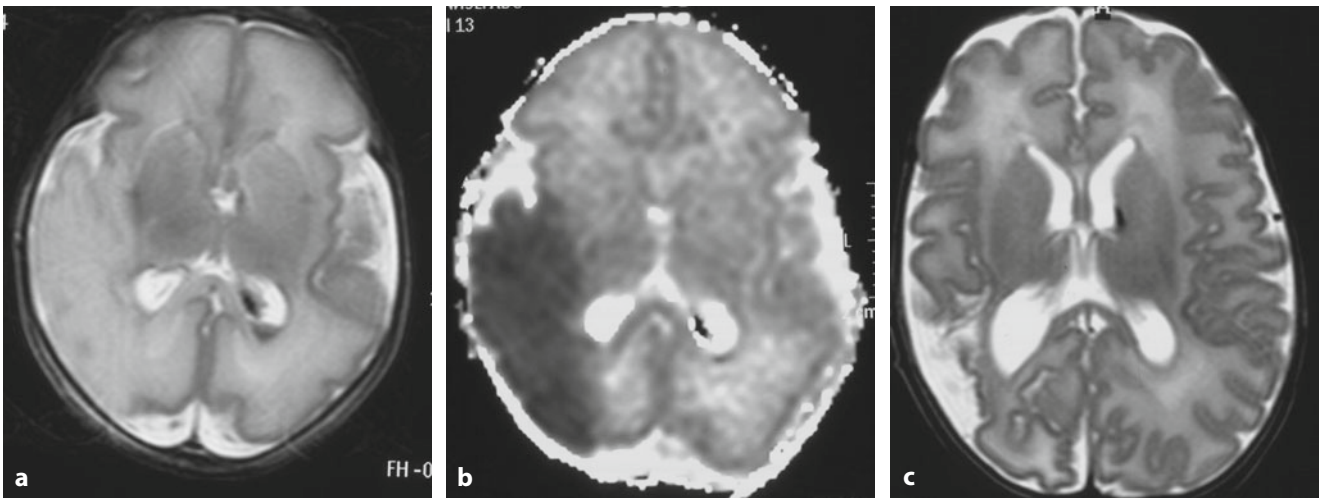

Fig. 132.3 A 30 weeks preterm baby showing at 4 days of life abnormal neuroimaging by MR axial T2 scan (**a**) and MR axial ADC map (**b**), highly suggestive of a right arterial infarct: loss of cortical details on T2, more obvious reduction in apparent diffusion coefficient values. At term-equivalence MR axial T2 scan (**c**) showed that the resulting infarcted area was smaller. At 2 years of age the child was treated for recurrent seizures, but 18 months later was off medications. At 5 years of age, the child presented with a left hemiplegia and good independent walking

to be less vulnerable to this disease, although the incidence has been reported as particularly high in certain studies [11, 12].

132.2.4 Asphyxia

Although antenatal factors have been implicated in the etiology of hypoxic–ischemic encephalopathy (HIE), evidence of antenatal injury is rarely seen on early MRI scans in neonates who present with HIE [3]. MRI remains the best technique to detect perinatally acquired cerebral lesions, and the pattern and severity of the lesions are a reliable guide to prognosis. In the presence of a sentinel event consistent with a severe acute hypoxic–ischemic insult, lesions in the basal ganglia and thalami can be associated with abnormalities in specific cortical regions and in the adjacent subcortical white matter. Abnormal signal intensity in the posterior limb of the internal capsule coexists with lesions in the basal ganglia and thalami (BGT) and is a powerful predictor of abnormal motor outcome (Fig. 132.4). Moderate and severe lesions in the basal ganglia and thalami and severe white matter lesions are associated with cerebral palsy [13]. In approximately 50% of neonates with BGT lesions there will be more extensive WM abnormalities. The motor outcome for these children is still dictated by the BGT lesions, but WM involvement may exacerbate any cognitive deficit. However, infants with severe BGT lesions have severe cognitive impairment regardless of the severity of additional WM involvement. Later there is often white matter atrophy due to the original lesions in the basal ganglia.

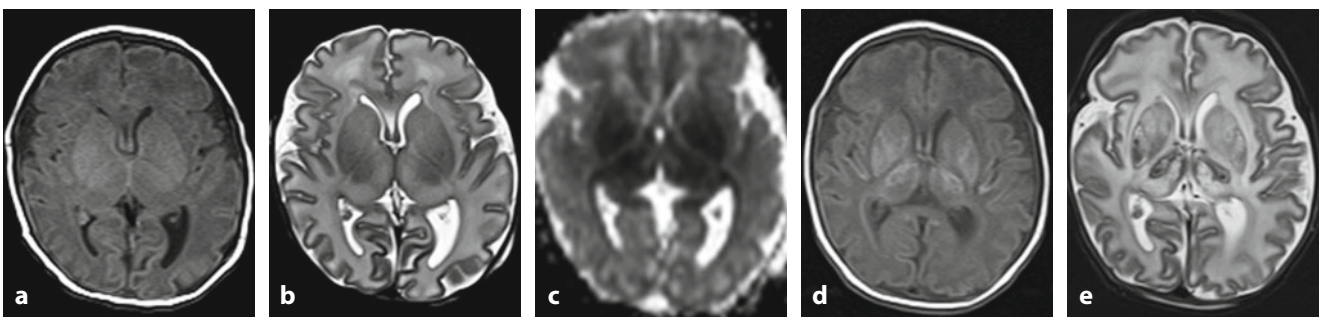

Fig. 132.4 A severe asphyxiated baby born by emergency cesarean section due to maternal rupture of the uterus. **a–c** MR axial T1 and T2 scans and ADC map. There is a markedly abnormal reduction in ADC values at the level of all basal ganglia and thalami on day 4 of life after being treated with hypothermia. **d–e** MR axial T1 and T2 scans. Two weeks later the severity of lesions at the basal ganglia and thalami is obvious. At 15 months, the baby developed severe developmental delay and epilepsy (West syndrome)

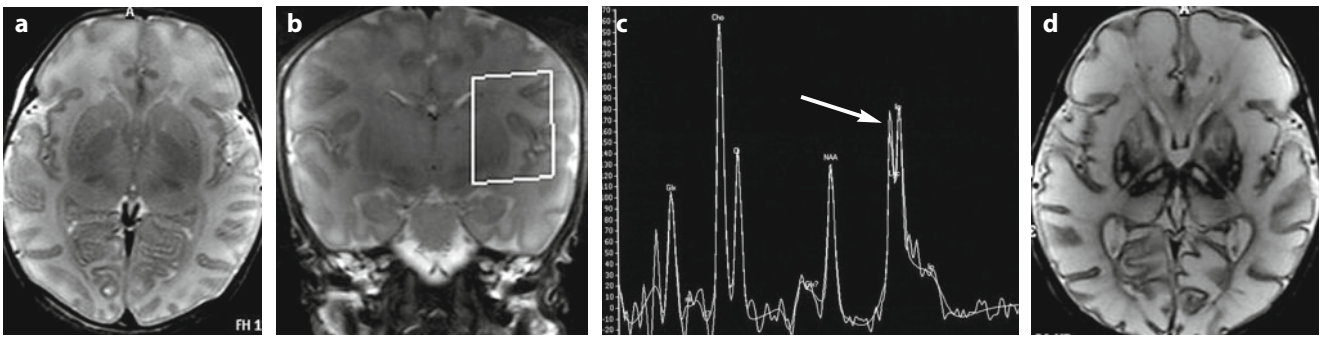

Fig. 132.5 A very severely asphyxiated baby with early scan at 36 h of life. MR axial and coronal T2 scans (**a**, **b**) show uncertain signs at this stage (diffuse increased signal), while MR spectroscopy (**c**) in the region of interest (highlighted) shows a severely abnormal peak of lactate (*arrow*). Three weeks later, an axial T2 scan (**d**) showed dramatic evolution in a pre-multicystic encephalomalacia damage. The baby was born by emergency cesarean section following severe abruptio placentae

DWI seems to underestimate the severity of brain lesions during perinatal asphyxia at early scans, particularly at the level of basal ganglia. Nevertheless, if DWI of the basal ganglia is abnormal, the developing lesions are very likely to be severe (Fig. 132.4).

The ability of MRI to predict neurological outcomes up to 18 months of age in babies who have undergone therapeutic hypothermia is unaffected. In a large cohort of infants who had an MRI after HIE and had previously undergone hypothermia, there were no unusual patterns of lesions and no increase in hemorrhagic or thrombotic lesions. [14]. A common question concerns the optimal timing of an MRI in perinatal asphyxia. The answer relates to the reason for the scan. If it is being done for a differential diagnosis (Fig. 132.1), the scan should be done as soon as possible. On the other hand, if the MRI is being done to predict prognosis, it is better to wait until the 7th day of life, and then to perform a second scan during the second week of life [3]. A repeat scan is particularly useful in the case of an asphyxiated baby born before the 37th week of gestation to look at the posterior limb of internal capsule (PLIC), which is such an important marker of the normal development.

Proton magnetic resonance spectroscopy (^{1}H-MRS) permits the non-invasive study of metabolic alterations in the brain tissue. It has also entered the clinical arena of MR techniques used routinely for the evaluation of the brain. When oxidative phosphorylation is impaired, energy metabolism follows the alternative route of anaerobic glycolysis and produces lactic acid. Lactate has a chemical shift of 1.3 ppm and presents as a doublet peak in the *in vivo* ^{1}H-MRS due to coupling effects. Groenendal et al [15] first described markedly elevated lactate levels in 5 infants with severe perinatal asphyxia. Early spectroscopy (<18h after the event) and measurement of high Lac/Cr ratios in ^{1}H-MRS correlate well with neurodevelopment at 1 year [16]. MRS performed in the first 24h after an insult is sensitive to the presence of hypoxic-ischemic brain injury, and seems to be suitable for the detection of brain injury on the first day when conventional MR imaging and DWI might not yet detect the injury (Fig. 132.5) [17].

132.3 Neurological Symptoms Associated with Neonatal Conditions

Unexpected neurological signs may be due to hypoglycemia [3]. An MRI brain scan is justified in the case of symptomatic hypoglycemia even in the absence of abnormalities at CUS. Infarction following hypoglycemia has been reported in the newborn and specific imaging patterns have been attributed to neonatal hypoglycemic injury [1], e.g. bilateral, fairly symmetrical, evidence of injury to the occipital and posterior parietal cortices and underlying white matter. The cortical ribbon may be lost on T2 as well as T1 MRI, and there may be infarction with subsequent cavitation. Injury beyond the area covered by the posterior cerebral artery is too extensive to be classified as watershed, but the appearance on imaging is similar. The lesion should not be regarded as a stroke (Fig. 132.6) [4]. Another less frequent post-hypoglycemic paradigm is unilateral complete hemispheric neocortical necrosis. The most frequent abnormalities affect occipital white matter and cortex, although there can be other lesions mimicking asphyxia and there is an overlap of symptoms between perinatal asphyxia and hypoglycemia [18].

132.4 Timing of Scanning

Perinatal brain injury leading to brain lesions visualized by MRI evolve over time and are fully developed between 1 and 2 weeks from delivery. By this time, neonates are likely to be clinically stable and off assisted ventilation and MRI can give

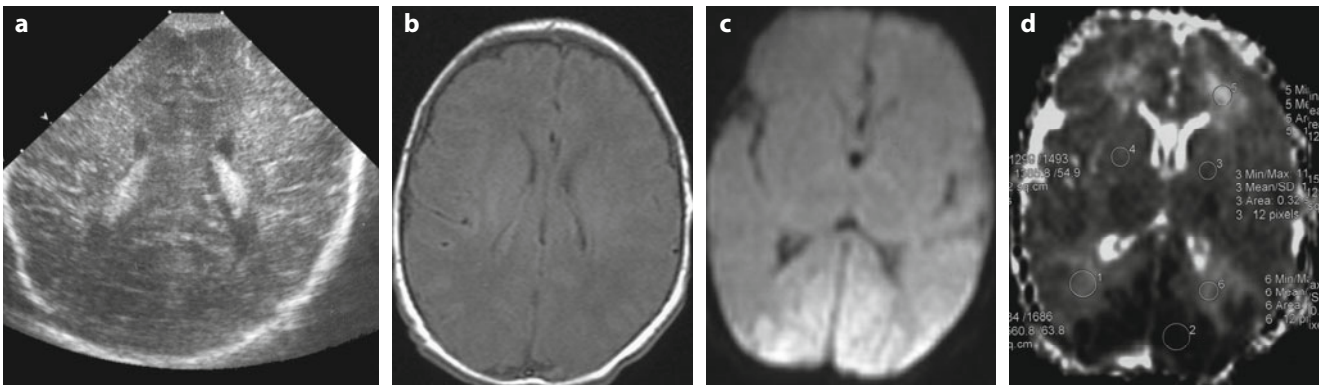

Fig. 132.6 Neuroimaging performed 2 h after the onset of a severe hypoglycaemic event: coronal CUS (**a**) and MR axial T1 (**b**) scans showed no abnormality, which was different to MR axial DWI (**c**) and the axial ADC map (**d**), which showed respectively reduction and pathologically low ADC values in the posterior areas of the brain

an estimation of the extent of lesion load. Although neonatologists may request earlier scanning to make a diagnosis or to assist clinical management, imaging within the first couple of days may show only minor abnormalities in the presence of significant brain injury. Early (<48h from insult) MRI should always include DWI and ^{1}H-MRS if possible. MRS can play an important role in the assessment of encephalopathic term infants. Raised lactate/creatine ratios or absolute concentrations of lactate earlier than 24 h are reliable indicators of cellular injury (Fig. 132.5).

DWI should identify infarcted WM but is not always so reliable at detecting significant injury to the basal ganglia and thalami. Measurement of ADC values and comparison with regional normal values during development are crucial for identifying areas of ongoing injury [5, 19]. As in the case of adult stroke, the DWI visual appearances of infarcted tissue are obvious early and last for approximately 1 week, by which time conventional imaging should be obviously abnormal. Sometimes visual analysis of the DWI is unremarkable or difficult to interpret, even in the presence of severe damage.

Most scanners have the software necessary to obtain ADC from the diffusion images. ADC values should be measured in all infants even when the DWI appears normal. During the first week after injury, ADC values are usually decreased in the presence of ischemic WM, but may be reduced, normal or elevated when there are clinically significant basal ganglia lesions. Difficulties in interpreting DWI findings have led to studies using diffusion tensor techniques to explore tissue microstructure further (see under advanced techniques).

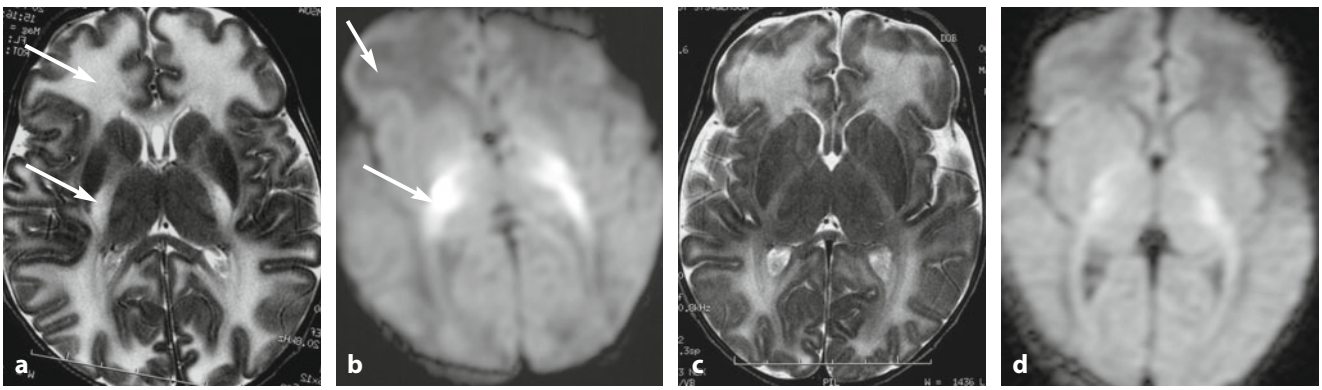

Fig. 132.7 A baby with maple syrup urine disease showing at the first MR (**a**, **b**) severe abnormalities of the signal (*arrows*). On axial T2 scan (**a**) increased signal (*arrows*) in the frontal white matter and at the level of posterior limbs of internal capsule (PLIC) are observed. Interestingly the DWI scan (**b**) shows a completely different pathogenesis; PLIC are represented by a restriction signal on DWI, signs of reduced movements of water molecules, while in the frontal areas DWI shows an opposite signal (increased water molecules movement) very likely expression of vasogenic oedema. **c**, **d** A week after renal dyalisis performed to reduce the amount of the toxic levels of leucine a dramatic improvement of the signal abnormalities is observed

132.5 Interpreting Difficult Cases

132.5.1 Metabolic Disorders

Occasionally infants with an apparent global hypoxic ischemic injury have a metabolic disorder which either masquerades as an acute insult or coexists with one. This is important to recognize because the implications for allegations of medical negligence and for genetic counseling are considerable. Conventional MRI is able to identify brain malformations that may accompany some metabolic disorders, such as callosal agenesis in non-ketotic hyperglycinemia or cortical migration defects in peroxisomal disorders such as Zellweger's syndrome [3]. White matter in these infants may have long T1 and long T2 times, and this may be reflected in increased ADC values. Occasionally the results from DWI are more informative. In infants with maple syrup urine disease DWI is pathognomonic, showing actively myelinating areas (Fig. 132.7) [20]. DWI may also allow differentiation between cytotoxic (reduced ADC) and vasogenic (increased ADC) edema. However, areas showing reduced ADC values may normalize with treatment, and therefore DWI has the potential to be used to monitor therapy. Reversible ADC reduction has also been documented in other metabolic conditions such as hypoglycemia and hypernatremia [21]. A suspicious pattern of diffusion should alert the clinician to the possibility of a metabolic disorder. Abnormalities e.g., affecting the cerebral peduncles and internal capsule, may mimic those found with more straightforward HIE, and an underlying metabolic disorder may be missed. This is particularly likely if a neonate dies in the first few days, as the characteristic clinical evolution of the metabolic disorder has not yet developed. This emphasizes further the need to investigate fully any infant presenting with neonatal seizures, not only by a careful history and examination, but also with metabolic investigations and neuroimaging [3]. The latter should be MRI and include DWI and 1H-MRS if possible. If an infant dies before imaging is possible, postmortem MRI should be considered as an adjunct to autopsy, especially if the parents are unlikely to agree to a conventional postmortem examination.

132.5.2 Sinovenous Thrombosis

The incidence of sinovenous thrombosis is not well known. It has been underestimated for several reasons: many clinicians are unaware of the condition, and the clinical presentation is not specific although it is possible to differentiate between an early presentation within 48 h of birth, and a later one. An early presentation may be confounded by co-morbidities (maternal pre-eclampsia/hypertension, fetal distress) and acute illness (asphyxia, respiratory problems), whereas a later presentation is more often associated with seizures, lethargy, apnea and poor feeding. Acute illness, e.g., dehydration, may also be associated with delayed presentation. Seizures occur in about two-thirds of cases and can be subtle, focal or generalized, irrespective of the time of presentation [22]. The two major goals of radiological diagnosis are imaging of the thrombus and any associated cerebral lesions such as hemorrhage due to venous infarction. An unexplained intraventricular hemorrhage in a term baby or a late-onset intraventricular hemorrhage in a late-preterm baby should raise the suspicion of a sinovenous thrombosis [23]. A typical infarct leaves hemosiderin and gliosis in the residual scar, sometimes with calcification along the vein. There may be evidence of collateral escape. Tissue damage is often overestimated because of the presence of blood that dissects or displaces tissue. Over of the folowing weeks or months, a sinus gradually recanalises. Sinovenous thrombosis in a preterm may present with WM lesions that look like leukomalacia [22]. Color flow Doppler can be useful when there is an inability to visualize a known vein (such as the internal cerebral vein), although it is very difficult to identify a clot in these vessels. The diagnosis by computed tomography (CT) requires administration of intravenous contrast medium highlighting filling defects in the sinuses, and may show classic signs, such as the empty delta sign or the cord sign, whereas CT venography (CTV) provides more accurate evaluation of the venous sinuses. MRI is an excellent tool for imaging the parenchyma, as it requires no ionising radiation or dye, but it is difficult to interpret signals in sinovenous channels. On conventional MRI, the thrombus appears as an increased signal on T1-weighted images and as a decreased signal on T2-weighted images along the vessels

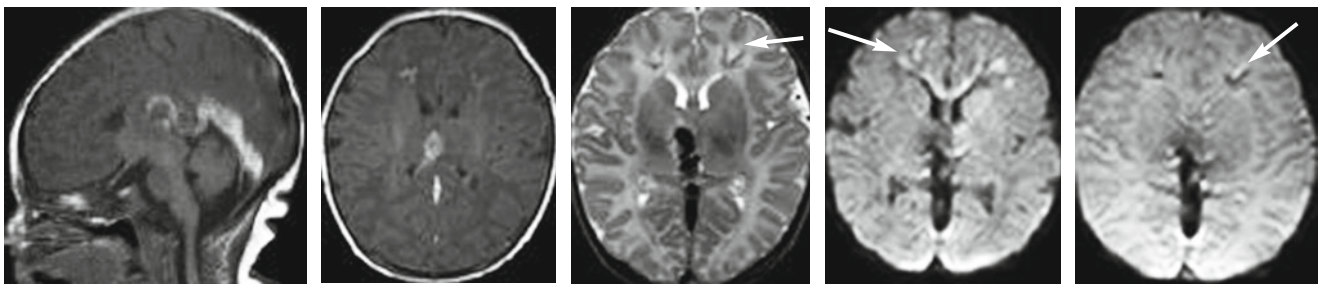

Fig. 132.8 A term baby with an evident and diffuse venous thrombosis, showing thrombi and mild involvement of frontal medullary veins (*arrows*). *Left to right*: MR sagittal T1, axial T1, axial T2, DWI and paramagnetic. (Courtesy of S. Martinelli)

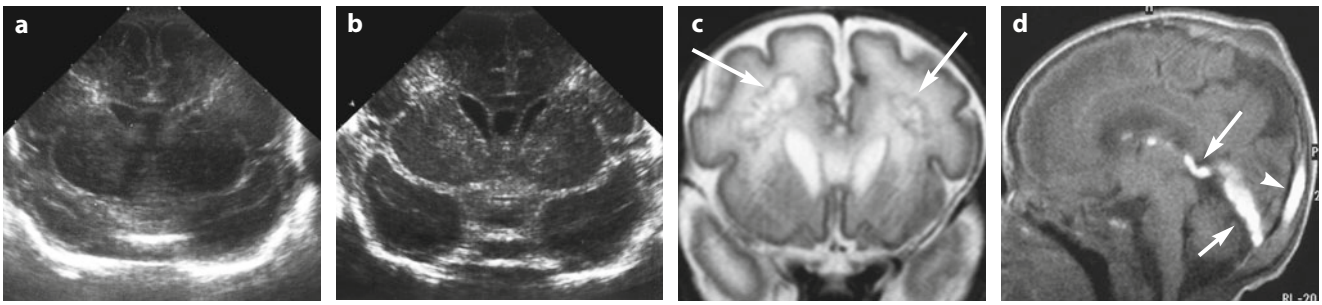

Fig. 132.9 CUS and MR scans at different times in a 35 weeks baby. The first US scan at 4 days of life (**a**) shows normal periventricular echogenicity, progressively increasing at day 9 (**b**). Later MR T2 scans at 3 weeks of age shows: (**c**) cavitations in periventricular area (*arrows*) and (**d**) thrombi in the deep venous system (*arrows*) and partially in the sagittal sinus (*arrowhead*)

involved (Fig. 132.8). Major venous cerebral sinuses are most frequently affected, but there may also be thrombosis in the inner small veins of the deep venous system draining the blood from the germinal matrix and the periventricular WM. A magnetic resonance venogram is an excellent aid, although caution is needed as the slow-flow signal can be misdiagnosed as a no-flow signal. Accordingly, the high proportion of flow gap in the venous sinuses of neonates, particularly the superior sagittal sinus, may be due to the smaller caliber of the venous sinuses, slow flow and skull moulding. The diagnosis of sinovenous thrombosis is further compounded by the fairly common observation of focal bilateral lesions in the brain parenchyma, which may be associated with intraventricular hemorrhage [24]. This strongly suggests sinovenous thrombosis in mildly preterm babies especially when increased periventricular echogenicity follows a normal echogenicity (Fig. 132.9).

132.6 Abnormal Fetal Neuroimaging

With the advent of prenatal neuroimaging, including fetal MRI, it is not uncommon to perform CUS or MRI in neonates to confirm or further investigate abnormalities suspected or diagnosed during fetal life. The most common conditions are idiopathic ventriculomegaly, agenesis of corpus callosum and abnormalities of posterior fossa. A postnatal MRI may be used also to investigate what has been called idiopathic fetal ventriculomegaly that could indicate brain maldevelopment. The MRI examination may rule out aqueduct stenosis or rarer causes of ventricular dilatation like fetal intraventricular hemorrhages. An MRI may be performed in neonates with agenesis of the corpus callosum, mainly to exclude additional cortical abnormalities which a prenatal MRI performed before gyration and sulcation (i.e. before the 25–26th week of gestation) could not definitely exclude.

Although fetal MRI can provide additional information about suspected posterior fossa anomalies, it is important to be aware of its limitations, particularly when performed very early in gestation. There is therefore a need for a follow-up MRI postnatal scan to confirm the posterior fossa abnormality.

132.7 Imaging the Preterm Newborn Brain

Several different aspects have to be considered when considering brain lesions affecting the developing brain of premature babies, i.e. before 37 weeks of gestation and including brains of very different developmental stages and vulnerability for injury. Typical brain lesions less frequently affect the relatively large number of late preterm babies, and are much more frequent in the extremely low birth weight (ELBW) babies, who are fewer in number but very vulnerable [2]. In the late preterm group, brain injury comprises multiple lesions, principally germinal matrix intraventricular hemorrhage, venous hemorrhagic infarction, post-hemorrhagic hydrocephalus, periventricular leukomalacia and cerebellar lesions. However, many preterm infants have neurodevelopmental delay without having been diagnosed with any of these typical perinatal brain injuries. In these babies, abnormal development of the brain is possible even in the absence of common brain lesions (i.e., there may be loss of WM, even in the absence of periventricular leukomalacia). Early exposure to a challenging postnatal environment and removal from a protective milieu are factors that interfere profoundly with normal development, especially in the most vulnerable babies [25, 26].

132.8 Specific Lesions in the Most Premature Babies

132.8.1 Germinal Matrix-Intraventricular Hemorrhage (GMH-IVH)

The lower the gestational age, the higher the risk of developing germinal matrix-intraventricular hemorrhage (GMH-IVH),

which is the most frequent cause of intracranial hemorrhage in the neonate. Ultrasound is now accepted as the primary modality for the diagnosis of GMH-IVH and there have been full descriptions of the ultrasonic findings [27]. GMH is seen as an area of intense increased echogenicity beneath the floor of the lateral ventricle, just anterior to the caudothalamic notch. The abnormality should be seen in two planes, and should be distinguished from other normal echogenic structures, such as the normal choroid plexus. Larger hemorrhages may rupture into the lateral ventricle, and, when acute, appear as an echogenic clot within the ventricle which may distend the ventricular lumen.

The appearance of GMH-IVH and venous infarction change with time (Fig. 132.10). GMHs resolve leaving a small subependymal cyst or a linear echodense line. The margins of a clot within the lateral ventricles remain echogenic, whilst the more central region gradually becomes increasingly echopoor and smaller until the hemorrhage finally resolves by approximately 12 weeks of age.

Several grading systems have been proposed to classify GMH-IVH. The majority are based on the extent of bleeding into the germinal matrix and lateral ventricle, the development of venous infarction and the presence of ventricular dilatation.

The accuracy of ultrasound imaging in the diagnosis of GMH-IVH is reported to be approximately 90%, which is comparable to diagnosis by CT [27]. Thus ultrasound imaging has now become the imaging modality of choice for the detection of GMH-IVH. It can also be performed on a daily basis if necessary, with no risk of exposure to ionizing radiation or the need to move the infant to the imaging department. A wider use of MRI on premature babies has shown excellent visualization of the germinal matrix (GM) with high signal on T1- and low signal on T2- weighted images, especially up to the 30th week of gestation. After this time, T2-weighted images remain the best sequence to follow the physiological GM involution, which occurs with increasing gestational age. Germinal matrix hemorrhage has similar characteristics to normal germinal matrix, but is detectable due to its irregular shape and asymmetry. Very preterm babies may show small lesions consistent with subependymal hemorrhage in areas other than the classic site of the caudo-thalamic notch, most often in the posterior horns. These hemorrhages seem not to be visible on ultrasound [28]. Intraventricular hemorrhage, more often identified in the posterior horns of the lateral ventricle, is an obvious diagnosis with MRI, making this technique the most accurate for GMH-IVH investigation, although MRI scanning is not practical for sick unstable neonates during the first days of life. MRI has improved the detection of venous infarction associated with GMH-IVH, although caution is needed because subependymal hemorrhages may appear to have white matter involvement due to partial volume effects. Keeney demonstrated that an MRI performed between 29 and 44 weeks' postmenstrual age was superior to both US and CT in assessing the extent of any parenchymal injury associated with GMH-IVH [29]. MRI signal shows changes following any form of intracranial hemorrhage, including IVH, according to the timing of hemorrhage. The typical hyperintense intraventricular hemorrhagic signal on T1 usually appears in the so-called subacute phase, usually between 4 days and 2 weeks after the initial bleed, while the long-lasting hemosiderin deposition seems to be visible only after 3–4 weeks [1].

132.8.2 Parenchymal Hemorrhage/Venous Infarction

In general, ultrasound scanning should be the first imaging modality, but if the ultrasound scan is non-conclusive and there is a strong clinical suspicion of acute hemorrhage, an MRI should be considered. Hemorrhage occurring peripherally in the brain or in the cerebellum may not be easy to visualize by ultrasound, particularly if the anterior fontanelle is relatively small. MRI scanning is the most sensitive technique and should be substituted for CT at all times.

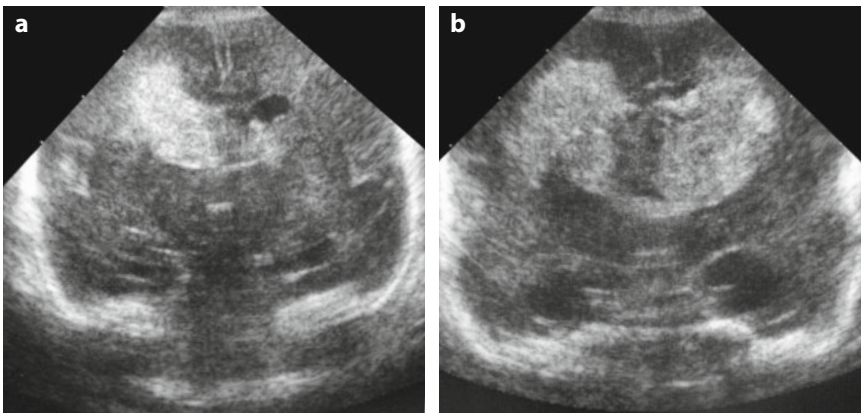

Fig. 132.10 CUS Coronal scans. **a** A 24 weeks baby scanned at 8 h of life and showing severe intraventricular hemorrhage on the right with adjacent venous infarct. **b** The same baby scanned 12 h later showing a further deterioration with a bilateral intraventricular hemorrhage and very rare double venous infarct. The baby died aged 36 h

GMH-IVH can present with unilateral parenchymal hemorrhage, better known as venous infarction at the first scan, or more commonly within a few hours in a later scan. The region involved can be quite large and just dorsal and lateral to the external angle of the lateral ventricle, usually sparing the cortical mantle, although location and size can vary [27]. Less often, the lesion develops in more posterior parts of the brain, in the temporal lobe or around the atrium. In these cases, the inferior ventricular veins or lateral atrial veins are involved. It is still possible to have bilateral venous infarction, but this condition is extremely rare and well differentiated from PVL. At first, the lesion appears as a triangular density often not touching the ventricle, but later the lesion grows and extends to the ventricle, merging the area of increased density due to matrix hemorrhage [27]. Sometimes there is no progression to this stage and the lesion remains as a triangular density. The hyperdense area tends to decrease in size during the second week and the real infarcted area bends up being smaller than expected. Cystic degeneration is the most common evolution of severe cases with a smooth-walled cavity in the parenchyma communicating with the ventricle (unlike in periventricular leukomalacia) [27].

132.8.3 Hydrocephalus

Ultrasound imaging is the most appropriate modality for the initial assessment of ventricular size. The slightly rounded shape of the frontal horns can represent the initial appearance of dilatation while balloon-shaped frontal horns are a sign of severe dilatation. Latero-lateral and diagonal measurements of the diameter are a well-established modality by which to monitor ventricular dilatation. Absence of widening of the frontal horns may be falsely reassuring as neonates tend to have dilated occipital horns (colpocephaly). Many units have their own guidelines for measuring frontal horns, but very often not for measuring the posterior horns [27].

MRI can be useful as detailed imaging is often required prior to shunting and also after surgery to verify the functioning of the shunt, provided the intraventricular device is MRI compatible .

132.8.4 Pseudocysts

Cavitation in the germinal matrix represents a phenomenon called germinolysis. There is a lack of proper epithelium and it occurs typically at the caudo-thalamic notch, causing a pseudocyst [30]. During the postnatal period, pseudocysts occur mainly following small to moderate GMH-IVH, although a mechanism based on pure infarction of the germinal matrix has been hypothesized. Pseudocysts are sometimes detected at the caudo-thalamic notch a few weeks after birth in normal preterm babies with no obvious reason [31].

132.8.5 Cerebellar Hemorrhages

Few *in vivo* studies have focused on cerebellar hemorrhagic lesions. Cerebellar hemorrhages (CH) are known to be highly represented in post mortem studies, varying from 10 to 25% in very low birth weight infants. However, an *in vivo* diagnosis, even with MRI, seems to be around only 10% in preterm infants less than 32 weeks of gestation [32]. Ultrasound studies performed through the posterior fontanelle, which is more sensitive for visualizing the cerebellum than the more conventional view through the anterior fontanelle, show a low incidence of about 3%, especially in extremely low birth weight babies. Ultrasound using the occipital window appears to be the best approach and the incidence is probably higher [1]. In some cases, cerebellar hemorrhages can be severe and associated with flattening of the pons (Fig. 132.11). A degree of pontine atrophy has been observed in preterm babies with PVL, and a flattened anterior curvature of the pons has been detected by MRI in 28 premature infants born before the 30th week of gestation [32].

Acquired pontocerebellar atrophy should be differentiated from congenital pontocerebellar hypoplasia (an association of pontine, vermis and cerebellar hemisphere hypoplasia) and marks a neurodegenerative disorder. Acquired forms of pontocerebellar atrophy have been described in association with fetal drug exposure, sepsis in premature babies, twin-to-twin transfusion syndrome and vascular undersupply.

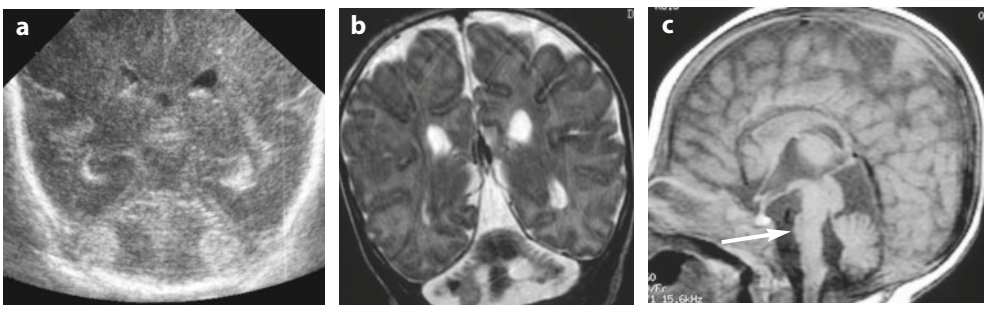

Fig. 132.11 Coronal CUS scan (**a**) of a 24 weeks baby scanned at 10 days and showing bilateral cerebellar hemorrhages. MR scans at term-equivalence: coronal T2 (**b**) showing cerebellar atrophy at the hemispheres; axial T1 (**c**) showing flattening of the pons (*arrow*)

The causes of the association between impaired pontine development and cerebellar hemorrhage remain unknown. The cerebellum receives excitatory input from the frontoparietal cortex via the corticopontocerebellar tracts; an interruption, with secondary degeneration of corticopontocerebellar tracts, could explain pontine atrophy linked to supratentorial lesions, which has been reported in premature babies with little or no PVL. In the same way, primary cerebellar lesions can cause degeneration of pontine fibers through the presence of pontocerebellar tracts. However, a sequence beginning with cerebellar hemorrhage and ending with pontine atrophy has not been demonstrated. The diagnosis of pontine flattening is often made by MRI at term-equivalence. This intrinsic vulnerability of the myelinating posterior fossa at low gestation may partly explain impaired development of the pons.

Clinical follow-up studies are needed to investigate whether or not pontine lesions worsen the outcome of babies with isolated cerebellar lesions.

132.9 Premature Babies: the Importance of White Matter

Periventricular leukomalacia (PVL) is described in detail in Chapters 135 and 136. In clinical practice, at least in the older preterm infant, a white matter disease is ascertained by comparing its echogenicity with that of the choroid plexus. Generally the echogenicity found in early periventricular leukomalacia is similar in intensity to that of the choroid plexus, usually bilateral, slightly asymmetric, sharply delineated, sometimes with nodular components. This has to be differentiated from normal peritrigonal flaring which is perfectly symmetric and has a radial appearance. The evolution of such hyperechogenecity can result in either complete disappearance or its evolution into cysts and/or ventricular dilatation [27]. Cyst formation typically occurs after the second week (10–40 days) after the insult. DeVries et al [33] postulated an ultrasound-based classification for PVL of four grades, increasing grades being associated with increasing neurodevelopmental handicap (Table 132.1). Grade I is transient (> 7 days) periventricular densities without cyst formation. Grade II is when cysts develop but are few in number or localized primarily to the frontal and frontoparietal white matter. When cysts are widespread and extend into the parieto-occipital region they are referred to as Grade III; they may grow and gradually disappear leaving an irregularly dilated lateral ventricle. If cysts are present all the way into the subcortical area resembling porencephaly, this is referred to as Grade IV.

Table 132.1 Ultrasound classification of PVL [33]

Grade I	Transient periventricular echodensities (PVE) (> 7 days)
Grade II	PVE evolving into localized fronto-parietal cystic lesions
Grade III	PVE evolving into extensive periventricular cystic lesions
Grade IV	Echodensities evolving into extensive periventricular and subcortical cysts

Classification requires longitudinal assessment with daily to weekly ultrasound scans.

The predilection of injury to the periventricular white matter is shared by the newer WM diseases identified by MRI *in vivo* studies. White matter injury in preterm neonates is accompanied by diffuse neuronal and axonal disease, affecting not only cerebral white matter but also deep gray, cortex and cerebellum. The vulnerability of the periventricular WM has been extensively studied in the context of PVL and is thought to be due to a combination of the presence of a vascular watershed and an inherent susceptibility of preoligodendrocytes to injury [26]. In addition, there are populations of resident microglia at these sites of periventricular white matter [34]. It is possible that these microglia, which are essential for axonal guidance and white matter tract modeling, are activated abnormally in the presence of injury. In infants with PVL it is recognized that the brain may show a diffuse component around and at a distance from the focal cystic lesions [35]. This is confirmed by *in vivo* imaging where there may be both cystic and chronic changes in diffusion parameters in the white matter of preterm infants who have white matter injury [36].

MR imaging of chronic white matter injury in the immature brain is characterized by the presence of cysts, and, more importantly, by a persistent high MR signal intensity of the white matter in T2-weighted images (DEHSI), which represents diffuse white matter injury or punctuate T1-weighted hyperintensities in the periventricular white matter. PVL is a pathological term that does not imply a particular etiology. Punctate lesions and DEHSI are imaging terms and therefore do not imply either etiology or pathology. Whilst there are many animal models of PVL like lesions, there is as yet no model that has produced an injury that is instantly recognisable as punctate lesions or DEHSI. To confirm such correlations we need either imaging studies of the animal model or human imaging and histological correlations. The latter is difficult because neonates with these milder forms of WM disease are unlikely to die. Attempts to obtain histological correlations would be easier if a diagnosis of punctate lesions and DEHSI could be made routinely using ultrasound [37–39].

The use of MRI as a routine imaging tool in the neonatal intensive care is limited. Florid punctate lesions are detectable by ultrasound, but may be missed, and there is not as yet an ultrasound correlate for DEHSI. *In vivo* imaging of the brain of an animal model has shown an increase in ADC values, as found in both DEHSI and diffuse PVL [40], and at histology this white matter contained increased numbers of activated microglia. It has often been assumed that the short T1, short T2 punctate lesions represent hemorrhage. Against this interpretation is the observation that the signal intensity on T1-weighted images is usually more pronounced than on T2-weighted images and not enhanced by gradient echo imaging. In one attempt at discovering the significance of these MR appearances, these punctate lesions were found

to represent clusters of activated microglia and macrophages containing lipid droplets.

Early assessment of periventricular white matter in preterm infants by DWI shows bilateral periventricular diffusion restriction, which has a distribution that is similar to the typical distribution of PVL when ultrasound and conventional MRI show no or non-specific abnormalities [41]. A reduced ADC in an otherwise normal preterm brain is considered an early indicator of white matter damage (just as a reduced ADC is seen shortly after the onset of an acute cerebral ischemic lesion in the full-term newborn) [42].

132.10 White Matter of Premature Babies at Term Corrected Age

Brain maturation is very rapid during the third trimester of pregnancy and for the preterm infant in the early weeks of life prior to term age. Assessment of brain maturation at term-equivalent age has therefore become an important indicator of brain development with implications for future functional outcome. When preterm infants are imaged at term-equivalent age, the secondary effects of white matter disease on various brain structures can be visualized and quantified. Infants with PVL characteristically show thalamic atrophy and abnormally delayed myelination within the PLIC [43]. These findings can be used to determine whether the child will walk independently. Quantitative studies have also demonstrated a reduced cortical volume at term-equivalent age in infants with white matter injury [42], reduced cerebellar volume [44] and reduced central gray matter volume in premature infants with respiratory problems [45]. Infants with punctate lesions usually show milder abnormalities (Fig. 132.12). A study at term-equivalent age showed that infants with punctuate lesions had reduced myelin and decreased cortical folding [46]. Infants with fewer lesions may show relatively normal imaging. By definition, DEHSI is diagnosed at term-equivalent age as regions of long T1 and long T2 within the white matter. The diffuse T2 hyperintensities or DEHSI, considered to be indicators of the chronic phase of white matter injury, are associated with higher ADC values, confirming a higher local tissue water content and loss of microstructure impeding water diffusion in those areas. Quantitative measures of diffusion at term showed that when compared to preterm infants without white matter injury, premature infants with perinatal white matter lesions had lower anisotropy values (a value that measures directionality of water diffusivity and an expression of fiber density) in the area of previous injury, i.e., the central periventricular white matter, and also in the underlying posterior limb of internal capsule. On quantitative analysis, DEHSI is associated with a reduction in central gray matter volume at term age [47].

Diffusion weighted imaging with diffusion tensor analysis (DTI) has provided new insights into the microstructural white matter development and seems to be an ideal tool to assess alteration of white matter pathways and its consequences for later motor development. Evaluating DTI studies at term-equivalent age with assessments at 18–24 months corrected age (CA), Arzoumanian [48] found that fractional anisotropy (FA) values in the right PLIC were significantly lower for preterms with cerebral palsy than for those with normal examinations. Correlations of DTI values and visual outcome have also been performed [49].

Several authors have investigated the influence of preterm birth on primary cortical folding [50] because of the potential of underlying white matter connectivity to determine gyrification in developing brain.

Functional MRI connectivity (fcMRI), which assesses both neural processing and resting state connectivity, has been less well studied in the preterm population, but may also offer insights into the microstructural mechanisms that support brain development [51]. As with term controls, neonates were found to have resting-state networks that encompassed the

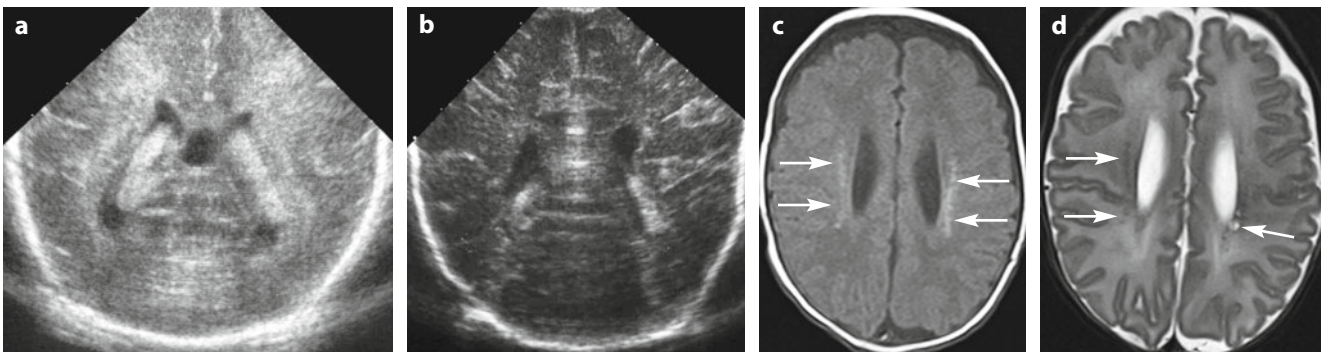

Fig. 132.12 **a** Coronal CUS scan showing a transient increased periventricular echogenicity at 10 days of a 29 weeks baby. **b** CUS scan at term-equivalence showing normal echogenicity, while MR axial scans (**c** T1, **d** T2) highlight periventricular abnormalities (*white arrows*) usually called punctate lesions. On T1 weighted images, these abnormalities at term-equivalence may also represent mild glial scars

primary visual cortex, bilateral sensorimotor areas, bilateral auditory cortex, a network including the precuneus, lateral parietal cortex and the cerebellum and an anterior region that incorporated medial and dorsolateral prefrontal cortex.

Imaging strategies that assess both connectivity and cortical development may provide important early biomarkers predictive of later development. Two relatively new technologies, DTI and fcMRI, combined with advanced image analysis tools such as voxel-based morphometry (VBM) and mathematical morphology-based analysis of cortical folding, provide complementary data for understanding development, injury and recovery in the developing brain. In a recent review Ment et al summarize studies using those new neuroimaging tools [25].

It is generally believed that neurological sequelae are based on specific patterns of nosologically identified brain lesions as an early bedside detection of the major cerebral pathologies, such as GMH-IVH, venous infarction/hemorrhagic parenchymal infarction (PVH), posthemorrhagic ventricular dilatation (PHVD) and cystic periventricular leukomalacia. All these conditions predict of severe neurological impairment. However, the lack of recognizable lesions is not a guarantee for a good neurological outcome, especially for extremely low birth weight babies. In this group of babies, the incidence of lesions which cannot be visualized on CUS, such as those in the posterior fossa, may be underestimated.

The use of CUS has been widely validated in neonatal intensive care units during the last 25–30 years to diagnose intraventricular hemorrhage with its complications (venous infarct, posthemorragic dilatation). More recently, MRI allows assessment of different degrees of white matter abnormalities affecting the brain of premature infants. The extent to which these new techniques are early biomarkers of cognitive outcome in the premature infants needs to be determined, although a recent review appeared to support this view, especially when diffusion tensor techniques were used.

Malformations of Cortical Development: Genetic Aspects

Renzo Guerrini and Elena Parrini

133.1 Introduction

The development of the human cerebral cortex is a complex dynamic process that occurs during several gestational weeks [1]. During the first stage, stem cells proliferate and differentiate into young neurons or glial cells deep in the forebrain in the ventricular and subventricular zones lining the cerebral cavity. During the second stage, cortical neurons migrate away from their place of origin: most cells migrate along the radial glial fibres from the periventricular region towards the pial surface, where each successive generation passes one another and settles in an inside-out pattern within the cortical plate. When neurons reach their destination, they stop migrating and order themselves into specific "architectonic" patterns guiding cells to the correct location in the cerebral cortex. This third phase involves final organization within the typical six layers of cortex, associated with synaptogenesis and apoptosis.

Abnormal cortical development is increasingly recognized as a cause of developmental disabilities and epilepsy. This recognition is due, in part, to the improved use of magnetic resonance imaging (MRI), which makes it possible to assess the distribution and depth of cortical sulci, cortical thickness, the boundaries between gray and white matter, and variations in signal intensity.

Abnormalities of any or all of these features may be observed in different malformations of cortical development (MCD), which may be restricted to discrete cortical areas or may, alternatively, be diffuse [2].

In the following sections, the most frequent causes of MCD will be discussed (Table 133.1).

133.2 Lissencephaly and Subcortical Band Heterotopia

Lissencephaly (LIS) is characterized by absent (agyria) or decreased (pachygyria) convolutions, cortical thickening and a smooth cerebral surface [3]. Several types of LIS have been recognized. The most common, classical LIS, features a very thick cortex (10–20 mm *vs* the normal 4 mm) and no other major brain malformations.

Subcortical band heterotopia (SBH) is a related disorder in which bands of gray matter are interposed in the white matter between the cortex and the lateral ventricles [3]. Histopathology demonstrates that heterotopic neurons settle close to the "true" cortex in a pattern suggestive of laminar organization.

Three rarer forms of LIS-pachygyria have been identified in recent years [4]. One form, due to mutations of the *TUBA1A* gene, exhibits characteristics that partially overlap with the LIS-SBH spectrum but is often accompanied by cerebellar hypoplasia. A second form, X-linked LIS with absent corpus callosum and ambiguous genitalia (XLAG), results from mutations of the *ARX* gene. A third, recessive form, results from homozygous mutations of the *RELN* gene. LIS due to *ARX* and *RELN* mutations exhibits particular features, which set them out of the classical LIS spectrum.

133.2.1 Genetic Basis and Diagnosis

Two major genes have been associated with classical LIS and SBH. The *LIS1* gene is responsible for the autosomal form of LIS [5], while the *DCX* gene is X-linked [6]. Although either gene can result in either LIS or SBH, most cases of classical LIS are due to deletions or mutations of *LIS1* [7], whereas most cases of SBH are due to mutations of *DCX* [6]. *LIS1*-related LIS is more severe in the posterior brain regions (posterior > anterior or p > a gradient) (Fig. 133.1a), whereas

AD Autosomal dominant, *AR* autosomal recessive, *PH* periventricular heterotopia.

DCX-related LIS is more severe in the anterior brain (anterior > posterior or a > p gradient) (Fig. 133.1b).

About 60% of patients with p>a isolated LIS (ILS) carry genomic alterations or mutations involving *LIS1* [7]. A simplified gyral pattern in the posterior brain with underlying SBH has been associated with mosaic mutations of *LIS1* [4]. Miller-Dieker syndrome (MDS) is caused by deletion of *LIS1* and contiguous genes and features severe p>a LIS, accompanied by distinct dysmorphic facial features and additional malformations (Fig. 133.1c) [5].

Most *DCX* mutations cause a>p SBH/pachygyria. Mutations of *DCX* have been found in all reported pedigrees and in 80% of sporadic females and 25% of sporadic males with SBH [6]. Genomic deletions of *DCX* are rarely observed [4]. Maternal germline or mosaic *DCX* mutations may occur in about 10% of cases of either SBH or X-linked LIS (XLIS) [8]. Hemizygous males with *DCX* mutations have classical LIS (Fig.133.1 d), but rare boys with missense mutations and SBH have been described [9].

133.2.2 Phenotype

Classical LIS is rare, with a prevalence of about 12 per million births. Patients with severe LIS have early developmental delay, early diffuse hypotonia, later spastic quadriplegia, and eventual severe or profound mental retardation. Seizures occur in over 90% of LIS children, with onset before 6 months in about 75% of cases. About 80% of children have infantile spasms, although electroencephalography (EEG) does not show typical hypsarrhythmia [4]. Most LIS children

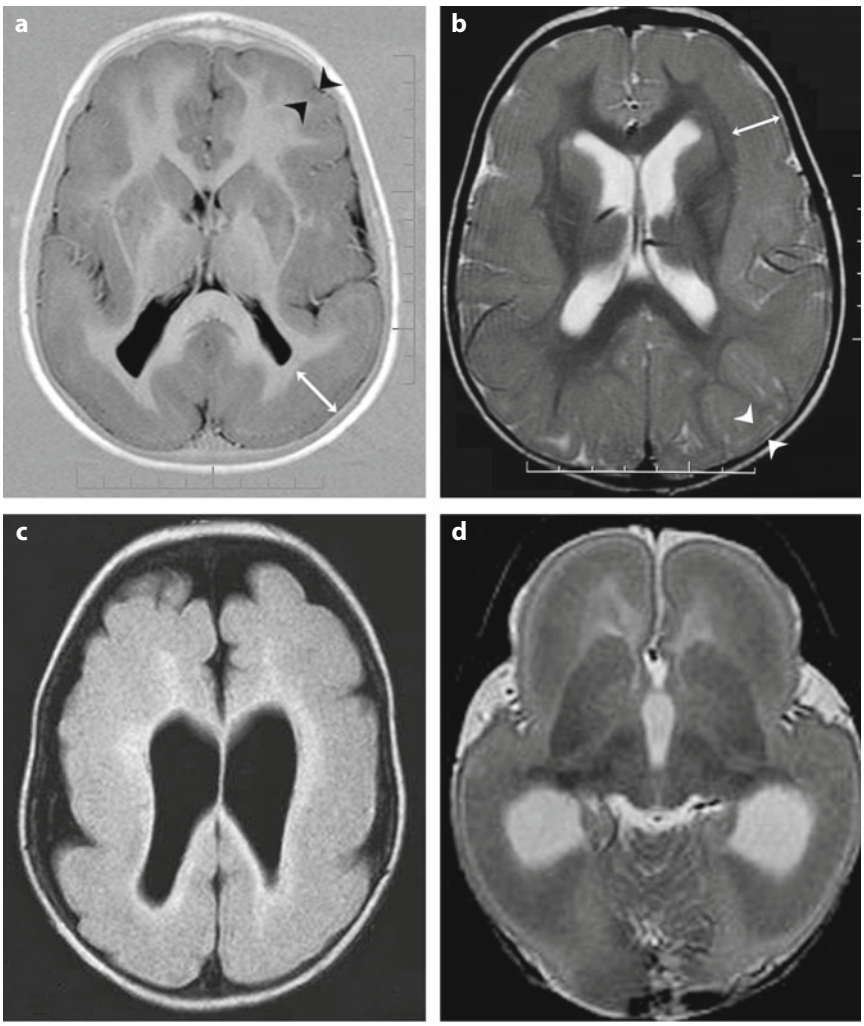

Fig. 133.1 Brain MRI of four different patients; axial sections. **a** classical LIS in a boy with *LIS1* gene mutation; **b** LIS in a girl with *DCX* mutation. In **a**, there is a p>a gradient, cortical thickness is around 6 mm in the frontal lobes (*two black arrowheads*) and around 3 cm in the posterior brain (*white arrow*). In **b** there is a typical a>p pattern; cortical thickness is around 2 cm in the frontal lobes (*white arrow*) and around 4 mm in the posterior brain (*two white arrowheads*). **c** LIS in a patient with MDS. **d** Severe diffuse LIS with relatively small frontal lobes in a boy with *DCX* mutation

subsequently have multiple seizure types. In patients with MDS, classical LIS is accompanied by distinct dysmorphic facial features [5]. The main clinical manifestations of SBH are mental retardation and epilepsy. Epilepsy is present in almost all patients and is intractable in about 65% of cases. About 50% of these epilepsy patients have focal seizures, and the remaining 50% have generalized epilepsy, often within the spectrum of Lennox-Gastaut syndrome.

133.2.3 Laboratory Investigations

In patients with classical LIS, the cytogenetic and molecular investigations are part of the diagnostic process. When MDS is suspected, a standard karyotype and FISH for the 17pl3.3 region is indicated. When isolated LIS is diagnosed, careful assessment of the antero-posterior gradient of cortical pattern abnormality will be suggestive of the involvement of either the *LIS1* or the *DCX* gene.

When LIS is more severe posteriorly, it is worth performing first multiplex ligation-dependent probe amplification (MLPA) in order to rule out *LIS1* deletions/duplications. If a deletion/duplication is not found, *LIS1* sequencing should then be performed. In boys, whose MRI shows more severe pachygyria in the frontal lobes, sequencing of the *DCX* gene is indicated. In patients with SBH direct sequencing of *DCX* should be performed. If a *DCX* mutation is not found, MLPA analysis should then be performed. Direct sequencing is also indicated in the mothers of patients harbouring a *DCX* mutation or other female relatives.

133.2.4 Genetic Counselling

All reported *LIS1* alterations are *de novo*. Given the theoretical risk of germline mosaicism in either parent (which has never been demonstrated for *LIS1*), a couple with a child with lissencephaly is usually given a 1% recurrence risk.

When a *DCX* mutation is found in a boy with LIS, mutation analysis of *DCX* should be extended to the proband's mother, even if her brain MRI is normal. If the mother is a mutation carrier, the mutation will be transmitted according to Mendelian inheritance. If the mother is not a carrier, she can still be at risk of germline mosaicism; the risk of transmitting the mutation may roughly be estimated at around 5%.

133.3 Heterotopia

There are three main groups of heterotopia: periventricular (usually nodular: PNH), subcortical (SBH) and leptomeningeal, of which only the first two can be detected by imaging. PNH is by far the most frequent. SBH is a mild form of LIS and classified in that group.

133.3.1 Periventricular Nodular Heterotopia

Periventricular nodular heterotopia (PNH) consists of nodules of gray matter located along the lateral ventricles with a total failure of migration of some neurons [3]. It ranges from isolated, single, to confluent bilateral nodules (Fig. 133.2). The overlying cortex may show an abnormal organization.

133.3.1.1 Genetic Basis and Diagnosis

PNH is a clinically and genetically heterogeneous disorder occurring most frequently in women as an X-linked trait (classical bilateral PNH), associated with high rates of prenatal lethality in male fetuses, and 50% recurrence risk in the female offspring. Almost 100% of families and 26% of sporadic patients, harbor mutations of the *FLNA* gene [10], which also causes cardiovascular abnormalities in some patients of both sexes and gut malformations in boys. Only a few living male patients with PNH due to *FLNA* mutations have been reported [11]. A rare recessive form of PNH owing to mutations of the *ARFGEF2* gene was described in two consanguineous pedigrees in which affected children had microcephaly, severe delay, and early-onset seizures [12]. PNH has been described in association with known genetic syndromes and a number of copy number variants (CNVs) in patients with variably impaired cognitive skills (Table 133.1).

133.3.1.2 Phenotype

Although most patients with PNH come to medical attention because they have focal epilepsy of variable severity, there is a wide spectrum of clinical presentations, including several syndromes with mental retardation and dysmorphic facial features. There is some correlation between the size of PNH and the likelihood of concomitant structural abnormality of the

Fig. 133.2 Brain MRI: Axial section. Typical, classical bilateral PNH in a woman with a missense *FLNA* mutation. Bilateral nodules of subependymal heterotopia are contiguous and rather symmetric, extensively lining the ventricular walls (*arrowheads*)

cortex and clinical severity [10] but there seems to be no correlation between the size and number of heterotopic nodules and cognitive outcome. Most female patients with PNH due to *FLNA* mutations have epileptic seizures, with normal or borderline cognitive level. However, patients with even small isolated nodules caused by unknown genetic abnormalities or by copy number variations and severe cognitive impairment have been reported.

133.3.1.3 Laboratory Investigations

FLNA mutation analysis should be performed in patients with "classical" bilateral PNH. When autosomal recessive PNH associated with microcephaly is suspected, *ARFGEF2* mutation analysis should be performed. Patients, who present with PNH associated with other brain malformations or extraneurological defects, should be studied with array-based comparative genomic hybridization (array-CGH), an emerging high-resolution and high-throughput molecular genetic technique that allows genome-wide screening for chromosome alterations (i.e. genomic deletions/duplications).

133.3.1.4 Genetic Counselling

Classical PNH is much more frequent in women and likely to be due to *FLNA* mutations. Among carrier women, about half have *de novo FLNA* mutations, whereas the remaining half have inherited mutations. Although maternal transmission is much more likely, father-to-daughter transmission is possible. Given that germline mosaicism of *FLNA* has never been reported, the recurrence risk (for other children) seems to be very low when a mutation is found in the proband but neither parent is a carrier. Counselling is very difficult when PNH is not related to either *FLNA* or *ARFGEF2*, array-CGH study for the search of copy number variations is advised. The number of known cases of familial PNH unrelated to these genes is extremely low.

133.4 Polymicrogyria Phenotypes and Genetics

The term "polymicrogyria" (PMG) defines an excessive number of abnormally small gyri that produce an irregular cortical surface with lumpy aspect [3]. PMG can be localized to a single gyrus, involve a portion of one hemisphere, be bilateral and asymmetrical, bilateral and symmetrical or diffuse. The imaging appearance of polymicrogyria varies with the patient's age. In newborns and young infants, the malformed cortex is very thin with multiple, very small undulations. After myelination, PMG appears as thickened cortex with irregular cortex-white matter junction [2]. Polymicrogyria is associated with a wide number of patterns and syndromes and with mutations in several genes (Table 133.1). Various PMG syndromes have been described, which have been designated according to their lobar topography [2].

Bilateral perisylvian polymicrogyria (BPP) (Fig. 133.3a, b) is the most frequent form. It is associated with mild to moderate mental retardation, epilepsy, and impaired oromotor skills. Most cases are sporadic but genetic heterogeneity is suggested [2, 13]. BPP, frequently asymmetric and with a striking predisposition for the right hemisphere, has also been reported in children with 22q11.2 deletion [2].

Bilateral frontoparietal polymicrogyria (BFPP) (Fig. 133.3c) has been reported in families with recessive pedigrees and has been associated with mutations of the *GPR56* gene

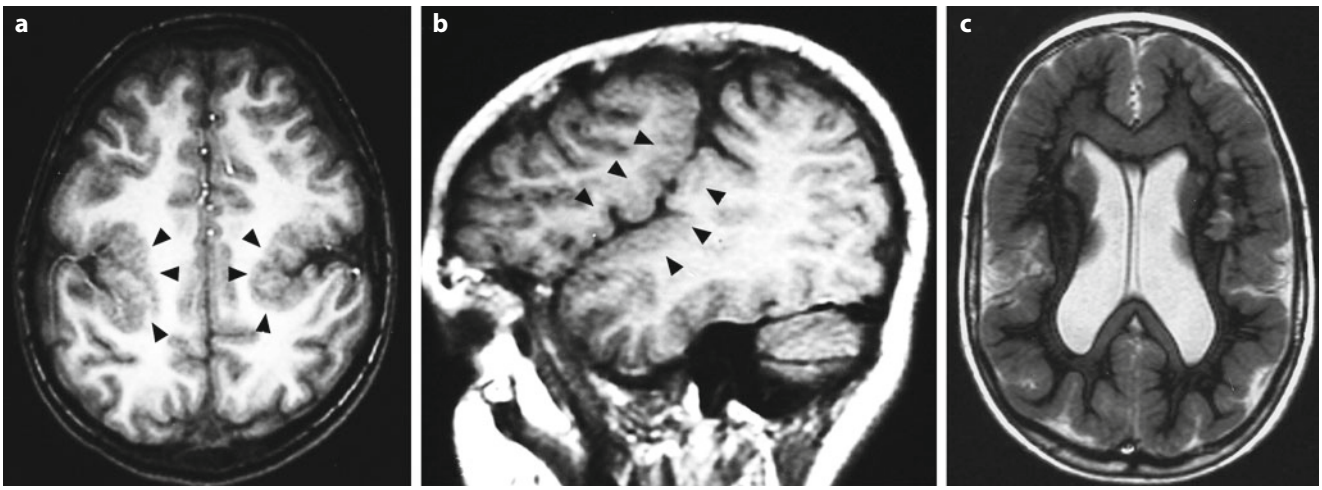

Fig. 133.3 Brain MRI scan in two patients with PMG (**a** and **b** belong to the same patient). **a** Axial section, BPP. The sylvian fissures are open and the perisylvian cortex is thickened and irregular (*arrowheads*). **b** Sagittal section. Note the abnormal vertical orientation of the sylvian fissure, which appears to be fused with the rolandic fissure. **c** Axial section. BFPP in a girl with a *GPR56* mutation and Lennox-Gastaut syndrome

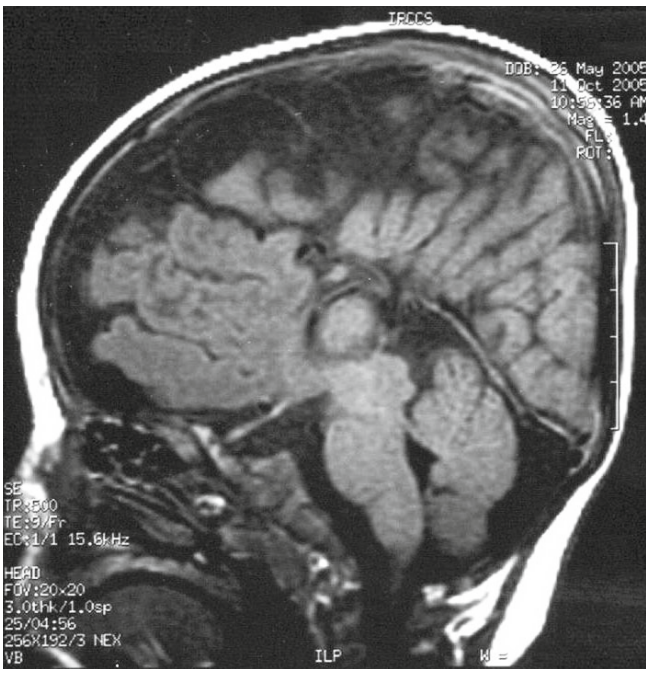

Fig. 133.4 T1 weighted sagittal MRI scan of the brain of a 5 months old girl with Aicardi syndrome and intractable infantile spasms Note the extremely hypoplastic corpus callosum with an extensive area of polymicrogyria involving the frontal lobe. There is a posterior fossa cyst

[14]. The imaging characteristics of BFPP resemble those of the cobblestone malformative spectrum (muscle-eye-brain disease and Fukuyama congenital muscular dystrophy) [2].

Mutations of the *TUBB2B* gene have been associated with asymmetric polymicrogyria [15] but genotype-phenotype correlations need to be clarified. Recently, different types of PMG as part of complex syndromes have been associated with pathogenic CNVs (Table 133.1) [16].

Aicardi syndrome is seen exclusively in females, with the exception of two reported males with two X-chromosomes. It is thought to be caused by an X-linked gene with lethality in the hemizygous male. However, the genetic basis is still unknown. Clinical features include severe mental retardation, infantile spasms and chorioretinal lacunae. Neuropathological findings are consistent with a neuronal migration disorder and include diffuse unlayered polymicrogyria with fused molecular layers, agenesis of the corpus callosum and nodular heterotopias in the periventricular or subcortical region. Microgyri are packed and usually not visible at MRI (Fig. 133.4).

Regrettably, while several causal genes for polymicrogyria have now been discovered, they only account for a small minority of cases and clinical testing is available for only a few. Genetic analysis and counselling in polymicrogyria is still problematic, considering anatomic and etiologic heterogeneity.

Congenital Malformations of the Brain: Prenatal Diagnosis, Spectrum and Causes

Elie Saliba and Christian Paillet

Defective nervous system development results in a diverse group of diseases, ranging from major malformations that are incompatible with postnatal life to moderate or severe disabilities (Table 134.1). The following pages review the main categories of central nervous system (CNS) malformations. A detailed description of the clinical and neuropathological aspects of these defects is beyond the scope of the present chapter.

Table 134.1 Cerebral development and major disorders

Developmental stage	Disorders
Primary neurulation (3–4 weeks' gestation)	Neural tube defects
Prosencephalic development (23 months' gestation)	Holoprosencephaly Agenesis of the corpus callosum
Neuronal proliferation (34 months' gestation)	Microcephaly
Neuronal migration (35 months' gestation)	Lissencephaly Polymicrogyria Schizencephaly Other migration disorders
Myelination (mainly after birth)	White matter hypoplasia

134.1 Prenatal Diagnosis

Suspicion of a congenital malformation may arise on clinical grounds or because of an abnormal result from a routine prenatal investigation. A pregnancy may be at high risk of abnormality because of a particular family history, the advanced age of the mother or some acquired etiologies (Table 134.2). Higher-risk groups for chromosome abnormalities include older mothers, those with a previous chromosomally abnormal child, and when one parent is a translocation carrier. Usually, these women are offered chorion villus sampling or amniocentesis. Ultrasonography is the method of choice for prenatal scanning of fetal anomalies. High-frequency ultrasonography allows visualization of the normal and abnormal development of the embryo or fetus. However, there remain circumstances in which ultrasound data obtained are limited or technically difficult, for example in oligohydramnios and unfavorable position of the fetus. Moreover, some subtle parenchymal abnormalities cannot be seen on ultrasound. Magnetic resonance imaging (MRI) may be a useful adjuvant when ultrasound is indeterminate. MRI is especially useful in cases in which fetal ventriculomegaly is associated with other CNS malformations. Other anomalies such as

Table 134.2 Example of acquired etiologies of human nervous malformations; neural tube defects (NTD); intrauterine growth restriction (IUGR)

Agent	Most common congenital anomalies
Drugs	
– Alcohol	Neuronal migration disorders; Fetal alcohol syndrome; IUGR; facial anomalies
– Cocaine	Microcephaly; IUGR
– Isotretinoin (Accutane)	NTD; craniofacial malformations
– Methotrexate	Hydrocephalus; myelomeningocele; skeletal anomalies
– Phenytoin (Dilantin)	Microcephaly; cleft lip/palate; facial anomalies
– Valproic acid	NTD; facial anomalies
Infectious agents	
– Cytomegalovirus	Microcephaly; hydrocephalus; brain calcifications
– Herpes virus type 1 and 2	Hydranencephaly
– Human immune-deficiency virus	Microcephaly; IUGR
– Rubella virus	Microcephaly; IUGR; heart abnormalities
– *Toxoplasmosa gondi*	Microcephaly; ventriculomegaly; brain calcifications
– Varicella virus	Hydrocephalus

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

lissencephaly and schizencephaly, and also more subtle parenchymal migration disorders such as heterotopia and polymicrogyria have been visualized with MRI.

134.2 Holoprosencephaly: Spectrum and Causes

Subdivision of the early embryonic forebrain to form the bilateral telencephalic vesicles, the precursors of the cerebral hemispheres, is defective in holoprosencephaly. At its most severe, the forebrain is completely undivided (alobar holoprosencephaly) leading to a monoventricle and non-separation of the thalami. Non-separation of these structures declines in less severe forms (e.g., semi-lobar holoprosencephaly). Holoprosencephaly is usually associated with craniofacial malformations such as brachycephaly, microcephaly and abnormal facial development (Table 134.3). In the most severe form, holoprosencephaly may be accompanied by failure of separation of the optic vesicles and eye primordia, yielding the birth defect cyclopia. In less severe forms, the most noticeable abnormalities are often a reduction of midline craniofacial features, with close-set eyes (hypotelorism) or a single central incisor tooth. The detection rate by routine fetal anomaly scan is high for both the lobar and semilobar forms of holoprosencephaly, even in the first trimester [1]. Several chromosomal regions have been linked to holoprosencephaly. The genetic basis of most of the chromosomal linkages in holoprosencephaly has now been elucidated. Several of the causative genes are transcription factors, (*ZIC2*, *SIX3* and *TGIF*) [2]. These genes are known to be expressed in the embryonic brain.

134.3 Neural Tube Defects

Failure of neural tube closure results in malformations termed neural tube defects (NTD). In craniorachischisis, the most severe type of NTD, the neural tube fails to close along most of the body axis, although the forebrain usually closes normally. If the neural tube fails to close specifically in future brain, exencephaly results, which is concerted to anencephaly owing to neurodegeneration in later gestation. In contrast, if the low spine is primarily affected, this leads to open spina bifida. Related to these open CNS defects are a series of closed defects in which the neural tube and/or meninges herniate through an opening in the skull or in the neural arches of the vertebral column. Brain herniation yields a defect called encephalocele, while herniation of the spinal cord is termed meningocele. A further category of neural tube defect are so-called occult spina bifida, which mainly affect the low spinal region and are skin-covered lesions in which the spinal cord may be split or tethered to the surrounding tissues, often in association with a bony spur or a fatty mass (lipoma). While covered lesions are protected from the potentially toxic amniotic environment, open neural tube defect lesions undergo erosion of the exposed neuroepithelium so that, by the late stages of gestation, the region of affected nervous system is largely degenerate, leading to severe disability or death after birth. Surgery of the human fetus during pregnancy, with the aim of covering the neural tube defect lesion with muscle and skin, has shown that this process of degeneration can be halted [3], minimizing damage to the exposed CNS but not recovering function.

Neural tube defects (NTD) are not only very heterogeneous in morphology but also in etiology [4]. Causes include chromosome abnormalities, single mutant genes, teratogens, maternal predisposing factors and multifactorial inheritance. The high recurrence in siblings and in close relatives of individual with NTD suggests a strong genetic basis, although there is a marked lack of large families with NTD, arguing against causation based on single genes. It has been suggested, therefore, that NTD have a multifactorial causation, with many variants interacting to determine individual risk of NTD, and with a marked contribution of environmental factors, both exacerbating and preventive. Despite the many genetic loci that have been implicated in mouse NTD, few human genes have so far been definitively shown to predispose to human NTD. The best known of these is the gene encoding 5, 10-methylene tetrahydrofolate reductase (MTHFR), an enzyme of folic acid metabolism. A polymorphic, variant of the MTHFR gene (the C677T variant) exhibits a higher frequency among NTD cases and their families than among normal controls in several populations and seems responsible for imparting an increased risk of NTDs, especially in combination with a low folate and/or vitamin B12 level during pregnancy [5].

Many environmental factors have been suggested to play a role in NTD etiology. [4]. Nutritional deficiency, maternal diabetes and the use of certain therapeutic drugs such as anticonvulsants and insulin are known risk factors. Periconceptional supplementation of folic acid lowers the occurrence and recurrence risks of human NTD. The mechanisms involved in NTD due to a lower maternal folate status may be defective folic acid mechanism in the mother [7]. A list of recognized cause of NTD in human is presented Table 134.4.

Table 134.3 Facial defects in holoprosencephaly

Cyclopia	Single eye or single orbit Arrhinia with proboscis
Ethmocephaly	Extreme hypotelorism Arrhinia with proboscis
Cebocephaly	Orbital hypotelorism Proboscis-like nose, no cleft
Median cleft	Orbital hypotelorism Flat nose
Agnathia-astomia	Hypoplasia or absence of the mandible Small or absent mouth Abnormal position of the ears

Table 134.4 Examples of recognized cause of NTD in human

Causes	Examples
Chromosome abnormalities	Trisomy 13 Trisomy 18 Various unbalanced chromosome rearrangements, ring chromosomes, triploidy
Single mutant genes: autosomal recessive	Walker-Warburg syndrome Jarco-Levin syndrome Meckel-Gruber syndrome Robert syndrome
Teratogens	Valproic acid Carbamazapine (possible) Hyperthermia (possible)
Maternal predisposing factors	Diabetes mellitus: anencephaly more frequent than spina bifida

134.3.1 Prenatal Diagnosis

NTD can be detected by ultrasound and by analysing the α-fetoprotein level in amniotic fluid or maternal serum. Increased levels of α-fetoprotein are also found in other fetal anomalies such as gastroschisis, esophageal and intestinal atresia, in sacrococcygeal teratoma and in Turner syndrome, but decreased levels are found in trisomies 21 and 18. Moreover, the α-fetoprotein method has a high false-positive rate and a relatively poor sensitivity. Ultrasound is the main method for detection of NTD. Prenatal diagnosis of a myelomeningocele is usually prompted by the recognition of the associated Chiari II malformation. The most efficient sonographic findings, indicating a Chiari II malformation, are the diagnostic "lemon" and "banana" signs (Fig. 134.1) [8]. The lemon sign of the head has become the diagnostic key for detecting spina bifida in the second trimester. The banana sign represents the cerebellum surrounding stem in a small posterior fossa. The lemon sign is transient and usually not present anymore by the end of the second trimester. It represents an abnormal cranial vault that is narrowed rostrally, and results from low pressure in the ventricular cavity due to loss of CSF through the open NTD to the amniotic cavity. With the introduction of transvaginal ultrasound, detailed diagnosis became possible in the early fetal period and even around the end of the embryonic period [9].

134.4 Developmental Disorders of the Cerebellum

Anatomically, cerebellar malformations may be classified into unilateral and bilateral abnormalities. Unilateral cerebellar malformations are most likely due to acquired insults, such as intracerebellar bleeding associated with prematurity. Depending on the part of the cerebellum involved, bilateral cerebellar malformations may be further classified into midline or vermis malformations, and malformations affecting both the vermis and the cerebellar hemispheres [10]. The combination of pontine hypoplasia with cerebellar malformation is considered as a separate group, i.e., the pontocerebellar hypoplasia.

134.4.1 Midline or Vermis Malformations

Agenesis or hypoplasia of the vermis may be found in a large number of malformations of the brain [11], including the Dandy-Walker malformation and syndromes with agenesis of

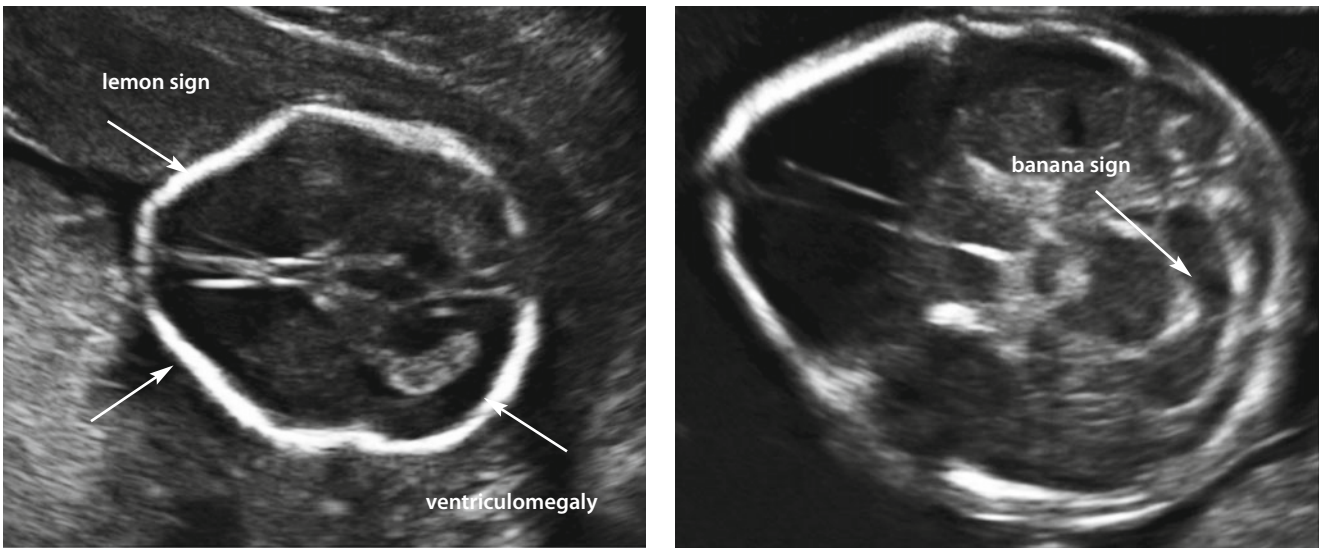

Fig. 134.1 The cranial signs ("lemon" and "banana") associated with open spina bifida

the vermis as a constant feature, such as the Joubert syndrome and Walker-Warburg syndrome, and a large group of syndromes in which absence of the vermis may occur, such as Meckel-Gruber and Smith-Lemli-Opitz syndromes.

The Dandy-Walker malformation is characterized by the following triad: cystic dilatation of the fourth ventricle and an enlarged posterior fossa; varying degrees of vermian aplasia or hypoplasia; and hydrocephalus (Fig. 134.2). Hydrocephalus, associated with a bulging occiput, is unusual at birth but is present by 3 months of age in about 75% of patients [12, 13]. Mental retardation and seizures have been reported in up to 50% of cases with a Dandy-Walker malformation [14]. Associated CNS malformations are present in up to 68% of the cases, the most common of which is agenesis or hypogenesis of the corpus callosum. Other CNS malformations include neuronal heterotopias, polymicrogyria, schizencephaly, occipital encephaloceles and lumbosacral meningoceles [12].

Most cases of Dandy-Walker malformation are sporadic. The etiology remains unknown. Distinguishing inheritable syndromes from isolated cases of vermian-cerebellar hypoplasia is important for genetic counseling. Bordarier and Aicardi classified the genetically heritable syndromes with complex vermian-cerebellar hypoplasia into two groups: 1) those in which vermis aplasia is a constant feature, the most common entities being Joubert syndrome, Walker-Warburg syndrome and related cerebro-oculomuscular syndromes; and 2) those in which vermis aplasia is an occasional component, such as Meckel-Gruber syndrome, Coffin-Siris syndrome, Smith-Lemli-Opitz syndrome and Ellis-van Crevel syndrome, all autosomal recessive traits [12]. Dandy-Walker syndrome has recently been shown to be related in some cases to genetic disorders of two members of the *ZIC* gene family, which encode zinc finger transcription factors [15].

Joubert syndrome is a relatively rare, autosomal recessive disorder defined by vermis hypoplasia, hypotonia, developmental delay and at least one of two additional manifestations: abnormal breathing pattern (hyperpnea intermixed with central apnea in the neonatal period) or abnormal eye movements [16]. In Joubert syndrome, ataxia, mental retardation and behavioral disorders become manifest in late infancy and childhood [11]. The prognosis of Joubert syndrome is poor; a causative gene was recently identified [17].

134.4.2 Cerebellar Hypoplasia

In cerebellar hypoplasia, the cerebellum does not reach its normal size. Global cerebellar hypoplasia may result from a variety of exogenous or endogenous factors. It is found as a result of intrauterine exposure to drugs (e.g., phenytoin) or irradiation, and as an autosomal recessive trait in a variety of chromosomal disorders such as trisomies 13, 18 and 21 [19]. Cerebellar hypoplasia may also be found in various complex malformations involving the brain and other systems. Primary degeneration of the granular layer of the cerebellum or granular layer aplasia (GLA) occurs as an autosomal regressive disorder [20]. Patients with features consistent with GLA have been found to have elevated levels of serum asialotransferrin and heterozygous deficiency of phosphomannomutase type 2 (PMM2). This deficit is involved in the congenital disorders of glycosylation (CDGs) [21].

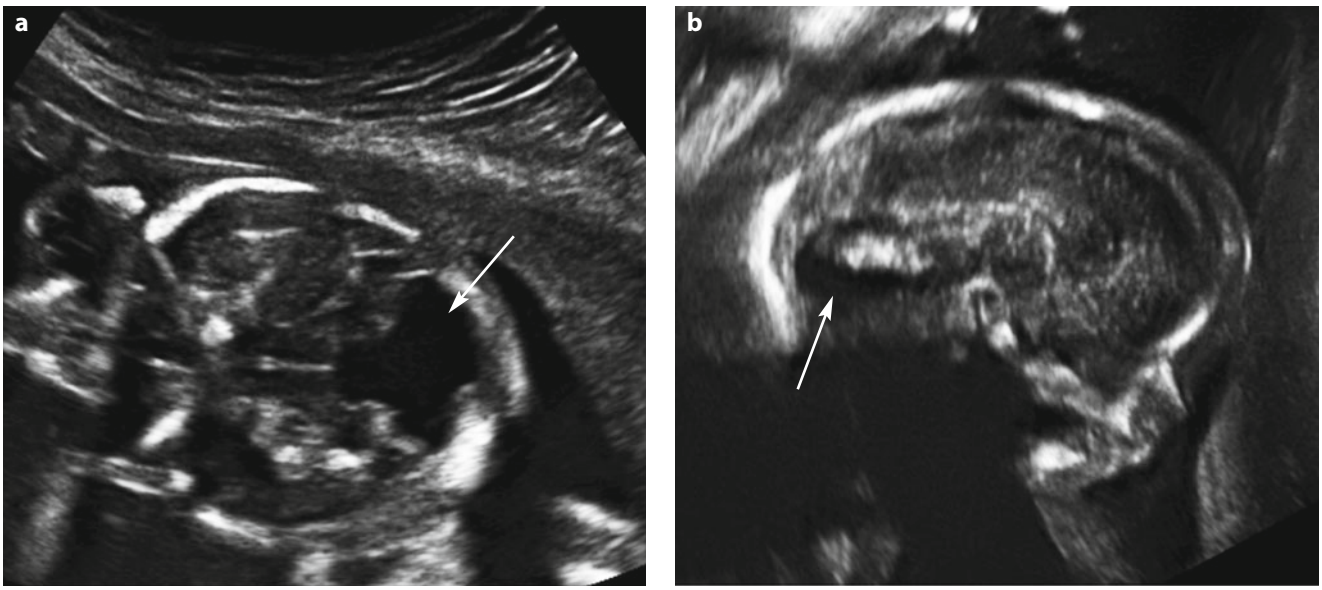

Fig. 134.2 Dandy-Walker malformation: **a** axial plane demonstrating a large cisterna communicating with the area of the fourth ventricle (*white arrow*); **b** sagittal view demonstratin a large cisterna magna

134.4.3 Pontocerebellar Hypoplasia

The pontocerebellar hypoplasias form a large group of disorders characterized by a smaller volume of the pons and varying degrees of cerebellar hypoplasia up to near-total absence of the cerebellum. Most types of pontocerebellar hypoplasia arise in the fetal period, suggesting a rhombic lip defect and the *MATH1* gene as candidate for this disorder. Most pontocerebellar hypoplasias are autosomal recessive disorders [22].

134.5 Neuronal Migration Disorders

Neuronal migration consists of nerve cells moving from their original site in the ventricular and subventricular zones to their final location. Regulation of timing and direction of these simultaneous migrations is carried out with extreme precision. Neurons originating in the cortical ventricular zone migrate radially to form the cortical plate and mainly become projection neurons [23]. Migration of neocortical neurons occurs mostly between the fifth gestational week, when the telencephalic vesicle appears, and 22 weeks of gestation in the human [24]. The neurons that migrate first will stop in the deepest cortical layers, those which migrate afterwards pass through the layers formed previously to form the outer cortical layers, according to a migration scheme defined as "inside-out". Neocortical migration neurons can adopt different types of trajectories: a large proportion of neurons migrate radially along radial glial guides, from the germinative zone to the cortical plate. Another important group of neurons adopt a tangential trajectory at the level of the ventricular or subventricular germinative zones before adopting a classic radial migrating pathway along glial guides. Tangentially migrating neurons have also been located at intermediate zone level (prospective white matter). Three large classes of genes underlie the vast majority of neuronal migration disorders that are seen clinically: 1) those involving the formation of the extracellular environment encountered by migrating neurons and axons; 2) those encoding for intracellular signaling mechanisms; and 3) those encoding the intracellular system that mediates cellular and axonal physical movements [25]. Another group of genes is involved in encoding for the enzymatic regulator of glycosylation, which, in turn, seems to provide stop signs for migrating neurons [26]. A list of genes implicated in neuronal migration disorders is presented in Table 134.5.

The neuronal migration disorders are a heterogeneous group of congenital brain defects. They are perhaps the most common form of CNS malformations. They include lissencephaly, heterotopia, focal cortical dysgenesis, polymicrogyria and schizencephaly.

134.5.1 Lissencephaly

Lissencephaly (LIS), which literally means smooth brain, consists of a set of rare brain disorders characterized by the lack of normal cortical convolutions. The severity ranges from absence (agyria) to reduction (pachygyria) of normal gyral pattern. On the basis of etiologies and associated malformations, five groups of lissencephaly can be identified: classical lissencephaly, cobblestone lissencephaly, X linked lissencephaly with agenesis of the corpus callosum, lissencephaly with cerebellar hypoplasia, microlissencephaly [27]. The onset of lissencephaly is considered to occur no later than the 12th–16th week of gestation [28].

The various clinical subtypes of lissencephaly have different risks of recurrence in siblings. Isolated lissencephaly is causally heterogeneous. The recurrence risk is 5–7% [28]. The recurrence for Miller-Dieker syndrome depends on results of chromosome and DNA analysis; it is not inherited as an autosomal-recessive trait. The recurrence risk is 25% for isolated lissencephaly with neonatal death, Norman-Roberts syndrome, Fukuyama congenital muscular dystrophy and Walker-Warburg syndrome. The recurrence risk for unusual lissencephaly such as lissencephaly with cerebellar hypoplasia

Table 134.5 Genes implicated in neuronal migration disorders

Neuronal migration disorder	Gene	Gene function	Location
Lissencephaly (Miller-Dieker and isolated lissencephaly sequence)	*LIS1*	Microtubule activating protein	17p13.3
X-linked lissencephaly	*DCX* (double-cortin)	Microtubule stabilizing protein	Xq22.3-q23
X-linked lissencephaly with ambiguous genitalia	*ARX*	Homeobox transcription factor	Xp22.13
Autosomal recessive lissencephaly	*RELN* (Reelin)	Extracellular matrix signaling protein	7q22
Cobblestone (Type 2) lissencephaly (Fukuyama muscular dystrophy)	*FCMD* (fukutin)		
Cobblestone (Type 2) lissencephaly (Walker-Warburg syndrome)	*POMT1*	α-Mannosyl transferase enzyme	9q34.1
Nodular periventricular heterotopia	*FLNA* (Filamin –A)	Actin binding protein	Xq28

or microcephaly may be as high as 25%. The recurrence risk is 50% for brothers of males having X-linked lissencephaly with microcephaly. Genetic counseling is always indicated for families with children with lissencephaly [28].

134.5.2 Neuronal Heterotopia

Neuronal heterotopia is a neuronal migration disorder characterized by a cluster of disorganized neurons in abnormal locations and it includes three main groups: periventricular nodular heterotopia (PNH), subcortical heterotopia (SBH) and marginal glioneural heterotopia. A classification of neuronal heterotopia is presented Table 134.6 [29].

Periventricular nodular heterotopia (PNH) is a rare malformation in which group of neurons are abnormally positioned close to the ventricular cavities. PNH can be caused by genetic mutations or extrinsic factors such as infections or prenatal injuries [30]. X-linked periventricular heterotopia results from mutation in the gene encoding Filamin-A (FLNA), an actin-cross-linking phosphoprotein that interacts with Filamin-B and Filamin-A-interacting protein (FILIP) to regulate the actin reorganization necessary for neuronal migration [31]. When the function of this protein complex is disturbed, neuroblasts are unable to initiate migration. Mutation of the FLNA gene (Xq28) causes bilateral PNH (OMIM # 300049) in the majority of patients; this form is often fatal for males, therefore explaining the female preponderance. The autosomal recessive form of PNH (OMIM # 608097) is caused by mutation in the *ARFGEF2* gene localized at 20q13.13, which encodes for the protein brefeldin-inhibited GEF2 (BIG2).

PNH has also been associated with chromosomopathies such as duplication of chromosome 5 (OMIM # 608098) and deletion on chromosome 6 or 7 [32].

MRI in patients with X-linked dominant mutation shows bilateral symmetric nodules adjacent to the lateral ventricular walls. Unilateral PNH is commonly located in the posterior paratrigonal zone of the lateral ventricles.

Table 134.6 Classification of heterotopia from Barkovich [29]

1. *Periventricular heterotopia*
   a. Periventricular nodular heterotopia (PNH)
      i. Bilateral PNH with FLN1 mutations
      ii. PNH with mutations of chromosome 5
      iii. PNH with bilateral polymicrogyria-perisylvian and posterior subtypes
   b. Periventricular linear heterotopia (unilateral or bilateral)
2. *Subcortical heterotopia*
   a. Large subcortical heterotopia with cortical infolding, abnormal cortex, hypogenetic corpus callosum
   b. Pure subcortical heterotopia nodules
   c. Columnar heterotopia
   d. Excessive single neurons in white matter
3. *Marginal glioneuronal heterotopia*

SBH is caused by alterations in two genes: *LIS1* at 17p13.32 (32) and *DCX* at Xq22.3-q23.3. MRI of the brain in SBH demonstrates two parallel layers of gray matter, a thin outer ribbon and a thick inner band, separated by a very thin layer of white matter [30].

134.5.3 Polymicrogyria

Polymicrogyria (PMG) is a cortical malformation characterized by an irregular brain surface with an excessive number of small and partly fused gyri separated by shallow sulci.

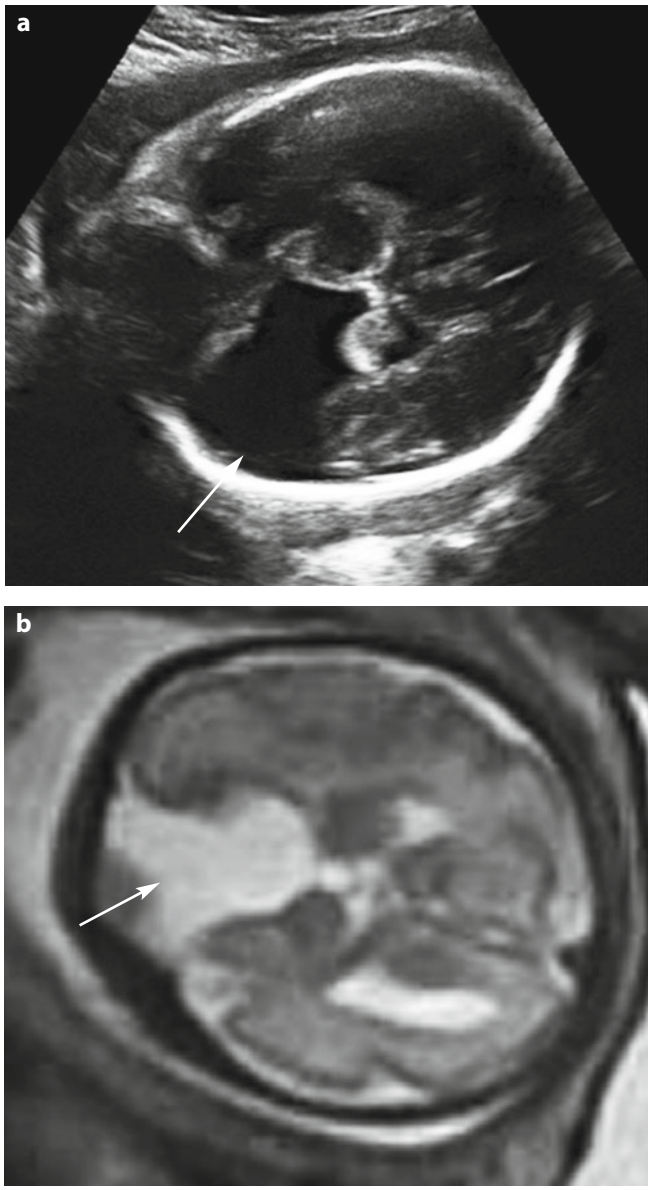

Fig. 134.3 Schizencephaly: **a** axial view (*arrow*); **b** magnetic resonance at 32 weeks (*arrow*)

PMG can be focal or diffused, unilateral or bilateral. It can be an isolated lesion or associated with other brain malformations such as heterotopia, white matter lesions or a part of several multiple congenital mental retardation syndromes [34]. Two types of polymicrogyria can be identified by histology: a simplified four layered form and an unlayered form [35]. PMG was found to be associated with congenital CMV infection, perinatal hypoxia-ischemia, twin-twin transfusion, loss of twin in utero or maternal drug ingestion [36]. PMG was found in association with genetic disorders such as Aicardi syndrome, Zellweger and Walker-Warburg syndromes or chromosomal abnormalities such as 22q11 deletion and trisomy 13.

134.5.4 Schizencephaly

Schizencephaly (SZC; OMIM # 269160) is a structural abnormality of the brain, characterized by congenital clefts spanning the cerebral hemisphere from the pial surface to the lateral ventricle and lined by cortical gray matter (Fig. 134.3) [37]. Cleft localization varies widely but perisylvian region is more often involved [38]. SCZ can be unilateral or bilateral. The etiology of this malformation is not well established and several causes including genetic, vascular, toxic, metabolic and infectious factors might be involved. Exposure in utero to toxins and CMV infections has been incriminated [37, 39, 40].

134.6 Disorders of CNS Cell Number: Microcephaly

Human microcephaly comprises a heterogeneous group of conditions that are characterized by a failure of normal brain growth. Microcephaly is usually defined as a condition in which the size of the head, measured by the occipitofrontal circumference (OFC), is greater than two standard deviations below the mean for gestational age and gender. The etiology of microcephaly can be broadly divided into environmental and genetic cause [41]. Common environmental causes are congenital infections such as cvytomegalovirus (CMV), intrauterine exposure to teratogenic agents, and hypoxic-ischemic injury in the fetal period (Fig. 134.4). The genetic causes of congenital microcephaly can be further subdivided, based on the presence of normal versus abnormal brain architecture as found on MRI examination, and its combination with non-CNS abnormalities. Microcephaly is a characteristic feature in holoprosencephaly and lissencephaly. Decreased neuronal proliferation may lead to microcephaly with a normal to thin cortex (primary microcephaly or microcephaly vera, and extreme forms of microcephaly with a simplified gyral pattern), microlissencephaly (extreme microcephaly with thick cortex) and microcephaly with polymicrogyria or other cortical dysplasias.

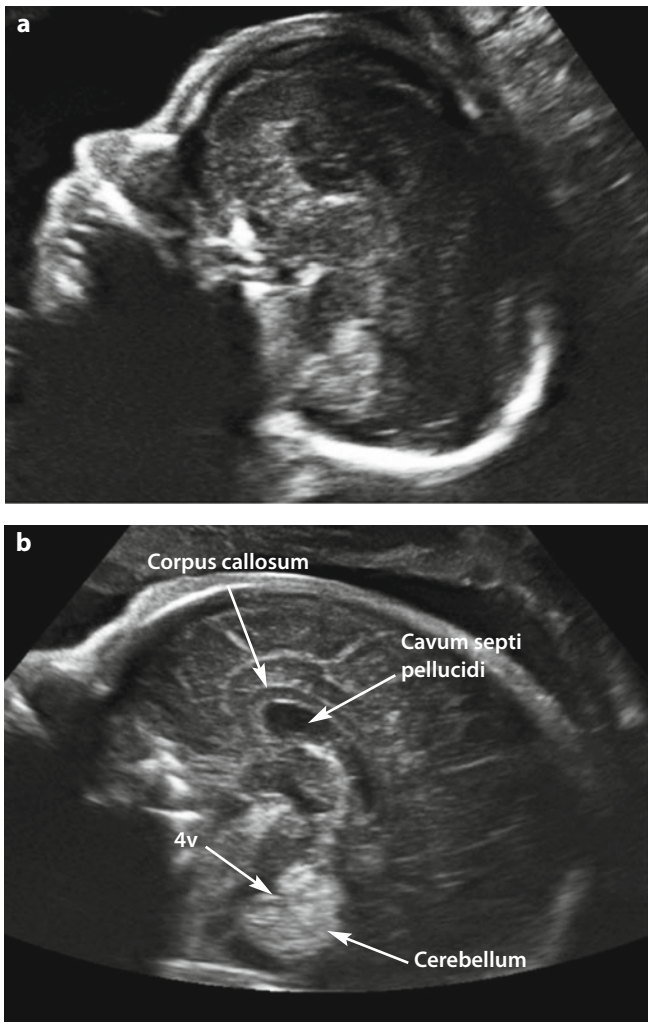

Fig. 134.4 Sagittal planes at 32 weeks: **a** complete agenesis of the corpus callosum; **b** normal sagittal plane

Investigation of patients with microcephaly includes evaluation for prenatal exposure to teratogens, especially alcohol, drugs and isotretinoin (a vitamin A analog), and assessment of the family history, birth history and associated dysmorphic conditions. Laboratory studies should include toxoplasmosis, rubella virus, CMV and herpes simplex; evaluation of maternal metabolic disorders; and chromosome analysis (Table 134.7)

Table 134.7 Assessment of a newborn with microcephaly

Family history	Parental consanguinity, family history, antenatal exposure to teratogens including alcohol
Parents' examination	Parental OFC
Child examination	Dysmorphic features
Special investigations	Chromosome analysis, congenital infection screening, metabolic screening, eye examination, brain MRI

134.7 Disorders of Cortical Connectivity: Malformations of the Corpus Callosum

Malformation of the corpus callosum, the large white matter tract that connects the cerebral hemispheres, is a common congenital anomaly [42]. If normal development of the corpus callosum is disturbed, it may be completely absent (agenetic), partially formed (hypogenetic), formed in a defective way (dysgenetic) or contain too few axons (hypoplastic).

Agenesis of the corpus callosum (ACC) occurs in about one to three per 1000 births, is usually sporadic, and may be transmitted as a sex-linked, autosomal-dominant, or autosomal-recessive trait [43]. Prenatal diagnosis of ACC can be established by 20 weeks' gestation with ultrasonography (Fig. 134.5). In about half of the reported fetal US studies, ACC is an isolated finding; in the remaining studies, other abnormalities or findings suggestive of specific syndromes are found. Male fetuses are more likely to have isolated agenesis that is considered benign. The etiology of ACC has been associated with numerous syndromes (Aicardi syndrome) and several inborn error of metabolism, including non-ketonic hyperglycinemia and fetal alcohol syndrome. ACC may be observed in various malformations of cortical development, including the lissencephalies, polymicrogyria and schizencephaly. Chromosomal disorders, particularly trisomies 8, 13 and 18 are also associated with ACC [44, 45]. Clinically, the extent and nature of neurologic compromise result from the congenital absence of the corpus callosum and the associated brain abnormalities.

134.8 Intracranial Arachnoid Cysts

Intracranial arachnoid cysts are benign, non-genetic developmental cysts that contain spinal fluid and occur within the arachnoid membrane [46]. The walls of the cyst result from splitting of the arachnoid membrane. There is no epithelium lining the cystic place and the fluid it contains is translucent. The cysts occur in proximity to arachnoid cisterns, most often in the sylvian fissure. Arachnoid cysts occur most often in males and in patients with Marfan syndrome and there are few reports of familial middle and posterior fossa arachnoid cysts. The mechanism of formation during embryogenesis is uncertain. Macrocephaly is the major presenting symptom and associated features include the following: cranial asymmetry, aqueductal stenosis and agenesis of the corpus callosum [46].

134.9 Hydrocephalus and Ventriculomegaly

Hydrocephalus signifies dilated lateral ventricles resulting from an increased amount of CSF inside the ventricles and increased intracranial pressure, while ventriculomegaly is a dilatation of lateral ventricles without increased intracranial

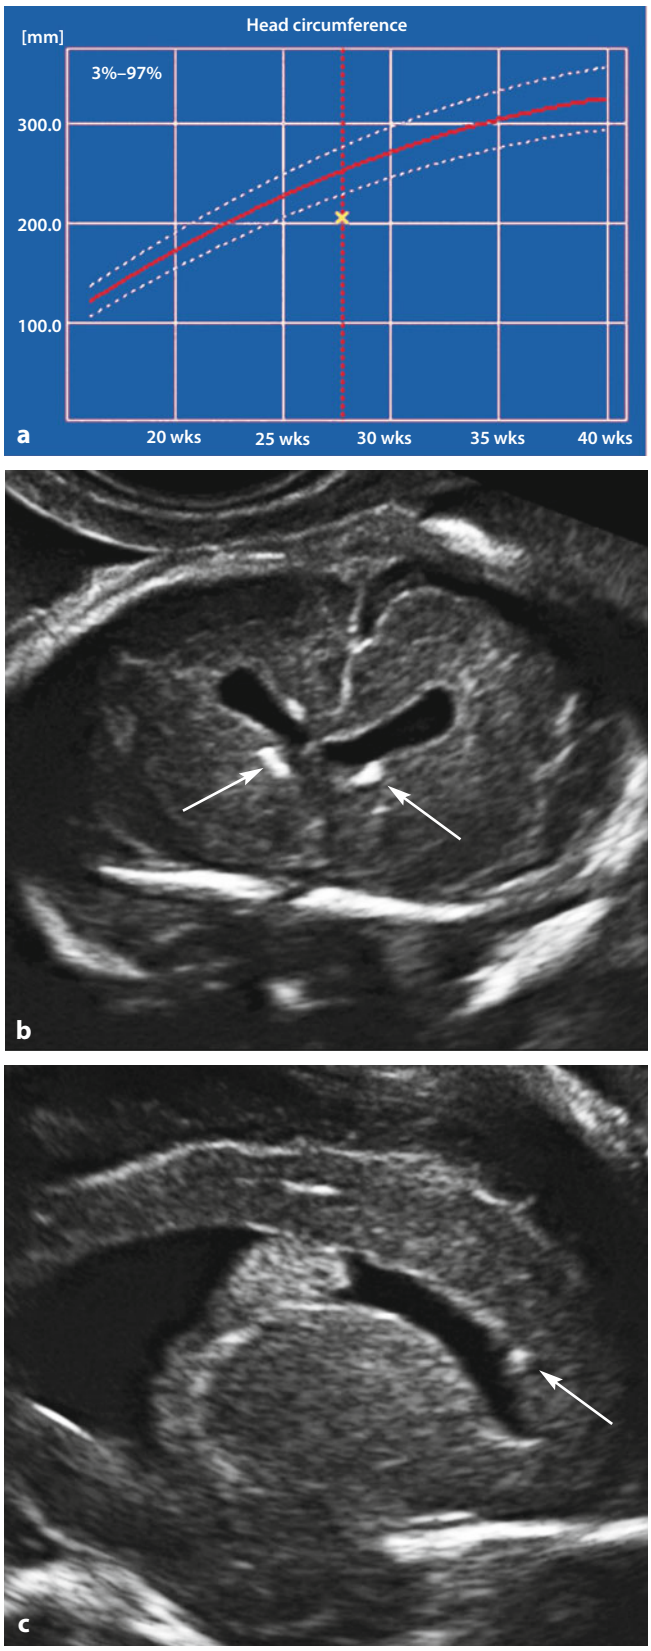

Fig. 134.5 Microcephaly in a 28 weeks' fetus with CMV infection. **a** head circumference: 203 mm (-2SD); **b** coronal view showing mild ventriculomegaly and calcifications (*white arrows*); **c** parasagittal view showing calcification

pressure, due to cerebral hypoplasia or CNS anomaly such as agenesis of the corpus callosum [47]. Ventriculomegaly is defined as an enlargement of the lateral cerebral ventricles. It can be regarded as a non-specific marker of abnormal brain development and is encountered with many different cerebral anomalies. Evaluation of the integrity of the cerebral lateral ventricles is therefore of particular importance while screening for fetal cerebral anomalies. Although many different approaches to the evaluation of the integrity of lateral ventricles have been proposed, measurement of the internal width of the atrium of the lateral ventricle at the level of the glomus of the choroid plexus is currently favored [48–50]. Under normal conditions, the measurement is less than 10 mm, while a value of more than 15 mm indicates severe ventriculomegaly, which is almost always associated with an intracranial malformation at birth. The outcome of these fetuses is variable and depends largely upon the underlying etiology of the ventricular dilatation. The available studies suggest that fetuses with isolated severe ventriculomegaly have an increased risk of perinatal death and a probability of severe neurologic sequelae in the range of 50% of survivors [51]. An intermediate value for the atrial width, 10–15 mm, is commonly referred as to as mild ventriculomegaly and is associated with a much increased probability of cerebral and extracerebral malformations, aneuploidies and infections and therefore should be carefully evaluated in an expert center. Fetuses with isolated mild ventriculomegaly usually have a good outcome and, in most infants, the ventricles return to normal size during pregnancy. However, these infants also run an increased risk of neurologic compromise and, in some cases, develop severe cerebral anomalies in the last of the gestation or after birth, including hydrocephalus, white matter injury and cortical plate abnormalities [52]. The risk is particularly increased when the atria width is greater than 12 mm, when the dilatation affects both ventricles and in females [53]. It has been suggested that the term mild ventriculomegaly should be limited only to cases with atrial measurements of 10–12 mm, while values of 12.1–15 mm should be referred to as moderate ventriculomegaly, as they tend to have, in general, a worse outcome [54–56].

Congenital hydrocephalus is classified into three categories by causes that disturb the CSF circulation pathway: simple hydrocephalus, dysgenetic hydrocephalus and secondary hydrocephalus.

- Simple hydrocephalus caused by developmental abnormality which is localized within the CSF circulation pathway includes aqueductal stenosis, atresia of foramen Monro and maldevelopment of arachnoid granulation.
- Dysgenetic hydrocephalus indicates hydrocephalus as a result of cerebral development disorder and includes hydranencephaly, holoprosencephaly, porencephaly, schizencephaly, Dandy-Walker malformation, dysraphism, and Chiari malformation.
- Secondary hydrocephalus is caused by an intracranial pathology such as: brain tumor, intracranial infection and intracranial hemorrhage.

Genetic hydrocephalus is rare but it is important in counseling couples on subsequent pregnancies. It is now well recognized that a small proportion of all cases of hydrocephalus show X-linked inheritance. Most of these X-linked cases are known to be caused by mutations in the *L1CAM* gene which is located at Xq28 [55]. The *L1CAM* gene encodes a neuronal cell adhesion molecule, known as L1, which is involved in neuronal migration and axonal extension. Mutation in *L1CAM* can result in several different phenotypes such as X-linked hydrocephalus, hydrocephalus due to stenosis of the aqueduct of Sylvius, the MASA syndrome (mental retardation-aphasia, shuffling gait, adducted thumbs), X-linked complicated spastic paresis and X-linked corpus callosum agenesis.

134.10 Conclusions

Congenital brain malformations are a significant cause of morbidity and mortality. In recent years, significant advances in basic neuroscience research have improved our understanding of the molecular and genetic underpinnings of brain development. Continued advances in genomics research will move us toward an even better understanding of these developmental, processes, with the hope of one day being able to provide parents and clinicians with the information they so desperately need to make informed decisions.

Biochemical Basis of Hypoxic-Ischemic Encephalopathy

Maria Delivoria-Papadopoulos and Endla Anday

135.1 Introduction

Perinatal hypoxia ischemia is the most common cause of neurologic disease during the neonatal period. Hypoxic ischemic encephalopathy (HIE), is associated with a high mortality and morbidity rate, including cerebral palsy, mental retardation, and seizures [1]. The incidence of perinatal asphyxia is about 1.0–1.5% in most centers and is usually related to gestational age and birth weight. It occurs in 9.0% of infants less than 36 weeks' gestation and in 0.5% of infants more than 36 weeks' gestation [2, 3]. The etiology of perinatal HIE includes those circumstances that can affect the cerebral blood flow in the fetus and newborn compromising the supply of oxygen to the brain. They may develop antepartum (20%), intrapartum (30%), antepartum and intrapartum (35%), or postpartum (10%) [4].

HIE develops in the setting of perinatal asphyxia, which is a multiorgan system disease [2]. Assessment and management of these complications is an integral part of the treatment of perinatal asphyxia/HIE [2]. The present chapter primarily focuses on cellular and molecular mechanisms of the hypoxic neuronal injury in the newborn brain.

A large amount of information has been collected on the fetal cardiovascular and respiratory response to oxygen limitations, giving rise to a better understanding and management of neonatal deterioration induced by hypoxia. Besides these physiologic studies, cellular and biochemical mechanisms that result in brain cell death are being increasingly explored, particularly in the adult with respect to focal (stroke) and global (cardiac arrest) hypoxia-ischemia [4]. These studies have shown that complex and interrelated biochemical alterations are triggered during hypoxia-ischemia in mature subjects that ultimately result in neuronal death. Studies are in progress to investigate mechanisms of hypoxic brain injury in the fetus and newborn brain [5]. To focus on cellular and molecular mechanisms of hypoxic injury in the developing brain, it is important to recognize the factors that may determine the susceptibility of the developing brain to neonatal and perinatal hypoxia.

The determinants of the susceptibility of the developing brain to hypoxia include the lipid composition of the brain cell membrane, the rate of lipid peroxidation, the presence of antioxidant defenses, the development and modulation of the excitatory neurotransmitter receptors such as the N-methyl-D-aspartate (NMDA) receptor, and the intracellular Ca^{++} influx mechanisms. In addition to the developmental status of these cellular components, the response of these potential mechanisms to hypoxia determines the fate of the hypoxic brain cell in the developing brain in the fetus and the newborn. Elucidating basic cellular mechanisms in response to hypoxia of the developing brain will enable the development of novel strategies for preventing or attenuating the deleterious effects of hypoxia in the human newborn. Several excellent reviews on different aspects of hypoxic/ischemic cell injury in the developing brain have been published recently [6, 7].

135.2 Steps of Posthypoxic Brain Injury

Acute or long-term consequences of hypoxic-ischemic encepholopathy are related either to necrosis or to apoptosis of neuronal cells. Necrosis is characterized by passive cell swelling, rapid energy loss, generalized disruption of internal homeostasis leading to eventual lysis of the nucleus, organelles and plasma cell membranes and the release of intracellular components that induce a local inflammatory response, resulting in edema and injury to the neighboring cells. This inflammatory response results in the expression of the cytokines interleukine-1-beta, (IL-beta) and tumor necrosis factor-alpha (TNF-alpha) stimulating oxygen free radicals release from neutrophils, activating microglical cells.

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

Necrosis is only one of the mechanisms of cell death following hypoxia or ischemia to the brain. Programmed cell death, or apoptosis, also appears to contribute to cell death following hypoxia-ischemia, especially cell death that occurs days to weeks following the insult [8, 9]. Apoptosis is an active process that requires the activation of a genetic program and specific endonucleolytic digestion of nuclear DNA. In contrast to necrosis, programmed cell death is characterized by cell shrinkage, coarse chromatin aggregation with extensive nuclear DNA fragmentation, nuclear pyknosis and extrusion of membrane-bound cytoplasmic fragments or apoptotic bodies, but is not associated with the lysis of the plasma membrane [10, 11].

Studies in cell culture models have demonstrated that hypoxia can trigger programmed cell death [12]. Programmed cell death as assessed by the cleavage of genomic DNA has also been shown to occur in the brain following focal [8, 13, 14] and global ischemia [9, 15].

The mechanism by which hypoxia causes DNA fragmentation has been extensively studied but is not well understood.

135.2.1 Energy Breakdown

Under normal conditions the oxidative phosphorylation and the synthesis of high energy phosphates like adenosine 5-phosphate or ATP need adequate oxygen supply. Under anaerobic conditions the metabolic cost of ATP production is critically increased leading to a breakdown of energy balance depleting the brain cells of high energy compounds, necessary for energy-dependent metabolic processes in neurons and glial cells.

135.2.2 Excitotoxic Mechanisms

The fall of ATP levels includes a cell membrane depolarization and a disruption of voltage dependent ion-channels allowing excessive amounts of Ca^{++} to enter the cytosol, initiating the release of glutamate consequently activating N-methyl-D-aspaptate (NMDA) receptors. The increased expression/activation of NMDA receptors further enhances cellular calcium influx. This whole mechanism is further accelerated by the dysfunction of the energy dependent reuptake of glutamate both in neurons and in astrocytes in a vicious circle manner.

135.3 NMDA Receptors

Glutamate is the major excitatory amino acid neurotransmitter that contributes to a number of developmental processes such as synaptogenesis, synaptic plasticity, long-term potentiation (LTP), learning and memory as well as neurodegeneration and hypoxia-induced injury [16, 17]. The physiological and pathological effects of glutamate in the central nervous system (CNS) are mediated through its interaction with specific cell membrane receptors, of which the N-methyl-D-aspartate (NMDA), kainate, and AMPA subtypes are the best characterized [18]. The use of specific antagonists [18–21] of the NMDA receptor support the role of receptor activation in long-term potentiation and hypoxic-ischemic cerebral injury. The NMDA-type glutamate receptor is a predominant mediator of excitotoxicity in the immature as compared to the adult brain due to overexpression of the receptor in the developing immature brain [22]. Within the developmental period however, the extent of NMDA receptor mediated processes such as LTP and hypoxia-induced excitotoxicity may depend on the ontogeny of the NMDA receptor sites and subunits leading to altered function of the ion-channel complex. In addition, the function of the receptor may be modified by intracellular mechanisms such as phosphorylation/dephosphorylation, nitration, and pathways of free radical generation.

135.3.1 Structure and Function of The NMDA Receptor

The activity of the NMDA receptor ion-channel complex is regulated by a number of pharmacologically distinct binding sites. The NMDA receptor possesses a neurotransmitter binding site, or recognition site, which binds glutamate or NMDA; a co-activator site which binds glycine; a channel site that binds MK-801 in its open state; a voltage-dependent Mg^{++} binding site; a polyamine site that binds spermine and spermidine; an ifenprodil site, and an inhibitory divalent cation site that binds Zn^{++} [18]. The activity of the receptor ion-channel can also be modified by redox agents [23, 24]. Ligand binding studies indicate that there are two distinct binding sites or states associated with the glutamate recognition site, one that preferentially binds agonists and one that preferentially binds anatognists [25].

The NMDA receptor is associated with a cation-selective ion-channel that gates Na^+, K^+, and Ca^{++} ions and, in the resting state, when blocked by Mg^{++} in a voltage-dependent manner [26, 27], the blockade of the ion-channel complex by glutamate or NMDA is allowed, and the agonist-dependent Ca^{++} influx occurs. The influx of Ca^{++} ions is thought to initiate biochemical processes responsible for both NMDA receptor-induced plasticity in the developing brain and NMDA receptor-mediated excitotoxic cell death [17, 28, 29].

Each of the regulatory sites of the NMDA receptor ion-channel complex is modified during brain development and may alter the site-dependent influx of NMDA receptor-mediated Ca^{++} and site-specific responses of the receptor during development and during hypoxia.

135.3.2 Mechanism of NMDA Receptor Modification During Hypoxia

Brain tissue hypoxia modifies the NMDA receptor recognition, co-activator, and the ion-channel sites. A decrease in the apparent number of NMDA receptors and an increase in receptor affinity for MK-801 were observed in hypoxic fetal guinea pig and newborn piglet brain [30, 31]. In these same studies, glutamate and glycine-dependent activation of the NMDA receptor was decreased and spermine-dependent and basal state receptor activation were increased during hypoxia. In brains of hypoxic newborn piglets, it was noted that hypoxia modified the recognition, co-activator, and modulatory sites of the NMDA receptor ion-channel complex, probably through NO-mediated nitration [31, 32]. Several lines of evidence support this conclusion.

First, in neurons of the central nervous system, neuronal nitric oxide synthase (nNOS) is colocalized with the NMDA receptor [33, 34], thereby favoring nitration of the receptor. Second, nNOS activity is decreased by phosphorylation and increased by dephosphorylation [35, 36], a condition that may be achieved during hypoxia.

Furthermore, dephosphorylation of the receptor will make tyrosine sites available for nitration by peroxynitrite, which is produced by NO and superoxide radicals, both of which are produced during hypoxia. Peroxynitrite-dependent nitration inhibits phosphorylation of proteins [37], indicating possible steric hindrance between the phospho-and nitro-groups on the same tyrosine residue. Thus, dephosphorylation during hypoxia may facilitate peroxynitrite-mediated nitration on the 3-position of tyrosine. In view of these considerations, a critical role of the nitric oxide synthase (NOS) pathway in NO mediated mechanism of hypoxia-induced modification of the NMDA receptor in newborn brain is strongly suggested.

In neurons of the central nervous system, nNOS is colocalized with NMDA receptors [33, 34]. In additions, neuronal NOS is activated by Ca^{++} influx through the NMDA receptor ion-channel, however, nNOS is not efficiently stimulated by activation of non-NMDA receptors that also induce Ca^{++} influx [38]. In synaptic plasma membranes, the nNOS immunoreactivity is associated with the NMDA receptor [39]. The synaptic localization of nNOS in the brain may be mediated by the postsynaptic density protein, PSD-95. Recently, it was demonstrated that nNOS, PSD-95, and NMDA receptor subunit NR2B from the brain coimmunoprecipitate and that the PSD-95 is sufficient to assemble a tight ternary complex with nNOS and the NR2B subunit of the NMDA receptor [40].

In summary, results of these studies indicate that NO production in the brain is preferentially activated by Ca^{++} influx through the NMDA receptor ion-channel and that there is a specific structural and functional link between the NMDA receptor and nNOS.

135.4 Free Radicals

Free radicals are molecular species with unpaired electrons in the outer orbit with a strong tendency to initiate chain reactions that result membrane peroxidation, protein oxidation, nucleic acid oxidation, and cell damage. Normally, more than 80% of the oxygen consumed by the cell is completely reduced by cytochrome oxidase to water without production of oxygen free radicals. The remaining 10–20% undergoes other oxidation reduction reactions in the cytoplasm and mitochondria that produce a superoxide anion radical.

135.4.1 Free Radical Generation in Cerebral Cortex of Newborn Piglets

The production of free radicals during hypoxia was documented by measuring the signal of spin adducts with electron spin resonance spectroscopy. Newborn piglets of 3–5 days were assigned to either normoxia (PaO_2 – 120 mmHg) or hypoxia (PaO_2 < 20 mmHg) for 1 hour. Cortical samples were obtained by biopsy from anesthetized, ventilated piglets.

The data provided direct evidence of increased free radical generation during hypoxia in the newborn model. On the basis of the characteristics of the spin adduct signal the free radical species present in the hypoxic tissue was identified to be an alkoxyl radical.

These studies demonstrate increased free radical generation during hypoxia in the cerebral cortex of the fetus and the newborn, and intervening with the inhibitors of pathways of free radical generation reduced the hypoxia-induced production of free radical species. Alkoxyl radical appears to be the predominant free radical species identified during hypoxia, indicating that free radical-mediated lipid peroxidation is an ongoing event during cerebral hypoxia, a mechanism of hypoxic neuronal injury.

135.4.2 Mechanisms of Free Radical Generation During Hypoxia

There are a number of potential mechanisms of free radical generation under hypoxic conditions. During hypoxia, the increased accumulation intracellular Ca^{++} due to excessive activation of NMDA [41] and non-NMDA receptors is crucial in hypoxia-induced excitotoxicity. Increased intracellular Ca^{++} can initiate a number of biochemical events that could lead to free radical generation and cell death such as: (1) activation of phospholipase A_2 leading to increased generation of oxygen-free radicals from cyclooxygenase and lipoxygenase pathways; (2) activation of NOS, leading to peroxynitrite formation and generation of free radicals; (3) activation of

proteases, leading to conversion of xanthine dehydrogenase to xanthine oxidase and resulting in increased free radical generation; (4) activation of phospholipase C_1 leading to IP3, formation and resulting in the release of Ca^{++} from intracellular stores; and (5) free radical generation further triggering the release of additional excitatory amino acids neurotransmitters as well as influencing the activation of the NMDA receptor ion-channel activity through the redox site.

In addition to Ca^{++} mediation, there are other potential mechanisms of free radical generation during hypoxia such as: (1) reduction of electron transport chain components including ubiquinone (a component that undergoes autooxidation to produce free radicals); (2) increased release of ferritin under the conditions of decreased cellular high energy compounds; and (3) increased degradation of ATP during hypoxia, increasing the substrate for the xanthine oxidase reaction and leading to increased free radical generation.

135.4.3 Nitric Oxide Free Radicals and Neuronal Injury

The role of nitric oxide (NO) in neuronal injury, both *in vitro* and *in vivo*, has been controversial [42, 43]. This controversy may be due to the use of nonspecific NOS inhibitors. Three major isoforms of NOS have been identified: constitutive neuronal, constitutive endothelial and inducible macrophage isoforms. Following ischemia, NO produced from neuronal NOS has toxic effects, but NO produced from endothelial NOS has protective effects in the brain [44].

Hypoxic brain injury is associated with the formation of NO, a gaseous free radical [45, 46]. Although under normal conditions NO physiologically mediates cerebral vasodilatation, [47] recent studies suggest that NO may react with superoxide anion to form peroxynitrite and cause neurotoxicity [48–51]. Furthermore, *Nw*-nitro-I-arginine (NNLA) a NOS inhibitor, administration in a middle cerebral artery occlusion model reduced the volume of cortical infarct in the mouse, indicating the role of NO in neurotoxicity [52].

Nitric oxide is reported to cause neuronal damage through various mechanisms. We tested the hypothesis that NO synthase inhibition by NNLA will result in decreased oxygen-derived free radical production, leading to the preservation of cell membrane structure and function during cerebral hypoxia [53]. Results demonstrated that free radicals, corresponding to alkoxyl radicals, were induced by hypoxia but were inhibited by pretreatment with NNLA before inducing hypoxia. NNLA also inhibited hypoxia-induced generation of conjugated dienes, products of lipid peroxidation. Na^+, K^+-ATPase activity, an index of cellular membrane function, decreased following hypoxia but was preserved by pretreatment with NNLA. This data demonstrated that during hypoxia NOS generates free radicals via peroxynitrite production, presumably causing lipid peroxidation and membrane dysfunction.

The appearance of primary free radicals, such as superoxide anion or hydroxyl radical, may not indicate oxidative injury. The reactivity of superoxide radicals is limited [54, 55] but hydroxyl radicals are highly reactive to almost all molecules [56] so that they can target even noncritical molecules. Therefore, their concentration does not necessarily correlate with the degree of oxidative damage, particularly when assessing lipid peroxidation. Furthermore, these radicals damage cells in cooperation with other radical species or oxidants [45–48]. In contrast, the production of secondarily formed lipid free radicals provides strong evidence of peroxidative injury. This is particularly true for alkoxyl radicals, which are generated from lipid peroxide by either iron or copper ions and can abstract hydrogen atoms from polyunsaturated fatty acids, leading to further lipid peroxidation [56]. Our results suggested that NO has an *in vivo* role in the generation of alkoxyl radicals, leading to free radical-mediated lipid peroxidation.

The exact molecular mechanism of hypoxic membrane damage is not clear. An appealing hypothesis is that when peroxynitrite (formed by the reaction between superoxide anions and NO) is protonated, it decomposes rapidly to form nitrogen dioxide and hydroxyl radicals, both of which are strong oxidants and can initiate oxidative reactions [45, 48, 57]. It has been shown that peroxynitrite can cause lipid peroxidation *in vitro* [57]. Therefore, high concentration of NO during may result in an increased production of peroxynitrite, causing lipid peroxidation.

135.5 Neuronal Nuclear Ca^{++} influx

A number of critical nuclear functions including regulation of transcription factors, cell cycle regulation transcription, DNA replication and nuclear envelope breakdown are controlled by intracellular Ca^{++} [56, 58]. Furthermore, nuclear Ca^{++} signals potentially control a number of events leading to hypoxia-induced programmed cell death. Nuclear and cytosolic Ca^{++} signals are differently regulated, and the extranuclear Ca^{++} concentration determines the mode of Ca^{++} entry into the nucleus.

The increased intracellular Ca^{++} is a primary mediator of activity-dependent gene transcription under a number of experimental conditions [59–61]. The patterns of neuronal impulse and the specific properties of the stimulus-induced calcium transients determine the nature and amplitude of the genomic response [60, 62]. Several factors including the site of calcium entry, the amplitude and the spatial properties of the calcium signals determine the calcium regulated gene expression [63–65]. Furthermore, the duration of calcium signal also contributes to the specificity of the transcription induction. In cells of the immune system only a continuous rise in intracellular Ca^{++} concentration, but not a brief spike, induced translocation of transcription factors, NF-ATc [66]. Gene expression in neurons is also determined by the duration of

calcium transients and the activity-dependent transcription is regulated by the duration of calcium transients [61].

In previous studies we have shown that cerebral hypoxia results in increased nuclear Ca^{++} influx in neuronal nuclei of the cerebral cortex of newborn piglets [58, 67]. The nuclear Ca^{++} influx increased as a function of increase in cerebral tissue hypoxia, as measured by decrease in high energy phosphates, ATP and phosphocreatine. Cerebral hypoxia results in increased Ca^{++}/calmodulin kinase (CaM kinase) IV activity and CREB protein phosphorylation in neuronal nuclei of newborn piglets [68]. NO donors increased neuronal nuclear Ca^{++} influx [69] and hypoxia resulted in generation of NO free radicals and increased high affinity Ca^{++}-ATPase activity in neuronal nuclei. The high affinity Ca^{++}-ATPase activity increased as a function of increase in cerebral tissue hypoxia [70]. In addition, IP3-dependent Ca^{++} influx is increased in neuronal nuclei of hypoxic animals as compared to normoxic ones and this increase was a function of cerebral tissue hypoxia.

During hypoxia, NO-mediated modification of the nuclear membrane high affinity Ca^{++}-ATPase and IP3 receptor is a potential mechanisms of increased intranuclear Ca^{++} that leads to activation of Ca^{++}-dependent nuclear mechanisms and activates cascades of hypoxic programmed cell death.

135.6 Expression and Post-Translational Modification of Apoptotic Proteins

Bcl-2 family of proteins (including Bc1-2 and Bax) control cell proliferation, differentiation, and programmed cell death during normal brain development [71]. Bax and Bcl-2 are inducible genes found in the developing and adult central and peripheral nervous systems [72, 73]. Bcl-2 prevents apoptosis by forming a heterodimer with the pro-apoptotic protein Bax and protects cells from programmed cell death following hypoxia [71].

Cerebral hypoxia results in increased expression of Bax protein in neuronal nuclei of the cerebral cortex of newborn piglets. The Bax protein increased as a function of increase in degree of cerebral tissue hypoxia as measured by decrease in high energy phosphates, ATP and phosphocreatine [74]. The expression of Bax protein increases in the mitochondrial, cytosolic as well as in the neuronal nuclear fractions indicating increased expression of the protein rather than its translocation e.g., from mitochondria to cytosol. The expression of anti-apoptotic protein Bax to antiapototic protein Bcl-2 did not increase during hypoxia. Therefore, the ratio of proapoptotic protein Bax to antiapototic protein Bcl-2 increases in all compartments of the cell during hypoxia that may lead to activation of hypoxia-induced cascade of neuronal death.

Administration of NOS inhibitor prevented the hypoxia-induced increased expression of proapoptotic protein Bax indicating that the hypoxia-induced increased expression of Bax is NO-mediated [75].

135.6.1 Posthypoxic Expression and Activation of Caspases-3, -8, and 9 in the Newborn Brain

Caspases are a unique family of proteases that play an important role in the initiation and execution of apoptosis [76]. All caspases contain a cysteine residue at their active site and specifically cleave substrate proteins at an aspartic acid residue. These cysteine proteases reside predominantly in the cytosolic compartment of animal cells as inactive zymogens and become activated by proteolytic cleavage at internal aspartate residues on apoptotic stimulation [77]. These are divided into two main classes: those with long prodomain are the Class I caspases, and those with short prodomain are the Class II caspases.

Class I caspases such as 8, 9, and 10 can autocatalyze their own activation and are activated in the early phase of apoptosis. These are called the initiator caspases. Class II caspases, such as 3, 6, and 7 require cleavage by another protease and are responsible for the breakdown of cells [76]. These are called the effector or the executioner caspases. The upstream caspases activated during apoptosis lead to the activation of downstream caspases in a self-amplifying cascade [76].

Two well-studied pathways of caspase activation are the cell surface death receptor-mediated pathway and the mitochondria-initiated pathways. The recruitment and the cleavage of procaspase-8 to produce the active form of caspase-8 is a critical biochemical event in the death receptor-mediated apoptosis [76]. Following its activation, caspase-8 can activate downstream caspase by direct cleavage or indirectly by cleaving the proapoptotic protein and inducing cytochrome c (cyt c) release from the mitochondria [76]. In the proposed mitochondria-initiated pathway, caspase activation is triggered by formation of an oligomeric apoptotic protease activation factor (Apaf-1)/ cyt c complex, which leads in recruiting and activating procaspase-9 an upstream caspase in this pathway [78]. The complex formed by the combination of Apaf-1, cyt c, Bax/Bcl-2, and procaspase-9 is referred to as the apoptosome [78, 79].

Two other less defined pathways of apoptotic caspase activation are the ceramide pathway that may act predominantly through the initiator caspases-8 or -9, depending on the stimulus that induces ceramide synthesis and the granzyme B-perforin pathway, which may be directly initiated by the effector caspases-3 and -7. All these pathways, with the exception of the granzyme pathway, are known to be active in neurons.

Studies were conducted to investigate the role of caspase-cascade-mediated programmed cell death. Using our 3- to 5-day old newborn piglet model, we investigated the hypoxia-induced alterations in the activity and expression of caspase-3, caspase-8, and caspase-9. Results of these studies after 1 hour of severe hypoxia in newborn piglets demonstrated that following hypoxia there is an increase in the activity of the initiator caspase-8 and caspase-9 in the cytosolic fraction of

the cerebral cortex. The activity of caspase-3 also increased in the cytosolic fraction of the cerebral cortex. In addition, the expression of caspase-8, caspase-9, and caspase-3 protein increased following hypoxia [76, 78, 79].

135.6.2 Mechanisms of Caspase Activation During Hypoxia in the Newborn Brain

To investigate the mechanism of caspase activation we used selective inhibitors such as clonidine an inhibitor of high-affinity Ca^{++}-ATPase, 7-nitro-indazole-sodium salt (7-NINA) inhibitor of neuronal NO synthase and Z-leu-Glu (OME) His-Asp (OME)-femomethyl Ketone (Z-LFHD-FMK), a selective caspase inhibitor.

135.6.2.1 The Role of Nuclear Ca^{++} influx in Caspase-9 and Caspase-3 Activation

Studies performed in newborn piglets were specifically designed to investigate the role of nuclear Ca^{++} influx in caspase activation during hypoxia by administration of a Ca^{++}-ATPase inhibitor (clonidine) to block the nuclear Ca^{++} influx. It was shown that the increased activity of casapse-9 and caspase-3 during hypoxia is mediated by nuclear Ca^{++} influx. The levels of tissue high-energy phosphates (ATP and PCr) in the cerebral cortex of normoxic-, hypoxic-, and hypoxic-pretreated with clonidine piglets were comparably decreased. The determination of caspase-9 activity in the normoxic-, hypoxic, and hypoxic-pretreated with clonidine groups of piglets showed that cerebral tissue hypoxia results in increased caspase-9 activity and that the pretreatment with high affinity Ca^{++}-ATPase inhibitor prevents this hypoxia-induced increase in caspase-9 activity.

Assessment of the activity of caspase-3 in the normoxic, hypoxic, and hypoxic pretreated with clonidine groups of piglets demonstrated that cerebral tissue hypoxia resulted in increased caspase-3 activity, a consequence of caspase-9 activation, and that the pretreatment with clonidine prevented this increase in caspase-3 activity. These results demonstrate that hypoxia-induced increase in caspase-3 activity is mediated by nuclear Ca^{++} influx.

135.6.2.2 The Role of NO in Caspase-9 and Caspase-3 Activation

These studies in newborn piglets were specifically designed to investigate the role of NO-derived from neuronal nNOS in caspase activation during hypoxia by administration of a relatively selective inhibitor of nNOS, 7-NINA salt [80]. After having confirmed that cerebral tissue hypoxia achieved in the hypoxic and hypoxic pretreated with 7-NINA groups were comparable, the activity of caspase-9 in the normoxic, hypoxic, and hypoxic-pretreated with 7-NINA groups of piglets was determined, the results demonstrated that cerebral tissue hypoxia results in increased caspase-9 activity and that the pretreatment with the nNOS inhibitor prevents the hypoxia-induced increase in caspase-9 activity.

Cerebral tissue hypoxia resulted in increased caspase-3 activity, a consequence of caspase-9 activation and the pretreatment with the nNOS inhibitor, prevented this hypoxia-induced increase in caspase-3 activity. It demonstrates that the hypoxia-induced increase in caspase-9 is mediated by nNOS-derived NO.

135.6.2.3 The Effect of Caspase-9 Inhibition During Hypoxia on Prevention of Downstream Events Including Caspase-3 Activation

To demonstrate that caspase-3 activation is a downstream event of caspase-9 activation during hypoxia we used its selective inhibitor Z-LEHD-FMK [81, 82].

The activity of caspase-9 was determined in the cytosolic fraction of the cerebral cortex of newborn piglets. Cerebral tissue hypoxia resulted in increased caspase-9 activity and the pretreatment with the caspase-9 inhibitor prevented the hypoxia-induced increase in caspase-9 activity.

The activity of caspase-3 in the cytosolic fraction of the cerebral cortex increased as a consequence of caspase-9 activation, and the pretreatment with a caspase-9 inhibitor prevented this hypoxia-induced increase. The same study showed that pretreatment with caspase-9 inhibitor prevents the hypoxia-induced increase in the expression of active caspase-9 and active caspase-3 (protein levels).

These studies demonstrate that caspase-9 can be activated during hypoxia by multiple mechanisms that are dependent on generation of nNOS-derived NO and neuronal nuclear Ca^{++} influx. The increase in nuclear Ca^{++} influx leading to Ca^{++}-dependent activation of Ca/Calmodulin-dependent protein kinase IV may result in increased phosphorylation or cyclic AMP-response element binding protein at Serine133 and transcription of caspases as well as proapoptotic proteins. NO-mediated phosphorylation of anti-apoptotic proteins may alter their anti-apoptotic potential due to a defect in dimerization and increased caspase-9 activation.

We have shown that NO increases Ca^{++} influx in synaptosomes as well as neuronal nuclei. By increasing nuclear Ca^{++} influx, NO can increase expression of caspase-9 as well as proapoptotic proteins. NO-mediated modification of caspase protein may alter its activation.

Thus, caspase activation during hypoxia in the newborn brain is mediated by transcription-dependent and transcription-independent mechanisms.

Studies using LEHD-FMK, a selective inhibitor of caspase-9, indicate that the role of caspase-9, the inhibitor caspase, is highly significant in the hypoxia-induced programmed cell death in the newborn brain.

135.7 DNA Fragmentation

It has been proposed that the cleavage of DNA at its intranucleosomal linkage region is produced by specific endonucleases that are Ca^{++}-dependent [83].

Caspase-3 acting as cystein protease cleaves and inactivates a chain reaction by nuclear enzymes like PARP, a DNA repair enzyme, and ICAD the inhibitor of caspase-activated DNase. Then the caspase-activated DNase enters the nucleus and cleaves genomic chromosomal DNA [84, 85]. This nuclear genomic DNA fragmentation correlates exponentially with the degree of cerebral tissue hypoxia in newborn piglets [86] and is characteristic of cellular apoptosis. However, in our study, there was no significant increase in fragmentation until the ATP and phosphocreatine levels decreased by more than 50%, compared with baseline levels.

135.8 Temporal Biochemical Changes

The steps of post-hypoxic neuronal injury are evolving within hours in the necrotic process and within days in the apoptotic process. Temporal biochemical changes and associated nuclear fragmentation have been assessed in the cerebral cortex of newborn guinea pigs following hypoxia. Initial cellular injury may be followed by a failure of cellular repair mechanisms leading to further delayed brain injury. Neuronal nuclear Ca^{++} influx increases immediately following hypoxia and remains elevated through 7 days of age. Similar nuclear Bax protein expression increases immediately following hypoxia and remains elevated through 7 days where Bcl-2 protein remains similar to control during hypoxia.

All these temporal (biphasic) temporal changes may reflect not only the primary hypoxic insult but also a secondary cellular damage due to a recurrent (continuing) free radical release during the reperfusion-reoxygenation phase.

135.9 Clinical Implications

The understanding of the very complex and interrelated mechanisms of cell death after a hypoxic-ischemic result may serve as background in critical care of the newborn.

Hypoxia at the cellular level is the consequence of failure in oxygen transport from the lung alveolar space to the mitochondria. In order to prevent neuronal cell death to restore any insufficiency or failure in the respiratory and circulatory systems is an emergency in terms of minutes.

Amongst the hazards in restoring oxygen supply, medically induced hyperoxia (high FIO_2) may worsen the neuronal insult by the production of additional oxygen free radicals.

The temporal evolution of the post-hypoxic biochemical disturbances may alter the opportunity of pharmacologic interventions at key steps of the biochemical events, like magnesium sulfate, a NMDA receptor antagonist, or allopurinol an inhibitor of the enzyme xanthine oxidase.

135.10 Neuroprotective Treatments with Suggested Efficacy in Humans

135.10.1 Magnesium Sulfate

In the clinical setting, $MgSO_4$ has been widely used in obstetrics practice for more than 60 years. Its indications include suppression of preterm labor and management of pregnancy-induced hypertension [87]. A retrospective epidemiologic study by Nelson and Grether [88] suggested that premature fetuses whose mothers received $MgSO_4$ for the treatment of preclampsia or as a tocolytic agent are less likely to develop cerebral palsy compared to a gestational age-matched group of fetuses not exposed to the drug. The Collaborative Eclampsia Trial [89] reported that babies of women who had been given $MgSO_4$ before delivery were significantly less likely to be intubated at the place of delivery or to be admitted to a special care nursery than the babies of mother who had been given phenytoin. These studies suggested that $MgSO_4$ might provide a protective effect against brain damage in immature fetuses and newborn infants. Randomized, controlled, double-blind trials were established to examine this hypothesis. One was discontinued after interim analysis showed that administration of $MgSO_4$ to mothers in preterm labor before 34 weeks of gestation was associated with significant increase in infants' mortality [90]. However, other trials have not shown any difference in the mortality rates between the placebo and treatment groups [91].

A multicenter randomized, controlled trial of $MgSO_4$ versus placebo, for the prevention of cerebral palsy, in 2,241 women at risk of imminent of premature delivery at 24–31 weeks of gestation carried out in the US was published in 2008 [92]. The primary outcome was the composite of stillbirth or infant death by 1 year of corrected age or moderate or severe cerebral palsy at or beyond 2 years of corrected age. The primary outcome was not significantly different in the $MgSO_4$ group and the placebo group. However, in a prespecified secondary anlaysis, moderate or sever cerebral palsy occurred significantly less frequently in the $MgSO_4$ group (1.9% *vs* 3.5%). A similar study in France followed-up 606 infants of less than 33 weeks of gestation, whose mothers were treated with $MgSO_4$. Compared to placebo, treated infants showed a decrease of all primary end points (total mortality, sever white matter injury and their combined outcome) and of all secondary endpoints (motor dysfunction, cerebral palsy, cognitive dysfunction and their combined outcomes at 2 years of age). The decrease was nearly significant or significant for gross motor dysfunction, and combined criteria: death and

cerebral palsy, death and gross motor dysfunction, death, cerebral palsy and cognitive dysfunction [93]. Doyle et al [94] reviewed the evidence of the neuroprotective effects of $MgSO_4$ given to women considered at risk of preterm birth. The authors concluded that the neuroprotective role for antenatal $MgSO_4$ therapy given to mothers at such risk is now established. The number of women needed to treat to benefit one baby by avoiding cerebral palsy is 63 (95% confidence interval 43 to 87). Given the beneficial effects of $MgSO_4$ on substantial gross motor function in early childhood, outcomes later in childhood should be evaluated to determine the presence of absence of later potentially important neurologic effects, particularly on motor or cognitive function.

135.10.2 Allopurinol

In experimental animal models, administration of allopurinol to immature rats 30 minutes before inducing focal hypoxia-ischemia reduced the severity of the secondary edema and the extent of the neuropathologic lesions in the treated compared with a control group [95]. Similarly, pretreatment with allopurinol preserved cerebral energy metabolism of the 7-day postnatal rat during hypoxia-ischemia [96]. The same group of researchers found that oxypurinol, the active metabolite of allopurinol, administered at the same dose and at the same time as allopurinol after hypoxia-ischemia reduced brain injury in the immature rat [97]. Administration of allopurinol in newborn piglets prevented the hypoxia-induced modification of NMDA receptor as well as cell membrane preoxidation and neuronal dysfunction [98, 99].

In the clinical setting, a 7-day course of enteral allopurinol (20 mg per kg) given after birth to 400 infants between 24 and 32 weeks' gestation did not change the incidence of periventricular leukomalacia [100]. In a study of 22 asphyxiated newborn infants, intravaneous allopurinol in a dose of 40 mg per kg given 4 hours after birth resulted in a decrease mortality (2/11 *vs* 6/11 in the control group), and in a beneficial effect on free radical formation, cerebral blood flow, and electrical brain activity, without toxic side effects [101]. Clancy et al [102] conducted a clinical trial to test the hypothesis that allopurinol could reduce death, seizures, coma, and cardiac events in infants who underwent heart surgery using deep hypothermic circulatory arrest. They studied a total of 318 infants, 131 hypoplastic left heart syndrome (HLHS) and 187 non-HLHS. In HLHS surgical survivors, 40 of 47 (85%) allopurinol-treated infants did not experience any endpoint event, compared to 27 of 49 (55%) controls ($p = 0.002$). There were fewer seizure-only ($p = 0.05$) and cardiac-only ($p = 0.03$) events in the allopurinol versus placebo groups. Allopurinol did not reduce efficacy endpoint events in non-HLHS infants. Treated and control infants did not differ in adverse events. Recently, Benders et al [103] investigated whether postnatal allopurinol would reduce free radical induced reperfusion/reoxygenation injury of the brain in severely asphyxiated neonates. In an interim analysis of a randomized, double blind, placebo controlled study, 32 severely asphyxiated infants were given allopurinol or a vehicle within four hours of birth. The analysis showed an unaltered (high) mortality and morbidity in infants treated with allopurinol. The authors concluded that allopurinol treatment started postnatally was too late to reduce the early reperfusion-induced free radical surge. Allopurinol administration to the fetus with (imminent) hypoxia via the mother during labor may be more effective in reducing free radical induced post-asphyxial brain damage.

Chaudhari and McGuire [104] performed a meta-analysis to evaluate the evidence of the effect of allopurinol on mortality or morbidity in newborn infants with suspected hypoxic-ischemic encephalopathy. The authors concluded that the available data are not sufficient to determine whether allopurinol has clinically important benefits for newborn infants with hypoxic-ischemic encephalopathy and, therefore, larger trials are needed. Such trials could assess allopurinol as an adjunct to therapeutic hypothermia in infants with moderate and severe encephalopathy and should be designed to exclude clinically important effects on mortality and adverse long-term neurodevelopmental outcomes.

135.10.3 Opioids

The antinociceptive effects of opioids are mediated through a combination of pre- and postsynaptic hyperpolarization, which produces a decrease in the release of and the sensitivity to endogenous mediators like glutamate [105, 106]. This suggests that they may have a neuroprotective effect. Indeed, studies in cell cultures have demonstrated that endogenous and exogenous opioids may protect cortical neurons from hypoxia-induced cell death [107, 108]. Similarly, opioids may induce ischemic tolerance in cerebellar Purkinje cells subject to ischemia-reperfusion [109]. Antagonists of opioid receptors increase the survival time during severe hypoxia in intact animals [110, 111] and enhance tissue preservation and survival time of organs used for transplants [112].

In 2005, Angeles et al [113] published the results of a retrospective study of 52 term newborns with perinatal asphyxia, in which they analyzed the relationship between treatment with opioid analgesics (morphine or fentanyl) and neurological damage. A total of 33% of them received opioids; in spite of having a more severe degree of asphyxia (higher levels of lactate, lower 5 minute Apgar scores), this group of patients had less severe signs of brain damage on the MRI performed after 7 days of life. Moreover, their neurologic outcome at a mean follow-up of 13 months was better than the group of newborns who did not receive opioids. The same group of researchers also performed a follow-up study with magnetic resonance (MR) spectroscopy of 28 term newborns treated

with opioids and 20 controls [114]. The results showed that occipital gray matter NAA/Cr was significantly decreased and pactate was present in a significantly higher amount in non-opioid-treated neonates compared with opioid-treated neonates. Also, compared with controls, untreated neonates showed large changes in more metabolites in basal ganglia, thalami, and occipital gray matter with greater significance than treated neonates. The authors concluded that the use of opioids during the first week following perinatal asphyxia has no long-term adverse effects, and may increase brain resistance to hypoxia-ischemia. The authors speculated that the neuroprotective effect of opioids may be mediated by increasing the levels of adenosine, and endogenous nucleoside with neuroprotective activity, or by inducing neuronal hyperpolarization, which results in diminishing intracellular penetration of calcium.

Despite the potential benefit of opioids on asphyxiated term neonates as indicated in these studies, caution must be exercised in the use of this class of medications. Available literature suggests that the routine use of opioid analgesics can be complicated by problems such as tolerance, withdrawal symptoms and ventilator dependence. Very few studies have examined the long-term effects of exposure to opioids in the neonatal period. In addition, previous reports indicate that endogenous opioids can suppress DNA synthesis *in vivo* in mature cerebellar and glial cells (opioid receptors are widely distributed in the CNS with functions that include pain modulation, cardiorespiratory regulation), whereas exogenous opioids can exacerbate neurotoxicity in animal models of cerebral ischemia. Future prospective randomized trials are warranted to determine whether there is truly an immediate neuroprotective effect on hypoxic-ischemic brain injury and whether these agents can play a role in improving long-term outcome.

135.10.4 Hypothermia

Hypothermia has developed during the past few yeas as an alternative for treating perinatal asphyxia/HIE [115, 116]. Hypothermia during experimental cerebral ischemia is associated with potent dose-related, long-lasting neuroprotection. Conversely, hyperthermia of only 1–2°C extends and markedly worsens damage, and in particular tends to promote pannecrosis [115]. Although the majority of such studies involved global ischemia in adult rodents [117], similar results were reported from studies on hypoxia-ischemia in 7-day old rats [118] and newborn piglets [119], kittens, rabbits, and puppies [120].

The study of the mechanisms of action of hypothermic neuroprotection suggests that cooling affects many or all of the pathways leading to delayed cell death [115]. Hypothermia reduces the rate of oxygen-requiring enzymatic reactions and cerebral oxygen consumption, slows the fall of phosphocreatine/inorganic phosphate (PCr/Pi), and confers a protective effect of the brain after ATP exhaustion. In addition, hypothermia decreases oxygen consumption of the brain by 6–7% and cerebral energy utilization rate by 5.3% per degree. Additional experimental evidence suggests that hypothermia suppresses cytotoxic excitatory amino acid accumulation, inhibits nitric oxide synthase activity, decreases interleukin-1 levels, decreases the release of other cytotoxic cytokines by microglial cells, and suppresses free radical activity and delayed cell death by apoptosis. Hypothermia also decreases blood-brain-barrier permeability and intracranial pressure, and facilitates recovery of electrophysiologic function after cerebral ischemia.

The efficacy of hypothermia is dependent on a number of factors, such as the timing of initiation of cooling, its duration, and the depth of cooling attained. Mild hypothermia is defined as a reduction in core temperature of 1–3°C, moderate as 4–6°C, severe as 8–10°C and profound as 15–20°C. Brief (0.5–3 hours), mild-to-moderate hypothermia immediately after hypoxia-ischemic injury may be most effective after relatively mild insults. Protection appears to be lost if brief hypothermia is delayed by as little as 15–45 minutes after the primary insult. A more recent approach has been to try to suppress the secondary encephalopathic processes by maintaining hypothermia throughout the course of the secondary phase. An extended period of cooling (between 5 and 72 hours) appears to be more consistently effective, and remains effective after significant delays (possibly up to 6 hours) between the primary insult and the start of cooling; however, the degree of neuroprotection progressively declines if cooling is initiated more than a few hours post-insult [115]. In addition, cerebral hypothermia is not neuroprotective when started after post-ischemic seizures occur [121].

Potential adverse effects of induced hypothermia (the risk increasing with depth of hypothermia) include increased blood viscosity, mild metabolic acidosis, decreased oxygen availability, intracellular shift of potassium, cardiac arrhythmias, coagulation abnormalities and platelet dysfunction, and choreic syndrome [116].

135.10.5 Selective Head Cooling

The first study on neuroprotection of perinatal HIE with selective head cooling was published in 1998 by Gunn et al [122], who basically proved the safety of this procedure. Later on, the same group of researchers published the results of other studies in a small number of patients, which confirmed the lack of side effects and a tendency to a better neurologic prognosis in those newborns with moderate or severe HIE treated with this hypothermia technique [123, 124].

In 2005 Gluckman et al [125] published the results of the most important study that has produced reliable and significant data about the neuroprotective effect of selective head cooling hypothermia. It was a multicenter investigation that

included 234 newborns with HIE and expected gestational age (EGA) above 36 weeks. Patients were randomized before 5.5 hours of life into two groups: body normothermia or hyporthermia of 34.5°C, induced through selective head cooling during 72 hours. Patients treated with hypothermia had a significantly higher incidence of arrhythmia (mostly sinus bradycardia). A total of 218 infants were followed-up until 18 months of age. The presence of death or neurological disability was found in 66% of patients in the control group and 55% in the hypothermia group ($p < 0.1$). However, when newborns with severe neurological depression or those who had seizures on the aEEG were excluded, 66% of infants in the control group and 48% in the hypothermia group died or had neurological disability ($p < 0.2$). Moreover, the presence of severe neurological disability was 28% and 12% in each group, respectively. The authors concluded that, except in newborns with the most severe forms of HIE, selective head cooling applied immediately following delivery, may be a feasible therapeutic technique to decrease neurological sequelae of perinatal HIE.

135.10.6 Generalized Body Hypothermia

The first study with generalized body hypothermia in perinatal HIE was published in 2000 by Azzopardi et al [126], who found that prolonged hypothermia of 33–34°C was associated with minimal physiological changes (e.g., decreased heart rate, increased blood pressure), but was well tolerated. During the next three years, other research protocols in a limited number of patients corroborated that generalized body hypothermia was a feasible and clinically safe technique [127, 128].

In 2005, Eicher et al [129] published the results of a pilot multicenter study about the safety and efficacy of generalized body hypothermia in the treatment of 32 newborns with perinatal HIE. Adverse effects included bradycardia, hypotension, decreased platelets, increased prothrombin time, and higher incidence of seizures, but none of them was severe, and they all responded to treatment [129]. The efficacy results showed a higher incidence of death or severe neurological motor involvement in the control group (82%) compared to the group of hypothermia-treated newborns (52%) ($p = 0.019$). A severe psychomotor developmental delay (less than 70%) was seen in 64% of infants in the control group and in 24% of those subjected to hypothermia ($p = 0.053$).

Also in 2005, Shankaran et al [130] published a large multicenter study on the use of body hypothermia to treat perinatal HIE. A total of 208 newborns with HIE and EGA more than 36 weeks, were included and randomized before 6 hours of life into two groups: body normothermia or hypothermia of 33.5°C, induced by body cooling, during 72 hours. Patients were followed-up until 18–22 months. The incidence of mild complications was similar in both groups. The incidence of death or moderate or severe neurological disability was 62% in the control group and 44% in the hypothermia treated group ($p = 0.01$). The incidence of cerebral palsy was 30% in the control newborns and 19% in those treated with hypothermia ($p = 0.20$). The authors concluded that generalized body hypothermia reduces the risk of death and neurological disability in newborns with moderate or severe HIE.

An magnetic resonance imaging (MRI) follow-up study of infants enrolled in the above mentioned trial [130] aimed to measure relative volumes of subcortical white matter. They were significantly large in hypothermia-treated than in control infants. Furthermore, relative total brain volumes correlated significantly with death or neurosensory impairments. Relative volumes of the cortical gray and subcortical white matter also correlated significantly with Bayley Scales psychomotor development index [131].

Hypothermia is currently in the process of translating from the clinical research experience to direct clinical application [132–141]. However, the clinical trials with hypothermia have also addressed many questions, which need to be answered before it becomes the standard of care to treat newborns with perinatal asphyxia.

Clinical Aspects and Treatment of the Hypoxic-Ischemic Syndrome

Floris Groenendaal and Frank van Bel

136.1 Epidemiology

In the Western world, perinatal asphyxia is still a relatively common phenomenon in perinatal care. Since differences in causes and patterns of brain injury following perinatal asphyxia exist between full-term and preterm neonates, this chapter will focus on full-term neonates.

Generally, it has been assumed that in the Western world 0.1–0.4 % of all full-term neonates need resuscitation at birth because of perinatal asphyxia [1, 2]. Recent studies indicated that at least 0.5% of full-term neonates needed some degree of resuscitation at birth because of a 5-minute Apgar score of 6 or less [3]. Of all full-term neonates, 0.07% had a 5-minute Apgar score of 3 or less. Mortality in these severely depressed neonates was 24%.

Data from the Netherlands Perinatal Registry show that at least 0.1% of all full-term neonates develop encephalopathy after severe perinatal asphyxia.

Although the concept of perinatal asphyxia has been challenged by some, a recent combined magnetic resonance imaging (MRI) and pathology study showed recent hypoxic-ischemic changes in brain tissue in 80% of full-term neonates with perinatal asphyxia and encephalopathy [4].

Perinatal asphyxia may be caused by antenatal factors, such as severe maternal diseases or shock, perinatal factors such as a difficult delivery with compromised blood flow through the umbilical cord, placental abruption or uterine rupture, or postnatal factors such as respiratory difficulties as in congenital diaphragmatic hernia or muscle diseases. The distribution of antenatal, perinatal or postnatal factors in the causation of asphyxia is largely unknown.

136.2 Pathology and Outcome

During perinatal asphyxia two different processes contribute to brain injury: hypoxia (lack of oxygen) as well as ischemia (lack of blood flow due to bradycardia, thereby reducing flow of e.g., glucose) contribute to cellular compromise. This is even further aggravated by reperfusion with production of a large amount of oxygen and nitrogen free radicals and non-protein bound iron. Brain injury is the resultant of hypoxia-ischemia and reperfusion.

Different patterns of cerebral involvement after perinatal asphyxia have been described in post mortem studies, and have been confirmed in experimental animals and *in vivo* in the human neonate using MRI:

1. Total brain necrosis
2. Injury of basal ganglia and thalamus
3. Watershed lesions

Total brain necrosis is the most serious form of brain injury. Most infants with this lesion will not survive, since the brain stem is involved in the pathology. Pathology studies have described this pattern in detail. In the rare neonate who survives, multicystic encephalomalacia or ulegyria can be seen [5]. These children will show major and multiple handicaps, including cerebral visual impairment.

Injury of the basal ganglia and thalamus are seen in neonates with an acute and severe insult with no previous signs of fetal compromise. This pattern has been demonstrated *in vivo* in neonates using cranial ultrasound, and in the last decade using MRI (Fig. 136.1). In many patients injury to the hippocampus, a brain region known to be sensitive to hypoxic-ischemic injury, can be identified using diffusion weighted MRI. In surviving neonates this pattern of brain injury leads to gliosis of the basal ganglia and thalamus. On post mortem examination this pattern has been referred to as status marmoratus because of the marble like appearance [5]. Children with this type of cerebral injury display the athetoid type of cerebral palsy. Epilepsy has been described, possibly due to injury of the hippocampus.

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

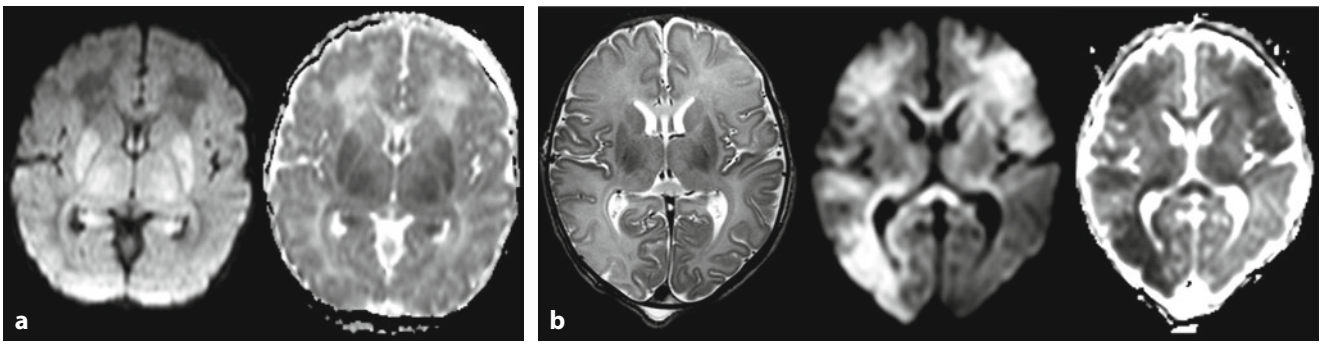

Fig. 136.1 MRI of two full-term neonates with perinatal asphyxia. **a** Abnormalities of the basal ganglia and thalamus on the 4th day of life in a full-term neonate with perinatal asphyxia: DWI (*left*) and ADC map (*right*). ADC values of the basal ganglia were 770×10^{-6} mm^2/s. The patient died 5 days after birth. **b** Abnormalities of gray and white matter in a full-term neonate with watershed infarcts. MRI on day 3 after birth. T2 weighted (*left*), diffusion weighted (*middle*) images, and ADC map (*right*). This infant showed normal development at 1 year of age

Watershed lesions were described in the late 1970s using technetium scans [6, 7]. Reduced perfusion of cerebral border zones between anterior and middle cerebral arteries and middle and posterior cerebral arteries are the most important aspect of this type of lesion. A more chronic, intrauterine form of perinatal asphyxia has been suggested as the causative factor of this type of lesion.

In more severe cases long-term effects are volume loss of the frontal and parieto-occipital parts of the cerebrum, but in milder cases we have observed normal development without long-term effects up to 2 years of age [8]. In more severe cases, disturbances of mental development are the most important long-term effects.

In the present chapter we will not discuss focal infarcts. Focal infarcts have been increasingly demonstrated in full-term as well as preterm neonates. However, since they occur in neonates who in most cases had no signs of perinatal asphyxia, these types of brain lesions are beyond the scope of this chapter.

136.3 Clinical Picture of Hypoxic-Ischemic Syndrome

As can be extracted from the former section discussing the etiology of the hypoxic-ischemic syndrome, the basis of this syndrome is mostly (± 70%) a disturbance in gas exchange between the fetus and mother in the direct antepartum and intrapartum period, at least when referring to the full-term infant. Although there is no ideal measure to assess, from the clinical point of view, the severity of perinatal hypoxia-ischemia during the initial clinical presentation of the infant immediately after birth, the most used instrument here is the Apgar score, introduced in 1953 by the anesthesiologist Virginia Apgar [9]. The Apgar score is usually recorded at 1 and 5 minutes after birth and includes an assessment of heart, pulmonary and neurological functions by an assessment of color, heart rate, respiration and tone (see also below). In 1992 the American Academy of Pediatrics and the American College of Obstetricians Committees on Maternal-Fetal Medicine defined the following criteria for the presence of perinatal asphyxia, consisting out of [10]:

- a metabolic parameter (arterial umbilical cord pH < 7.00);
- a persistence of an Apgar score of 0-to-3 at 5-minutes of extrauterine life;
- clinical and neurological sequelae in the immediate neonatal period;
- clinical and chemical evidence of multi-organ failure in the early neonatal period.

Lactate levels and lactate/pyruvate ratios in arterial umbilical cord blood or neonatal arterial blood in the first hour of life are also indicators of pre-existing substantial perinatal asphyxia [11]. Heavy meconium staining of amniotic fluid before delivery is associated with perinatal asphyxia and a poor clinical condition at birth, and related to early death [12]. We will discuss these issues more in detail under the section dealing with diagnosis and prognosis.

The persistence of clinical symptoms after antepartum- and perinatal hypoxia-ischemia differ and are related to the severity and duration of the actual hypoxic-ischemic insult [13]. Symptoms can range from subtle neurological symptoms such as a transient drowsiness without involvement of other organ systems to overt involvement of important organ systems with renal, cardiac and pulmonary abnormalities in association with a full-blown neurological syndrome [14–17]. We will discuss here those conditions where perinatal hypoxia leads to dysfunctions of the central nervous system and other important organ systems.

During the first 12 to 24 hours of life after moderate-to-severe perinatal fetal hypoxia-ischemia, infants show abnormal neurological behavior which ranges from relatively mild to an overt abnormal neurological picture. Mildly affected infants show increased restlessness and moderate hypertonia

often accompanied by periodic breathing and feeding difficulties, which subside in the first days of life [18]. Part of these symptoms may be related to an abnormal stimulation or transient malfunction of certain regions of the central nervous system.

Severely asphyxiated infants show a variety of neurological symptoms such as a lowered level of consciousness, hypotonia, gazing with abnormal papillary size, eventually with subtle signs of seizure activity (sucking, odd movements of the mouth with smacking etc.). The most severely affected infants are often profound lethargic or even stuporous and show already in an early phase overt convulsive activity as indicated by apneic spells and abnormal (clonic or tonic) movements. In full-term infants these seizures are mostly multifocal with clonic characteristics, whereas less mature infants show often tonic seizures which are often generalized [19–21]. Systemic symptoms may be lacking in the mildly affected infants but mostly there is a decrease or even a lack of urinary production because of a mostly transient hypoxic damage to the kidneys. Renal function recovers almost always unless hypoxic-ischemic damage has been irreversible, which is always related to extensive damage to the brain [22]. In the more severely affected babies there is almost always respiratory insufficiency with prolonged apnea, probably related to malfunction of the central nervous system, sometimes giving rise for the need of artificial ventilation, often somewhat later in life, after 48 to 72 hours of life. An hypoxia-induced myocardiopathy is a prominent feature and its severity mirrors the severity of the perinatal hypoxic-ischemic insult [23, 24]. In most cases, however, there are no or only mild clinical signs, although relatively often inotropes are needed to prevent hypotension [24]. In most infants recovery of myocardial contractility occurs in the first 24 to 48 hours after birth [23]. In a minority of cases massive cardiac failure occurs, but in such situations there is invariably severe irreversible brain damage.

From 24 hours onward, those infants with initially mild-to-moderate neurological symptoms can exhibit an improvement of their clinical and neurological condition with normalization of consciousness and neurological behavior and start to drink their feedings. In these infants also urine production starts or increases and no further support of blood pressure is necessary. This is accompanied by normalization of their plasma parameters of renal (creatinine, urea) and liver functions and of echocardiographically determined cardiac function. Infants who are neurologically normal at one week of life have mostly a normal developmental outcome [25, 26]. Those infants with more severe neurological symptoms, often accompanied with renal and cardiac failure will often deteriorate. The level of consciousness decreases and in this particular time frame respiratory insufficiency becomes manifest and intubation and assisted ventilation is necessary, probably on a neurological basis. Derailment of brain stem functions become manifest now with further loss of responsiveness, overt and increasing frequency of clinical and subclinical seizure activity and abnormal movements of the eyes and dilated pupils [17]. An explanation for this delayed deterioration is probably related to secondary energy failure of the brain which occurs typically between 24 and 72 hours after birth or the hypoxic-ischemic insult [27, 28]. In this particular time frame the most severely affected children die and autopsy invariably shows cytotoxic brain swelling and major and extensive neuronal damage [24]. When these severely asphyxiated infants survive, their physical condition shows a sustained improvement but they will continue to have abnormal neurological features with (slight) disturbances in consciousness, feeding difficulties because of decreased sucking and swallow abnormalities. Dependent of the site of cerebral damage, the infants show overt hypotonia or hypertonia (in particular during involvement of the basal ganglia). Also here it is important to realize that the stage of development of the nervous system gives rise to a different clinical symptom-complex after perinatal hypoxia-ischemia especially in relation to tone and the occurrence of hemiparesis.

It was already years ago suggested that the neurological condition in the first few days of life was a more specific predictor of subsequent neurological outcome than signs of fetal distress or the Apgar score [29].

In 1976 Sarnat and Sarnat [25] therefore carried out a score, the Sarnat score, which was a combination of neurological symptoms as described above and the accompanying electro-encephalographic (EEG) features. This score was in fact a grading of the severity of the encephalopathy caused by the perinatal hypoxia-ischemia. It contains three stages, hypoxic-ischemic encephalopathy (HIE) stage 1, HIE stage 2 and HIE stage 3, the latest the most severe stage of encephalopathy. The most severely affected infants typically progress from stage 1 to 3 (Table 136.1). In 1983 Fenichel modified this score to a score solely on clinical symptoms, which distinguishes a mild, moderate and severe encephalopathy which could be linked to later neurodevelopmental outcome (Table 136.1) [30–32].

The Thompson score [33] is comparable to the Sarnat and Fenichel scores but can be used already shortly after birth, whereas the Sarnat and Fenichel scores can be done earliest at 24 hours after birth. These scores indicate the severity of the hypoxic-ischemic encephalopathy which correlate directly with the incidence of neurological sequelae [34, 35]. Follow-up studies showed that infants with mild hypoxic-ischemic encephalopathy (Sarnat HIE stage 1) did not have subsequent deficits, whereas in infants with moderate encephalopathy, 5% died (Sarnat HIE stage 3), 24% had neurological sequelae and 71% were apparently normal. Of those infants with severe encephalopathy, 80% died and 20% had severe neurological sequelae [17]. In particular the Sarnat score is widely used these days to assess the severity of hypoxia-ischemia-induced encephalopathy and subsequent outcome and to assess the positive impact on outcome of newly designed therapies such as hypothermia and other means of neuroprotection [36–39].

Table 136.1 Hypoxic-ischemic encephalopathy (HIE) according to Sarnat [25] (a) and Fenichel [30] (b)

a. Symptoms	Stage 1	Stage 2	Stage 3
Consciousness	hyperalert	lethargic or obtunded	stuporous
Neuromuscular control	normal	mild hypotonia	flaccid
Suck/Moro reflex	normal	weak	absent
OV/TN reflex	normal	strong	absent
Autonomic function	in general sympathetic	in general parasympathic	both depressed
Seizures	none	(multi)-focal	decerebrated
EEG findings	normal	low voltage (δ/0 waves)	isoelectric
Duration	<24 h	2-14 days	hours to weeks
b. Symptoms	**Mild**	**Moderate**	**Severe**
Consciousness	irritable/hyperalert	lethargic	comatose
Tone	mildly abnormal	moderately abnormal	severely abnormal
Suck reflex	abnormal	poor	absent
Primitive reflexes	exaggerated	depressed	absent
Seizures	absent	present	present
Brain stem reflexes	normal	normal	impaired
Respiration	tachypneic	occasional apnea	severe apnea

OV oculo-vestibular, *TN* tonic neck.

136.4 Treatment of Hypoxic-Ischemic Syndrome

136.4.1 Reduction or Prevention of Fetal Hypoxia

Prevention may be the most important issue when discussing treatment modalities with respect to perinatal hypoxia-ischemia syndrome. Since the primary insult is in a vast majority of cases intrauterine hypoxia, early identification may alter long-term consequences of hypoxia-ischemia syndrome. However, it must be admitted that extensive ante- and intrapartum monitoring of the heart rate of the high risk fetus has led to increased obstetrical interventions without improving neonatal outcome [40], although the combination with fetal blood gas assessment and the introduction of the fetal electrocardiography technique may contribute to a reduction of fetal hypoxia-related long-term adverse outcome [41, 42]. Adequate interventions such as emergency cesarean section may prevent progression from mild fetal hypoxia to a moderate or severe perinatal hypoxic-ischemic syndrome. Although beyond the scope of this chapter, antenatal drug treatment via the mother with free radical scavengers or other neuroprotective agents may be an option to reduce or prevent hypoxic brain damage of the fetus [38, 43].

136.4.2 General Supportive Care

The baby born after substantial perinatal hypoxia-ischemia shows, in addition to nervous system damage, mostly dysfunction of several other important organ systems. In order of occurrence and importance one should mention here: pulmonary dysfunction with insufficient ventilation and oxygenation and cardiac dysfunction with suboptimal or overtly low blood pressure [23, 44]. Later on renal and liver function disturbances and clotting abnormalities and hyperviscosity can occur which need treatment [22, 45]. Details are presented in Table 136.2.

136.4.2.1 Ventilation and Oxygenation

Especially non-adequate ventilation and persistence of hypoxia can further aggravate nervous system damage and

Table 136.2 General supportive care

During resuscitation phase
- Establish heart rate monitoring
- Establish adequate ventilation (if needed: intubation and artificial ventilation)
- Connect infant with pulse oximeter for appropriate oxygenation
- Avoid hyperoxygenation (to avoid free radical production and ROP [preterm baby])
- Avoid hyper-/hypocapnia (preterm baby)
- Correct metabolic acidosis (after normalization of $PaCO_2$)
- Insert intravenous line for fluid and glucose administration

Subcutane phase
- Cardiac support, if necessary, with positive inotropes (hypotension) and/or fluid (blood loss)
- Aim for normoglycemic plasma levels

After stabilization
- Ensure appropriate caloric intake by intravenous route
- First 48 h no enteral feeding
- Monitor urine production
- Monitor coagulation and thrombocytes
- Treat convulsive activity (see also Table 136.3)

should be treated promptly. Although oxygen supplementation is an issue nowadays and hyperoxia during the resuscitation phase has been reported to contribute to additional reperfusion injury to neuronal cells, adequate oxygenation of the compromised newborn is crucial. It becomes more and more clear that this is also possible with room air and that resuscitation with 100% of oxygen is not desirable and damaging [46–48]. In our unit, as soon as possible the high risk infant is connected to the pulse oximeter to monitor systemic arterial saturation in order to avoid hyperoxia and/or hypoxia during the initial phase of resuscitation [49]. It is further important to realize that hypoxia and hypercapnia negatively influence the infant's capability to autoregulate the cerebral vascular bed with, as a consequence, blood pressure passive cerebral perfusion. Therefore assisted ventilation with mask and balloon or after endotracheal intubation and artificial ventilation may be an important option to stabilize the newborn and to correct in a quick and appropriate way the blood gases and metabolic demands. A special remark should be made with regard to hypocapnia, since the effects of hypocapnia are pronounced and have important metabolic and vascular effects [50].

136.4.2.2 Cardiac Dysfunction

Adequate perfusion of the brain is mandatory to prevent additional cerebral damage. Perinatal hypoxia-ischemia has been known to cause hypoxia-induced myocardiopathy which can lead to transient hypotension and hypoperfusion of important organs such as the brain [23]. Especially during severe perinatal hypoxia-ischemia, positive inotropes may be needed to prevent hypotension, although this myocardiopathy subsides mostly within the first 24 to 48 hours of life [23]. Mostly dobutamine is preferred above dopamine because of its positive inotropic effect on the myocardium without the peripheral effects such as peripheral vasoconstriction which may further compromise cardiac function. This is also the reason to avoid volume expanders if possible, although in a number of conditions circulating blood volume can be too low, such as in cases with fetal and neonatal blood loss during the perinatal period and/or delivery.

136.4.2.3 Additional Measures

Normoglycemic levels should be maintained, and adequate protein and caloric intake should be provided as soon as possible. Furthermore it is important to realize that early enteral feeding may facilitate the occurrence of necrotizing enterocolitis, because the gut may be already affected by hypoxic-ischemic damage [51]. We systematically postpone enteral feeding up to 48 hours of life and start as soon as possible after birth parenteral feeding. It is generally accepted that seizure activity, especially when occurring frequently and prolonged, is associated with a high metabolic demand and can, ultimately, adversely affect the brain. Below we will discuss in more detail treatment of seizure activity [52]. Birth asphyxia-related disseminated intravascular coagulation reduces levels of coagulation factors and thrombocytes, which can result in prolonged bleeding times [53]. Renal dysfunction accompanied by acute necrosis of the tubules is often a temporary problem that resolves over the first week of life and needs rarely more specific therapy such as hemodilution [54]. Table 136.2 summarizes the general care measures to be undertaken in the perinatally hypoxic-ischemic infant.

136.4.3 Treatment of Seizures

Since seizure activity has been recognized to be related to add substantially to additional neuronal damage [52], early recognition of seizure activity is extremely important. It therefore recommended to connect the neonate at risk for birth asphyxia-related brain damage to a one or two-channel continuous amplitude-integrated electroencephalography monitor, which facilitates detection of subclinical seizures which frequently occur during the first days after perinatal hypoxia-ischemia [55, 56]. Furthermore seizures can cause sudden increase of blood pressure and hypoglycemia, further aggravating asphyxia-related brain damage [57].

In our institution we use phenobarbital as a first line anticonvulsive with a total dose not exceeding 30 mg/kg iv. If necessary, phenobarbital can be given as maintenance, starting 1 week after the first dose. When seizure activity continues or reappears we use midazolam as a second drug starting with a loading dose followed by a maintenance dose as a continuous infusion (up to 0.5 mg/kg iv). In the baby with a gestational age of less than 35 weeks the second choice is clonazepam with a loading dose and maintenance dose (up to 0.5 mg/kg iv), since midazolam can induce hypotension in the preterm

Table 136.3 Dosing scheme of anticonvulsive drugs used in our institution for full-term neonates

Full-term infant	
• First choice	Phenobarbital: 20 mg/kg iv; if necessary 2nd dose of 10 mg/kg iv
• Second choice	Midazolam (baby CA > 35): – loading dose 0.05 kg in 10 min iv – maintenance dose 0.15-0.5 mg/kg/h continuous iv
• Third choice	Lidocaine*: loading dose 2 mg/kg in 10 min iv 6 mg/kg continuous infusion for 6 h 4 mg/kg continuous infusion for 12 h 2 mg/kg continuous infusion for 12 h
During hypothermia	
Lidocaine: loading dose	
	2 mg/kg in 10 min iv; 4 mg/kg continuous infusion for 6 h 2 mg/kg continuous infusion for 12 h

* A new dose schedule was suggested recently [156].

baby because of its vasodilating effect [58]. If a third antiepileptic drug is necessary, we use a tapering continuous iv infusion of lidocaine. Although the effect of lidocaine can be sustained (after 1 to 1.5 hours) it has a very good antiepileptic activity. During lidocaine treatment the ECG should be monitored because lidocaine can cause cardiac arrhythmia although in our hands and dosing regimen it is extremely rare [59]. If possible we recommend serial determinations of plasma lidocaine concentrations. This is also true when we use it in severely asphyxiated infants on moderate hypothermia, from which it is known that hypothermia influences pharmacokinetics [60]. Table 136.3 provides a detailed dosing scheme of mostly used anticonvulsive drugs in our institution.

136.4.4 Specific Treatment of Perinatal Hypoxic-Ischemic Syndrome

During perinatal hypoxia and concomitant ischemia and especially during reoxygenation and reperfusion at birth, potentially destructive molecular pathways are activated in the fetal and neonatal brain that ultimately lead to brain damage [61]. Animal and clinical studies demonstrated excessive influx of calcium into the neuronal cells through ion-regulated and N-methyl-D-aspartic acid (NMDA)-receptor-regulated channels. This intracellular calcium gives rise to enzyme activation and production of reactive oxygen and nitrogen species which damages neuronal cell membranes and DNA. Moreover, anti-inflammatory and apoptotic activity is activated [62]. Experimental and human studies have shown that the energy metabolism of the perinatally hypoxic-ischemic brain recovers upon reperfusion/reoxygenation, but that after 6 to 12 hours the energy metabolism of the brain becomes increasingly disturbed and irreversible brain damage occur [27, 28, 63]. It is likely that full development of destructive molecular pathways as mentioned above occurs in this time frame and that in the first 6 hours after recovery of brain perfusion and oxygenation (also called the therapeutic window) (pharmacologic) therapies aimed to prevent activation of these destructive molecular pathways may have a neuroprotective effect. This assumption was indeed supported by evidence from experimental studies in several newborn animal species [64, 65]. A more detailed review is beyond the aim of this chapter , but we will briefly summarize those therapies already established in daily practice, such as moderate hypothermia, and those which may be suitable for clinical use in the near future. Moderate hypothermia down to 33–34°C for 72 hours and starting within 6 hours after birth, either selective head cooling [36] or total body cooling [37], has been proven to be neuroprotective after moderate-to-severe perinatal hypoxia-ischemia. A meta-analysis of two large cooling studies showed that especially the infants eventually developing moderate birth-related encephalopathy benefit from this approach [66]. Although hypothermia seems to be a rather safe therapy, adverse effects may occur. During cooling hypertension, pulmonary hypertension, thrombocytopenia and hypokaliemia are reported, whereas during rewarming hypotension may occur [67]. There are preliminary studies which report an altered pharmacokinetic pattern of anticonvulsants and morphine, which are frequently used during this condition [60]. We suggest therefore to confine hypothermia for treatment of neonatal posthypoxic-ischemic encephalopathy to neonatal intensive care units [68].

It is conceivable that combining moderate hypothermia with a pharmacological means of treatment may further improve outcome after perinatal hypoxia-ischemia [65]. It is even possible that fetuses with imminent hypoxia, if timely detected, will receive neuroprotective (pharmacologic) treatment in utero, further ameliorating the consequences of perinatal hypoxia-ischemia. In the Chapter 137 this will be discussed more in detail.

136.5 Diagnosis of the Severity of Perinatal Asphyxia and Prediction of Long-term Outcome

Animal experiments have demonstrated that perinatal asphyxia can lead to brain injury and cerebral palsy comparable to patterns seen in the human neonate [17, 69, 70]. During the last decade many studies have focused on early detection of brain injury in neonates following perinatal asphyxia. Meanwhile, research has focused on neuroprotective strategies aiming at a reduction of permanent brain injury. In this section both assessment of the severity of the hypoxic-ischemic event as well as prediction of long-term outcome will be discussed.

136.5.1 Prenatal Assessment of Fetal Hypoxia

Abnormal fetal heart rate patterns [71, 72], changes in umbilical and cerebral blood flow observed using antenatal Doppler examinations [71, 73], altered fetal behavior [74, 75], abnormal scalp blood gas values [76] or the intrauterine passage of meconium [77] may indicate fetal hypoxia. However, they do

Table 136.4 Indications of fetal hypoxia

Indications of fetal hypoxia	Reference
Fetal heart rate patterns	[71, 72]
Doppler examinations	[71, 73]
Fetal behavior	[74, 75]
Scalp blood gases	[76]
Meconium production	[77]
Fetal ECG changes	[79]

not predict the development of neonatal encephalopathy, and are poor predictors of the development of cerebral palsy [78]. Recently, changes in the fetal electrocardiogram (ECG) have been reported to correlate well with fetal hypoxia. This so-called STAN method needs further study, but appears a promising tool for better evaluation of the fetus (Table 136.4) [79].

136.5.2 Postnatal Assessment of the Neonate

136.5.2.1 Apgar Score

Virginia Apgar has published a scoring systems for clinical assessment of the neonate [9]. This scoring system has been designed to help in the decision whether or not to resuscitate the neonate, but has been wrongfully used to make the diagnosis of perinatal asphyxia [80].

Since the Apgar score can be low due to transplacentally obtained drugs that depress the central nervous system (like anesthesia), trauma during delivery or reflex inhibition of breathing due to frequent suctioning, clinicians debated whether a low Apgar score always reflects perinatal asphyxia, and predicts neonatal encephalopathy and cerebral palsy. Nevertheless a 10 min Apgar score of 5 or less had a sensitivity of 43% and a specificity of 95% towards an adverse outcome [31]. A good Apgar score does not guarantee the absence of cerebral palsy (CP) in later life, since neonates with antenatally acquired brain lesions may have normal Apgar scores [81]. Apgar scores of 0–3 at one minute were found in 31% of full-term neonates with encephalopathy compared to 1% of control infants [82]. In neonates with seizures Apgar scores were significantly lower at 1–20 minutes after birth compared to control neonates [83].

In preterm infants the Apgar score may be influenced by prematurity [84]. Respiratory efforts, muscle tone, and reflex activity were significantly lower at declining gestational ages. The Apgar score alone is not enough to ascertain perinatal asphyxia and predict neonatal encephalopathy.

136.5.2.2 Blood Gas Values

In the years following the use of the Apgar score insight was obtained in the values of pH, oxygen and carbon dioxide in fetal scalp blood [76] and umbilical cord blood [85]. It was shown that severely depressed neonates had lower pH values, larger base deficits and elevated levels of lactate compared to vigorous and moderately depressed neonates, reflecting anaerobic glycolysis [85]. Sykes et al demonstrated that Apgar scores do not reflect the degree of acidosis at delivery [86], as only 19% of the neonates with a 5 min Apgar score < 7 had a pH ≤ 7.10 and a base deficit ≥ 13 mmol/L and 86% of the neonates with a pH ≤ 7.10 and a base deficit ≥ 13 mmol/L had a 5 min Apgar score ≥ 7. Similar findings were reported thereafter [87]. A pH value below 7.0 seems to have a better predictive value towards a poor outcome than higher cut-off values [15, 88, 89]. In the study by Goodwin et al, 31% of the term neonates with a pH of the umbilical artery below 7.0 developed neonatal encephalopathy. Neonates with more severe forms of acidosis had a much higher chance of seizures and more severe forms of neonatal encephalopathy [15]. Recently, this was confirmed in our institute. In addition, the good outcome in the encephalopathic neonates suggests that an adverse long-term outcome could be prevented with adequate neonatal care (Table 136.5) [90].

Table 136.5 Postnatal evidence of asphyxia

Postnatal evidence of asphyxia	Reference

• Neurophysiology	
– Evoked Potentials	[150–155]
– aEEG	[56, 143–145, 147, 149]
• Neuroimaging	
– CBF	[32, 124]
– NIRS	[123, 125]
– Ultrasound	[126]
– MRI	[4, 8, 127–134]
– MRS	[135–137]

Others have used a low buffer base in the umbilical artery as a sign of fetal hypoxia. Of the 25 neonates with a buffer base < 30 mmol/L, 14 (56%) developed neonatal encephalopathy, and only six (2%) severe neonatal encephalopathy [91]. Nevertheless, unexpectedly low pH values in vigorous neonates do not seem to result in neonatal encephalopathy [92]. Elevated levels of (nor)adrenalin may play a role in these hypoxic but vigorous neonates [93].

Belai studied umbilical arteriovenous PCO_2 differences in neonates with an umbilical artery pH < 7.00 in relation to neonatal encephalopathy [94]. Cut-off value of the AV-PCO_2 difference was 25 mmHg or more (sensitivity 89%, specificity 56%).

Scoring systems combining Apgar scores, or the need for resuscitation, blood gas values and fetal monitoring have claimed to be of a better predictive value towards the development of severe clinical complications, including neonatal encephalopathy [95–98]. These systems, however, have not yet been widely used.

In a group of term and preterm neonates with a pH < 7.0 a high arterial base deficit (> 16 mmol/L) and a 5-min Apgar score < 7 predicted neonatal morbidity, including cerebral complications [99].

Blood gas values cannot be used for prediction of long-term outcome. This may be caused in part by the reflection of total body metabolism with blood gases, whereas specific CNS measurements would render more specific information.

136.5.2.3 Other Biochemical Markers of Perinatal Asphyxia

Umbilical cord blood lactate levels and lactate/pyruvate ratios were found to be elevated in all full-term neonates with neonatal encephalopathy [11], and these may be more accurate than blood gases, although this has been questioned in an earlier study [87]. Cerebrospinal fluid (CSF) lactate was elevated in a small sample of asphyxiated infants within 8 hours after birth [100]. Urine lactate/creatine ratios identified newborn infants at risk for hypoxic-ischemic encephalopathy [101]. Decreased cAMP levels were described in neonates with severe neonatal encephalopathy and a poor outcome [102]. Hypoxanthine has also been used as a biochemical marker of birth asphyxia [103, 104]. Hypoxanthine correlated well with plasma malondialdehyde levels of cord blood, indicating free radical-induced oxidative stress [105]. Also non-protein bound iron and nucleated red blood cells count at birth reflect fetal hypoxia (Table 136.5) [106, 107].

All the aforementioned biochemical methods were used to determine the severity of hypoxia, but were not specific in predicting neonatal encephalopathy.

It was hoped that more specific markers of brain injury could be used for early prediction. CK-BB, the brain fraction of creatine kinase, was elevated in cord blood of term neonates with asphyxia [108]. However, the time course of CK-BB rise in peripheral blood following neonatal encephalopathy is unknown. Neuron specific enolase (NSE) in serum was significantly increased in neonates with neonatal encephalopathy, but levels of brain specific proteins (S-100B, NSE, and CK-BB) on the first day of life were of limited value in predicting a poor outcome [109, 110]. Brain specific proteins (neurofilament protein, glial fibrillary acidic protein, S-100B, NSE) in the CSF of asphyxiated neonates correlated with outcome at 1 year [111, 112].

Production of cytokines has been demonstrated in plasma and CSF and correlated with severity of encephalopathy and long-term outcome [113–118].

136.5.2.4 Clinical Scoring Systems

As described above the Sarnat score consists of a combined clinical and electrophysiological (EEG) score [25]. The Sarnat score has been used to predict long-term outcome. Whereas neonates with a score of I mostly showed a normal development and neonates with grade III were almost uniformly abnormal [31, 83, 119, 120], prediction of development in neonates with grade II neonatal encephalopathy was very difficult, as 25% had an abnormal outcome. As the Sarnat score is performed at 24 hours, its value in selection of neonates for intervention is very limited.

Wayenberg et al developed an early neurological score which was assigned at 30 min of life based on consciousness, respiratory pattern, Moro and grasp reflexes [121]. The predictive value towards the development of neonatal encephalopathy was not better than measurement of an arterial base deficit. Similar observations were done by Perlman: the triad of delivery room intubation, a five minute Apgar score of ≤ 5, an umbilical arterial pH <7.00 and/or initial arterial postnatal base deficit of ≥14 mmol/L, followed by an abnormal neurological examination at 3 ± 2.5 hours of life predicted an abnormal outcome (sensitivity 92%, specificity 52%) [122].

Thompson et al designed a clinical scoring system to quantify encephalopathy during the first few hours after birth [33]. Larger studies are needed to verify the usefulness of this system.

136.5.2.5 Neuroimaging

Cerebral Blood Flow and Oxygen Consumption

Studies in term neonates with severe neonatal encephalopathy using Doppler ultrasound or Near Infrared Spectrophotometry (NIRS) demonstrated changes in cerebral blood flow (CBF) and blood volume predicting an adverse outcome [32, 123–125]. Further studies are needed to assess the clinical value of NIRS and CBF measurements.

Cranial Ultrasound Imaging

Cranial ultrasound abnormalities, such as lesions in the thalami and basal ganglia, are usually first seen after the first day of life [126]. The presence of the abnormalities mentioned above on the first day of life, would therefore strongly suggest an antenatal onset of the insult.

Magnetic Resonance Imaging

Cranial magnetic resonance imaging (MRI) is increasingly being used during the immediate neonatal period [127–129]. MRI on the first day of life may still be normal [130]. Diffusion-weighted MRI has been extremely useful to detect early changes in hypoxic-ischemic brain tissue. By creating maps of the Apparent Diffusion Coefficient of water (ADC-maps) values of individual areas can be calculated. These ADC changes reflect cytotoxic edema, and are dependent on the time after the insult, since cytotoxic edema will change into vasogenic edema which has a different ADC value [131]. When MRI is performed before the second day of life images may still be normal since full secondary energy failure has not yet developed [132]. We and others advise to perform MRI after day 3–4 in asphyxiated full-term neonates. MRI is a good predictor of long-term motor development.

In a recent study using MRI we have demonstrated that acute insults were common in neonates with neonatal encephalopathy [4].

Different patterns of cerebral involvement after perinatal asphyxia have been described using MRI [133, 134]. In brief, abnormalities of the basal ganglia and thalamus are seen after an acute hypoxic-ischemic event such as placental abruption or uterine rupture. In the most severe cases abnormalities of the white matter can be seen. In more chronic hypoxic-ischemic events abnormalities of the white matter are encountered, sometimes in a watershed-like distribution [8]. Neonates with these abnormalities do not show any changes in basal ganglia or thalamus.

These different patterns are similar to those in animal experiments in the 1970s and in human post mortem studies [70].

Magnetic Resonance Spectroscopy

Cerebral metabolism will change during and following asphyxia. High energy phosphates will decrease, and lactate will be increased. Changes in energy metabolism can be visualized by 31-Phosphorus magnetic resonance spectroscopy (MRS). Decreased phosphocreatine and ATP levels in the first week of life correlated with an abnormal outcome [135]. In addition, the presence of a secondary energy failure could be identified in experiments and human neonates [28]. Elevated cellular pH levels could be demonstrated in neonates with perinatal asphyxia and a poor long-term outcome [136].

With 1H-MRS, increased lactate levels could be seen in brain tissue of asphyxiated neonates with a poor neurodevelopmental outcome. In addition, decreased levels of N-acetylaspartate, a neuronal marker, could be identified (Fig. 136.2) [137]. These abnormalities may persist for a prolonged period.

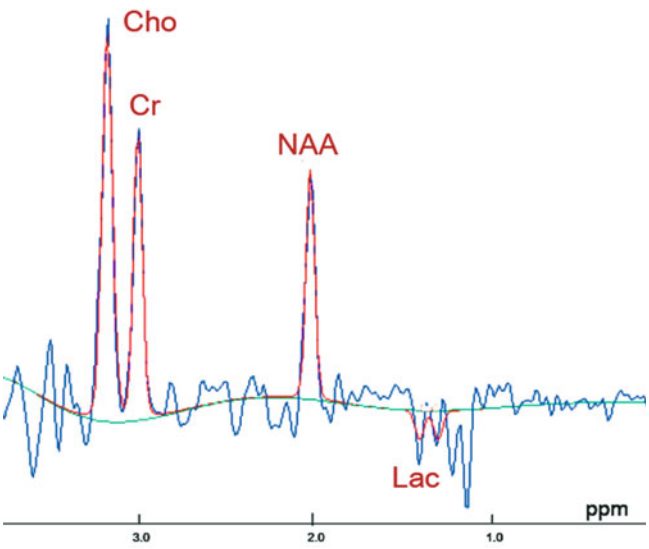

Fig. 136.2 Proton Magnetic Resonance Spectroscopy of the basal ganglia of patient A in Fig. 136.1, demonstrating a low N-acetyl-aspartate/choline ratio and elevated lactate (inverted doublet at 1.33 ppm). At 1.1 ppm the inverted doublet of propan-1,2-diol (component of phenobarbital solution) is visible (not fitted)

Neurophysiology

The electroencephalogram (EEG) has been used during the last few decades in asphyxiated neonates and is recognized to be of predictive value with regard to neurodevelopmental outcome [138–140]. These studies showed that the electrical background activity was more predictive than the presence or absence of seizure activity [138–141].

The use of conventional multichannel recordings has practical limitations. Recordings usually last 30–45 minutes, making it difficult to follow changes over a longer period of time and recognition of prolonged subclinical seizures [142]. Smaller systems have been used in neonatal intensive care units. The cerebral function monitor (CFM) was first introduced in the neonatal intensive care unit by Bjerre [143]. Since then, many studies have been performed in newborn infants using this technique [143–145]. It records a single channel EEG from biparietal electrodes. The filtered signal is rectified, smoothed and amplitude integrated before it is written out on a semilogarithmic scale at slow speed (6 cm/hr). The CFM, usually referred to as the aEEG (amplitude integrated EEG) is easy to apply and has a high concordance with the standard EEG [56, 146]. Continuous recordings can be made, allowing us to assess the background pattern and the presence or absence of sleep-wake cycling. Seizure activity can be recognized as a saw-tooth pattern. In the newer types of the devices, the raw EEG is stored on hard disk and available for evaluation. Several groups have now used the aEEG in infants with neonatal encephalopathy [143, 144]. Recovery of the aEEG background pattern within 24 hours after birth resulted in a good outcome in 61%, whereas all infants with a suppressed background pattern after 24 hours showed a poor outcome [147].

Several studies have shown that aEEG and EEG performed before 6 hours of age can be used to reliably select infants at risk of subsequent neurological handicap. Hellström-Westas et al [148] were the first to report infants, in whom aEEG registration was started before 6 hours of age. A continuous aEEG background pattern was almost a guarantee of a normal outcome. A flat or CLV pattern predicted death or a severe handicap. Very similar data were obtained by Eken et al [149]. Techniques such as aEEG are extremely useful to select neonates who may benefit from an intervention after perinatal asphyxia (Fig. 136.3) [36].

Evoked potentials (EPs) are averaged clinical responses, occurring in the EEG in response to repetitive stimuli (auditory, visual, somatosensory) and can examine the functional integrity of the sensory pathways within the nervous system in a non-invasive way [150, 151]. The EEG is of higher amplitude than the EP, but is random to the applied stimulus. The EP is of small amplitude, but constant relative to the applied stimulus and will gradually emerge from the EEG, when an adequate number of stimuli are averaged.

Both visual (VEP) and somatosensory (SEP) potentials have a very strong predictive value with regard to neurodevelopmental

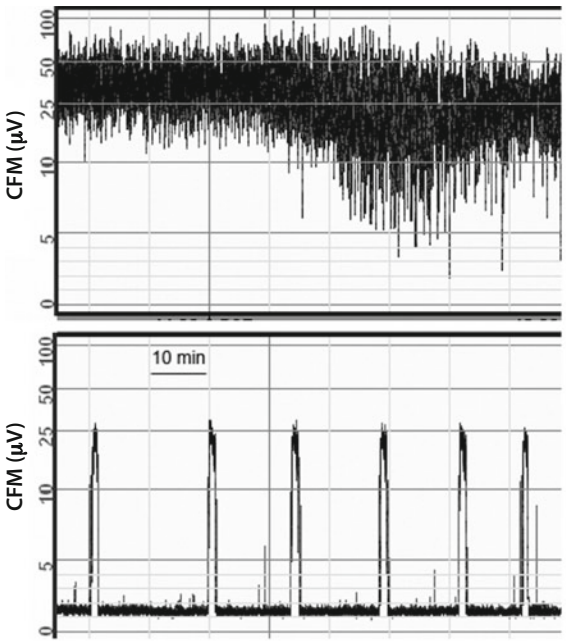

Fig. 136.3 Different aEEG patterns in asphyxiated full-term neonates written on a semilogarithmic scale (Courtesy Dr. Mona C. Toet). *Upper panel*: continuous normal voltage. *Lower panel*: repetitive seizures on a very suppressed background pattern

outcome, when performed during the first week of life [150, 152, 153]. SEPs are more likely to be abnormal on the initial test, but normalization within the first 3–4 days of life is still compatible with a normal neurological outcome [150, 153–155]. Abnormal VEPs during the first week of life were always predictive of death or cerebral palsy according to Taylor, but this was not supported by our own data.

During the last decade aEEG has replaced VEP and SEP as a bedside tool to assess the severity of neonatal encephalopathy after perinatal asphyxia.

136.6 Summary

At present, clinical observations, acidosis of cord blood, in combination with continuous aEEG monitoring are the best way to detect neonatal encephalopathy after perinatal asphyxia. Well-documented asphyxia, including need for resuscitation and neonatal encephalopathy are good predictors of a poor outcome, and could be used to select neonates for neuroprotective strategies. Patterns of brain injury can be visualized with MRI, especially diffusion-weighted MRI and ADC maps, preferably performed after the third day of life.

Neuroprotective Strategies

Angela M. Kaindl, Géraldine Favrais and Pierre Gressens

137.1 Introduction

The mortality of infants, especially premature infants, has decreased remarkably in recent decades, but their morbidity has not followed the path at the same pace. Thus, neurocognitive morbidity, especially following premature birth, is a dominating health care issue. While the development of strategies to improve the neurologic outcome of infants suffering from perinatal brain damage is thereby essential, currently available intervention strategies are limited. Perinatal brain damage is believed to be a multifactorial, multihit process that varies in severity between individuals, affects infants of different genetic backgrounds and occurs at various stages of the physiological developmental program (Fig. 137.1). This said, it becomes clear that the respective pathologies, even following one type of injury, are likely multiple. Patterns of brain lesions depend on developmental stage. Periventricular leucomalacia is particularly frequent in the premature infant, while hypoxic-ischemic encephalopathy affects predominantly the term infant. The development of novel neuroprotective strategies thereby demands a clear understanding of the pathophysiology of each of the disorders in order to identify readouts or targets/pathways to test for the efficacy of candidate molecules. Since many developmental processes underlie a fine balance, careful attention needs to be paid to acute and long-term toxic effects. It remains to be elucidated, for example, when a decrease of apoptotic cell death is beneficial or detrimental.

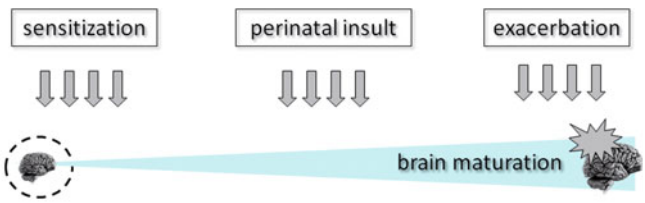

Fig. 137.1 Multiple-hit hypothesis for the development of perinatal brain damage. Schematic representation illustrates the multiple-hit hypothesis including pre-, peri- and postnatal factors. Several risk factors are implicated and are frequently associated with the pathogenesis of perinatal brain damage in animal models. These comprise prenatal risk factors such as inflammation/cytokine release and maternal stress, perinatal factors such as hypoxic-ischemic stimuli, and postnatal factors such as growth factor deprivation, inflammation/cytokine release, drug side effects and pain (see Table 137.1). Furthermore, a combination of such factors in experimental models has resulted in the emergence of a multiple-hit hypothesis, which consists of a sensitization state created by a mild first event, leading to an increased susceptibility to a second injury. These factors may cause various lesions depending also on the developmental stage of the brain

137.2 Pathophysiology of Brain Diseases and Definition of Targets

The development of neuroprotective strategies is based on fundamental knowledge of the induction and progression of brain damage. For this, brain pathology has been studied in postmortem tissues from patients as well as in animal models that mimic human pathology. Such approaches have allowed various intertwined causes and mechanisms that induce white and/or grey matter damage of the central nervous system to be distinguished (Table 137.1), for review see [1]).

Table 137.1 Risk factors for encephalopathy of prematurity

Antenatal factors	Perinatal factors	Postnatal factors
Inflammation	Hypoxia-ischemia	Oxidative stress
Hypoxia-ischemia	Excitotoxicity	Inflammation
Toxins	Oxidative stress	Pain
Malnutrition	Loss of maternal GF	Excitotoxicity
Maternal stress	Drugs	Drugs
Genetic factors	Genetic factors	Loss of maternal GF Genetic factors

GF growth factor.

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

Owing to epidemiologic and experimental studies, neonatal brain susceptibility to perinatal insults is well known. Periventricular white matter damage (PWMD) affects preterm neonates born between 23 and 32 weeks of gestation and follows successive pathologic events from pre- to postnatal period. In parallel, brain lesions proceeding from acute hypoxia-ischemia in at term neonates involve an apoptotic/necrotic process leading to early and delayed neuronal cell death in the gray matter, mainly at thalamic level. Pathophysiologic events in conditions of perinatal brain damage that represent targets for neuroprotective therapy are summarized in Table 137.2 (Figs. 137.2 and 137.3).

Table 137.2 Pathophysiologic events in conditions of perinatal brain damage that represent targets for neuroprotective therapy

Primary and secondary energy failure	– In situations of reduced oxygen supply the metabolism is redirected towards anaerobic glycolysis to reduce the requirement for oxygen – This leads to a decreased production of ATP and primary energy metabolites and thus to a secondary energy failure
Excitotoxicity	– Energetic breakdown induces a surge of glutamate that accumulates in the synaptic gap due to cell damage and the inability of astrocytes to recycle these high levels of the neurotransmitter at an adequate pace – Excitotoxicity refers to the deleterious effects of such high glutamate levels on brain tissue: overactivation of glutamate receptors, massive influx of calcium, secondary cell damage, etc
Oxidative stress	– Oxidative stress, i.e., an increase of free radicals, results from activation of multiple pathways such as excitotoxicity or microglia activation – This can lead to fragmentation of DNA and of membranes and thereby trigger necrotic cell death – During the fetal and neonatal phase, recycling of such free radicals by scavengers is limited, and this renders the developing brain particularly vulnerable to oxidative stress
Mitochondrial failure and cell death	– Mitochondria are central organelles implicated in physiological energy supply, but also in the process of cell death following initial brain injury through activation of the cytochrome C and caspase pathways
Microglia activation	– Microglia, the resident macrophages of the central nervous system (CNS), constantly screen the CNS and can be activated rapidly through various environmental changes. In the activation process, microglia change their phenotype, proliferate, migrate to the site of damage and secrete pro-inflammatory factors and participate in the generation of oxidative stress (of note, a protective role of microglia is also known)
Increase in brain blood barrier (BBB) permeability	– Brain damage increases the permeability of the BBB and thereby facilitates the infiltration of immune cells (e.g., macrophages, lymphocytes), toxic molecules and of water from the circulating blood pool – One reason for the dysfunction of the BBB is the degradation of tight junctions within this barrier by increased activation of matrix metalloproteases (MMPs) in the extracellular matrix
Neuroplasticity	– Neuroplasticity refers to changes that occur in the organization of the CNS throughout brain development and also within the mature brain – Following lesions, various phenomena of plasticity and reparation can appear such as increased rates of stem cell proliferation and differentiation

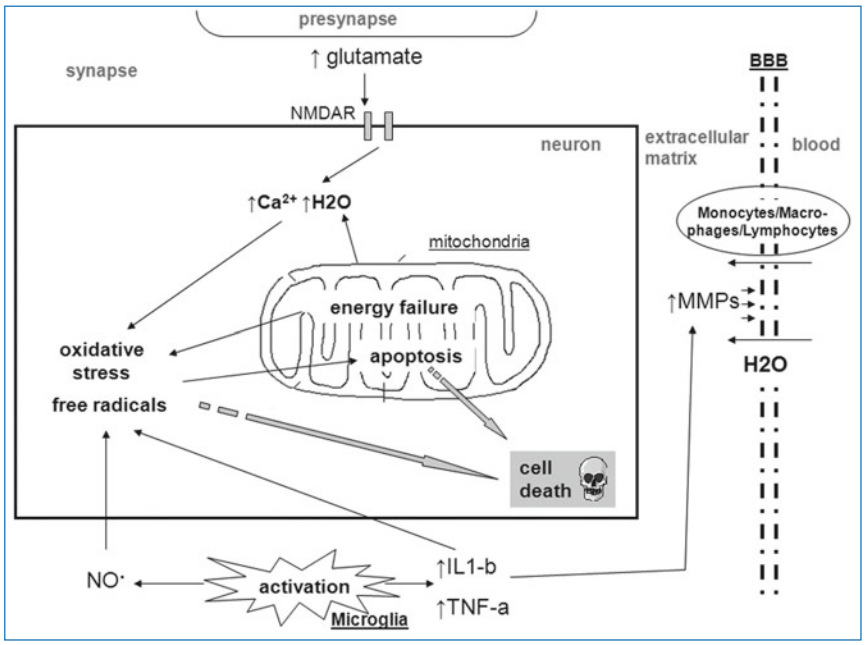

Fig. 137.2 Pathophysiologic mechanisms implicated in cell death following a brain lesion. *MMPs* metalloproteinases, *NO* nitric oxide, *NMDAR* N-methyl-D-aspartate receptor, *BBB* blood brain barrier

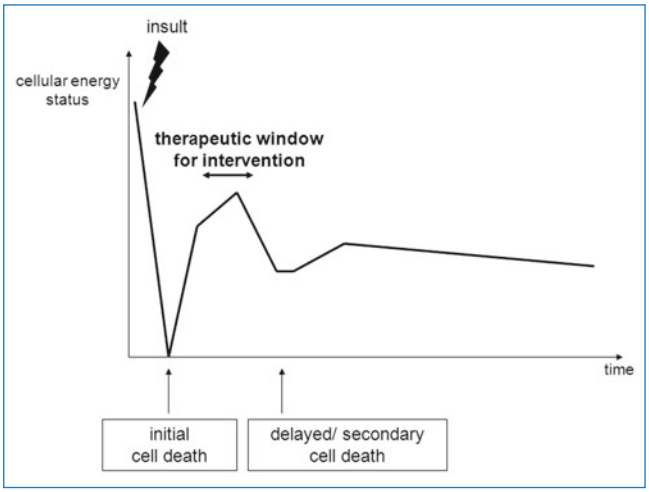

Fig. 137.3 Kinetics of cellular energy status following an acute brain lesion. Results of an *in vivo* study of phosphate metabolites during hypoxic-ischemic brain damage have permitted a biphasic kinetic of the energy breakdown to be identified. Primary energy breakdown occurs in the initial phase of brain damage. Later, during reperfusion, a transitory reconstitution of ATP and antioxidant levels is noted, preceding a further dip in the production of ATP. The latter is referred to as secondary energy breakdown and occurs about 4–8 hours after the initial damage. Its time of occurrence offers a feasible therapeutic window for neuroprotective strategies. Modified from [2]

137.3 Neuroprotective Strategies: Experimental Results

Deciphering the nature and temporal appearance of phenomena that follow damage to the cerebral parenchyma allows for the identification of potential therapeutic targets and the therapeutic window preceding the onset of secondary cell death. Various therapeutic strategies have been tested *in vitro* and *in vivo* in animal models. Principal limiting factors of these pharmacologic approaches are 1) the passage of molecules via the BBB, 2) the potential toxicity of applied molecules, 3) the therapeutic window and thus the existence of a beneficial effect even when a molecule is applied relatively late after a brain damage, and 4) the persistence of a long-term protective effect.

Several molecules have been shown to be efficient in the reduction of lesion sizes/extents and their consequences. In general, neuroprotective approaches can include mechanisms such as an inhibition of sensitizing factors, preconditioning against damage, a pharmacological blockage of mechanisms involved in primary or secondary damage or treatment that increases endogenous reparation processes or cause reparation by themselves (Fig. 137.4). Even though these drugs usually act on several levels of a damage cascade, we will classify them below according to their most prominent (or most studied) effect.

137.3.1 Anti-inflammatory Agents

137.3.1.1 Minocyclin

Minocyclin is an antibiotic of the tetracycline family and can pass the blood-brain barrier (BBB). In addition to its antibacterial effect, its administration immediately after a hypoxic-ischemic or infectious damage to the brain in animals has disclosed a significant reduction of microglia activation, of pro-inflammatory cytokine production and of oxidative stress induction in the brain. This anti-inflammatory effect is accompanied by a reduction of matrix metalloproteinase (MMP) production and an increased tightness of the BBB by magnetic resonance imaging. Minocyclin also has anti-apoptic properties that are mediated on the level of mitochondrial transition permeability. This pluripotent molecule is well tolerated by adults, and a positive effect in the treatment of neurodegenerative diseases has been demonstrated. However, the effect of minocyclin regarding an improvement of the neurologic prognosis stays controversial. In addition, minocyclin is contraindicated in children below an age of 9 years.

137.3.1.2 Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

Cyclo-oxygenases are essential for the formation of prostaglandins and thromboxan from membranous arachidonic acid. Two types of cyclo-oxygenase are distinguished: the cyclooxygenase type 1 (COX-1) or constitutive type and the cyclooxygenase type 2 (COX-2) or inflammation inducible type. NSAIDs that selectively block COX-2, such as nimesulid, are preferably applied, even though positive results have been obtained with indomethacin and ibuprofen. Nimesulid has been shown to have a neuroprotective effect in models of focal and diffuse ischemia and systemic inflammation

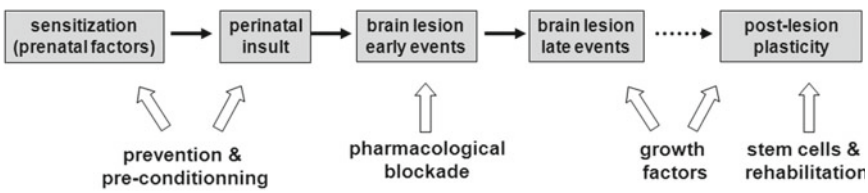

Fig. 137.4 Schematic representation of the potential strategies for neuroprotection against perinatal brain damage

in a sustained manner despite a late application up to 6 hours after the acute incident. Neuroprotective mechanisms include an inhibition of TNFa expression while increasing that of interleukin-10 (IL-10), a prevention of BBB dysfunction and a reduction of oxidative stress [3–5]. These promising results have not been confirmed in humans so far. Thus, their administration needs to be seen with caution in the context of inflammatory brain diseases, also because of potentially toxic effects in the newborn in which the hepatic metabolism for NSAIDs is reduced.

137.3.2 Excitotoxicity Reducing Agents

Strategies developed to limit excitotoxicity are based on an inhibition of postsynaptic glutamate receptors. Thereby, the principal difficulty is to block toxic/overstimulated receptors without inhibiting the physiologic function of these receptors essential for normal brain development and function. It has been demonstrated that an unselective inhibition of the N-methyl-D-aspartic acid (NMDA) receptor in critical periods of brain development triggers apoptosis, inhibits cell proliferation and causes neurobehavioral deficits in rodents. Still, blockage of NMDA receptors, especially of certain subunits, can be neuroprotectrive, as has been shown in various animal models for example using memantine. This paradox illustrates the difficulty in the balance between beneficial and harmful effects of neuroprotective strategies in the course of brain development.

137.3.2.1 Magnesium

Magnesium binds NMDA receptors and inhibits their activation; this block is removed by membrane depolarization. Thereby, magnesium possesses a modulatory role and inhibits excitotoxic stress. An anti-apoptotic effect has been demonstrated in animal models. The administration of magnesium to pregnant women presenting with threatening premature birth has shown to be beneficial with regard to the incidence of cerebral palsy and motor dysfunction in the infant born prematurely [6] with a good tolerance of the protocols administrated [7]. In adult victims of traumatic brain injury, epidemiologic studies have identified low magnesium levels < 1.3 mmol/L as a negative prognostic factor [8]. Still, a prolonged intravenous supplementation of high doses of magnesium was not beneficial, and the passage of magnesium across the BBB in the adult is uncertain [9, 10].

137.3.2.2 Topiramate

The antagonism of α-amino-3-hydroxyl-5-methyl-4-isoxazole-propionate (AMPA) and kainat receptors, for example through topiramate, has not shown effects as deleterious on neuronal survival as those acknowledged for NMDA receptor antagonists in the developing brain. In addition, a protective effect of topiramate on preoligendrocytes, cells that have been shown to be severely affected after an excitotoxic stress or hypoxic-ischemic stress in the neonatal period, has been demonstrated [11]. Topiramate has been approved for use as an antiepileptic drug in children older than 2 years. So far, topiramate is not used as a neuroprotective agent but its good tolerance and further experimental data argument for further analysis of this application.

137.3.3 Antioxidants

Two approaches have been developed to limit oxidative stress. The first consists of a reduction of free radical production through xanthine oxidase inhibition, of lipid peroxidation and of inducible nitric oxide synthase (iNOS). The second approach consists of increasing antioxidant defense mechanisms through an increase of reactive oxygen species (ROS) and reactive nitrogen species (RNS) scavengers.

137.3.3.1 Allopurinol

Allopurinol is an inhibitor of the xanthine oxidase. Its neuroprotective action, particularly through the reduction of oxidative stress and of cerebral edema, and its good tolerance has been shown in various animal models; this supports the realization of clinical studies in humans. It has been employed in therapeutic essays in infants with hypoxic-ishemic encephalopathy. In a first study, a reduction of the nitric oxide (NO) concentrations at 72–96 hours of life were measured in the serum of newborns suffering of moderate to severe hypoxic-ishemic encephalopathy following allopurinol treatment. This was associated with an amelioration of the neurologic outcome at 12 months of life [12]. Despite this, a meta-analysis of various therapeutic essays realized for this indication has not been able to show a beneficial effect of allopurinol on mortality or on progression of neonatal convulsions [13].

137.3.3.2 Vitamin E

Vitamin E has an anti-oxidant effect through the elimination of free radicals. On the other hand, high doses have been shown to induce neuronal apoptosis *in vitro* [14]. In newborns, vitamin E supplementation reduces the risk of intraventricular hemorrhage and of retinopathy but favors the progression of sepsis, especially if its serum concentration is above 3.5 mg/dL [15]. This toxic effect of high concentrations demands caution when using this agent as a neuroprotector.

137.3.3.3 N-acetylcysteine

N-acetylcysteine (NAC) induces the production of glutathione which permits the clearance of free radicals. In

various animal models, especially those of maternal-fetal infection, a robust neuroprotective effect has been found which is accompanied by a reduction of oxidative stress, of pro-inflammatory cytokine production and of apoptosis [16, 17]. No secondary effects were observed when NAC was administered to humans in the framework of clinical studies. In the premature infant, systemic parenteral nutritional supplementation neither modified the mean mortality at 36 weeks of gestation, nor the frequency of retinopathy, periventricular leucomalacia or intraventricular hemorrhage [18]. A randomized controlled clinical study is currently being performed in children.

137.3.3.4 Melatonin

Melatonin is a hormone that participates in sleep regulation and that is secreted physiologically by the pineal gland. Its role as a neuroprotector has been shown in several animal models in the framework of degenerative diseases such as acute brain lesions. Two of the implicated mechanisms seem to dominate this effect. First, its antioxidant effect can inhibit the NO synthase and lipid peroxidation as well as RNA degradation, favoring the transcription of other antioxidant enzymes. Further, in acute lesion animal models, melatonin favors axonal outgrowth with a long-term improvement of neurocognitive function in comparison to the control animals [19–21]. Melatonin is well tolerated and crosses the BBB passively. In the near future, this drug should be used in clinical studies in order to evaluate it efficacy as a neuroprotective agent in humans.

137.3.4 Prevention of Protracted Cell Death and Modulation of Plasticity

Possible strategies against apoptotic cell death or those that favor mechanisms of reparation are particularly interesting because the treatment window relative to the initial damage is particularly large.

137.3.4.1 Erythropoietin

Erythropoietin (Epo) is a hematopoietic growth factor whose secretion is sensible to hypoxia. It is also a ubiquitous cytokine for which receptors exist on cells of the central nervous system. Moreover, it is currently applied in its recombinant form (rEpo) in neonatal medicine for treatment of anemia of prematurity and because of that has also been tested in experimental animal models regarding its effect on lesions of the developing brain. Experimental data have demonstrated an anti-apoptotic effect. This effect is accompanied by a reduction of pro-inflammatory cytokines, a reduction of oxidative stress, a recuperation of the energetic level and an increase of trophic factors involved in reparative processes [22–25]. In animal models, often high doses of rEpo are applied (higher than those currently used in the human newborns), and the beneficial effects are dose-dependant [25]. Using the currently applied doses, no study has been able to show a beneficial effect on brain development [26]. Due to concern regarding negative effects such as thrombosis and hypertension in adults with kidney failure, clinical trials have been placed on hold.

137.3.4.2 Progesterone

The better outcomes of female subjects in behavioral tests after a cerebral lesion have drawn attention to the neuroprotective potential of sex hormones, in particular of progesterone. In fact, treatment of animals with intravenous progesterone has shown a neuroprotective effect in various animal models, particularly in adult ovariectomized subjects. In parallel, progesterone is also secreted by glial cells independent of the sex, especially in the inflammatory context. The neuroprotective and neurotrophic effect of progesterone is multifactorial. Its modulatory effect on postsynaptic receptors, particularly on $GABA_A$ receptors, and on transmembrane ion movements via Na-K-ATPases has been most extensively studied. It also has an anti-edematous effect. Progesterone has been the focus of several clinical phase II studies in human adults particularly in the treatment of traumatic brain injury (TBI) where a good tolerance, a reduction of mortality and an amelioration of the neurologic outcome 6 months after TBI has been shown. So far, no study has been performed in children.

137.3.4.3 Cyclosporine A

Cyclosporine A is an immunosuppressant and has been shown to be neuroprotective in various models of brain damage including TBI and hypoxia-ischemia in adults. This is in part due to its ability to inhibit an increase of mitochondrial permeability, an initial step in apoptotic cell death preceding the breakdown of mitochondria, and to modulate calcineurin which intervenes in the regulation of ion channels and the synaptic plasticity favoring axonal regrowth. A phase II clinical study has established the doses permitting a good tolerance after a TBI in adults prior to tests regarding its efficacy on the neurologic outcome.

137.3.4.4 Hypothermia

Since the early 90s, hypothermia has been in the focus of several animal studies regarding its neuroprotective effect following hypoxia-ischemia or traumatic brain injury. Results

of these studies have indicated that hypothermia reduces secondary energy breakdown, oxidative stress, BBB rupture extent and apoptotic cell death (for review see [27]). These studies have allowed the window for therapy initiation (within 6 hours of life), the duration of therapy (72 hours) and the ideal cooling temperatures (33–35°C) to be determined. The clinical studies have allowed the relative innocuousness of moderate hypothermia in the term newborn to be established and have only shown individual cases of sinus bradycardia and thrombopenia without hemorrhage. Two cooling procedures have been applied in these clinical studies with the indication of hypoxic-ischemic encephalopathy stage II or III: 1) selective head cooling using a cooling cap with a maintenance of the body temperature at 34.5°C and a gradient between the scalp (25°C) and the deep brain structures (35°C); 2) a cooling of the entire body to 33.5°C leading to a homogenous cooling of the cerebral structures. So far, clinical studies have not allowed a difference between the two currently available protocols to be convincingly demonstrated. Recent experimental results demonstrated different susceptibilities of various brain structures towards hypothermia. The results of clinical studies (two were randomized controlled multicenter studies) in the newborn suffering from a stage II or III hypoxic-ischemic encephalopathy have been reviewed in a metaanalysis published in 2007. The latter supported the notion that moderate hypothermia has a benefit on mean mortality and severe handicap at 18 months of age [28]. Currently, another multicenter study (TOBY) is being performed and appears to support previous positive results. Moreover, several studies now focus on the combination of hypothermia with other agents such as rEPO.

137.3.4.5 Xenon

Xenon is an odorless gas that exists in the Earth's atmosphere in traces, can be produced by distillation processes from air and is currently being evaluated regarding is neuroprotective potential with regard to perinatal brain damage.

137.3.5 Stem Cell Therapy

The development of an adequate protocol for stem cell culturing and application has permitted the use of these cells for the reparation of cerebral lesions to be envisaged. While some studies have shown a positive effect of stem cell therapy on the lesion size/extent and/or outcome following brain lesions, it is not clear yet whether the stem cells themselves or factors secreted by stem cells mediate the positive effect. In case stem cell integration is important for their effect, these cells need to proliferate, find the site of lesion and differentiate into an adequate cell type (e.g., neuron, oligodendrocyte) and integrate into the tissue to be functional. The ethical problem associated with the use of human stem cells is less evident in mesenchymal stem cells that can be taken from cord blood or when induced pluripotent stem cells (iPS) are used. Such cells permit an autologous transplant and do not entail the problem of immune tolerance of the transplanted cells. A clinical study is currently being performed using stem cells in children with neurodegenerative diseases at the Duke University.

A further intriguing alternative to treatment with stem cells is to stimulate the production of endogenous neuronal stem cells. It has already been shown that stem cells accumulate in the subventricular zone following an acute brain lesion. These results open a new perspective: the stimulation of this stem cell population to support the physiological reparation processes of a lesion. Still, these cells will need to integrate and function correctly in the damaged tissue (for review, see [29]). Moreover, stimulation of stem cell proliferation bears the risk of cancer induction.

137.4 Neuroprotective Strategies and the Reality

Only a few drugs that have been shown to be neuroprotective in experimental models of perinatal brain damage are being studied in clinical randomized controlled studies. There are several reasons for this, including the hesitation to carry out and finance studies in infants and the uncertainty of innocuousness on development. Moreover, the neuroprotective effect of numerous molecules has been confirmed only in clinical studies performed in adults [30]. Therefore, despite an increase in research initiatives in this field, neuroprotective measures are limited in everyday clinical practice. Moderate hypothermia has been shown to improve the neurologic outcome of infants with stage II and III hypoxic ischemic encephalopathy. Despite all the positive results, hypothermia still needs to be applied with caution and in a controlled fashion since the long-term outcome of treated infants has not been sufficiently studied and so far unknown complications may occur. A central registry permitting evaluation of the clinical practice of hypothermia is warranted. In parallel, the treatment of magnesium in mothers in the case of imminent premature birth has been shown to be positive with regard to the outcome of premature infants. Other neuroprotective strategies consist mainly of preventing aggravating situations such as pain, cardiovascular instability and hyperthermia.

137.5 Conclusions

The neuroprotective concept and protocols for neuroprotective strategies have been largely developed through experimental studies. Despite this, the application in humans is limited due to difficulties of performing clinical studies in

infants with drugs that have for the most part not been FDA approved at that age in their primary indication, due to the heterogeneity of the population and the mostly moderate results in animal models. Moreover, a world-wide systematization of clinical studies on neuroprotective strategies is needed. Since the pathologies are not homogeneous, several molecules or techniques may need to be combined to further ameliorate the neurologic prognosis.

Cerebral Hemorrhage

Linda S. de Vries

138.1 Neonatal Intracranial Hemorrhage in Preterm Infants

In the late 1970s, computed tomography (CT), and shortly afterwards cranial ultrasound (cUS), was used for the first time to visualize intracranial lesions [1]. cUS initially used the temporal bone but soon the anterior fontanelle was preferred as an acoustic window. The first cUS studies used a low resolution linear mechanical sector transducer, limiting the field of view to the lateral ventricles. The adjacent white matter was poorly visualized, until mechanical sector scanning was introduced with a wider angle of insonation. Data collected in the early years is therefore very different from the data that can be obtained today, using high resolution cUS as well as magnetic resonance imaging (MRI). Since the more routine use of neonatal MRI, it has become clear that injury of the vulnerable white matter of the preterm infant is more important than hemorrhages in the germinal matrix and the ventricles (germinal matrix hemorrhage-intraventricular hemorrhage [GMH-IVH]). Lesions that were in the past visualized as GMH-IVH are often associated with subtle injury to the white matter, which can either be entirely overlooked using cUS or underestimated. Long-term outcome data of preterm infants studied in the eighties with cUS therefore need to be interpreted with care. A decline in the incidence of severe white matter lesions, referred to as cystic periventricular leukomalacia (PVL) has been reported [2, 3]. However, although a decline in the overall incidence of GMH-IVH has been reported as well, there appears to have been no decline in the incidence of more severe grades of GMH-IVH and these severe hemorrhagic lesions still have a major impact on neurodevelopmental outcome [2, 4]. Use of additional acoustic windows to the anterior fontanelle, for example the mastoid window, has allowed for the recognition of hemorrhagic lesions of the cerebellum, especially in very immature and extremely low-birth weight infants [5, 6].

138.2 Neuropathology and Pathogenesis

The germinal matrix area is highly vascularized and is described as an immature vascular rete as the vessels within the germinal matrix are primitive and cannot be classified as arterioles, venules or capillaries. It is a transient structure, initially the site of neuroblast and glioblast mitotic activity, before cells migrate to other parts of the brain. Once cell division and migration is complete, the germinal matrix progressively decreases in size with regression being almost complete by term equivalent age. The germinal matrix area is most abundant over the head and body of the caudate nucleus, but is also seen in the roof of the temporal horn until approximately 33–34 weeks of gestation. MRI has recently confirmed the abundance of the germinal matrix and has shown that small GMHs, which were not identified on cUS, may often be seen on MRI in the temporal horn. A large autopsy series from New Jersey reported that more than a third of cases with germinal matrix hemorrhage had involvement of the temporal or occipital germinal matrix [7]. The arterial supply of the germinal matrix is from the recurrent artery of Heubner (a branch of the anterior cerebral artery), as well as terminal branches of the lateral striate arteries. Venous drainage of the deep white matter occurs through a fan-shaped leash of short and long medullary veins through which blood flows into the germinal matrix and subsequently into the terminal vein which lies below the germinal matrix [8]. This has led to the understanding that a unilateral parenchymal hemorrhage is due to venous infarction [9, 10] or to reperfusion injury following an ischemic insult.

It is most often considered that hemorrhage arises from the thin walled veins [11, 12], although Pape and Wigglesworth [13] suggested from injection studies that capillary bleeding was more common than terminal vein rupture. Ment et al [14]

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

have suggested that germinal matrix vessels change significantly over the first days of life to develop greater continuity of the basement membrane. This rapid maturation, presumably as a result of early birth, may be one of the reasons why GMH-IVH usually occurs during the first few days of life.

138.3 Risk Factors Related to the Prenatal and Perinatal Periods

In the prenatal period, amniotic infection, diagnosed by histology, has been shown to increase the risk of GMH-IVH [15]. A correlation was shown between raised blood cytokine concentrations and altered hemodynamic function [16]. In a recent study, the presence of clinical maternal chorioamnionitis was associated with an increased risk of early sepsis (OR, 5.5; 95% [CI] 2.9–10.7) and severe intraventricular haemorrhage (OR, 1.6; 95% [CI] 1.2–2.2), adjusted by multivariate regression analysis for illness severity [17].

There is no evidence that cesarean section protects the premature infant against GMH-IVH. In a recent hospital based study of preterm infants with a birthweight of ≤ 1250 g, elective cesarean section had no beneficial effect on either mortality or neuro-disability at two years of age [18]. Breech delivery is in some studies associated with a higher risk of large GMH-IVH, but this effect was lost in multivariate analysis [19]. In another study, cesarean section was beneficial for the most immature infants with a gestation < 27 weeks [15]; reduced mortality, but not a reduced risk of a GMH-IVH, was reported in a Swedish population-based study of preterm infants with a gestation of 25–36 weeks [19].

Delayed cord clamping has been demonstrated to reduce GMH-IVH with five [14%] in the delayed clamping group compared with 13 [36%] in the non-delayed group; $P = 0.03$) [20]. When the impact of delayed cord-clamping on IVH was evaluated adjusting for gestational age and cesarean section, the final model indicated that the IVH rate was > 3 times higher in the immediate cord clamping group ([OR]: 3.5, 95% [CI] 1.1–11.1). In a systematic review by Rabe et al, no significant differences for infant deaths was found, but a significantly increased incidence of IVH was reported in seven of the ten published studies (p = 0.002) [21].

Infants born outside a perinatal center and transported to one also have a higher incidence of GMH-IVH [15, 22, 23]. The NEOPAIN trial showed that outborn babies were more likely to have severe IVH (p = 0.0005) and this increased risk persisted after controlling for severity of illness, but when adjustments were made for use of antenatal steroids, the effect of birth center was no longer significant [23].

Cardiovascular and respiratory problems have always been considered to play a major role in the development of a GMH-IVH in the immediate neonatal period. Fluctuations of the intravascular pressure or blood flow may lead to rupture of the immature vascular rete in the germinal matrix and hemorrhage is known to occur during reperfusion following a period of hypotension. Studies of flow in the superior vena cava during the first hours after birth, showed that low flow preceded a GMH-IVH [24]. Although the possible lack of cerebral autoregulation, rendering the cerebral circulation pressure-passive is still considered important, it is not present in all preterm infants [25]. Continuous monitoring with near infrared spectroscopy may be a useful tool in the identification of infants at risk [26]. Respiratory risk factors can occur with complications during mechanical ventilation, such as vasodilatation secondary to hypercapnia, for instance following a pneumothorax [27]. Improvement in ventilatory techniques, increased use of non-ventilatory support, such as CPAP and even variable/bilevel positive airway pressure BIPAP are likely to further reduce the incidence of GMH-IVH.

138.4 Genetic Factors

More recently there has been an interest in the role of thrombophilic disorders in the development of GMH-IVH. Factors include heterozygosity for factor V Leiden mutation, which renders factor V resistant to cleavage by activated protein C, and heterozygosity for prothrombin G20210A mutation, which was found to be associated with raised plasma concentrations of prothrombin. A large prospective study was unable to confirm previously reported associations between the above mentioned gene variants and development of intraventricular hemorrhage in very low birth weight infants [28]. Interleukin-6 CC genotype increased the risk of the development of severe hemorrhagic lesions ([OR]: 3.5; 95% [CI]: 1.0–12.2; $P = 0.038$) [29]. However, this observation could not be confirmed in a considerably larger sample [30]. Antenatal porencephaly in two preterm siblings was recently reported in association with a mutation in the collagen 4 A 1 gene (*COL4A1*) encoding procollagen type 4 α1, a basement membrane protein [31].

A reduced risk of GMH-IVH was found with maternal pre-eclampsia. This appears to be due to enhanced in-utero maturation of the fetus, associated with a reduced risk of postnatal development of respiratory distress [32].

Routine use of inhaled nitric oxide (iNO) in intubated preterm infants seems to show a reduction in the risk of severe IVH or PVL (typical RR 0.70 [95% CI 0.53, 0.91]; typical RD - 0.07 [95% CI - 0.12, - 0.02]). However, early rescue treatment with iNO was associated with a trend towards increased risk of severe IVH [33].

138.5 Incidence of GMH-IVH

The incidence of GMH-IVH is directly related to the maturity of the infant [15]. Initial studies in the late 1970s and early 1980s showed an incidence as high as 40–50% in those weighing

< 1500 g [1, 34] but these numbers reduced to 20% in the 1990s according to some studies [4, 22] but not others [35]. The average incidence of a unilateral parenchymal hemorrhage varies from 3–11% with the lowest incidence in a French population based study [36–38]. No decrease in this type of lesion was seen by Hamrick et al [2] in contrast to their decrease in cystic white matter disease and in a recent study by Sarkar [39].

138.6 Diagnosis

Even though MRI is increasingly being used, GMH-IVH is still more likely to be diagnosed during routine bedside cUS. Performing ultrasound as part of the admission procedure and several times during the first week, allows accurate timing and identification of lesions of antenatal onset. Almost all hemorrhages will have developed by the end of the first week after birth and many within the first hours after birth. Only about 10% of the GMH-IVH occur after the first week. This is in contrast to white matter injury, where a late onset is not uncommon [40]. Progression from small GMH-IVH to a parenchymal hemorrhage can occur and is most likely related to impaired venous drainage of the medullary veins in the white matter with obstruction at the site of the germinal matrix [36].

Table 138.1 Classification of cerebral hemorrhage

Description	Generic term
Grade I: Germinal matrix hemorrhage	GMH-IVH
Grade II: Intraventricular hemorrhage without ventricular dilatation	GMH-IVH
Grade III: Intraventricular hemorrhage with acute ventricular dilatation (clot fills > 50% of the ventricle)	GMH-IVH and ventriculomegaly
Hemorrhagic parenchymal infarction (describe size, location)	HPI

Modified from [41].

Clinical diagnosis does not play a major role, as most cases of the GMH-IVH will be silent. Three clinical syndromes have been described [41]. The first is associated with a catastrophic deterioration, with a sudden deterioration in the clinical state of the infant, such as a sudden fall in blood pressure and or metabolic acidosis. It is however more common to find a sudden fall in hemoglobin without a clear change in the condition of the child. The second clinical syndrome is a saltatory one, with a more gradual onset, presenting with a change in general movements. The silent, asymptomatic syndrome is most common and can even occur in infants who show a parenchymal hemorrhage on a routine repeat ultrasound examination.

Volpe suggested a classification system [41] to describe early and late ultrasound appearances (Table 138.1). The use of grade IV is avoided and a separate description of the size, site and appearance of a parenchymal lesion is preferred. It is not always possible to distinguish between a small hemorrhage restricted to the germinal matrix and a GMH with some blood ruptured through the ependyma into the ventricular lumen. The use of the posterior fontanelle as an alternative acoustic window has been advocated by Correa et al [42] showing improvement in the diagnosis of a small IVH (Fig. 138.1). GMH at sites other than the head of the caudate nucleus, like the roof of the temporal horn, often remain undiagnosed and will only be diagnosed when an MRI is also performed [43].

A large IVH can be confidently identified by US, although associated white matter damage may be more reliably diagnosed with early MRI (Figs. 138.2, 138.3). Distinguishing a large, bulky choroid plexus, which is common in very immature infants, from a large IVH is not always easy and sequential examinations and examination through the posterior fontanelle may help. Blood can acutely dilate the ventricle or can lead to posthemorrhagic ventricular dilatation (PHVD) a few weeks later; the larger the amount of blood, the more likely for this to occur. Blood spreads rapidly through the foramen of Monro into the third ventricle, the aqueduct of Sylvius, the fourth ventricle, the foramina of Magendie and Luschka and eventually into the posterior fossa. Clot formation can

Fig. 138.1 Cranial ultrasound of a preterm infant born at 29 weeks GA, coronal and parasagittal views, taken through the anterior (**a**, **b**) and posterior (**c**) fontanelle, showing an intraventricular clot and a dilated occipital horn

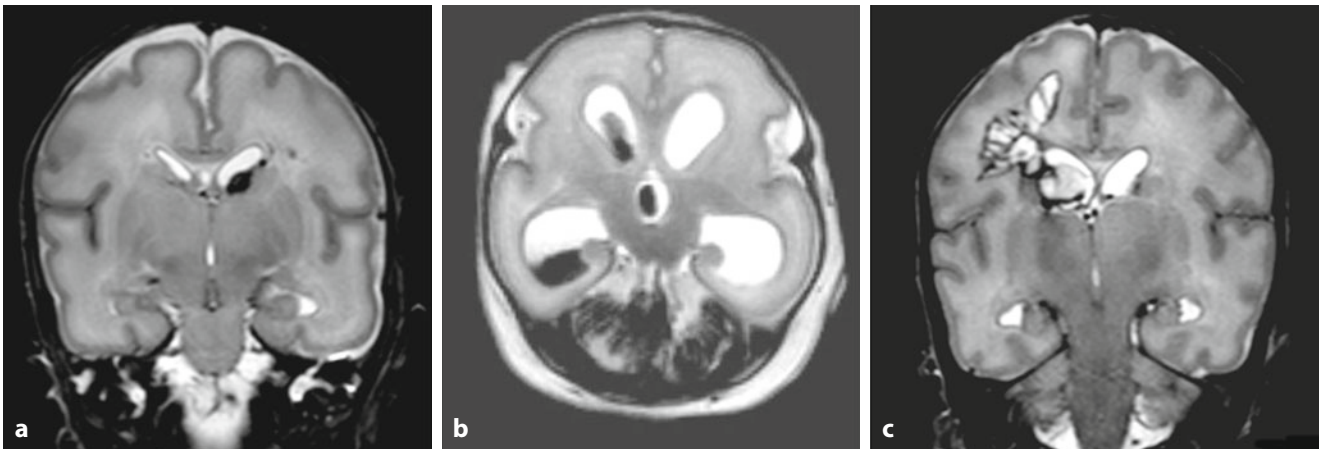

Fig. 138.3 MRI (T2 weighted sequence) of the three preterm infants shown in Fig. 138.2; IVH associated with petechial hemorrhage in the left periventricular white matter (**a**); besides large IVH, bilateral cerebellar hemorrhages are seen (**b**); IVH and PHI, similar to cUS (**c**)

occur at any level and lead to outflow obstruction, but it is most commonly seen at the level of the aqueduct or, more diffusely, in the posterior fossa. Depending on the degree of blood and the site of obstruction, PHVD can be rapidly progressive and non-communicating; it is usually due to obstruction at the level of the aqueduct of Sylvius, or, if more gradual in onset and communicating, due to obliterative arachnoiditis.

A unilateral parenchymal hemorrhage, referred to in the literature as hemorrhagic parenchymal infarction (HPI) or venous infarction (VI) accounts for 3–15% of all GMH-IVH [36–38]. It is usually unilateral, triangular in shape, with the apex at the outer border of the lateral ventricle and associated with a moderate to large ipsilateral GMH-IVH. It has been thought in the past that parenchymal hemorrhage was due to direct extension of hemorrhage into the periventricular white matter, but this is no longer considered to be the most likely explanation for this type of parenchymal lesion. Most would now agree, that this type of lesion is caused by the presence of GMH-IVH, which can lead to impaired venous drainage of the medullary veins and subsequent venous infarction of the white matter. This sequence of events can sometimes be seen by sequential ultrasound examinations, when there is a change from a normal image, to simple GMH-IVH and then involvement of the parenchyma on the following day. This type of lesion is generally globular and usually communicates with the lateral ventricle with subsequent evolution into a porencephalic cyst. Recently this pattern has been shown to be more variable, with a discrete parenchymal lesion, which does not necessarily communicate with the lateral ventricle and can evolve into a few small cysts in the white matter that may resolve with eventual ex-vacuo dilatation of the lateral ventricle on the affected side. These white matter cysts can be misinterpreted as unilateral cystic leukomalacia, but seeing the evolution of this unilateral lesion on sequential ultrasound examinations would not favour leukomalacia, which is almost invariably bilateral and not often associated with a large IVH. MRI performed later in infancy or early childhood will also help to make a distinction between the two conditions, showing more focal injury in those with a unilateral parenchymal hemorrhage. Detailed studies by Dudink et al [44] have made

it possible to identify the veins involved in the parenchymal injury. Bassan et al [45] have suggested grading the parenchymal lesion, taking account of the extent of the lesion, the presence of a contralateral parenchymal lesion and the presence of a midline shift due to this lesion. This grading system has predicted neurodevelopmental outcome at 2 years of age [46].

138.6.1 Intracerebellar Hemorrhage

An important recent development, when discussing GMH-IVH in the preterm infants, is the recognition of intracerebellar hemorrhages. This type of lesion is most often associated with a GMH-IVH and is especially common in those with a birth weight < 750 grams and gestational age below 27 weeks [47–49]. Twenty-five of the 35 infants studied by Limeroupolos et al [48] had a unilateral hemispheric hemorrhage. Of the 35 infants, 27 also had supratentorial lesions. Apnea, bradycardia and a falling hematocrit may be associated with this type of lesion. Ultrasonography can be diagnostic when the lesion is large or when the posterolateral fontanelle is used as the acoustic window [47–49]. MRI will give better definition of the extent of the lesion and will also identify punctate lesions in the cerebellar hemisphere [49]. Follow-up at a mean age of 32 months showed neurologic abnormalities in 66% of infants with isolated cerebellar hemorrhagic injury compared with 5% of control preterm infants [50]. Infants with isolated cerebellar hemorrhagic injury versus controls had severe motor disabilities (48 *vs* 0%), expressive language (42 *vs* 0%), delayed receptive language (37 *vs* 0%), and cognitive deficits (40 *vs* 0%). Preterm infants with cerebellar hemorrhagic injury and supratentorial parenchymal injury were not at overall greater risk for neurodevelopmental disabilities, although neuromotor impairment was more severe. Cerebellar atrophy without apparent cerebellar hemorrhage has also been reported as a common sequel of severe immaturity [51–53]. Srinivasan et al [54] only showed reduced cerebellar volume in preterm infants at term-equivalent age in association with supratentorial pathology such as hemorrhagic parenchymal infarction, intraventricular hemorrhage with dilation, and periventricular leukomalacia.

138.7 Management

Once the diagnosis of a GMH-IVH has been made, the immediate clinical management is similar to that of other at risk preterm infants. Optimalization of any coagulopathy, minimal handling, prevention of fluctuations in blood pressure or CO_2 levels, prevention of breathing against the ventilator may be used try to prevent extension of the initial hemorrhage. A continuous record of an amplitude-integrated EEG (aEEG) registration may help to detect subclinical seizures, which will often be subclinical and may require treatment [55].

Especially in infants with a large IVH with or without associated parenchymal hemorrhage, posthemorrhagic ventricular dilatation (PHVD) may develop over the next 10–14 days. Repeat US scans are indicated to diagnose this complication. PHVD can progress either slowly or rapidly. In two-thirds of cases, slowly progressive PHVD is followed by spontaneous arrest; in the remaining one-third of infants with PHVD, ventricular size increases rapidly over the course of days to weeks [56].

There is no agreement about whether treatment of progressive PHVD before the occurrence of clinical symptoms is beneficial to the child. Due to the large extracerebral space and the high water content of the white matter, increased ventricular size, as assessed by repeated ultrasound examinations, will precede by several weeks clinical signs, such as a rapid increase in head circumference (> 2 cm/week), diastasis of the sutures, a full fontanelle, vomiting, irritability, bradycardias and apneas. Sunsetting is only seen at a late stage. Measurements are usually taken in the coronal view at the foramen of Monro, using the ventricular width [57]. The ventricular index is the distance between the midline and the lateral border of the ventricle. Most intervention studies have taken 4 mm above the 97th percentile as a starting point for randomization. Another useful measurement is the so-called anterior horn width, taken just anterior to the thalamic notch [58]. This anterior horn width measurement does not change much with increasing maturation and should be < 3 mm; measurements > 6 mm suggest PHVD. Measuring the occipital horn in a sagittal plane can also be useful, as there can be a discrepancy between dilatation of the anterior and posterior horn. Although the angle of insonation may be more variable in the sagittal plane, any measurement of the occipital horn ≥ 25 mm also suggests severe PHVD. Assessing the shape of the lateral ventricles may be useful, when making a distinction between pressure driven PHVD and ex-vacuo dilatation following white matter injury. Measuring the cerebrospinal fluid pressure may also aid in making a distinction, but reliable measurements can be hard to obtain [59].

Adverse short-term effects on the central nervous system have been shown using different techniques, including evoked potentials, aEEG, Doppler ultrasonography and near infrared spectroscopy (NIRS) [60, 61]. Cerebrospinal fluid (CSF) measurements of cytokines, non-protein bound iron, hypoxanthine and soluble anti-apoptotic factor sFas have all been found to be raised in infants with PHVD and especially so in those with associated periventricular leukomalacia [62–65]. In spite of these data, there is no direct evidence that early drainage of CSF alters the natural and long-term outcome of children with PHVD.

In the two largest randomized controlled trials (RCTs) so far, randomization was done once the 97th percentile + 4 mm line was crossed and 60% of the infants in both arms subsequently required shunt placement [66, 67]. The RCT for DRIFT (drainage intervention fibrinolytic therapy) also used this measurement as an entry point for the study [68]. The

initial data were promising with shunt requirement in 22%, but the RCT was stopped early, due to a high risk (33%) of rebleeding in the DRIFT group, without an apparent positive effect on the need for a ventriculo-peritoneal shunt [69]. In two retrospective observational studies, a significant reduction in the need for shunt placement was seen when intervention was started before this line was crossed and when the threshold for inserting a subcutaneous reservoir was low [70, 71]. Whether earlier and more active intervention is effective is now being studied by a prospective RCT.

138.7.1 Outcome Following GMH-IVH

Most studies of infants with mild grades of GMH-IVH (hemorrhage restricted to the germinal matrix or small amount of ventricular blood) suggest that these infants perform as well in cognitive and motor developmental outcome as preterm infants with no GMH-IVH, although a lower score was found with regard to their visual-motor integration [72]. Recent neonatal 3D-volumetric imaging studies, however, have shown reduced gray matter volumes at term equivalent age [73–75] associated with a reduced mental developmental index on the Bayley scale for infant development, 2nd edition (BSID-II), but this was only seen in the most immature infants with gestation below 30 weeks. Whether associated mild white matter abnormalities were present and could have played a role is not discussed in these reports. This association was previously suggested by Kuban et al [76].

The term ventriculomegaly (VM) has been used for infants with ventricular enlargement following a GMH-IVH, but also for those without apparent preceding hemorrhage when it is more likely to be due to white matter loss. It is therefore preferable to use VM to refer to babies without an apparent preceding large GMH-IVH and to use the term posthemorrhagic ventricular dilatation (PHVD) when ventricular enlargement follows a large hemorrhage [76, 77]. Sequential ultrasound examinations and consideration of the shape of the ventricles enables this important distinction in most cases.

The risk of a poor outcome has been reported to increase significantly with the presence of PHVD following a large GMH-IVH (40–60%) and even further in those who require shunt insertion (75–88%). [66, 78, 79]. In a cohort from Sweden, associated problems (cerebral visual impairment, epilepsy and especially cognitive problems) were very common [79]. In a retrospective hospital-based population study, outcome was better than reported previously: cerebral palsy occurred in only 7% of infants with a large IVH (grade III) compared to 49% of the 76 infants with a parenchymal hemorrhage ($p < 0.001$). The mean developmental quotient (DQ) in the grade III group was 99; if there was parenchymal involvement, DQ was 95 at 24 months' corrected age [61]. Whether this better outcome was related to earlier treatment of PHVD or due to a cohort with more localized lesions and of higher GA needs to be confirmed and a prospective randomized controlled trial is now underway.

While infants without apparent parenchymal involvement are more likely to develop diplegia, those with a venous infarct are at risk of developing a hemiplegia. It has been suggested that outcome with unilateral parenchymal hemorrhage varies and depends on the extent and site of the lesion [46, 80] although others have not found the site of the lesion to be predictive [81]. A recent score reported by Bassan et al showed an association between a higher score, based on the presence of a more extensive lesion, a midline shift, or bilateral parenchymal involvement and mortality and outcome at 2 years of age [46]. Long-term follow-up into childhood and adolescence showed that most children with a parenchymal hemorrhage and subsequent porencephaly were ambulatory, but required learning assistance in school and had social challenges [82, 83].

Early prediction of development of a hemiplegia is now possible using MRI at 40–42 weeks. Myelination of the posterior limb of the internal capsule (PLIC) should be present at term equivalent age. In infants who go on to develop a hemiplegia, asymmetry and even lack of myelination of the PLIC was noted in those who subsequently developed a hemiplegia [84, 85]. Using diffusion tensor imaging, visualization of the tracts is possible at an earlier stage, but data are only available in preterm born children studied in childhood looking at thalamo-cortical connectivity [86, 87].

138.8 Prevention of GMH-IVH in the Preterm Infant

Most studies have shown a reduction in the incidence of GMH-IVH over time. Both prenatal and postnatal pharmacologic prophylaxis has been used to reduce the incidence of GMH-IVH. Many different drugs have been used, such as phenobarbital, tranexamic acid, pancuronium, etamsylate, vitamin E, and indomethacin. Only a few of these will be discussed here in more detail.

138.8.1 Antenatal Prevention

138.8.1.1 Antenatal Steroids

Antenatal administration of corticosteroids has been shown by several studies to be the most important protective factor for development of GMH-IVH [88, 89]. A systematic review of 21 randomized controlled trials involving over 4000 babies has shown that corticosteroid administration is associated with a significant reduction in the risk of GMH-IVH (OR 0.54; CI 0.43, 0.69) and with a strong trend towards improving long-term neurologic outcome in survivors (OR 0.64; CI 0.14, 2.98)

[89]. The effect of steroid administration could be due to a reduction in risk and severity of respiratory distress syndrome, postnatal stabilization of blood pressure, or maybe even a direct cerebral protective effect. Repeated courses of antenatal corticosteroids are not recommended as a negative effect on brain growth has been shown [90]. without a further reduction of the incidences of GMH-IVH or leukomalacia.[91] Bethamethasone instead of dexamethasone is recommended as the latter has been associated with an increased incidence of PVL [92].

138.8.1.2 Magnesium Sulphate

Antenatal administration of magnesium sulphate was not associated with a reduction in the incidence of GMH-IVH in a large randomized multi-centre study [93]. A meta-analysis showed that antenatal magnesium sulphate therapy given to women at risk of preterm birth substantially reduced the risk of cerebral palsy in their children (relative risk [RR] 0.69; 95% confidence interval [CI] 0.54–0.87). The number needed to treat to prevent one case of cerebral palsy was 63 (95% CI 43–155). Moreover, there was a significant reduction in the rate of substantial gross motor dysfunction (RR 0.61; 95% CI 0.44–0.85) [94].

138.8.1.3 Vitamin K

Vitamin K has been used antenatally to prevent neonatal GMH-IVH, as vitamin K-dependent factors are deficient in preterm infants. Although initial reports were promising, this was not supported by a recent systemic review of 9 randomized studies involving 1750 women to evaluate the role of vitamin K in the prevention of GMH-IVH, given to women in labor or very likely to deliver a premature infant. Only two trials were of sufficient quality to be used for the final analysis [95–97].

138.9 Postnatal Prevention

138.9.1 Phenobarbital

The rationale for phenobarbital use was sedation of the preterm infant to prevent the fluctuations of blood pressure that occur with clinical care of high-risk infants. Phenobarbital was the first drug used postnatally in the prevention of GMH-IVH. A meta-analysis of 10 trials was unable to show a reduction in the incidence or severity of GMH-IVH (relative risk 1.04, 95% CI 0.87, 1.25), severe IVH (relative risk 0.91, 95% CI 0.66, 1.24) [98]. There was a consistent trend in the trials towards increased use of mechanical ventilation in the phenobarbital treated group, which was supported by the meta-analysis (typical relative risk 1.18, 95% CI 1.06, 1.32).

138.9.2 Indomethacin

A meta-analysis of the postnatal use of indomethacin in the prevention of GMH-IVH and subsequent brain injury showed a significant reduction in the incidence of GMH-IVH of all grades in indomethacin treated groups (RR 0.88; CI 0.80, 0.96) [99]. When only more severe degrees of hemorrhage were reported (Papile grade III and IV) this effect was still present (RR 0.66; CI 0.53, 0.82).

Outcome measures of death or severe neurosensory impairment was reported in four studies, but no significant effect of indomethacin could be found (RR 1.02; CI 0.90, 1.15) [99, 100]. A recent post-hoc analysis of the orginal indomethacin trial suggested that boys exposed to indomethacin had significantly better outcome in verbal test scores than females, suggesting a gender specific effect [101].

138.9.3 Ibuprofen

Ibuprofen is used as an alternative to indomethacin for use in the medical management of patent ductus arteriosus and also acts by prostaglandin synthase inhibition. A recent RCT evaluated whether ibuprofen when given shortly after birth to a group of premature infants (< 28 weeks' gestation) reduced the incidence of GMH-IVH [102]. Ibuprofen did not reduce the incidence of any degree of GMH-IVH when compared to controls (OR 0.96 CI 0.48, 2.03) or more severe GMH-IVH (grade II–IV) (OR 0.87 CI 0.25, 3.05) compared with controls.

138.9.4 General Measurements

Paying closer attention to blood pressure, gentle handling, synchronous ventilation and less severe respiratory distress syndrome due to antenatal and postnatal surfactant therapy was associated with a reduction in GMH-IVH [103]. Data from the Canadian network also showed that the incidence and severity of GMH-IVH is affected by NICU characteristics. A high patient volume and a high neonatologist/staff ratio was associated with a lower rate of severe IVH [104].

138.10 IVH in the Full-term Infant

Intraventricular hemorrhage (IVH) is an uncommon problem in full-term as compared to preterm neonates. Origins of the IVH can be the germinal matrix, choroid plexus, or parenchyma. The latter was recently reported as hemorrhagic parenchymal infarction [105]. In term infants only remnants of the germinal matrix remain. The incidence of germinal matrix hemorrhage is therefore considered to be low, but the true incidence is not really known as infants are usually asymptomatic.

The mechanism of IVH in term infants has been attributed to trauma at birth (precipitous delivery) or hypoxia; however, no etiology is detected in most cases. Recently, thalamic hemorrhage associated with an intraventricular hemorrhage was recognized to be related to cerebral sinovenous thrombosis (CSVT) involving the straight sinus [106, 107]. The pathogenesis of thalamic hemorrhage is hemorrhagic venous infarction of the large venous channels that are in close proximity to the ventricular walls. In the majority of infants none of the previously associated risk factors for thalamic hemorrhage were noted, such as coagulation disorders or hypoxic-ischemic birth injury. Predisposing factors noted by Roland et al [108] included sepsis, cyanotic heart disease, and polycythemia. Physical signs (irritability, seizures, apnea, bulging fontanel) occurred later than in infants with IVH due to choroid plexus or germinal matrix hemorrhage. Anticoagulation therapy may be considered to prevent propagation of the thrombosis [107].

Management of IVH in term infants is supportive. Prognosis depends on the location and extent of the underlying insult. As a rule, among infants for whom no etiology of the IVH is detected, outcome appears to be good. Neurodevelopmental sequelae are seen in infants with IVH with parenchymal involvement [109]. When bilateral thalamic hemorrhage is associated with birth asphyxia, mortality is high and sequelae in survivors are high. Thalamic hemorrhage with IVH seen in infants with an uneventful birth history is associated with a greater risk for cerebral palsy than IVH from other sites.

138.10.1 Subdural Hemorrhage in Term Infants

Subdural and subarachnoid hemorrhages are probably under diagnosed as they are difficult to recognize using cranial ultrasound. Subdural haemorrhage usually occurs secondary to birth trauma. These hemorrhages are relatively uncommon currently because of improvements in obstetric care. Vaginal breech deliveries are for instance less common since recent multicenter randomized studies [110]. Occipital diastasis can occur during a vaginal breech delivery with excessive extension of the neck of the infant. The pathogenesis is secondary to mechanical injury to the cranium associated with instrumental delivery with forceps or Ventouse extraction of the head, abnormal presentation (face or brow), precipitous delivery, and a large infant resulting in a difficult delivery, although others did not find an increased risk with assisted vaginal delivery. MRI scanning showed a prevalence of 26% following vaginal birth in a group of 97 infants [111–113]. Shearing forces act on the tentorium and the deep venous system. Children are usually born at term and present with a full fontanelle, lethargy, apnea and or seizures. Hydrocephalus may develop due to outflow obstruction and temporary external drainage, sometimes followed by permanent drainage, due to impaired CSF reabsorption at the level of the arachnoid granulations. Secondary cerebral infarction has also been has been related to prolonged arterial compression [114]. The majority of subdural hemorrhages are infratentorial but a supratentorial location can also be seen and is then sometimes associated with a lobar hemorrhage, which can be large and associated with a shift of the midline, requiring neurosurgical intervention (Fig. 138.4). Short-term outcome in children with an isolated infratentorial subdural hemorrhage, but also in those with a lobar hemorrhage has often been reported to be more favorable than expected, but the groups studied have been small [112, 115].

138.10.2 Subgaleal Hemorrhage in Term Infants

Subgaleal hemorrhage is a rare and potentially fatal condition of the neonate often associated with instrumental delivery. It is caused by rupture of the emissary veins, which are connections between the dural sinuses and the scalp veins. Blood accumulates between the epicranial aponeurosis of the scalp and the periosteum. Most cases of subgaleal hemorrhage reported have been associated with the use of the vacuum extractor. The incidence of subgaleal hemorrhage is estimated to occur in 4–6 of 10,000 spontaneous vaginal deliveries and in 46–59 of 10,000 vacuum-assisted deliveries [116, 117]. Children present with diffuse swelling of the head and evidence of hypovolaemic shock. In a study by Kilani et al [118] associated intracranial hemorrhage was present in half of the 34 infants studied and four died. In another study 31% had a poor outcome (five died, four had epilepsy, three with severe auditory dysfunction, two with cerebral palsy, and one with renal vein thrombosis) [119]. The group with the poor outcome had significantly more patients who had been transferred from other hospitals ($P < 0.001$). Those with a poor outcome had significantly more hypotension ($P < 0.001$) and seizures ($P < 0.05$). Prompt and aggressive administration of blood products and treatment of an associated coagulopathy are recommended to improve outcome.

138.11 ICH in Other Specific Conditions in Full-term Infants

138.11.1 Neonatal Alloimmune Thrombocytopenia

In neonatal alloimmune thrombocytopenia (NAITP), fetal and neonatal thrombocytopenia results from the formation of a maternal antiplatelet antibody to a paternally derived platelet antigen, usually platelet surface antigen (PLAI) and expressed on the surface of the fetal platelets. Neonatal

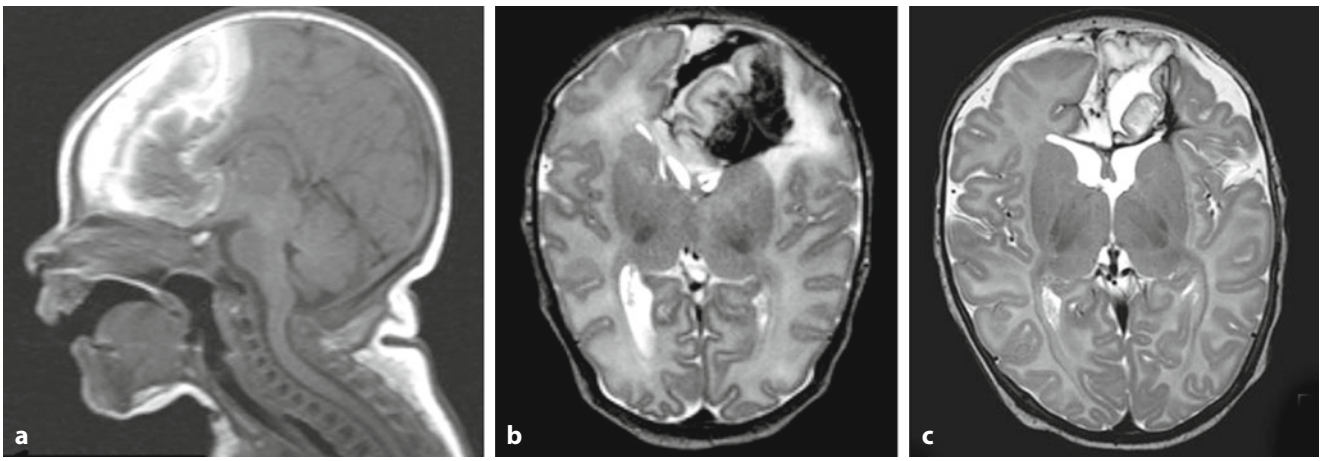

Fig. 138.4 Full-term infant, easy vaginal delivery, admitted with neonatal seizures. MRI on day 7 (**a** and **b**) and at 3 months (**c**), showing a supratentorial subdural hemorrhage and a large frontal intraparenchymal hemorrhage, with a shift of the midline. A repeat scan at 3 months, shows resolution of the hemorrhage and associated loss of brain tissue

alloimune thrombocytopenia occurs in 1 in 2000 to 1 in 5000 fetuses. ICH occurs in as many as 10–30% of the infants with alloimmune thrombocytopenia, 25–50% of which occur in utero [120]. NAITP has an estimated mortality rate of 15%, with ICH accounting for most deaths. Fetal and neonatal platelet counts below 20 x 109 are common even before 24 weeks' gestation and repeated episodes of antenatal hemorrhage have been reported [121]. Management in the antenatal period includes the administration of intravenous gammaglobulin to the mother with or without corticosteroids prior to delivery. Transfusion of matched compatible platelets to the fetus may protect against ICH during the birthing process. Cesarean section is suggested if cordocentesis reveals fetal thrombocytopenia. After birth, transfusion with antigen-negative platelets (maternal platelets) is recommended [122]. A hemispheric porencephalic cyst, following a hemorrhage which is most commonly located within a temporal lobe is usually present at birth; extra-axial hemorrhages, intraventricular hemorrhage, acute parenchymal hemorrhage, and neuronal migrational disorder have also been reported [120].

138.11.2 Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO) is the treatment of choice for infants with persistent pulmonary hypertension and cardiorespiratory failure unresponsive to inhaled nitric oxide.

In term infants, ICH following ECMO occurs in 10–13% of infants [123–124] (see Chapter 72).

Neonatal Arterial Stroke

Daniela Ricci and Eugenio Mercuri

139.1 Introduction

The term neonatal arterial stroke is used to define focal ischemic brain injuries occurring in the distribution of the territory of one (or more) cerebral arteries. Recently the term perinatal arterial ischemic stroke (PAIS) has been coined to define a group of heterogeneous conditions in which focal disruption of cerebral blood flow occurred between 20 weeks of fetal life through the 28th postnatal day [1] and confirmed by neuroimaging or neuropathological studies.

Until recently, arterial ischemic stroke was considered an uncommon condition in the neonatal period, frequently associated with motor and cognitive deficits. Lesions were usually identified on imaging obtained after the child presented with hemiplegia or epilepsy in early infancy [2, 3]. The wider availability of neonatal cranial ultrasound (cUS) and magnetic resonance imaging (MRI) has increased the detection of such lesions in the neonatal period and has changed our knowledge on their incidence and on the modality of presentation in both term and preterm infants. It is now generally agreed that stroke is the second most common cause for neonatal seizures after hypoxic-ischemic encephalopathy [4]. Recent studies report that perinatal stroke is 17 times more frequent then those occurring later in childhood [5]. Perinatal arterial ischemic stroke is estimate to occur in around 1/2,300 to 1/5,000 term neonates [6, 7] with the great majority presenting acutely, usually with seizures within 72 hours after birth, but without focal deficits or encephalopathy [8].

There have been several attempts to classify arterial strokes, with most classifications being based either on the extent of the lesions or on the timing of the insult.

In 2007 in a workshop on ischemic perinatal stroke, a classification of PAIS based on gestational age or postnatal age at diagnosis was suggested: 1) fetal ischemic stroke, diagnosed before birth by using fetal imaging methods or in stillbirths on the basis of neuropathologic examinations; 2) neonatal ischemic stroke, diagnosed after birth and before the 28th postnatal day (including preterm infants); 3) presumed perinatal ischemic stroke (PPERI), diagnosed in infants aged > 28 days in whom it is presumed (but not certain) that the ischemic event occurred some time between the 20th week of fetal life through the 28th postnatal day [1, 7].

More recently Govaert and colleagues [9], using the same classification, proposed a slightly different division within the subgroups, according to the timing of stroke, considering that lesions detected in the newborn period that presumably preceded labour should be considered separately from those that occurred during or just after labour.

They also divided infants with neonatal stroke into two subgroups by age of presentation of the symptoms. An early presentation, within the first 3 days of birth, is likely to be related to labor or delivery while a late neonatal presentation (between 4 and 28 days after birth) can be related to disorder of the late neonatal period including cardiac disease, extracorporeal membrane oxygenation, postnatal infection or other postnatal causes.

Other attempts at classification have been based on the extent of the lesion, according to the distribution of the lesion. Lesions in the territory of the middle cerebral artery (MCA) are the most common and they occur much more commonly in the left than in the right hemisphere. MCA have been further subdivided into: main branch, cortical branches, lenticulostriate branches (Fig. 139.1) [10]. This classification has been extensively used for both diagnostic and prognostic purposes.

Main branch MCA involvement is the lesion most easily detected on cranial ultrasound while infarctions in the anterior and posterior regions and smaller branch MCA infarcts can be more difficult to visualize [11, 12].

In our experience, in a cohort of over 60 cases of full-term infants with perinatal arterial lesions detected in the first days after birth, the great majority had lesions in the cortical or main branch of the MCA and only a minority had lesions in

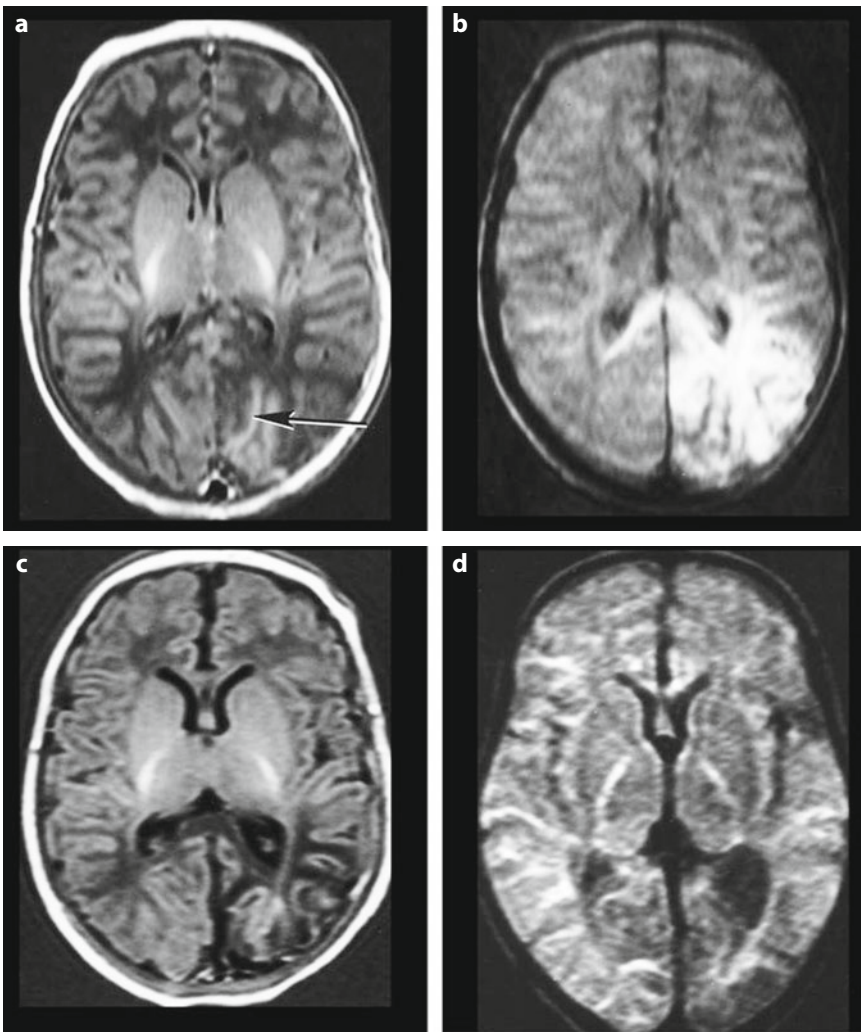

Fig. 139.1 T1 weighted images (*left*) and diffusion weighted images (*right*) performed on day 3 (*top*) and day 9 (*bottom*). Note that in the first scans the abnormalities are more obvious on diffusion (**b**) than on conventional imaging (**a**), while they become more obvious on the conventional imaging on day 9 (**c**) when they are barely visible on diffusion (**d**)

the lenticulostriate branch only or in the anterior or posterior cerebral artery.

In contrast DeVries and colleagues have reported that, in preterm infants, the lenticulostriate branches appears to be more frequently involved than in full-term infants. Until recently, most of the published studies have reported PAIS in full-term infants. In the last few years however, there has been a sharp increase in the studies reporting PAIS in preterm infants suggesting that such lesions may be more frequent than initially assumed. Bender and colleagues [6, 7] reported an incidence of 7 in 1,000 admissions in their neonatal intensive care unit. The gestational age of the infants was less than 35 weeks. They hypothesized that the higher incidence of PAIS in preterm infants might be explained by the routine use of cranial ultrasound in all the preterm infants admitted to the unit, even in those without any clinical symptoms, and the high exposure to invasive procedures.

These new findings suggest that the occurrence of strokes in units where there is not such careful ultrasound monitoring may be underestimated.

139.2 Etiology of Perinatal Arterial Stroke

Although an association between stroke and hypoxic-ischemic encephalopathy undoubtedly exists [13], in our experience it is uncommon. Possible etiological factors involved in neonatal stroke have been extensively investigated and different factors have been thought to be potentially involved in determining strokes in a number of cases [14, 15]. However, none of the individual factors reported so far appear to be consistently involved in all the cases studied [15]. Furthermore, when individual factors are assessed in a cohort of strokes and in controls several risk factors are generally present in both groups even though are significantly more frequent in the study group than in controls [16].

These findings strongly suggest not only that there is a multiplicity of etiological factors, but also that none of them, when considered separately, can be considered as the only factor responsible for the lesion. It has now been accepted that it is more likely that the risk of lesions increases when

multiple factors are present [15, 17] with a possible co-occurrence of prenatal, perinatal and other factors further increasing the risk of developing the insult and the lesion.

For preterm infants data in the literature are scarcer but some data have become recently available [18]. Particular attention has been devoted to antenatal or perinatal predisposing factors and to prothrombotic and coagulation abnormalities.

139.3 Maternal Factors

In our own studies [19] most term infants with focal infarction are born to primigravidas and this was also a risk factor in the study of Lee et al [17]. In a recently study of a cohort of proven perinatal strokes, maternal primiparity, infertility and cocaine use, were reported risk factors in term infants compared to controls [15]. Wu et al [16] also reported a significant association between perinatal strokes and prepartum risk factors such as pre-eclampsia and intrauterine growth restriction.

In infants with AIS labor is often prolonged and the delivery complicated, with emergency cesarean section and vacuum extraction significantly higher than in controls [17, 19]. In the study of Wu et al [16], newborns with PAS were at higher risk of delivery complications, such as emergency cesarean section, 5-minute Apgar < 7, and resuscitation at birth. Abnormal cardiotocograph, instrumental deliveries and emergency cesarean sections have also been reported to be significantly higher in another cohort of perinatal strokes [15]. Intrapartum complications, such as vacuum extraction, emergency cesarean section, ventouse delivery, use of oxytocin and fetal heart rate abnormality, have recently also been found to be significantly higher in preterm infants with AIS, compared to matched controls [18].

139.4 Prothrombotic Abnormalities

In the last decade we and others have suggested and reported a significant association between neonatal stroke and thromboembolic disorders [15, 20–29]. In our cohort, 10 of 24 (42%) neonates with stroke of perinatal origin had at least one prothrombotic risk factor. Five were heterozygous for the factor V Leiden (G1691A) mutation (FVL) and six had high levels of factor VIIIc [23]. Günther et al [20] also found that 68% of 91 term neonates with PAS had at least one prothrombotic factor compared with 24% of 182 controls. The most common finding was an increase in the level of Lp(a) FVL mutation in the PT gene and protein C in neonatal stroke in combination with other perinatal risk factors.

Hogeveen et al [30] found homocysteine levels to be higher in neonates with stroke, compared with healthy age-matched controls. However, in a recent study, there was no evidence for an excess of any candidate gene polymorphisms [31].

There remains much scope for research into prothrombotic abnormalities in neonatal stroke and thrombosis in the newborn infant. A recent review suggests that when combining arterial stokes and thrombosis in neonates, although prothrombotic coagulation factors are present in more than half of the cases, they are individually unlikely to play a major role in the pathogenesis of PAIS [32].

139.5 Other Factors

Sepsis, disseminated intravascular coagulation, polycythemia [33], congenital heart disease [34], and the need for vascular cannulation (all frequent occurrences in sick newborns), as well as extracorporeal membrane oxygenation (ECMO) and endocarditis, have definite associations with stroke, although these problems are more commonly seen in the preterm infant or in specialist units and we have rarely seen them in our own term patients.

Circulatory factors such as patent foramen ovale [35, 36], atrial septal defect [37] or aging placenta [38, 39] have also been reported.

139.6 Clinical Presentation

In the past strokes were mainly found in neonates with asphyxia or with severe clinical signs associated with cardiac or infective disorders. In a number of cases the presenting signs were hemiplegia or other neurological signs occurring in infants and children well beyond the neonatal period in infants who had evidence of focal lesions that were classified as presumed neonatal strokes in the absence of postnatal acute events.

More recently it has been established that in full-term infants neonatal seizures, generally occurring in the first 24–72 hours after birth, are the commonest first clinical sign in infants who were born with normal Apgar scores and were on the postnatal wards with their mothers [19]. Neurological examination may be normal, but as infants with seizures are often given anticonvulsants, they may present with generalised hypotonia [19]. Asymmetry of tone pattern may be noted but these are usually transient and are not predictive of hemiplegia at a later age [19]. This presentation is common among the infants in whom the lesion occurs perinatally but has also been reported with prenatal lesions. Low Apgar scores and neurological signs of asphyxia have been reported [13] but are less common.

In preterm infants symptoms such as clinical seizures or apneas, are frequent in preterm infants due to other underlying problems and the diagnosis is generally made on cUS but could be delayed or missed if these are not performed routinely and accurately [7].

139.7 Diagnosis

The first evidence of a lesion generally comes from US scans, even though it should be kept in mind that if the scans are performed soon after the onset of symptoms these may not be sufficient to provide a diagnosis [40–43]. In contrast, scans performed at the end of the first week usually provide evidence of focal changes suggestive of infarction. In our recent study of 47 infants who had early (day 1–3) and later (day 4–14) ultrasound we found that the early US scans were abnormal in 68% of the infants whereas the late CUS scans were abnormal in 87%, even though they were not always accurate to predict the extension of the lesion. Specific site and lesion diagnosis and identifying additional smaller peripheral lesions are better seen on MRI, which is the preferred method of diagnosis and also provides prognostic information. As for US, early MRI scans using T1 and T2-weighted images do not always identify early signal change. Most lesions can be detected on both US and MRI within 24–48 hours from seizure onset and are more clearly seen on T2 than T1-weighted images, but a proportion of lesions may be missed if the scans are performed within one or two days from the onset of seizures. In contrast, using diffusion weighted imaging (DWI), all lesions can be clearly observed even a few hours after the seizures (Fig. 139.2) [41, 42, 44, 45]. The DWI becomes less abnormal 5–7 days after birth, at the time when the signal on conventional T1 and T2-weighted images become more clearly abnormal. This pattern suggests that the insult has occurred recently, around the perinatal period. Diffusion restriction in the corticospinal tracts is an early sign of pre-Wallerian degeneration and can be used to predict outcome [46–48]. On conventional imaging, Wallerian degeneration in the brain stem can be seen as persisting abnormal signal intensity with atrophy appearing over 5–8 weeks and it is generally associated with the development of contralateral hemiplegia [49].

T1 and T2-weighted images allow the identification of the vascular distribution of the lesion and the extent of involvement of cortical and subcortical structures, such as the internal capsule, basal ganglia and also secondary changes in the brainstem and thalami or in the contralateral hemisphere that have been reported in a proportion of cases with arterial infarcts [19, 50].

The combination of very early and sequential ultrasound, and conventional and diffusion weighted MRI in the first few days after symptom onset is the most helpful to detect the lesion and to obtain information on the extent and the timing of the lesion. It has also been suggested that electroencephalography (EEG) performed soon after seizures may help in suggesting the diagnosis of stroke. More specifically, the occurrence of periodic lateralized epileptiform discharges (PLEDs) can help to suspect a focal lesion [51]. EEG has also been used as a prognostic indicator with the persistence of abnormal background activity rather than the occurrence of seizures being associated with a poor motor prognosis [19, 52].

139.8 Prognosis

While in the past stokes were mainly detected in patients who had severe clinical signs at birth or who were referred for epilepsy or motor sequelae, in the last two decades a better surveillance of neonatal seizures and the increased recognition of smaller strokes in the neonatal period has led to the identification of a number of lesions that are not always associated with abnormal outcome [53]. The issue of prognosis is however still controversial [14, 32].

The reported outcome data of neonatal stroke, however, provides very different rates of normal and abnormal outcome, depending on the inclusion criteria and on the study

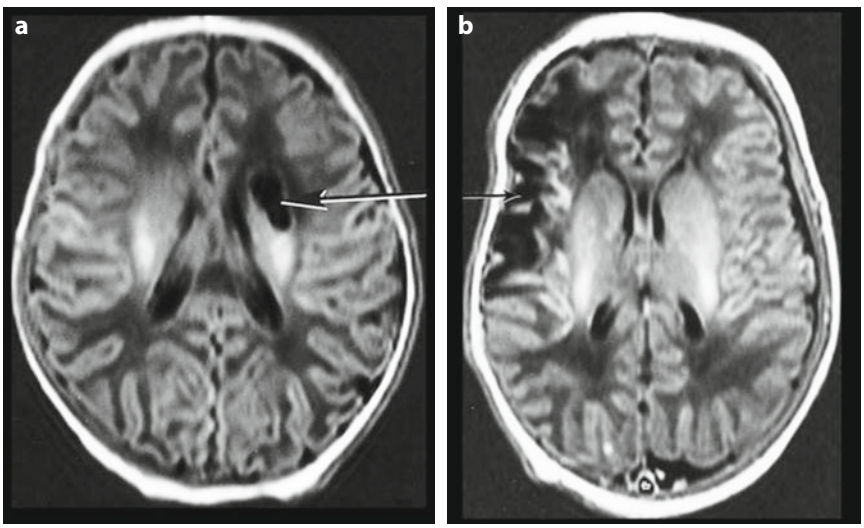

Fig. 139.2 Early brain MRI showing examples of middle cerebral artery infarcts involving the lenticulostriate branch (**a**) and the main branch (**b**)

populations. While most studies mainly include perinatal arterial infarcts in term infants, other include preterm infants, and others also those who present late with symptoms and are regarded as presumed neonatal. Because of this, comparisons of the different data sets are often difficult.

Most of the studies report short-term outcomes and mainly focus on motor outcome. Hemiplegia is the most frequently reported sequela [53] but its incidence, for the reasons given is very variable [54–64]. In our cohort of term-born infants mainly presenting with early seizures, less than a third develop a hemiplegia [19, 53, 65]. The first clinical signs of hemiplegia, when present, can be detected between 3 and 6 months and consist of mild asymmetry or abnormal patterns of movements [49, 66] and generally become more evident between 6 and 12 months [49]. In a few infants with evidence of prenatal lesions, however, clear signs of hemiplegia could already be detected in the first few months.

As not all the neonatal strokes are associated with development of hemiplegia, it is important to identify early signs which predict outcome. In our experience, neither the neonatal clinical examination nor the neonatal cranial ultrasound was helpful in prognosis [19]. Neonatal brain MRI in contrast provided better prognostic information. In our cohort motor outcome did not appear to depend on the vascular distribution of the lesion while the concomitant involvement of hemispheric tissue, the posterior limb of the internal capsule (PLIC) and the basal ganglia was always associated with an abnormal motor outcome. The involvement of only one or two of the three regions in contrast was associated with a normal outcome [19, 67]. In more recent studies [46, 48] it has also been reported that early acute DWI changes in the corticospinal tracts also predict hemiplegia.

De Vries et al [7] have recently reported that in preterm infants hemiplegia is more frequent than in full-term infants with similar lesions.

We have also found that abnormal background EEG activity in the neonatal period was also associated with abnormal motor outcome whilst a normal background, with or without seizure activity, was related to normal outcome [19].

Hemiplegia is, however, not the only possible sequela of strokes and other studies have reported the occurrence of language, vision and behavioral abnormalities and the risk of developing seizures.

139.8.1 Cognitive Outcome

In general children with neonatal stroke are thought to have a better cognitive outcome than those who suffered more global perinatal insults. Because of the site of the lesions there has been concern of the possible association between parietal lesions and language and more generally, cognitive development. In the Golomb et al [68] series, children with cerebral palsy after perinatal stroke who had neonatal presentation were more likely to have severe cognitive impairment than children with delayed presentation. In our own studies, which included all infants with neonatal infarcts and not only those with hemiplegia, however, over 80% of school age children were in a mainstream school setting with an IQ in the normal range [65]. Speech delay has been observed in children more commonly with left hemisphere infarcts [69–71] but it has been recently suggested that these early abnormalities tend to recover in the course of development [72] and that there is no evidence of decline in cognitive function over time in children with perinatal unilateral brain damage [73].

139.8.2 Visual Development

As most strokes involve the middle cerebral artery and therefore spare the occipital lobes and often also the occipital radiations, it is not surprising that visual field abnormalities are unusual. Early abnormalities of visual fields may be related to the method of assessment that also include a shift of attention, with a mechanism involving the parietal lobes. Acuity is generally normal but and other aspects of abnormal visual processing (fixation shifts, orientation-reversal visual evoked potentials [VEP]) can be found in children with neonatal focal infarction when assessed in the first years after birth [74 orientation-reversal VEP 76], even though they may recover by school age [77].

139.8.3 Psychological and Behavioral Problems

Psychological and behavioral problems have been extensively studied by Goodman [78], who finds problems with behavior, emotions and relationships in 50% of children with hemiplegia.

139.8.4 Seizures

It should also been mentioned that seizures have been reported to be common in children who suffered neonatal infarction [58, 60, 69], especially in those who developed hemiplegia. The incidence of later seizures in those who do not develop hemiplegia is low but in most studies follow up is relatively short-term [19, 40, 65, 79, 80]. It has been recently been reported that the presence of seizure may limit the chance of plasticity of the developing brain [73].

139.9 Treatment

At present there is no specific acute therapy for neonatal stroke. As strokes generally occur in infants with normal

Apgar scores in whom the only clinical sign is the onset of seizures several hours after birth, there is generally no need for intensive care, ventilation, or other types of support. Clinical seizures should be treated if they last longer than 5 minutes and occur on two occasions.

As there is little evidence of a recurrence of neonatal stroke either in the child or in the family, there is generally the tendency to avoid treatment in newborns with stroke [29]. All infants should have coagulation and thrombophilic studies and treatment should be reserved for those with abnormalities requiring it.

Anticoagulants are generally not used as there is concern about bleeding into infarcted tissue, unless there are other problems such as cardiac abnormalities or thrombi that might lead to further stroke.

Neonatal Seizures

Malcolm Levene

140.1 Introduction

Seizures are more common during the neonatal period than at any other time of life. This is because the neonatal brain is in a hyper-excitable state with an imbalance between the activities of neurotransmitters. During the early neonatal period, immature neurons express mainly GABA-nergic activity and paradoxically at this age GABA exerts a neuroexcitatory action. This appears to change in the early weeks of life when GABA receptors develop a more inhibitory effect [1]. As a result of this the neonatal brain is more likely to seize as a result of a variety of causes.

Clinical seizures in the neonatal period are often a dramatic symptom of brain compromise demanding urgent investigation and management. Unfortunately it is now apparent that clinically evident seizures may not reflect cortical malfunction and conversely electrographic seizures are not necessarily manifest by abnormal neurological behaviour, the so-called electro-clinical dissociation. A number of studies have shown that only between 30–50% of electroconvulsive seizures are detected clinically [2, 3]. Furthermore the management of neonatal seizures is also not clear as there is evidence that traditional anticonvulsant drugs do not stop seizures and that these drugs may actually be neurotoxic in therapeutic dosage regimens. Consequently the whole area of neonatal seizures must be revisited with a view to a reasonable clinical approach to this problem.

A recent development in the investigation of neonatal seizures are monitors that record digitally electrocortical activity and display it at the baby's bedside in a way that can be interpreted by clinical staff with basic training in EEG interpretation. This has allowed a more rational basis for investigation and management of neonatal convulsions.

140.2 Definition of Seizure Activity

The term fits, convulsions and seizures are often used interchangeably to describe the phenomenon of the clinical manifestations of abnormal electrocortical activity. Volpe [4] defines a seizure as "a paroxysmal alteration in neurological function (ie behavioural, motor or autonomic function)." These clinical manifestations are expected to be accompanied by abnormal electrical activity recorded from scalp electrodes which are synchronous in time with the abnormal clinical manifestation, but it is now well recognized that clinical manifestations may occur in isolation to epileptic cortical electrical discharges. It is possible that the origin of these abnormal clinical manifestations may be from subcortical structures but this is difficult to show in a clinical setting. Unfortunately, it is now recognized that the clinical manifestations can be very varied and change even within the same infant in a relatively short period of time and stereotypic movements which are thought to be seizures may not be associated with abnormal electrocortical activity. To make the discussion even more complicated, it is now well recognized from video-EEG studies that neonates can show extensive electrical seizures, even amounting to status epilepticus without abnormal clinical manifestations.

As a result of this, two definitions of seizure activity need to be considered; clinical and electroseizure and there may not be synchronicity between these two types. Clinical seizures are only a symptom and should be confirmed by EEG monitoring.

140.3 Clinical Classification

The clinical manifestations of neonatal seizures have been well described, but there is no internationally agreed classification system. Clinical seizures present in a number of different ways and may vary considerably in the same baby over a number of hours. These main patterns are shown in Table 140.1 along with their relative frequency.

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

Table 140.1 Frequency and causes of clinically evident seizures

Seizure type	Frequency*	Specific causes
Clonic	60%	HIE Cerebral artery infarction Metabolic encephalopathy
Tonic	20%	HIE Severe IVH
Myoclonic	5%	Metabolic encephalopathy Midazolam infusion HIE
Subtle	15%	Particularly seen in preterm infants HIE

* Data adapted from [5].
HIE hypoxic-ischemic encephalopathy, *IVH* intraventricular hemorrhage.

140.3.1 Clonic Seizures

These are reported to be the most frequently identified form of seizure in term infants [5]. Clonic seizures are more commonly seen in older children and comprise regular rhythmic jerking of limbs or face with a frequency of 1–3 cycles per second. They are often fragmentary and may be focal or multifocal in nature. Focal clonic seizures are particularly seen in term babies as a result of a focal neuropathology (e.g., middle cerebral artery infarction) but may be seen also in a variety of metabolic disorders. Multifocal clonic seizures may affect different parts of the body in a rapidly progressive manner although a Jacksonian type migration in the newborn is very rare. More commonly beats of clonic activity is seen in a limb, which fades in frequency to be replaced by similar abnormal movements in another limb or face. This may repeat itself frequently in the same patient. It is the most common clinical type which is associated with synchronous abnormal EEG.

140.3.2 Tonic Seizures

This refers to stiffening of a muscle group(s) for several seconds followed by slow relaxation. Limbs, face, neck or trunk involvement may occur. Involvement of the back muscles may cause opisthotonic posturing to occur. It is often associated with simultaneous deviation of the eyes. The tonic seizure may be focal or generalized. Tonic seizures are often associated with either abnormal background EEG features or simultaneous synchronous EEG activity. These movements should be distinguished from hyperekplexia where similar movements are seen but always as a result of stimulation.

140.3.3 Myoclonic Seizures

This refers to a short lasting contraction of a muscle group most commonly in the limbs and resembles twitching movements. They are not uncommon in normal babies during sleep and if they do not occur during wakeful periods are usually benign. These seizures may occur frequently but are often seen in isolation to a synchronous abnormal EEG discharge.

140.3.4 Subtle Seizures

Subtle abnormal movements in neonates are often characterised as subtle seizures, and this classification is the most variable of the above groups. Almost any repetitive and stereotypical movement can be considered as a manifestation of subtle seizures. These include sucking movements, chewing, tongue thrusting, transient eye deviation, pedalling or swimming-type movements, apnea (rare as an isolated phenomenon in term babies), transient bradycardic episodes and hiccoughs.

Subtle abnormal movements are more commonly seen in preterm infants and are often not associated with synchronous abnormal EEG activity which makes diagnosis of these movements difficult. In term infants abnormal EEG activity, either synchronous with the abnormal movements or as an abnormal background trace, is much more commonly seen.

140.3.5 Differential Diagnosis

The most common movement pattern confused with seizures are jittery movements. These are very common in preterm infants and may be due to hypocalcemia or hypomagnesemia. The frequency of jitteriness movements is significantly higher than the 1–3 cycle per second of clonic convulsive movements. The onset of jitters is almost always the result of some external stimulus and can usually be inhibited by holding the affected limb whereas movements due to clonic seizures are transmitted to the examiners hand when the limb is held.

Occasional myoclonic jerks are often seen in normal sleeping babies and provided they do not occur when the baby is awake they may be described as benign neonatal sleep myoclonus. This is associated with a normal EEG.

Hyperekplexia is a rare genetic condition (usually autosomal dominant) where babies have a very exaggerated response to external stimuli such that they have generalised muscle contractions which may be confused with myoclonic epilepsy. Patients with hyperekplexia (also called congenital stiff-man syndrome) have a normal EEG and usually have a family history. A molecular marker has been described for this condition [6].

140.4 EEG Classification

Traditionally formal EEG assessment has presented considerably logistic and diagnostic difficulties in neonatal intensive

care units for a number of reasons. The technique requires considerable technical skills to apply electrodes correctly, to ensure appropriately low electrode impedance, expert diagnostic interpretation of traces from an experienced neurophysiologist, the potentially hostile environment of a neonatal unit with regards to electrical interference and the practicality of being able to access the technique on all occasions that a baby shows possible convulsive activity. This has largely put the routine use of this technique out of reach for all but a few neonatal intensive care units in the acute situation. A more recent development has been the introduction of video-EEG where a more continuous digital EEG signal is acquired from the baby simultaneously with a continuous video recording of the babies' movements. The two outputs can then be displayed side by side on one screen so that correlation can be made retrospectively between potentially abnormal movements and EEG activity. This technique has proven very important in understanding the correlation of unusual clinical features with synchronous discharge activity of the EEG and also in recognizing the extent of electroclinical dissociation in the newborn infant, but it is of very limited value in routine clinical practice.

Particular problems in the interpretation of the neonatal EEG arise as a result of the considerable maturation of the EEG pattern in preterm infants progressively up to term and beyond. A description of this maturation is beyond the scope of this chapter but is reviewed by Mizrahi [7] and Hellstrom Westas [8]. For these reasons, recording of a highly modified and compressed continuous EEG signal has been developed and this is referred to as amplitude integrated EEG (aEEG) or cerebral function monitoring (CFM). Newer machines have attempted to integrate raw EEG signals with a compressed aEEG trace displayed in real-time on a semi-logarithmic scale and displayed on the monitor by a baby's cot-side. The majority of cot-side machines display a signal from a single pair of electrodes placed in a biparietal distribution with a midline reference electrode. aEEG is valuable in recognizing seizure activity and abnormal background activity (Fig. 140.1) and has been used as a criterion for entry into studies assessing neuroprotection in term asphyxiated babies [9].

The limitation of aEEG monitoring is that of very localized acquisition of EEG from a single pair of electrodes. The aEEG is particularly unreliable in the presence of multi-focal or localized seizure activity and seizure activity of short duration. In a study comparing aEEG with continuous video EEG recording, approximately half of all neonatal seizures detected by video-EEG were missed by aEEG [10]. Nevertheless aEEG is now increasingly used as a method of brain monitoring in neonatal intensive care units. Providing its limitations are recognized and suspicious traces are evaluated by full EEG assessment, it is likely to be a useful technique.

140.4.1 Status Epilepticus

There is no internationally accepted definition of status epilepticus in the newborn and it is considered to be a rare condition in preterm infants. One definition is continuous electro-convulsive activity in the newborn lasting 30 minutes or more or comprising > 50% of the EEG record [11, 12]. Boylan et al [13] have shown that continuous seizure activity lasting for 30 minutes is rare in the neonate, and have suggested that repeated seizure activity for 15–30 minutes in a 1 hour period represents a high-risk appearance for poor outcome.

140.5 Etiology of Neonatal Seizures

The incidence of clinically evident neonatal seizures has been variously reported to be 1.8–3.5 per 1000 live births [14–16], but in very immature babies (< 1500 g) this was considerably higher at 19–57.5 per 1000 [15, 16]. This data should be treated with caution because there are no studies of a large group of EEG diagnosed seizures in the newborn and there was little consistency in the studies about the definition of clinical seizures.

There are many causes of neonatal seizures and the more carefully a baby is investigated the more likely it is that a cause will be identified. In some cases no cause is found (idiopathic group) and these babies often have a good prognosis. Table 140.2 lists the most common causes of neonatal

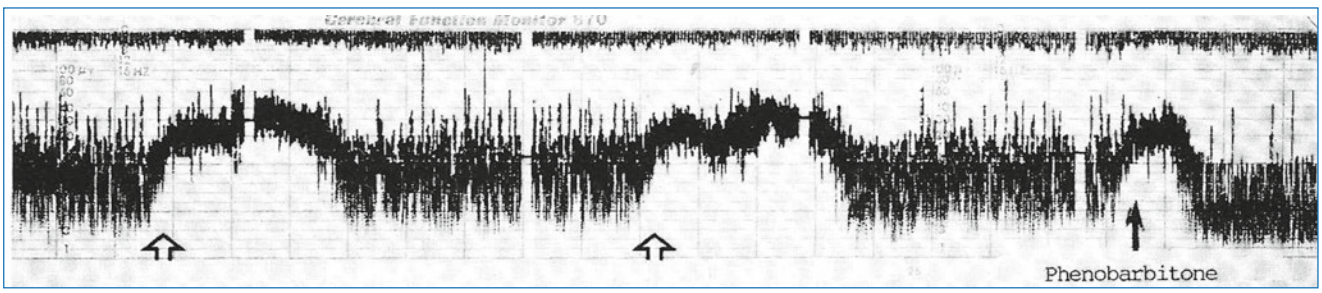

Fig. 140.1 Cerebral function monitor (aEEG) trace showing two convulsions (*wide arrows*) and the effect of phenobarbitone infusion during a third convulsion in a full-term infant. Note also that the voltage background trace between the first two convulsions is abnormally low

Table 140.2 Cause, incidence and outcome of neonatal convulsions in term infants [32]

Etiological factors	Incidence (%)	Poor outcome (%)*
Asphyxia	40	50

** Numbers too small to make meaningful predictions.

seizures together with incidence and outcome for each group. The following represent the main causation groupings.

140.5.1 Hypoxic-Ischemic Encephalopathy

Approximately one half of all infants who develop neonatal seizures have hypoxic-ischaemic encephalopathy (HIE) as the underlying cause. This condition can only be reliably recognized in term infants although infants of 35 and 36 weeks' gestational age may often show at least partial features of HIE. The incidence of HIE is 3–4 per 1000 full-term infants but seizures only occur in 1–2 per 1000 of these. Seizures develop in the first 24 hours of life and in some severe cases may be present within the first 3 hours after the hypoxic-ischemic insult. The seizures usually persist for 2–7 days although in the most severe cases seizure activity may continue for weeks or months. The most commonly observed seizures in these babies are clonic or subtle, particularly with swimming, doggy-paddling or pedalling-type abnormal movements.

140.5.2 Cerebral Artery Infarction

Infarction of a major cerebral artery, usually the middle cerebral artery, occurs in 4 per 1000 babies and the most common clinical manifestation are focal clonic seizures. Characteristically these babies appear to be neurologically normal between seizures although asymmetry of tone is often seen in unilateral middle cerebral artery infarction. Diagnosis is made on magnetic resonance (MR) brain scan, particularly on diffusion weighted sequences in the early stages of the disease evolution. Ultrasound is a much less reliable method of making the diagnosis.

Sinovenous thrombosis is increasingly recognized and may present with neonatal seizures particularly if the thrombosis causes intracranial hemorrhage, most commonly in the region of the thalamus.

140.5.3 Intracranial Hemorrhage

Neonatal seizures are much less commonly seen in very immature infants than in those at term, consequently although abnormal electroconvulsive activity may be present on EEG evaluation, clinical seizures are not evident or only partial or subtle in type. Therefore, although germinal matrix hemorrhage-intraventricular hemorrhage (GMH-IVH) is common in very immature infants, these babies do not commonly present with seizures. Large parenchymal venous infarction secondary to GMH-IVH may present with clinical seizures (usually tonic) but in my experience this is uncommon.

Other forms of hemorrhage which may cause neonatal seizures include subarachnoid, subdural or less commonly cerebellar hemorrhage. A subdural hematoma in a term infant more commonly is associated with seizures than a similar hemorrhage in premature infants. Large subarachnoid hemorrhages are reported to commonly present with neonatal seizures, but it may be difficult to separate the subarachnoid hemorrhage from underlying hypoxic-ischemic brain injury. It is reported that babies with large subarachnoid hemorrhage (SAH) show normal interseizure behavior.

140.5.4 Infection

Meningitis may present with neonatal seizures although these babies usually show non-specific abnormalities prior to the onset of seizures. The incidence of neonatal meningitis is 0.25–0.5 per 1000 babies and the commonest bacterial cause is group B beta hemolytic streptococcus. Other causes of brain infection including encephalitis which may cause neonatal seizures include cytomegalovirus, toxoplasma and herpes simplex. Lumbar puncture is indicated in all cases where neonatal meningitis/encephalitis is suspected. Management should include broad spectrum antibiotics and acyclovir intravenously.

140.6 Metabolic

140.6.1 Hypoglycemia

Hypoglycemia is an important avoidable cause of brain damage. Symptomatic hypoglycemia is associated with a variety of non-specific neurological signs; seizures are seen in about 50% of those with symptoms. Blood glucose assessment should be included in the work-up of all neurologically abnormal neonates and any hypoglycemia rapidly treated. Persistent hypoglycemia may be due to hyperinsulinism. Adverse neurodevelopmental outcome is reported in up to 50% of hypoglycemic infants who develop neonatal convulsions. Hypoglycemia may lead to encephalopathy with continuing convulsions after the biochemical hypoglycemia has been corrected.

140.6.2 Hyponatremia/Hypernatremia

Another relatively common metabolic cause of neonatal convulsions include severe hyponatremia particularly when this occurs rapidly as differences between intracerebral and extracerebral osmolality across the blood-brain barrier result in brain swelling. Similarly rapid development of hypernatremia may result in brain shrinkage and neonatal convulsions possibly induced by secondary subdural hemorrhage. Rehydration should be introduced slowly to prevent rapid shifts in intracellular water content.

140.6.3 Hypoglycemia/Hypomagnesemia

Convulsions associated with hypocalcemia occurs in the first few days of life. These babies usually respond rapidly to intravenous calcium infusion. The prognosis is usually good. Persistent hypocalcemia indicates the need for careful investigation of maternal calcium metabolism and infant parathyroid function.

Late onset hypocalcemia occurs much less frequently than in the past due to enhanced phosphate supplementation in infant formula feed preparations.

Hypomagnesemia can also provoke a condition which resembles neonatal seizures but this is rare and is managed by additional magnesium and calcium infusion.

140.7 Congenital Brain Anomalies

Congenital brain anomalies, particularly those affecting cortical development are commonly associated with neonatal convulsions and may present with abnormal fetal movements which are subsequently shown to be convulsive in nature. The most common abnormality associated with the development of seizures in the neonatal period is neuronal migration disorder including pachygyria, lissencephaly and micropolygyria. Seizures due to these conditions more commonly occur after 3 days of age but may have their onset at any time in infancy.

140.8 Inborn Errors of Metabolism

Some inborn errors of metabolism (IEMs) commonly present with neonatal encephalopathy and neonatal seizures [17]. These infants usually present once milk feeding has commenced, but a few disorders present early before feeding is established. The most common IEMs causing neonatal encephalopathy and seizures are listed in Table 140.3.

Table 140.3 Metabolic disorders most commonly associated with neonatal seizures

Early onset of seizures in neonatal period
Amino Acid disorders
– Non-ketotic hyperglycinemia
– Pyridoxine-dependent seizures
– Biotinodase deficiency
– Menkes syndrome
Late onset of seizures in neonatal period
Branched-chain organic acidurias
– Maple syrup urine disease
– Proprionic aciduria
– Isovaleric aciduria
– Methylmalonic acidemia

140.8.1 Vitamin-Dependent Seizures

As a group of causes of neonatal seizures these are very rare, but an important group because early recognition and effective treatment will prevent protracted seizures into older life and will reduce brain injury.

140.8.2 Pyridoxine-Dependent Epilepsy

This is an autosomal recessive disorder associated with very early onset of seizures. Sometimes the mother describes abnormal movements felt before the baby is born. Although biochemical markers have been described, the diagnosis is usually made in infants with refractory seizures who respond to intravenous pyridoxine infusion. Although there is no specific EEG marker for this condition, there is usually a marked change in the EEG activity during infusion. Treatment is with life-long pyridoxine (vitamin B6) replacement therapy.

140.8.3 Pyridoxamine Phosphate Oxidase Deficiency

More recently a deficiency in the pyridoximine enzyme pathway has been described which normally regulates dopamine and serotonin pathways. Deficiency causes intractable seizures which is responsive to pyridoxal phosphate infusion.

140.8.4 Folinic Acid-Response Seizures

Presentation is in the first few days of life with seizures intractable to traditional anticonvulsant drugs. The seizures respond rapidly to infusion with folinic acid (2.5–5 mg twice a day), but later recurrence may occur requiring an increased dose of folinic acid.

140.9 Other Causes

140.9.1 Drug Withdrawal

Seizures are rarely seen in neonatal abstinence syndrome, although less specific abnormal neurological signs are common. Methadone, heroin, cocaine, tricyclic antidepressant and benzodiazepine drugs given to the mother or taken illicitly during pregnancy may all be associated with neonatal abstinence syndrome. The onset of seizures usually occurs between day 1–7 after birth.

140.9.2 Benign Familial Neonatal Convulsions

This disorder is due to an autosomal dominant gene with high penetrance. Multiple generations are usually affected in the same family and the prognosis is good with resolution of seizures after a few months. Between seizures the baby appears neurologically normal. Mutations have been reported in the long arms of chromosomes 20 and 8 which determines voltage-gated K^+ channels.

140.9.3 Early Myoclonic Encephalopathy

This is a severe form of recurrent myoclonic and sometimes clonic seizures which usually start by 2–3 weeks of life. It is associated with a characteristically abnormal EEG trace worsening during sleep. It may be due to an inborn error of metabolism. Seizure control with anticonvulsive drugs is difficult and prognosis is poor.

140.9.4 Otohara Syndrome

The condition, also called early infantile epileptic encephalopathy presents with multiple tonic spasms in the first few weeks of life. The EEG shows initially a burst suppression pattern, later evolving to a very disordered pattern similar to hypsarrthymia. Otohara syndrome may be associated with cerebral dysgenesis. The prognosis is very poor and is usually associated with early death.

140.10 Idiopathic

After very careful investigation, no cause can be found for the seizures in some infants. The frequency of so-called idiopathic (probably better referred to as cryptogenic) depends on the extent to which investigations have been pursued. Generally if no cause is found after careful investigation the prognosis is good particularly if the baby remains neurologically normal between seizures.

140.10.1 Fifth-day Fits

This is also referred to as benign idiopathic neonatal seizures and has been described in most parts of the world. The infant develops seizures at between 4–6 days of life having shown quite normal neurological behavior up to the time that the seizures are first recognized. The seizures are usually multifocal clonic and rarely persist beyond 24 hours although they may be frequent during that time. Cerebrospinal fluid (CSF) zinc deficiency has been described in some cases. The prognosis is good and if the diagnosis can be confidently made anticonvulsant medication is probably not required.

140.11 Management

140.11.1 Do Seizures Cause Brain Damage?

The answer to this question determines how aggressively management with antiepileptic drugs should be pursued. Understanding of this question has been recently informed by experiments in immature animals which have attempted to model short but frequent seizures as occurs commonly in the neonate. Older studies looking at the effect of prolonged status epilepticus in mature animals have little relevance on understanding the neonatal situation. Frequent short-lived electroconvulsive seizures were produced in neonatal rat pups by brief periods of fluorothyl inhalation exposure. The usual paradigm was to induce 5 seizures for 5 consecutive days and then examine the brain for neuropathological evidence of damage and to test the surviving animals for measures of cognitive function [18, 19]. The investigators had shown that a single prolonged neonatal seizure did not produce neuronal injury.

This model of multiple short seizures did not produce any neuronal damage evident at examination under the microscope when the neonatal brain was sacrificed, but if the animal was allowed to survive into adult life and then the brain examined there was clear evidence of morphological change including cortical neuronal activation and changes in cell density [18]. In surviving adult rats that were subject to short but frequent neonatal seizures they showed learning and memory deficits compared with control animals. In support of this, when status epilepticus was induced in adolescent animals who had been previously exposed to short seizures in the neonatal period, neuronal necrosis resulted compared with controls subjected to adolescent status but no neonatal convulsions [19]. It appears that neonatal seizures may prime the developing brain to damage if a subsequent insult occurs.

In summary there is now good data from immature animal studies suggesting that although neonatal seizures do not cause neuronal necrosis, neurological function may be adversely affected with long-term adverse effects. Consequently, the control of neonatal seizures by antiepileptic drugs may be more important than previously believed. Unfortunately the current choice of antiepileptic drugs (AEDs) for neonatal seizures have not been shown to be particularly effective in reducing the burden of seizure activity and concern is mounting whether these drugs may cause additional brain injury.

140.11.2 Antiepileptic Drugs for Neonatal Seizures

If there is a specific cause identified for the seizures then specific therapy is indicated such as intravenous glucose for hypoglycemic convulsions. If there is no specific treatment or when seizures continue despite appropriate specific therapy (e.g., hypoglycemic encephalopathy), then antiepileptic drugs (AEDs) are usually indicated. The two most widely used AEDs in the neonatal period are phenobarbitone and phenytoin.

There have been very few randomized controlled trials of phenobarbitone and the few that have been done do not show a high response rate to this drug. Painter et al [20] compared the efficacies of two AEDs, phenobarbitone and phenytoin, in a group of full-term infants with EEG diagnosed seizure activity. The study design randomly allocated each fitting baby to receive either phenobarbitone or phenytoin to achieve free plasma concentration levels in the therapeutic range. If the infant continued to have significant seizure activity the other drug was added to the regimen. In less than 50% of either group were the seizures completely controlled on the first drug and in only 59% was adequate control achieved when both drugs were used together. Those babies that responded best to the first line drug were those with the least frequent seizures registered on the EEG.

In another EEG study of neonatal seizures where continuous video and EEG were co-registered the authors [21] showed that only four of 14 infants responded to phenobarbitone (20–40 mg/kg) and in the other ten babies EEG evident seizures actually increased although the clinically evident seizure activity reduced. This electro-clinical dissociation is a worrying feature of phenobarbitone use as clinical staff may be given a false sense of security by a reduction in the clinical seizure burden. Those babies that responded best to phenobarbitone were those with the least abnormal background EEG trace. Two other studies [22, 23] evaluated phenobaribitone treatment in babies with seizures secondary to HIE. Hall [22] showed that high dose phenobarbitone (mean dosage 39 mg/kg) compared with standard dose (mean 27 mg/kg) reduced clinical seizure activity and subsequently showed a significant reduction in death and disability (RR 0.30, CI 0.10–0.93) but this benefit has not been confirmed in a Cochrane meta-analysis [24]. Singh et al [23] also showed a reduction in clinically evident seizures following administration of phenobarbitone. These results may reflect a reduction in clinical seizures rather than electroconvulsive seizures as shown by Boylan et al [21].

Midazolam has been evaluated as a second or third line AED in neonates who fail to respond adequately to phenobarbitone or phenytoin infusion [25]. Castro Conde et al [26] used midazolam (iv bolus of 0.15 mg/kg, followed by continuous infusion (1 μg/kg/min) increasing by 0.5 to 1 μg/kg/min every 2 minutes until either a favorable response had been achieved or the dosage reached 18 μg/kg/min). A favorable response was defined as no more than two electrical seizures lasting < 30 seconds per hour. They showed that in 10 of the 13 neonates given midazolam for status epilepticus, the infusion successfully stopped seizure activity although some required a second bolus infusion before seizures were controlled.

Lidocaine is also used in some European countries as a second/third line anticonvulsant. Malingre et al [27] reported the effects of this drug on 20 neonates with ongoing electroconvulsive seizures refractory to phenobarbitone and midazolam. Abolition of seizures was achieved in 76% of the treatment courses and no baby was reported to have developed a cardiac arrhythmia as a result of the lidocaine infusion. Cardiac arrhythmia as a result of lidocaine infusion is thought to be a particular risk if the baby is pretreated with phenytoin and this combination of drugs should be avoided. The dosage regimen is shown in Table 140.4.

Table 140.4 AED dosage regimens for use in the neonatal period

Drug	Loading dose	Second loading	Maintenance dose
Phenobarbitone	20 mg/kg by slow iv infusion over 20 min	10 mg/kg	2.5–5 mg/kg/per day
Phenytoin*	20 mg/kg by slow iv infusion over 20 min	Not recommended	
Midazolam	150–200 μg/kg iv infusion	1 μg/kg/min iv infusion increasing to 5 μg/kg/min until appropriate response	
Lidocaine*	2 mg/kg iv over 10 min	6 mg/kg/hr for 6 hr	then 4 mg/kg/hr for 12 hr, then 2 mg/kg/hr for 12 hr
Lorazepam	0.05–0.1 mg/kg by slow iv injection		
Diazepam	0.3–0.4 mg/kg iv over 3–5 min		

* Phenytoin should not be used with lidocaine.

There are few scientific data on the use of other anticonvulsants in the management of neonatal seizures although a number of benzodiazepines (diazepam, clonazepam, lorazepam) have been used in an uncontrolled manner for many years. Thiopental has been used to treat intractable seizures in the newborn, but is associated with a worrying reduction in blood pressure.

140.11.3 Do AEDs Cause Brain Damage?

A further dimension to consider in the conundrum of managing neonatal seizures concerns the risks that AEDs may cause neuronal damage in addition to any damage secondary to the seizures themselves. Phenobarbitone and phenytoin stop seizure activity in only 50% of patients as first line AEDs and complications of these drugs have been reported including inhibition of brain growth [28], neuronal toxicity [29] and adverse behavioral and cognitive effects lasting into adult life [30].

There are also reports that AEDs used in doses which produce serum levels not uncommonly seen in the neonatal period cause neuronal apoptosis in neonatal rats [31]. Phenobarbitone, phenytoin, diazepam, and clonazepam all produce this effect. The use of phenobarbitone and diazepam together produced profound apoptotic neurodegeneration. This data causes anxiety that AEDs used in the neonatal period may themselves be neurotoxic and for this reason that they should be used with caution. Monotherapy is safer than using two or more of these agents together. The most resistant seizures in the newborn occur in those babies who have sustained the most severe brain insult. The combination of severe insult, prolonged seizures and multiple use of anticonvulsants is a potentially disastrous occurrence.

140.12 Prognosis

The prognosis of neonatal seizures depends predominately on the underlying cause of the seizures. In one recent study, 72% of term infants with seizures were described as normal at 1 year of age [5]. Normal or mildly abnormal background EEG traces were associated with a favorable outcome in 89% of cases [5].Poor outcome is particularly seen in babies with asphyxia and congenital cerebral dysgenesis. The outcome is best in infants with convulsions that respond rapidly to AEDs or those in whom no cause is found after careful investigation. There is evidence that prolonged neonatal convulsions may affect brain function measurable in later life and some AEDs may themselves have a deleterious effect on reduction of neuronal numbers. About 20% of infants with neonatal seizures had seizures again after discharge from the neonatal unit [5].

The following principles should be followed in all babies with neonatal seizures:

- Carefully investigate every seizing baby including brain imaging, and metabolic screen.
- Monitor frequent seizures with aEEG to aid treatment
- Avoid using multiple AEDs whenever possible and it is preferable to use a single drug to maximum dosage
- Stop AEDs prior to discharge from hospital wherever possible.

141

The Timing of Neonatal Brain Damage

Giuseppe Buonocore and Serafina Perrone

141.1 Introduction

Early abnormalities of brain development and underlying genetic factors can affect brain susceptibility to the injury [1–3]. Some infants may inherit a predisposition to have significant injury in the event of a normally sublethal insult [4]. These newly identified risk factors for brain damage in different periods make the timing of lesions important for exact diagnosis and prevention.

Incidence of neonatal encephalopathy ranges from about 2.0 to 6.0 per 1000 live births [5–7]. Hypoxic ischemic encephalopathy ranges from about 1.0 to 8.0 per 1000 live births. Epidemiological data shows that 30% of cases of neonatal encepalophaty in developed populations and 60% in developing populations have some evidence of intrapartum hypoxic-ischemia [8].

Perinatal hypoxic ischemic brain injury was demonstrated to be a major contributor to developmental disabilities in children, accounting for 25% of all cases [9].

Of the antepartum events that contribute significantly to the development of neonatal encephalopathy, fetal growth restriction ranks high. Increasingly, a strong role for fetal inflammation as one of the most frequent causes of acquired brain damage in perinatal period is being recognized.

141.2 Placental Pathology

The placenta has been described as a diary of intrauterine life and placental pathology assists in characterizing the antenatal environment. Dramatic, but at least common, are sentinel lesions, each of which can cause hypoxia sufficient to result in brain injury. There are three mechanisms for sudden catastrophic injury: (1) the placenta becomes prematurely separated from the underlying maternal uterine vascular supply: abruptio placenta or uterine rupture; (2) fetal placental blood vessels rupture; or (3) prolonged umbilical venous blood flow interruption. Placental findings that support a diagnosis of massive fetomaternal hemorrhage include a profound increase in the number of circulating nucleated red blood cells in the villous circulation, the finding of a large intervillous hematoma, villous edema, fetal arterial constriction, and villous capillary-venous dilatation. Large vessel hemorrhages generally affect vessels that are not protected by Wharton's jelly or the chorionic plate. Pathologic lesions associated with complete umbilical vessel occlusion include tight true umbilical cord knots, occlusive umbilical vein thrombi, tightly twisted (hypercoiled) umbilical cords, prolapse or tight entanglements around body parts. When this occurs, there may be an abrupt change in umbilical cord color, shape, or diameter that suggests chronicity. Other pathologic umbilical cord lesions, such as an excessively long cord length, lesser degrees of hypercoiling, abnormal cord insertion sites, and paucity of Wharton's jelly, are significantly more common in infants with cerebral palsy [10–12].

The mechanisms by which feto-placental large vessel lesions act on the vascular wall include toxic damage (meconium-associated vascular necrosis), maternal antifetal vasculitis (obliterative fetal vasculopathy), infiltration by activated fetal neutrophils (chorioamnionitis with intense fetal inflammatory response) and thrombosis (fetal thrombotic vasculopathy) [13–15]. Fetal thrombotic vasculopathy and chronic villitis with obliterative fetal vasculopathy begin weeks before delivery but continue to evolve and progress until parturition [16]. Vascular occlusion is the result of an inflammatory vasodestructive process that develops when maternal leukocytes inappropriately cross the trophoblastic barrier to enter fetal tissue. Chorioamnionitis with a severe fetal inflammatory response (intense chorionic vasculitis) and meconium-associated necrosis of vascular smooth muscle cells develop as a consequence of subacute processes beginning days before delivery [15–18]. An increased time of

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

exposure to meconium-stained amniotic fluid leads to a gradual progression of pigment through the amnion into the chorionic plate and eventually into contact with large fetal vessels.

Placentas can be abnormally small and have a decreased total gas-exchanging surface area. Alternatively, they may have decreased efficiency owing to diffuse chronic injury.

Other placental findings are markers for processes affecting either mother or fetus. In some cases, they may represent attempts to ameliorate an adverse environment; in others, they may be maladaptive consequences of it. Perhaps the most controversial of these findings is a significant increase in the number of circulating nucleated red blood cells to more than 2500/cm^3 in the fetal placental capillary circulation [19, 20]. An increase of this magnitude represents a fetal bone marrow response to hypoxia that takes 6–12 hours or more to mount [21]. A second adaptive response is a generalized increase in the number of fetal capillaries per terminal villous cross-section or chorangiosis [22, 23].

Placental pathology assists in characterizing the antenatal environment. Histological examination of the placenta is a sensitive and accurate diagnostic system for identifying lesions that can either directly cause or decrease the threshold for brain injury. The high prevalence of inadequate placental examination in cases without an identified clinical or pathologic lesion highlights the importance of a thorough placental examination in all potential cases of adverse neurologic outcomes.

141.3 Cardiotocography and Fetal Doppler Studies

Cardiotocography (CTG) is an indirect sign of fetal well-being with various technical pitfalls and a high incidence of false positives. Currently the technique is improved in the determination of the risk and timing of brain injury. In particular, the evaluation of trends and the speed of CTG changes in deceleration patterns makes it possible to distinguish harmful ischemic events from other forms of hypoxia which do not necessarily injure the fetal brain [24]. CTG combined with pulse oximetry, fetal blood pH and ECG provides further advantages [25]. Fetal electrocardiography (ECG) wave form analysis indicates the ability of the fetal heart to respond to the stress of labor. An increased T/QRS ratio identifies a fetal heart muscle that responds to hypoxia by increased utilization of heart glycogen [26]. ST segment depression may indicate a situation in which the heart does not respond fully and a negative ST may signify cardiac dysfunction and hypotension. It has been suggested that an increase in T/QRS ratio maintained for more than 10 minutes is associated with aggravation of fetal condition when intrapartum hypoxia may progress to asphyxia. Automatic analysis of CTG and ECG has been reported to enable a reduction in the incidence of newborns with severe neurological symptoms [26].

Doppler ultrasound of the blood flow in the umbilical artery (UA), descending fetal aorta (DAo), middle cerebral artery (MCA) gives insight into fetal cardiovascular responses to intrauterine growth restriction, fetal anemia, and fetal hypoxia [27]. Blood flow is classified as abnormal when pulsatility index (PI) values of MCA falling below the 5th percentile or PI value of UA, DAo, UA/MCA ratio, Dao/MCA ratio above the 95th [28]. Absent or reversed end diastolic flow of the UA, absent or retrograde net blood flow of the aortic isthmus, and the absent or retrograde end-diastolic flow of the ductus venosus are also classified as abnormal. The presence of a notch, as signals of increased perinatal vascular impedance and of brain sparing, is also highly significantly related to maternal blood serum concentration of tumor necrosis factor-alpha (TNF-alpha) and interleukin-6 (IL-6) level [29]. Severe abnormalities in fetal blood flow might result in neuroanatomical or functional changes that correlate to later cognitive capacity [30].

141.4 Neuroimaging

Cranial ultrasound (US) has been used for many years to determine the type and evolution of brain damage. The ultrasound criteria of cerebral cavitation have been selected in order to give assurance that the damage may have occurred before delivery. US and post mortem studies of the evolution of brain abnormalities suggest that cystic lesions develop over 14 days [31, 32]. Serial US images have been used to study the timing of hypoxic-ischemic injury, though the reliability of US is limited by poor visualization of the subarachnoid space, cerebral cortex and posterior fossa. It is also difficult to distinguish between hemorrhagic and non hemorrhagic ischemic damage.

Conventional magnetic resonance imaging (MRI), volumetric analysis, diffusion tensor imaging (DTI) methods and surface-based morphometry (SBM) methods has recently been used to detect antenatal, perinatal and neonatal abnormalities and timing on the basis of standardized assessment of brain maturation [33, 34]. MR imaging allows reliable assessment of myelinization and establishment of a timetable for maturation and myelination of the developing brain *in vivo*.

The peak of subplate formation and function that are required for normal cortical development correlates with the peak period of vulnerability to injury in preterm infants. Injury to subplate cells has been implicated in the causation of cortical deficits in preterm infants [35, 36].

If lesions or delayed maturation of with matter (WM) disrupt specific subsets of cortico-cortical, long distance connections, these altered connectivity patterns could in turn give rise to specific abnormalities in cortical folding patterns. Thus, WM injury resulting in a secondary disruption of cortical gray matter (GM) development may be a major mediator of cognitive deficits faced by preterm infants.

Cortical development may be also altered in the absence of WM or subplate injury in preterm infants. The high sensitivity of MR is important to detect early damage occurring before reliable US imaging, particularly for WM lesions in the preterm infants.

Accurate measurement of specific cerebral tissue volumes is achieved by segmentation of the imaged volume into tissue types, followed by 3D reconstructions. Volume changes during normal maturation of cerebral tissue between 29 and 41 weeks gestation have been defined in vivo using MR tissue segmentation of the brain. Segmentation is the process wherein contours are constructed that divide the brain into the representative structures of interest depending on their signal intensity (e.g., gray matter, myelinated white matter, cerebrospinal fluid [CFS]) determined using mathematic algorihms [37].

Preterm infants with WM lesions have a 17% reduction in absolute cortical GM volume as well as a 25% reduction in absolute myelinated WM volume compared with preterm infants without WM lesions [38]. Volumetric MRI studies conducted in school aged preterm children have reported shorter corpus callosum [39, 40], hippocampus [41], basal ganglia, and amygdala [40] as well as enlarged lateral ventricles [41]. All have been shown to be associated with neuropsycological impairment.

Diffusion tensor imaging and diffusion anisotropy are based on measurement of physical caracteristics of water molecules in tissue. One parameter describing these displacements is the apparent diffusion coefficient (ADC). ADC values are commonly used clinically for the detection of acute cerebral injury.

Diffusion anisotropy provides information about the local environment.

Anisotropy values for WM show a steady increase during development, particularly when fiber tracts undergo myelination [42].

Anisotropy can also be applied to GM maturation. The loss of anisotropy associated with maturation can be used to assess cortical development and reflects varying rates of development among different cortical areas [43]. The developing cortex showed lower ACD values and anisotropy with increasing maturation, likely related to the increasing complexity in tissue organization in the mature cortex [44].

Diffusion-based MR images may be normal on the first day after injury, decrease between 2 and 4 days after injury, and return to normal after approximately 7 days [45]. MR images illustrate the natural history of acquired fetal brain lesions in relation to stage of development [46]. The detection of a single type of damage in the developing fetus is evidence of acute or chronic lesions which can be seen alone or in combination. Patterns can indicate infection or hypoxia-ischemia at various stages of intrauterine life.

Phosphorus magnetic resonance spectroscopy studies changes of cerebral oxidative metabolism during and following asphyxia [47]. Infants with neonatal encephalopathy often have normal cerebral oxidative metabolism on magnetic resonance spectroscopy shortly after birth, but many then develop delayed energy failure 6–15 h later. In survivors, the degree of secondary energy failure after 24–48 h was closely associated with neurodevelopmental impairments at 18 months and 4 years of age [48]. Sequential MRI allows demonstration that the acute brain injury associated with encephalopathy in term infants evolves progressively over time to involve initially unaffected regions [49].

141.5 Electroencephalography

The timing of brain insult can be assessed by considering serial EEG recordings findings in relation to the time of birth [50, 51]. The timing can be considered prenatal if an EEG immediately after birth already shows chronic stage abnormalities, perinatal if it shows acute stage abnormalities, and postnatal if it is normal and a later EEG shows acute stage abnormalities. The detection of even mild seizures is an important indication of timing since prolonged seizures exacerbate hypoxic brain damage [52].

Routine serial EEG studies in preterm infants demonstrated that one fourth of cerebral palsies in these infants were of antenatal origin, two thirds of perinatal origin and postnatal injuries played the smallest role. Periventricular leucomalacia (PVL) manifesting itself on the ultrasound in the late neonatal period and suggesting postnatal origin was often found to be of antenatal origin with an EEG soon after birth [51]. PVL without apparent causes was often associated with abnormal fetal heart rate patterns and early neonatal EEG abnormalities, and considered to have originated in the antepartum period.

141.6 Hematology

Nucleated red blood cell (NRBC) count indicates fetal hypoxia in term and preterm newborns. Since NRBC is physiological in cord blood of preterm neonates, single NRBC counts need to be compared with standard values for the baby's gestational age [53]. Use of NRBC as a marker of timing of asphyxia is justified by information about fetal response to hypoxia, namely increased erythropoietin (Epo) secretion due to decreased fetal PO2 [54]. A relationship between asphyxia, high levels of circulating Epo and high NRBC has been demonstrated [55]. Although the exact time elapsing between hypoxia and appearance of NRBC is not known, experimental studies showed a complex mechanism of Epo-induced late erythroid differentiation and there is evidence that a period of more than 24 hours is necessary between decreased fetal PO_2 and appearance of NRBC in blood [56]. The concept that increased NRBC in cord blood may be regarded as a marker of hypoxia for a period of more than 24

hours before birth has also been accepted on the basis of clinical observations [57, 58].

Increased lymphocyte count is considered a reliable index of brain damage and makes it possible to establish timing since the increase seems to occur approximately 25 minutes after fetal bradycardia and hypoxia [20]. Thrombocytopenia can also help to determine the timing of brain damage since it appears 20–28 hours after bradycardia. Thrombocytopenia has been confirmed to occur after fetal hypoxia although the cause is unknown [59]. Although it may be misleading in certain conditions, the number of circulating lymphocytes together with other markers such as bradycardia, time of correcting acidosis, thrombocytopenia and clinical condition may be useful in determining the time of brain lesions.

141.7 Clinical Assessment

There is no ideal measure to assess the severity of perinatal hypoxia-ischemia during the initial clinical presentation of the infant immediately after birth. A persistence of an Apgar score of 0–3 at 5 min of life is one of the criteria for the presence of perinatal asphyxia.

During the first 12–24 h of life, after moderate to severe perinatal fetal hypoxia-ischemia, signs of neonatal encephalopathy include poor tone and feeding, difficulty maintaining respiration seizures and lethargy or coma.

141.8 Biomarkers

The term biomarker can refer to any entity that occurs in the body and can be measured to predict the diagnosis, onset or progression of disease process.

Laboratory studies generally use cord blood or amniotic fluid. They provide much information about conditions jeopardizing the central nervous system. Cord blood pH was the most widely used test for additional information on the severity of intrauterine asphyxia.

The criteria promulgated by ACOG and AAP [60] to attribute intrapartum hypoxia as a cause of neonatal encephalopathy and later cerebral palsy include: (1) an umbilical arterial PH of ≤7.0, (2) early onset of moderate-to-severe neonatal encephalopathy, (3) a diagnosis of cerebral palsy with quadriparesis of the spastic or dyskinetic type, and (4) the absence of other possible causes.

When using an umbilical arterial pH at the time of birth to define intrapartum asphyxia, the incidence an umbilical arterial pH <7.0 is 3.7 of 1000 term live births. Of neonates with this degree of acidosis 17.2% survived with neonatal neurologic morbidity, 16.3% had seizures and 5.9% died during the neonatal period. In developed countries the incidence of hypoxic ischemia encephalopathy (HIE) at term is 2.5 of 1000 live births and the proportion of cases of cerebral palsy associated with intrapartum asphyxia is 14.5% [61].

Since pH is influenced by both respiratory and metabolic factors, it represents an inverse log of the hydrogen ion concentration; before it does not change linearly with hydrogen ion concentration or with the use of base. If one assumes that organ and cellular response to hypoxia-ischemia result in accumulation of acid in a relatively linear proportion to the degree and duration of the insult, the exponential function pH has limited usefulness in the prediction of hypoxia timing. On the contrary, the base excess represents a linear correlate and thus a potentially valuable index of the degree and duration of metabolic acidosis. It has been proposed that a base excess of –12 mmol/L is a threshold of a metabolic acidosis associated with newborn complication [62] while a base excess of –22 has been reported to be associated with minor or major deficit in 80% of infants with intrapartum asphyxia [63]. Following Hagelin and Leyon [64] on average, the second stage labor decreases base excess by approximately 1 mmol/L per hour in the normal fetus. Studies carried out with the comparison between base excess and prolonged heart deceleration suggest a loss of 1 mmol/L per 2 minutes of severe compromise while subacute fetal compromise may reduce the buffer base by 1 mmol/L per 6–15 minutes.

Measurement of the degree of acidosis should be associated with heart rate and blood pressure recording. In particular, unremitting bradycardia has been observed to coincide with the development of ischemic basal ganglial brain damage [65]. Studies on timing have been carried out with heart rate and pH recording at birth together with lymphocyte and thrombocyte count [66]. Neonates may have severe metabolic acidosis and disorders responsible for hypoxia-ischemia, unremitting until birth. An hypoxia-induced myocardiopathy mirrors the severity of perinatal hypoxic-ischemic insult. Myocardiopathy can lead to hypothension and hypoperfusion of important organs, such as the brain. In most infants recovery of myocardial contractility occurs in the first 24–48 h after birth [67].

The availability of rapid methods for measuring lactate in cord blood and blood of neonates suggests their extensive use for the detection of severe metabolic acidosis which reflects asphyxia and is a signal of brain damage [68]. Da Silva et al [69] showed that blood lactate concentrations over 9 mmol/L at 30 minutes of life have 84% sensitivity and 67% specificity in the prediction of moderate to severe brain damage. Values less than 5 mmol/L indicate absence of risk [70].

The occurrence of oxidative stress in cord blood appears to be a good index of severe prenatal hypoxia/asphyxia.

During hypoxia, increased production of free radicals and/or decreased detoxification lead to mitochondrial dysfunction, inhibition of protein synthesis, inhibition of adenosine-5-triphosphate synthesis, inner mitochondrial membrane damage, activation of pro-caspase and other mechanism of apoptosis, generation of nitroperoxide and increased oxidative stress [71]. Free radicals affect glial cells, consequently decreasing glutamate uptake, and N-methyl-D-aspartate receptor

dysfunction, increasing intracellular calcium and further increasing brain cell damage [72]. Free radical excess may also be responsible for endothelial dysfunction, coagulation disorders and vasoconstriction. The central nervous system is vulnerable to free radical damage due to its high content of metals which may catalyze formation of free radicals, especially hydroxyl radicals and nitroperoxide. Antioxidant defences, which are even low in the central nervous system of adults, are particularly low in fetal and neonatal oligodendroglia.

Increased oxidative stress in hypoxic fetuses and neonates can be detected by assaying serum isoprostanes, serum total hydroperoxides, advanced oxidative protein products and increased non protein bound iron (NPBI) in serum. These markers can be used for the early prediction of the risk for oxidative stress-related diseases [73]. Plasma NPBI has been found to be the best early predictive marker of neurodevelopmental outcome, with 100% sensitivity and 100% specificity for good outcome at 0–1.16 μmol/L and for poor outcome at > 15.2 μmol/L [74].

Post mortem assessment of oxidative stress has been proposed in order to clarify the origin of brain lesions. Assessment is currently made by measuring advanced glycation end products from oxidation of proteins, carbohydrates and lipids in cytoplasm, nucleus and membranes [75]. The results of studies using these methods may help to determine the timing the brain injury, since oxidation products appear to vary in relation to gestational age. By measuring isoprostanes in amniotic fluid it is possible to distinguish fetal growth restriction pregnancies from normal ones [76]. Oxidative stress in pregnancy it is also associated with preterm premature rupture of membranes (PROM) and amniotic fluid isoprostanes may be a reliable predictive index of risk of preterm PROM [77].

Considering the close relationships between free radical release and phagocyte function and the relationship between phagocyte activation and infection, additional markers of infection, particularly those of so-called remote infection, could be exploited to determine the occurrence of oxidative stress. Intrauterine infection may be followed by brain damage due to the direct effects of bacterial toxins and lipopolysaccharides on glial cells, due to astrocyte deregulation and due to the effects of phagocyte activation, particularly on coagulation and the endothelium [78]. The many observations of poor outcome in babies whose gestations were complicated by chorioamnionitis, and of high cytokines such as IL-6, IL-1β, IL-8, IL-9, TNF-α in serum of premature and full-term newborns with placental lesions typical of chorioamnionitis, suggest that it may at least be worthwhile assaying IL-6 as a marker of brain damage in utero [79, 80].

A meta-analysis of chorioamnionitis and cerebral palsy indicated a positive association among preterm and full-term infants, with a relative risk of 4.7 for the full-term infants [81]. Similarly, maternal fever was linked with an increased incidence of neonatal encephalopathy [82].

Cord blood concentrations of B-lymphocyte chemoattractants, ciliary neutrophil factor, epidermal growth factor, IL-5, IL-12, IL-13, IL-15, macrophage migration inhibitory factor, monocyte chemoattractant protein-3, monokine induced by interferon-γ and tumor necrosis factor-related apoptosis-inducing ligands have been found significantly high in preterm and full-term newborns who develop cerebral palsy. Preterm infants with cerebral palsy have higher epidermal growth factor and lower levels of granulocyte macrophage colony stimulating factor, IL-23, macrophage derived chemokine as well as pulmonary and activation regulated chemokine than matched controls [83]. IL-18 has also been identified as a marker of brain damage risk [84].

Matrix metalloproteinases (MMPs) and their inhibitors, the tissue inhibitors of metalloproteinases (TIMPs), are microglial secreted proteins, making them easily measurable in fluids, including the peripheral blood [85, 86]. MMPs and TIMPs MMP-9 is upregulated in peripheral infracted cortex at 24–48 hours after cerebral ischemia in human forensic study in brain tissue after ischemic and hemorrhagic stroke [87]. Plasmatic levels of MMP-9 and TIMP-1 were explored in perinatal asphyxia: MMP-9 levels were significantly higher in the group of patients with unfavorable outcomes [88].

Protein S100 is brain-specific and is a very promising marker of brain damage in newborn, also providing information about timing [89].

The glial protein S100 belongs to a family of calcium binding proteins found as homo- or hetero-dimers of two different subunits (α and β). Different combinations of the subunits make up the heterodimeric forms α-α, α-β and β-β; types α-β and β-β are described as S100B protein and are shown to be highly specific for nervous tissue [90].

S100B can be measured in several biological fluids such as CSF, blood, amniotic fluid and urine.

During active brain injury at least some of the S100B released from the damaged tissue could spread into the systemic circulation as a result of hemodynamic rearrangement of the blood brain barrier.

In preterm infants with intraventricular hemorrhage (IVH), concentrations of S100 in blood were elevated before a radiological diagnosis could be made [91]. S100B blood concentrations also correlated with abnormal cerebral hemodynamic patterns (increased cerebrovascular resistance) and with the extent of IVH both in preterm and in full-term asphyxiated infants [91, 92]. In asphyxiated full-term infants, an early increase in S100B was found to be predictive of HIE and subsequent adverse neurological outcomes [93]. Longitudinal S100B protein monitoring in peripheral blood demonstrated a peak concentration of the protein 6 h after birth with a progressive decrease in S100B at 24 h. The positive predictive value of S100B for HIE with a protein cut-off of 8.5 μg/L at 2 h from birth was 71%, the negative predictive value was 90%, the sensitivity was 71%, and the specificity was 90% [93].

In intrauterine growth restriction (IUGR) fetuses a significant correlation between protein S100 and cerebral hemodynamics was observed, and high values of this protein were detected in the maternal bloodstream of pregnant women

complicated by IUGR whose newborns developed IVH [94]. S100B is also measurable in the urine fluid, and its concentrations at birth are significantly higher in preterm newborns who later developed cerebral bleeding and/or brain damage at a stage when all routine clinical, laboratory, and ultrasound investigations were still silent [95]. The very fast increase in S100 protein after hypoxic insult may be useful in determining the timing of brain injury occurring independently of enduring CTG abnormalities. Serial urine determinations of S100 protein showed increasing values from birth to 72 hours in newborns with abnormal outcome, and were higher than in babies with normal outcome. The values were reported in relation to time and severity of brain insult.

Hypoxemia is a specific trigger for an increase in activin A in the circulation of fetal lambs. Activin A is a dimeric protein belonging to the transforming growth factor-β superfamily, mainly produced by the placenta, decidua and fetal membranes and secreted in large amounts in the maternal circulation [96]. Activin A is involved in cell growth and differentiation, neuronal survival, early embryonic development, and erythropoiesis. Activin A concentrations significantly increase in maternal serum with advancing gestation [97]. Disorders of pregnancy due to reduced placental perfusion and various degrees of feto-placental hypoxemia, such as pre-eclampsia and fetal growth restriction are characterized by increased levels of maternal and umbilical cord activin A [98]. Feto-placental or maternal isocapnic hypoxemia are specific triggers for an increase in activin A.

Cord blood activin A levels increase in sheep after induction of hypoxia, remain elevated throughout hypoxia, and return to control values when normal blood flow is restored [99]. Neonates with clinical signs of perinatal hypoxia had higher activin A levels, which are correlated with biochemical features of hypoxia, such as higher nucleated red blood cell counts, plasma hypoxanthine, xanthine, base deficit levels, and lower pH [100].

Activin A concentration at birth is increased in preterm newborns who later develop IVH, and is useful for the early identification of infants with hypoxic-ischemic brain insults who are at high risk for IVH [101].

In conclusion NRBC, NPBI, isoprostanes, Activin A, protein S-100 and cytokines may be measured singularly or together to predict of brain injury earlier. The assessment of multiple biomarkers, combined with neuroimaging, has greater clinical utility for the formulation of diagnosis and the process of following diseases outcome.

Thrombosis in the Development of Newborn Brain Damage

Paul Govaert

142.1 Introduction

Neonatal stroke is defined as a group of heterogeneous conditions in which there is focal disruption of cerebral blood flow secondary to arterial or cerebral venous thrombosis or embolization, between 20 weeks of fetal life through 28th postnatal day, and confirmed by neuroimaging or neuropathological studies [1]. Two types of ischemic neonatal strokes are arterial ischemic stroke (NAIS) and cerebral sinovenous thrombosis (CSVT). The third stroke type is primary bleeding (hemorrhagic stroke). Additional forms of ischemic stroke unique to the perinatal period include periventricular venous infarction (PVI) and presumed perinatal stroke detected in infancy or childhood (both are not discussed in this chapter). Vessels are occluded by thrombosis, embolism, direct trauma, compression, spasm or obliteration by an inflammatory process. Open vessel ischemia, e.g., during hypovolaemia, arrhythmia or asphyxia, is not included in the definition of stroke.

Neonatal arterial ischemic stroke (NAIS) can be defined by either of two methods: (i) documenting partial or complete occlusion of the artery related to a focal brain lesion; (ii) using imaging to document a lesion pattern that cannot be otherwise explained than by occlusion of a specific brain artery. Precise vascular designation [2] and site description are important in reporting perinatal stroke. Middle cerebral artery (MCA) stroke covers more than 50% of the pial strokes, complete and posterior truncal stroke being most common. Templates for the diagnosis of neonatal perforator stroke have been published, with ultrasound and magnetic resonance imaging (MRI) for MCA stroke types [3]; and with ultrasound for the other perforator stroke types [4]. Multiple separate strokes in the same infant can be due to: infarction with meningitis, embolism (including air), thrombophilia, arteriopathy, breakdown of a large thrombus into several emboli and triggered arterial spasm.

Neonatal cerebral sinovenous thrombosis (NCSVT) is defined as the presence of thrombus in a sinus, a large deep brain vein or a smaller pial vein, with partial or complete occlusion. Complete occlusion, depending on tempo of thrombosis, hemostatic dysfunction and collateral potential, may or may not cause venous infarction (red softening) in brain areas draining into the vessel. In a minority such infarcts remain purely ischemic, suggesting that arterial occlusion in response to venous ischemia occurs prior to vein rupture. Specific hemorrhagic lesions have been reported in this context: thalamo-ventricular hemorrhage with occlusion of the internal cerebral vein (bilateral with great vein of Galen occlusion) [5], striato-hippocampal bleeding with basal vein thrombosis [6], parasagittal subcortical bleeding with superior sagittal sinus thrombosis [7], temporal lobe or cerebellar hemorrhage with transverse sinus thrombosis [8], temporal lobe anterolateral hemorrhage with tentorial sinus or temporal diploic vein rupture [9] and temporal lobe hemorrhage with vein of Labbé thrombosis [10]. Large veins and sinuses usually recanalize following thrombosis, over a period of weeks to months [11].

Hemorrhagic stroke results from rupture of an (ab)normal intracranial blood vessel, but it is difficult to document damage of a vessel in such instances. In the newborn, intracranial hemorrhage is usually described under the heading of the brain compartment affected: intraventricular (bleeding in choroid plexus and ventricle), thalamoventricular (related to internal cerebral vein occlusion), lobar cerebral (bleeding in the parenchyma of a cerebral lobe), cerebellar, subarachnoid and sub/epidural. Because sub/epidural bleeding is often due to trauma or hemostatic failure, and because intraventricular hemorrhage cannot be confused with arterial stroke, it seems appropriate to register only lobar (including subarachnoid) hematoma as stroke [12–14]. Specific types of frank hemorrhage are due to venous thrombosis (see above).

This chapter is a guide to the diagnosis of primary thrombosis in the newborn brain, be it arterial or venous. The likelihood of finding a prothrombotic condition and/or a dysfunctional platelet-endothelium interaction is probably greater

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

in such instances. A systematic exclusion of mechanisms other than primary thrombosis is therefore clinically relevant.

142.2 Clinical Presentation

Seizures are the usual presentation of NAIS [15]. Onset is fifty-fifty divided between day one and later in the first week, rarely beyond day three [16]. Focal seizures are a more common first sign of NAIS than general seizures (see Chapter 139). Because the interval insult to seizures may be short (less than an hour) but also add up to several hours, the timing in hours of an arterial insult in relation to labor stages is impossible. Acute embolic stroke may cause seizures within the hour of the event [17] or onset of seizures may be delayed for several hours [18]. Some newborns present with apneic spells or cyanotic attacks, possibly of epileptic nature [19]. Most children seem to be alert between seizures and even accept oral feeding. Some present with temperature instability [20], others with bouts of hyper- or hypotension due to hypothalamic injury. In some infants hemiplegia can be predicted from neonatal appreciation of asymmetrical general movements [21], but most often future hemiplegia is inconspicuous in the neonatal period. Neurologic alarm signs are usually lacking in perforator stroke and in the preterm, where stroke is often a surprise finding at brain ultrasound (US) scanning.

In the context of NAIS an alarming event is acute pallor and loss of pulsation of (part of) a limb due to arterial embolism (or spasm ?), as reported by several authors [22–28, one personal observation]. Most of these limb-brain strokes present with limb pallor within minutes of delivery, strongly suggesting that embolic stroke preceded delivery. In some cases antiphospholipid antibodies in newborn serum were associated, and aortic thrombosis has been documented in this setting [25, 28, personal observation]. In this context subclavian steal from the vertebrobasilar circulation has been documented with MRI [28].

Neonates with NCSVT present with seizures (two thirds) or focal neurological signs like hemimotor paresis or cranial nerve palsies [29, 30]. These signs suggest that parenchymal destruction around veins followed an increase of venous tension above the arterial pressure level. Fever, altered level of consciousness or jitteriness are possible but not typical. The underlying cause may dominate the picture as with asphyxia, congenital heart disease or dehydration. Thrombosis without infarction is asymptomatic and thus an incidental finding (for instance in a search for the cause of a low platelet count or during extracorporeal membrane oxygenation [ECMO]). Platelet consumption is seen with NCSVT, with or without venous infarction, but is only seen with NAIS if the arterial process causes organ or limb necrosis [31]. Propagation of thrombosis is common in the first week, perhaps explaining evolving clinical signs [11].

142.3 Etiology, Pathogenesis and Differential Diagnosis

142.3.1 Step 1: Exclude Entities Mimicking Stroke

Several focal lesions have to be differentiated from NAIS and NCSVT: kernicterus, encephalitis (bacterial and viral), mitochondrial disorders, posterior reversible encephalopathy and tumor. Consistent imaging patterns of neonatal hypoglycemic injury have been reported. Bilateral, rather symmetrical, injury of occipital and posterior parietal cortex and underlying white matter was well documented in a postmortem study of three patients [32] and subsequently in many *in vivo* studies [33].

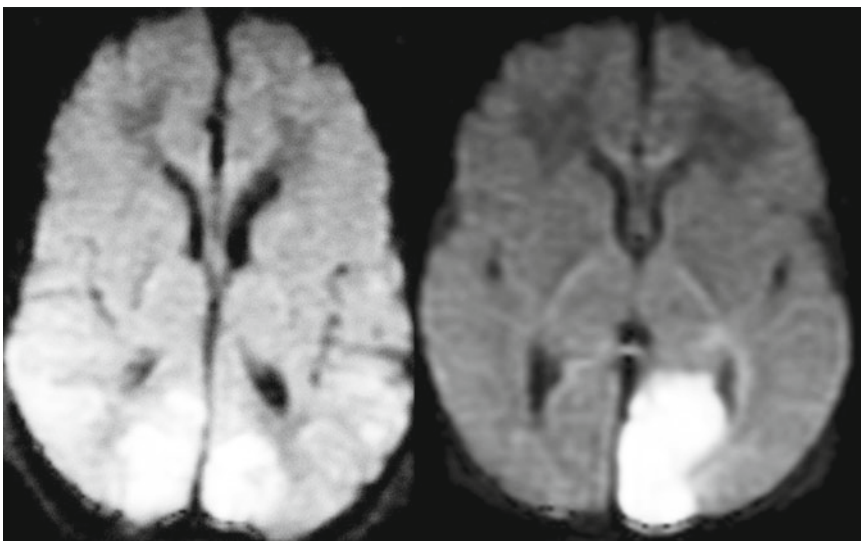

Fig. 142.1 DW axial MRI in a term infant with profound hypoglycemia and seizures: focal bilateral occipital subcortical cell injury may mimick posterior cerebral artery (PCA) stroke (compare with DWI on the right of infant with tip of the basilar artery stroke leading to cerebellar infarction and left PCA pial stroke)

Injury spreads beyond the area covered by the posterior cerebral artery and is too extensive to be classified as watershed infarction (Fig. 142.1). Infarction with cavitation, not a feature in adults, has been reported in the newborn [34]. A second paradigm seems to be unilateral hemispheric necrosis [35].

Bleeding from a vascular anomaly should be distinguished from stroke. It is advised to repeat ultrasound Doppler exams or even magnetic resonance angiography (MRA) 4–6 weeks after hemorrhagic stroke, if the cause of the insult is not obvious (no source of embolism, no infection, no trauma, normal hemostasis) [36, 37]. Developmental venous anomalies may resemble focal pial stroke in some infants.

Watershed injury resulting from partial asphyxia or hypotension (e.g., due to acute blood loss) does not fit under the stroke umbrella. However, one must be aware that hyperechoic change in parasagittal areas can be due to interarterial watershed injury but also to superior sagittal sinus thrombosis.

It is important not to confuse stroke with different degrees of bilateral white matter injury typical of the preterm (former leukomalacia, often with petechial or nodular hemorrhage in affected areas). Matters are more complicated concerning periventricular venous infarction (PVI), regularly seen in the preterm infant [38]. Such (almost invariably) unilateral white matter hemorrhage in preterm infants is in fact consequent to venous obstruction following ipsilateral germinal matrix hemorrhage or intraventricular hemorrhage (IVH), but the clinical context is different from NAIS or NCSVT. In addition, routine serial sonographic screening reliably offers recognition of PVI in the acute stage [39, 40]. Some instances will not be due to compression of a medullary collector vein by germinal matrix hemorrhage but to primary thrombosis.

142.3.2 Step 2: Recognize Hemorrhagic Stroke

142.3.2.1 Lobar Hematoma

In a limited number of newborn infants, often in the absence of IVH, one may find hemorrhage in one or more brain lobes, outside the basal ganglia and thalamus [13, 14, 41, 42]. Lesions in every lobe of the cerebrum have been described, and the prevalence amounts to about one hemorrhagic stroke for five ischemic ones (Fig. 142.2) [42]. It is common for lobar hematomas to be associated with a subdural or subarachnoid extra-axial component: this raises the question where the primary focus is, in parenchyma or in the extracerebral space. The presenting sign has often been apnea [19, 43] or (multi)focal convulsive activity, but some lobar hematomas are asymptomatic [44]. In most instances the mechanism remains unknown [12]. There are no reports of documented sinus thrombosis causing large lobar hemorrhage in the absence of a hemostatic problem [9]. The association of lobar hematoma with focal arterial ischemia in another additional brain area is suggestive of embolism with hemorrhagic conversion of arterial ischemic stroke.

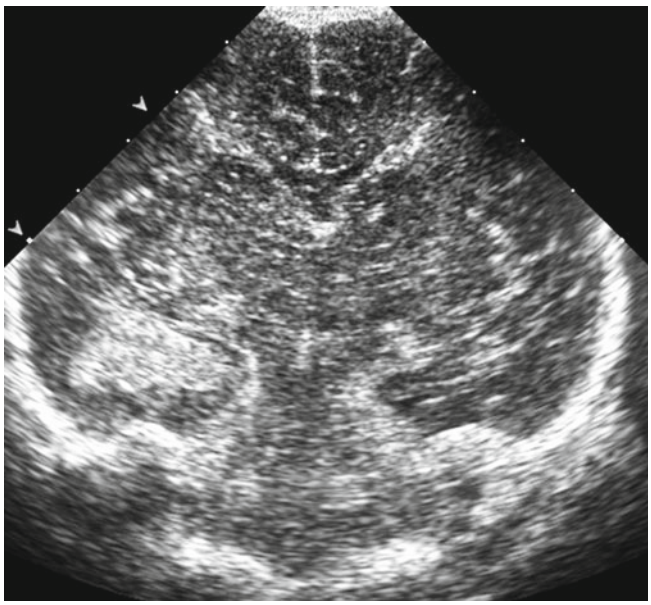

Fig. 142.2 Coronal US 6 hours after birth of a term infant presenting with apnea and cyanosis: hyperechoic right temporal lobe lesion, later demonstrated to be a hematoma; vascular malformation excluded by MRA and serial Doppler imaging

Lobar lesions also warrant a diligent search for evidence of trauma, hemostatic failure [45], a prothrombotic tendency and a vascular malformation. Saccular arterial aneurysms can present with seizures and meningeal signs in infancy: the MCA is commonly affected but location can be within the posterior fossa or in other supratentorial arteries. Most aneurysms exceede 1 cm in diameter and should be MRA-present. Arterio-venous malformations (other than vein of Galen malformation) present with congestive heart failure (usually large fistulae), hemorrhage or hydrocephalus of the communicating type. Most are supratentorial (9/10). Spontaneous thrombosis of an arteriovenous malformation (AVM) is exceptional. Cavernous angiomata are associated with hemorrhage as a rule, from mild to extensive. One must be aware of an underlying tumor facing lobar, subdural or intraventricular hemorrhage: astrocytoma is a rare cause of neonatal lobar hematoma.

142.3.2.2 Subarachnoid Hematoma

Subarachnoid hematoma refers to a space-occupying hemorrhage on the brain surface, located under the arachnoid membranes [46, 47]. The primary lesion is a fast growing subarachnoid or subpial hemorrhage [48], mostly along and under the temporal and parietal lobes, more often on the left. There is usually a context of hemorrhagic diathesis, frequently intravascular coagulation (or thrombocytopenia of any cause) during sepsis. On any imaging technique the borders of the hematoma irregularly penetrate the parenchyma

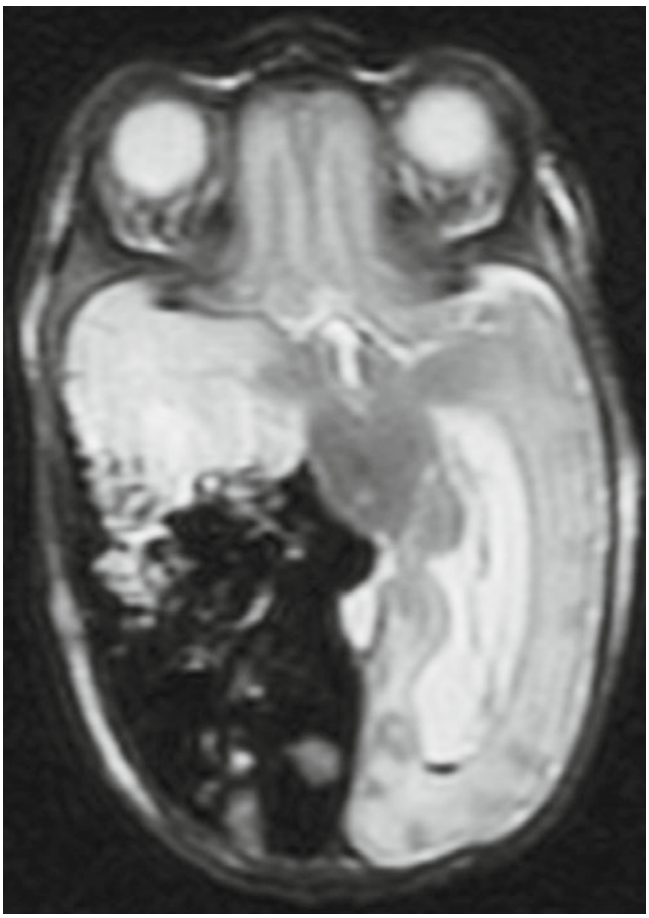

Fig. 142.3 Axial T2 MRI: subarachnoid hematoma associated with gram-negative septicemia in a preterm infant

because sulci and fissures are filled with clot (Fig. 142.3). Subdural hemorrhage displaces but does not penetrate the adjacent parenchyma. The midline may be shifted and the ipsilateral ventricle can be closed under pressure. Rupture of an arterial aneurysm or AVM is another cause of subarachnoid hematoma [49–51]. Subarachnoid hemorrhage was one of the components of a strange and often fatal pattern of hemorrhagic necrosis in both parietal lobes of extremely preterm infants [52]. These lesions cavitated in the parenchyma. Vigorous chest physiotherapy was recognized as the underlying mechanism and the situation is thereafter discussed as shaken newborn syndrome [53, 54].

142.3.3 Step 3: Link Stroke to (Birth) Trauma

There are several possibilites that explain how difficult delivery can cause vessel occlusion. Direct injury to the vertebro-basilar arterial system is possible [55]. Several reports associated difficult instrumental traction with intimal damage to the internal carotid or middle cerebral artery resulting in local occlusion from thrombosis and stroke [56–60]. Focal brain damage in the sense of contusion can be observed with bone fracture or dehiscence [61, 62]. Both PCA and superior cerebellar artery can be compressed and occluded during uncal herniation induced by lobar parenchymal, epidural or subdural hematoma [63–67]. In the vicinity of subdural or subarachnoid bleeding stroke has been tentatively (because never angiographically documented in the newborn) linked to spasm [15, 60, 62, 68, 69]. Trauma may predispose to arterial infarction outside the context of difficult delivery. During ECMO embolism from the canulated (traumatized)

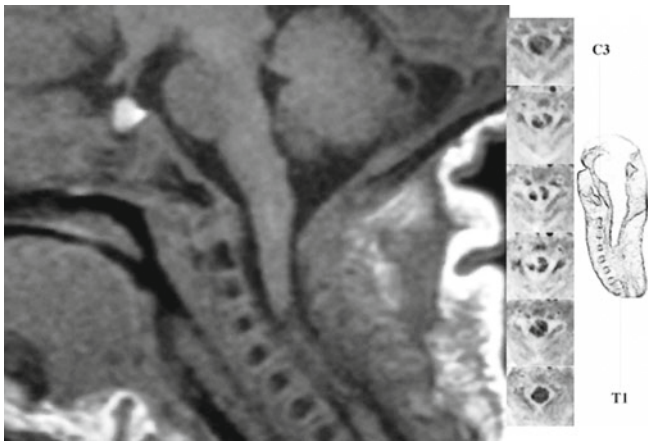

Fig. 142.4 Term boy with quadriparesis from birth (hyperextended breech for which elective cesarean) deceased due to respiratory insufficiency in early infancy. MRI (sagittal T1 with assorted T2 axial scans at different cervical levels) pointed to a lesion from C3 to T1 that divided the cervical cord into a smaller right and larger left portion

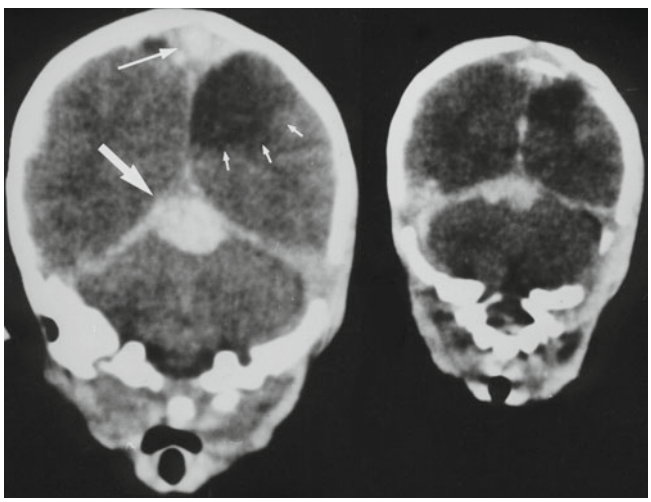

Fig. 142.5 Coronal CT sections in a term infant with sinus thrombosis (*left*) due to impressed occipital squame (*right*). Also observe tentorial subdural hematoma (*large arrow*) and area of ischemia on the left convexity (*small arrows*)

carotid artery or hypoperfusion on that part of the circle of Willis can cause stroke [3]. Chronic cord ischemia has been related to in utero high spinal cord infarction in case of hyperextended breech presentation (Fig. 142.4) [70–72].

CSVT of traumatic origin has been reported as: infected cephalhematoma, osteitis and transverse sinus thrombosis [73], superior sagittal sinus thrombosis due to impression of the occcipital squame [74, 75], propagated thrombosis from superior sagittal sinus into deep veins [5] and transverse sinus thrombosis (Fig. 142.5) [8]. Direct sinus trauma from a penetrating scalp electrode can also induce thrombosis [76].

142.3.4 Step 4: Link Brain Inflammation to Stroke

Both meningitis and ventriculitis can lead to inflammation and occlusion of arteries and veins with focal or diffuse subcortical and/or periventricular infarction [77, 78]. Large vessel NAIS has been reported infrequently, sometimes with exotic organisms: syphilis [79, 80]; *Enterobacter* [81]; *Meningococcus* [82]; *Listeria* [83] (Fig. 142.6); *Pasteurella multocida* [84]; *Salmonella* [85]. Sinus thrombosis similarly can follow bacterial meningitis [86–88]. Local infection may be a portal of entry for thrombophlebitis of a sinus: from scalp infection via emissary veins to a sinus [7, 89], infection in aplasia cutis invading superior sagittal sinus [90, 91] or from orbital cellulitis into the cavernous sinus [92].

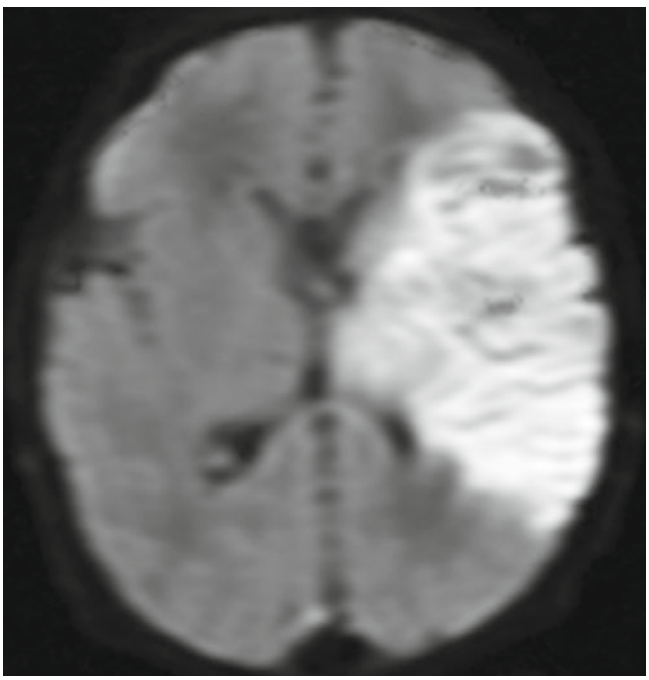

Fig. 142.6 DW MRI: focal large artery stroke (MCA) associated with *Listeria meningitis* in a term infant

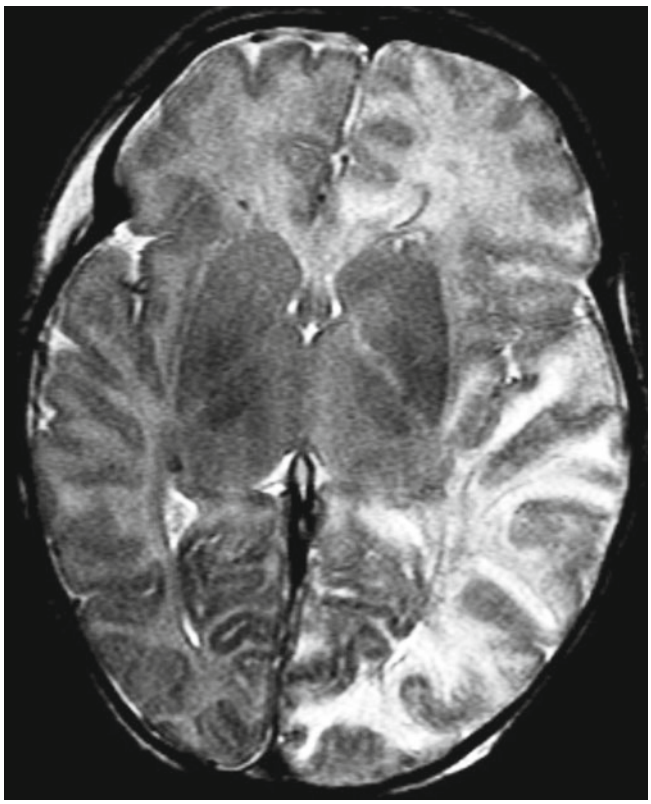

Fig. 142.7 T1 MRI: multifocal ischemic infarction of the left side of the brain in incontinentia pigmenti

Acute chorioamnionitis has recently been suggested as a possible cause of first umbilical venous and later cardiac or brain thromboembolism [93]. There is no evidence for direct cerebral arteritis in this situation. Non-infectious inflammatory conditions can also predispose to arterial stroke. Incontinentia pigmenti probably causes obliteration of small and medium sized arteries in the neonatal period [94] (Fig. 142.7), Aicardi-Goutières syndrome can lead to focal arterial ischemia [95] and infantile arterial calcinosis can induce focal infarction in the basal ganglia and watershed injury at cortical level [96, 97]. Fetal infections like rubella, CMV and toxoplasmosis can be associated with brain arteritis.

142.3.5 Step 5: Recognize an Arteriopathy (Venopathy) or Arterial (Venous) Malformation

Some genetic perinatal arteriopathies were described above with inflammatory conditions. Other hereditary conditions associated with arterial occlusion present in the neonatal period or early infancy: inborn errors of metabolism (hyperhomocysteinaemia, primary hyperoxaluria, galactosialidosis, molybdenum cofactor deficiency, mitochondrial disorders);

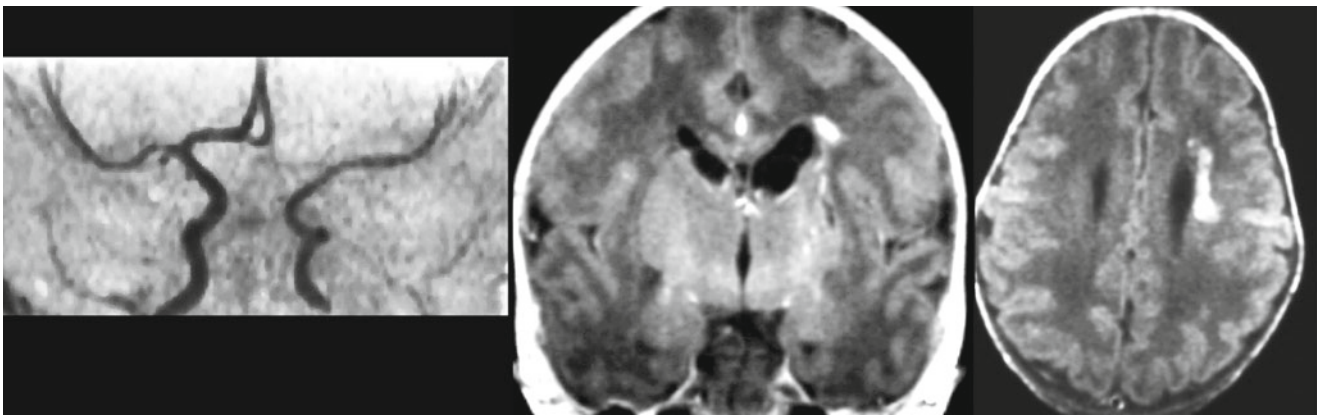

Fig. 142.8 Absence of the left ACA A1 part, attenuated left MCA and ipsilateral periventricular injury, in a term infant with one episode of neonatal convulsions (*left* MRA, *middle* coronal and *right* axial T1 MRI)

anomalies of karyotype (Miller-Dieker lissencephaly, trisomy 13, trisomy 21, 22q11 deletion). Hypoplastic or absent (malformed) arteries can be associated with congenital or postnatal brain tissue loss [98]. Such malformations are seen in PHACE syndrome [99–101] and in Goldenhar syndrome [102]. Carotid hypoplasia may lack an obvious cause [103] or be associated with maternal drug abuse, toxins or infectious agents [26, 104, 105]. Other neonatal arterial anomalies have been linked to fibromuscular dysplasia, to carotid elastin hyperplasia [106], or to Ehlers-Danlos I or Stickler syndrome [107]. We have observed perinatal MCA stroke associated with altered shape and thrombosis of the aortic arch. All these observations warrant documentation of the structure and patency of large intracranial arteries in diverse instances of NAIS (Fig. 142.8). Scarce case reports of sinus thrombosis associated with jugular vein hypoplasia [108] or with abnormal superior vena cava anatomy [109], suggest it may be informative to search for such venous anomalies in instances where neonatal sinus thrombosis is without obvious cause (Fig. 142.8).

142.3.6 Step 6: Find an Embolic Source for Arterial Ischemic Stroke

Emboli find brain arteries in many situations [110]. The source may be: in the left heart (following exchange transfusion, Rashkind procedure, cardiac surgery; due to tumor or arrhythmia); in the carotid or vertebral artery or in the aortic arch; anywhere in the body because of paradoxal embolism through a patent foramen ovale: right heart, umbilical vein, ductus venosus, portal vein, renal vein or inferior caval vein (Fig. 142.9). The existence of a central venous line with thrombus around the tip must be excluded. An embolic mechanism can underly stroke in twin to twin transfusion. Inadvertent injection of embolism-prone material and air embolism are other

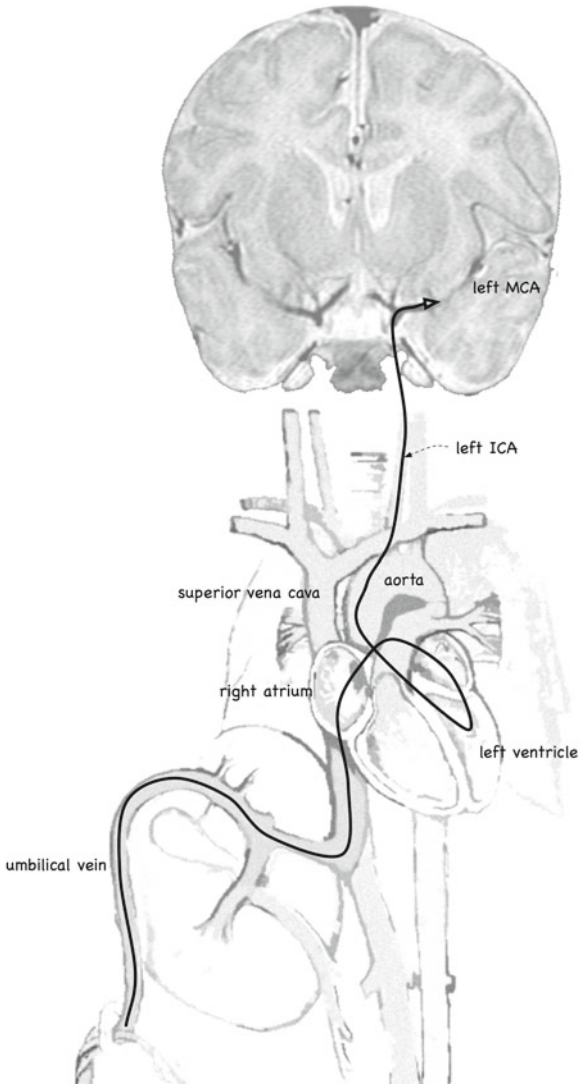

Fig. 142.9 Schematic presentation of paradoxal embolism from inferior caval vein into the left MCA. *ICA* internal carotid artery

possibilities. Flushing a temporal artery catheter [111, 112] and instrumentation of the carotid artery for an ECMO procedure [113] can both cause NAIS. The type of stroke (e.g., the fact that only a trunk of the MCA is affected) may suggest that the mechanism was embolic [114]. It is important to document associated limb (see clinical presentation above) or visceral (heart, gut) infarction: concurrent independent infarction in- and outside the brain increases the likelihood of detecting a prothrombotic condition, an arteriopathy or embolism [115].

142.3.7 Step 7: Diagnose Primary Thrombotic Arterial Ischemic Stroke

Spasm and primary thrombosis are two conditions where vessel occlusion is intrinsic. The balance of hemostasis can be disturbed in the direction of thrombosis, even in the absence of all extrinsic conditions mentioned above. Hypotension (due to infection, heart tamponade or acute blood loss), septicemia and asphyxia probably contribute to thrombosis through endothelial injury [116]. Intrinsic prothrombotic conditions, detailed in the hematological chapters of this book, manifest via several pathways: reduced fibrinolytic activity, enhanced generation or function of thrombin, enhanced platelet aggregation and endothelial dysfunction promoting platelet adhesion.

The extent of testing for genetic prothrombotic risk factors needed in clinical practice is not determined, but extensive screening is often recommended, largely based on experience with older children [117–120]. Prothrombotic risk factors readily find partners in the perinatal period to cause NAIS, as reported in many small cohort and a few case control studies. Familial activated protein C resistance due to factor V Leiden mutation was mentioned first [17, 121, 122]. A modest state of thrombophilia can also be induced by hyperhomocysteinemia above 10 μmol/L. One multicenter case-control study of stroke at term found that none of 91 instances were associated with protein S deficiency [123]. Other factors enhancing the risk of thrombosis detected included increased serum lipoprotein A, homozygous C677T polymorphism in methylenetetrahydrofolate reductase (MTHFR), protein C deficiency and prothrombin (factor II) mutation. Antithrombin deficiency is exceptionally part of the list [124]. Multiple heterozygosity or other risk combinations enhance the prothrombotic tendency. At present there is not enough evidence to prompt clinicians into an exhaustive search for thrombophilia faced with a first and recent perinatal stroke, mainly because of the very low recurrence rate. Doubt remains however because the detection of antithrombin heterozygous deficiency or a combination of genetic prothrombotic risk factors may necessitate secondary prevention with use of anticoagulants during periods of increased risk (immobilization, puberty, pregnancy).

Maternal antiphospholipid antibodies (detected as lupus anticoagulant, anticardiolipin IgG and/or anti-beta2-GPI antibodies in mother and/or infant) may induce thrombosis within the fetoplacental vasculature resulting in paradoxal embolism from the umbilical vein; IgG antibodies may also cross the placenta and potentially cause thrombosis directly within fetal organs [125]. The true significance of fetal thrombotic vasculopathy in relation to NAIS is not yet clear [126]. A hypothetical sequence from amnionitis to fetal vasculitis (and systemic inflammation) to intracardiac thrombosis to embolic stroke was recently discussed [93].

The possible link between arterial ischemic stroke and hyperviscosity (in practice polycythemia) - long ago referred to as a risk factor for lateral striate infarction [127] - has not been recently confirmed. Congenital nephrotic syndrome can present in the neonatal period with both arterial and venous cerebral thrombosis [128, 129]. Congenital disorders of glycosylation (CDG) balance the clotting equilibrium towards thrombosis [130]. Clotting factor suppletion could be a risk factor for NAIS [131].

Prolonged arterial spasm with subsequent infarction, has been linked to endogenous constrictors like subarachnoid hemorrhage, and to exogenous constrictors like cocaine and others (amphetamines, blue cohosh, codein) [132, 133]. Spasm in a brain artery by blunt skull trauma is common in children but has not been reported in the newborn.

142.3.8 Step 8: Diagnose Primary Sinovenous Thrombosis with(out) Infarction

As described above both trauma and inflammation are associated with NCSVT. Venous malformations rarely induce sinus thrombosis. Embolism is not a cause of sinus thrombosis, but the reverse may exist in the newborn: fragmentation of clot in a thrombosed sinus, migration along the jugular vein into the heart and paradoxally into the brain. Hyperviscosity was on occasion mentioned as a risk factor for NCSVT, e.g., in infants of a diabetic mother [134, 135]. The limited number of descriptions of thrombophilia associated with NCSVT does not permit conclusions about the differential sensitivity with arterial thrombosis. Predispositions implicated are: deficiency in antithrombin III, homozygous deficiency of protein C (or S), fV Leiden mutation, fII mutation (Fig. 142.10), the presence of antiphospholipid antibodies, tPAI1 polymorphism, high lipoprotein A, factor VII replacement, congenital nephrotic syndrome and the presence of (post hepatitis B vaccination) antinuclear antibodies [136–147]. The combination of neonatal brain hemorrhage and sinus thrombosis has been recently found with von Willebrand type 3 disease [148]. A contribution of cooling to postasphyxial NCSVT was suggested in a pilot study, but not confirmed later [149]. Dehydration, such as by insufficient breast feeding, is a risk factor specific for venous thrombosis, decades ago referred to as marantic thrombosis [7, 150–152]. Sinus thrombosis can follow endovascular

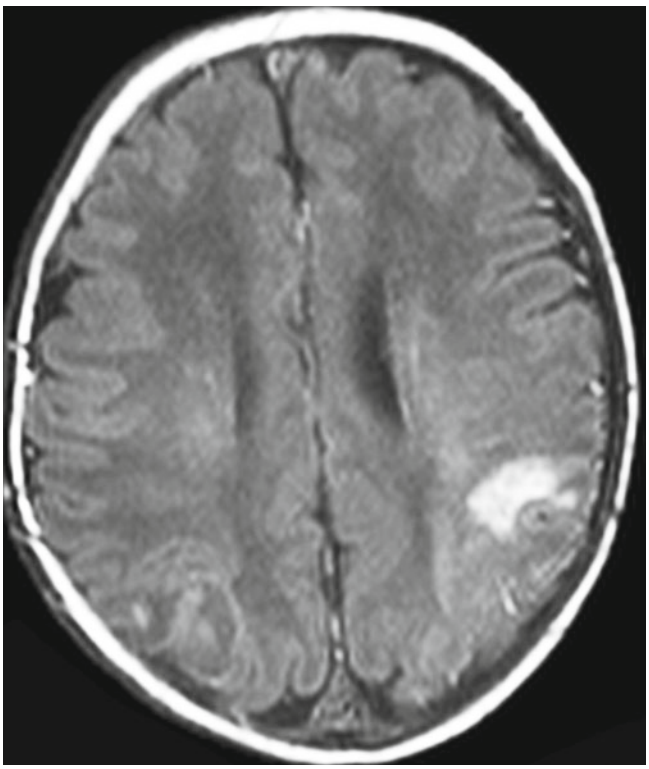

Fig. 142.10 Term infant with first day thrombocytopenia and focal seizures: T1-MR showing superior sagittal sinus thrombosis with hemorrhagic parasagittal infarction

treatment of a vein of Galen malformation [153]. A relation between pre-eclampsia and sinus thrombosis remains to be confirmed [154].

142.4 Medical Treatment

There are guidelines for the treatment of pediatric arterial ischemic childhood stroke: outside pro-active transfusion policy in sickle cell disease, the suggested treatment schedules are mainly based on cohort studies and extrapolation from adult stroke insights (Table 142.1) [155–157]. There are, therefore, no evidence-based treatment options.

In the acute phase of NAIS, supportive measures such as hydration and anticonvulsants are part of standard care. Thrombolysis is not recommended as neither effectiveness nor safety have been demonstrated in neonates. Recommendations propose heparinisation (for a period of months in some cases) in instances with ongoing thrombosis in the heart or a large systemic vein or with carotid artery dissection [158, 159]. For the remainder, anticoagulation or antiplatelet therapy are not recommended as the risk of recurrent stroke is low [160]. A study of 215 neonates with AIS followed for a median of 3.5 years, documented symptomatic recurrence in seven (AIS in four, CVST in two, and deep venous thrombosis in one patient). Factors associated with an increased recurrence rate included thrombophilia and the presence of comorbidities such as complex congenital heart disease or dehydration [125]. Only when AIS reoccurs, therapy is suggested. A heparinization protocol following cardiac catheterization may be useful [161].

It seems obvious that efforts be undertaken to maintain and salvage tissue, particularly within the ischemic penumbra. The synthesis of suggestions for pharmacological intervention from animal stroke experiments is beyond our scope [162]. Easily applicable candidates could be albumin or hypothermia [163]. Insight has to be gained in many areas of NAIS to arrive at treatment options. Theoretically this may facilitate intervention

Table 142.1 Guidelines for treatment of neonatal stroke

		Royal College of Physicians (UK)	American College of Chest Physicians (USA)
Acute AIS	– Acute systemic thrombolysis	No evidence to support use of thrombolytic agents such as tissue plasminogen activator (tPA)	Use of thrombolytic agents in children with AIS has been rare, and the risk/benefit ratio is unknown
	– Acute intraarterial thrombolysis	Not recommended	Not recommended
	– Acute heparinisation	Not recommended, except in case of dissection or cardioembolic stroke	UFHeparin or LMWHeparin for 5–7 days and until cardioembolic stroke and vascular dissection have been excluded
Secondary prevention of AIS	– Dissection	Anticoagulation for ≤ 6 months	Anticoagulation with heparin for 3–6 months
	– Cardioembolic stroke	Anticoagulation in consultation with cardiologist	Anticoagulation with heparin for 3–6 months
	– APL antibodies or inherited thrombophilia	No recommendations	No recommendations
Sinovenous thrombosis		Consider anticoagulation (LMWH or UFH) in selected neonates with – severe thrombophilic disorders – multiple cerebral or systemic emboli – propagating SVT despite supportive therapy Thrombolytic agents are not recommended	Heparin (first unfractionated, later fractionated) is recommended if no significant intracranial hemorrhage is associated, for 6 (if early recanalization is observed) up to 12 weeks (if recanalization is incomplete at 6 weeks)

AIS arterial ischemic stroke, *SVT* sinovenous thrombosis, *LMWH* low molecular weight heparin, *UFH* unfractionated heparin.

at five levels: (i) prevention of risk factors (like vaginal breech delivery or difficult instrumental traction, like catheter-related embolism), (ii) reopening of an occluded vessel with fibrinolytics and/or maintaining collateral patency, (iii) protection of cells in the penumbra from secondary excitotoxic or apoptotic death (by maintaining perfusion and metabolic homeostasis), (iv) prevention of recurrence (in children with important risk factors) and finally (v) specific rehabilitation strategies. Some of these will have to be tested in trials including identical strokes, e.g., complete MCA stroke, to avoid the confounding influence of stroke type on outcome [164–167].

The role of anticoagulants in NCSVT is controversial as recurrency is also rare. Recurrent thrombotic episodes occurred in 6% of children during a mean follow-up period of 36 months [168]. Strikingly, children younger than 2 years of age did not develop recurrent thrombosis at all. However, prolongation of the initial thrombus 1 week after diagnosis has been reported in a cohort study of 68 neonates: in ten out of 40 neonates without anticoagulation (25%), in comparison to one of 28 neonates on anticoagulants (3%). Extension of the thrombus was asymptomatic in all but one neonate, who presented with a novel venous infarction [11]. Although randomized controlled trials were not performed, safety of anticoagulation in NSVT has been monitored [29, 169, 170]. In the Canadian Stroke Registry no patients died or or showed signs of neurologic deterioration due to bleeding during heparin treatment [29]. Consequently, the ACCP guidelines recommend treatment of neonates with SVT without significant intracranial hemorrhage, with unfractionated heparin (UFH) or low molecular weight heparin (LMWH) initially, followed by LMWH or vitamin K antagonists for 6–12 weeks. For neonates with SVT and significant hemorrhage, radiological monitoring is recommended and anticoagulation therapy warranted if extension of the thrombus occurs, 5–7 days after the onset of the initial hemorrhage [156]. Antithrombin concentrates may be needed in addition to heparin in rare instances of sinovenous thrombosis due to antithrombin deficiency and protein C concentrates can be of use in situations where sinovenous thrombosis is associated with protein C deficiency or the presence of antiphospholipid antibodies [125, 171].

Epidemiology of Adverse Cerebral Outcome

Neil Marlow

143.1 Introduction

Since the beginnings of neonatal intensive care, in particular the recognition that mechanical ventilation could improve survival, there has been debate and discussion as to whether the steady advancement of survival rates comes at the cost of an increased risk of adverse outcomes. This was addressed in 1981 by Stewart, Reynolds and Lipscomb in a review of the world literature on outcomes for very low birth weight (VLBW) births [1]. Since the mid 1940s survival across a range of reports had steadily improved and despite increasing numbers of survivors the proportion of all births surviving with handicaps had remained constant at 6–8%. Indeed, the rate of impaired outcome as a proportion of survivors had progressively increased.

Since then improvements in survival have continued and the lowest birthweight and gestations reported with survival have fallen progressively so that now it is not unusual for babies to survive birth as early as 22 weeks of gestation or weighing < 500 g at birth. These extremely preterm infants (sometimes referred to as previable (not strictly accurate) or micropremies) excite much the same debate as raged in the 1970s over instituting invasive intensive care. It is therefore of great importance to monitor and record the outcomes for such children so that accurate prognostic data can be provided.

One problem is that the numbers of such children cared for by individual institutions over any year is very small – for example in England during 2006 there were only four survivors after birth at 22 weeks and the number of babies surviving at 23 weeks equates to an average of under one per NICU (source EPICure 2). Hence reliable evidence of the proportion surviving with adverse outcome, and with narrow confidence intervals, can only be achieved by averaging over many years, encompassing changing care practices, or by performing large population studies. Population studies are often compared to studies from centers of excellence, something which is really not feasible unless there is 100% referral into such centers, as it is well-described that children survive more frequently in such settings and it is likely that morbidities will be reduced. Thus all reports of comparisons have to come with caveats because of a range of rarely matched issues (Table 143.1). It is possible to make careful comparisons of outcomes between epidemiological studies – for example there are remarkable similarities in outcomes between the EPICure (UK and Ireland) and EPIPAGE (regional study, France) in terms of prevalence of both cerebral palsy and cognitive impairment [2].

Morbidity following extremely preterm birth must be considered with reference to survival as the profit and loss for care at such low gestations is key information for parents. Indeed whereas the outcome for many studies of perinatal care has been traditionally a composite of death of moderate/severe neurodevelopmental impairment, increasingly unimpaired outcome is being preferred as that is the goal of our care [3]. However, for parents the guide still remains the risk of death or serious disability.

Since the mid-1990s there have been several population based studies of outcomes among extremely preterm children (Fig. 143.1). They report a range of outcomes of which two predominate – cerebral palsy and serious developmental delay. Such studies cannot be directly compared, however, because of differences in population definitions of extremely preterm birth (some include births 22–25 weeks and others up to 27 weeks), differences in definitions of disability, variation in follow-up rate, different methods of obtaining denominator data (for survival) and differences in baseline prematurity rates in different populations (Table 143.1).

143.2 Cerebral Palsy

The prevalence of cerebral palsy (CP) increases with both decreasing gestational age and birthweight. The rate of CP in

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

Table 143.1 Pitfalls in the comparison of data from different studies of adverse outcomes

Problem		Suggested solution for reports
Gestational ages and birth weights	*No agreed definition of "extremely low GA", more consensus over birthweight categories*	Report in fixed categories by: – single completed gestational weeks (to 30 w) – 250 g weight intervals (to 1500 g) – always use confidence intervals
Population bases	*Some report hospital based outcomes other community or population*	Population data preferred for comparative data as circumvents issues of referral bias
Perinatal baseline	*Some units report outcomes only for admissions, others live births, others for babies alive at the onset of labor*	Report all three statistics if possible; important as parents need updated risk information depending upon their pathway though labor and delivery
Assessment ages	*Most authorities agree that more accurate data come from later acquisition of information*	18–24 months is the most common age of initial assessment and should be adhered to
Outcome measures	*Variation in definition, cut offs, and tests used*	Use standard published definitions of outcome and ensure contemporary developmental tests, where not possible collect reference or comparator data for term infants
Population	*Immigration and social disadvantage important contributors to rate of preterm birth and morbidity*	Evaluate and report population mix in terms of ethnicity, social advantage and baseline prematurity rate
Health systems	*No clarity on policy al extremely low GA in terms of options for parents and for babies*	State policy (even if cannot be agreed, estimate variation) and proportion of children at each GA week in whom resuscitation is attempted

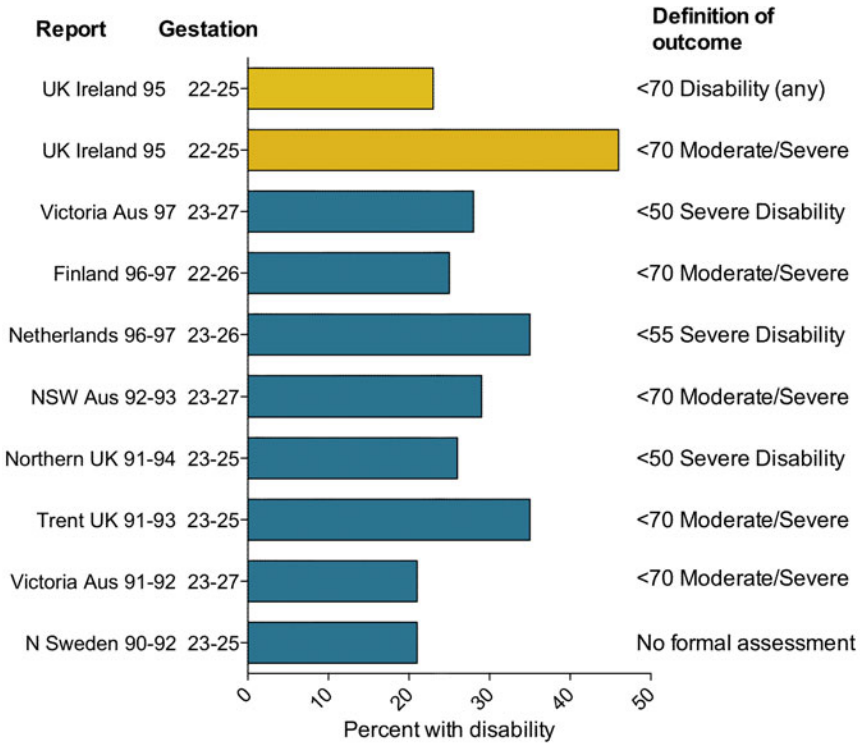

Fig. 143.1 Summary of outcomes from national or geographically based studies of outcome in extremely preterm infants showing the variability in the gestation range included and in the definition of outcome. Two definitions are shown for the UK and Ireland report to demonstrate the effect of differences in definitions. Data adapted from [20]

the individual populations cited in Fig. 143.1 varies between 10 and 20% with all the caveats mentioned above. Better data come from the reports of population studies, such of those of Hagberg and colleagues from southern Sweden, (Fig. 143.2) [4] or the *UK 4*-Child register. In these studies care has been taken to use a geographically based approach and careful case definition to produce consistent trends.

The rise in prevalence of all types of CP seen from the late 1960s has now been replaced by a steady decline during the 1990s [4]. In particular, there has been a decrease in the

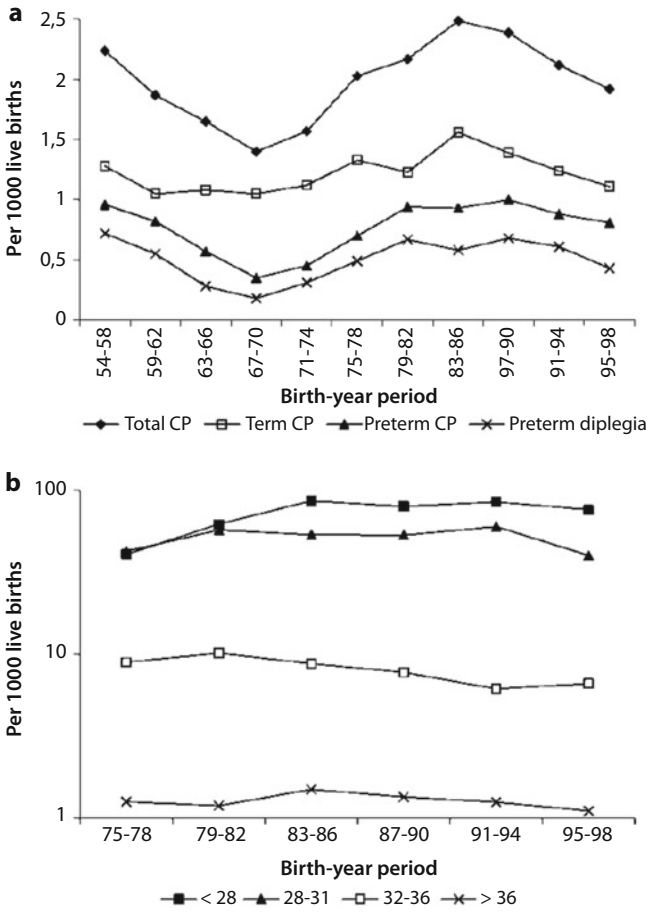

Fig. 143.2 Trends in the prevalence of cerebral palsy in Southern Sweden 1954–1998. **a** Prevalence by type of cerebral palsy; **b** Gestation specific prevalence. Reproduced from [4], with permission

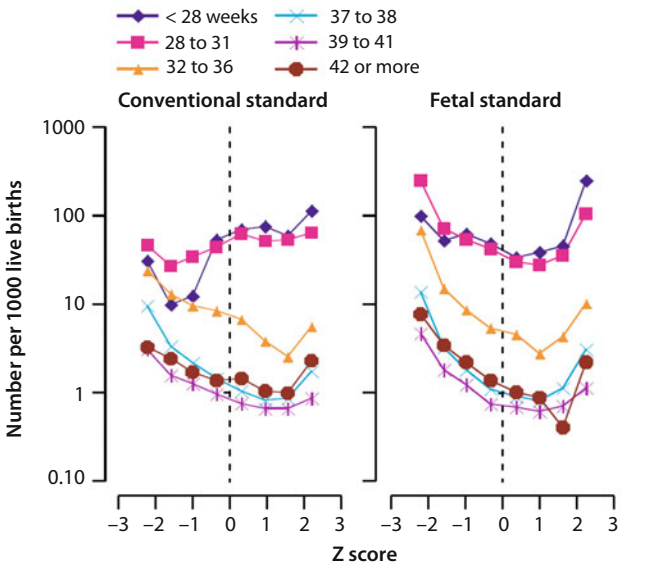

Fig. 143.3 Prevalence of cerebral palsy by gestational age and size at birth: effect of different growth standards. Reproduced from [9], with permission

prevalence of diplegia, itself associated with preterm birth, and a small increase in dyskinetic types of CP – more associated with term acute intrapartum hypoxia. Furthermore CP associated with preterm or very low birthweight births tends to have less associated disability [5, 6].

It seems clear that the population risk of CP is relatively stable or falling slightly but that, as the children born at extremely low gestational age (GA) (in whom survival is increasing) predominate, in individual gestational age categories above 28 weeks it seems likely that the prevalence is falling in keeping with the reduction seen in ultrasound diagnosed brain-injury from hemorrhagic parenchymal infarction and cystic periventricular leukomalacia (PVL). This mirrors the observation of Pharoah and colleagues that birthweight specific prevalence of CP first increased in line with survival (a possible practice effect) before falling as practice improves further [7]. CP is also more common among children who are small-for-gestational age at birth. For some time it has been considered that the effect of prematurity swamped any relationship at gestational ages below 34 weeks [8]. In fact most preterm children are in fact small at birth compared to well fetuses of a similar gestational age. When estimated fetal weight standards are used this relationship is clearly seen (Fig. 143.3) [9]. Interestingly, it is seen that being large-for-gestational age also increases risk across the gestational range.

143.3 Developmental or Cognitive Outcomes

There are fewer systematic studies associating cognitive outcomes over time. Partly this is due to the difficulty of drifting test norms and evolving developmental or psychometric test development, making it very difficult to compare changes over time.

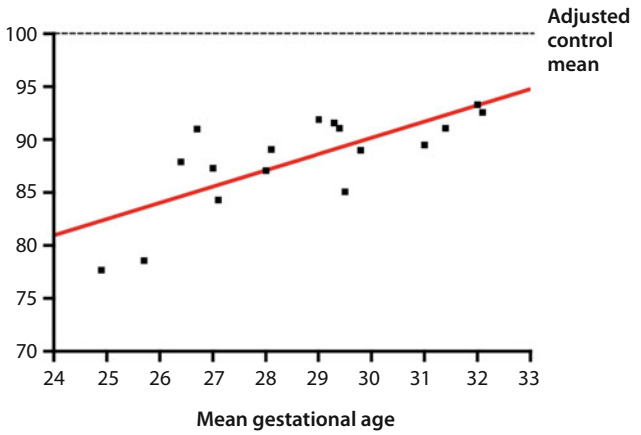

Fig. 143.4 Relationship between mean IQ and mean GA in 17 studies reporting outcomes with comparison populations; scores have been normalised to a consistent comparison population score of 100. Reproduced from [13], with permission

Cognitive scores are related to gestational age at birth. In a whole population study in Bavaria a clear relationship is seen with no significant correlation at gestations above 33 weeks whereas below 33 weeks there is a steady fall off with gestational age [10]. The EPICure data are consistent with this trend [11] and if one evaluates the mean IQ of studies of very preterm children by their mean GA at birth there is a similar relationship (Fig. 143.4) [12, 13].

The relationship with size at birth in epidemiological studies is less clear. Where there is evidence of fetal growth restriction, cognitive scores are reduced [14, 15] but recent data suggest this is not so [16]. Systematic reviews indicate that an effect by gestational age is difficult to determine [17, 18], but in some recent large studies scores tend to be lower than appropriately grown babies. Some of this variation must relate to policy of delivery early or later in the course of evolving growth restriction, although evidence for this is wanting [19].

Further discussion of these areas is outside the remit of this chapter but may be found in Chapter 129.

Neuromuscular Disorders

Paolo Balestri and Salvatore Grosso

144.1 Introduction

Neuromuscular disorders (NDs) are important causes of neonatal weakness and hypotonia. They are caused by disorders affecting the motor unit which anatomically includes a motor neuron, its axon, the neuromuscular junction, and all muscle fibers innervated by that single motor neuron [1].

NDs can be acquired or genetically determined with variable inheritance [2, 3]. A transient neuromuscular disorder such as neonatal myasthenia may affect children born to mothers with myasthenia gravis as a consequence of passive transfer of the antibody across the placenta [2].

Chief laboratory investigations include:

- Serum creatine kinase (CK) levels which, although a highly sensitive indicator of a muscle disorder, can be normal in some congenital dystrophies and congenital myopathies. High CK levels, up to 1000 units (normal adult level < 200 IU/L), are commonly observed during the first few days of life after vaginal delivery, reflecting muscle damage during labor;
- Motor nerve conduction studies which may detect a disorder of the peripheral nerve;
- Electromyography (EMG), which provides information about every level of motor unit, is generally obtained with the muscle at rest and with spontaneous or elicited contractions, but may be difficult to interpret as severely hypotonic neonates make few spontaneous movements;
- Muscle biopsy is often a crucial diagnostic procedure in the evaluation of a child with a disorder of the motor unit. In neonates, indications for muscle biopsy should be carefully considered in patients in whom the diagnosis remains uncertain in spite of laboratory, electrophysiologic and DNA analysis investigations [2, 3].

144.2 Congenital Myopathies

The congenital myopathies (CM) are a group of disorders characterized by: (1) distinctive and specific morphologic anomalies in skeletal muscle on light and/or electron microscopy as the main pathological feature (i.e., cores, rods, and central nuclei); (2) pathological features originating within the myofiber and, therefore, distinct from the muscular dystrophies where the primary pathology affects the stability of the sarcolemmal membrane; (3) a genetic etiology; and (4) clinical presentation with weakness and hypotonia. A neonatal onset with delay in motor milestones can be observed [4].

144.2.1 Central Core Disease

144.2.1.1 Etiology and Pathogenesis

Central core disease (CCD) is an autosomal dominant disorder related to mutations in the RYR1 gene which encodes for the skeletal muscle ryanodine receptor involved in the internally stored calcium and in the excitation-contraction mechanisms [5]. Pathological features include the presence of cores (unstained) on oxidative stains in the sarcomeres of type 1 fibers, which are central or somewhat eccentric in location. The exact mechanism of core formation is not clear. They are immunohistochemically characterized by increased RYR-1 protein, desmin, vimentin, tubulin and developmental myosin heavy chain [6].

144.2.1.2 Clinical Aspects

CCD shows considerable clinical variability and severity. Cardinal features are early onset hypotonia, weakness mainly affecting the proximal muscles, and hip dislocation. Patients with a static or nonprogressive course may achieve motor

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

milestones, although at a slow rate. Contractures and kyphoscoliosis may occur with progressive weakness. Extraocular muscle weakness, bulbar signs and respiratory impairment do not occur [6–8].

144.2.1.3 Laboratory Studies

CK levels are usually normal and EMG shows evidence of a mild myopathy. Muscle biopsy is crucial for the diagnosis. Muscle magnetic resonance (MR) imaging has a role in the diagnosis of CCD [9]. Patients with RYR1 mutations have a recognizable pattern of muscle involvement irrespective of the variability of histopathological features [7, 8].

144.2.1.4 Differential Diagnosis

During the neonatal period, classical histopathological abnormalities may be lacking and the differential diagnosis from multi-minicore disease may be difficult. Peculiar clinical features such as external ophthalmoplegia and respiratory impairment, commonly lacking in CCD, may help in differentiation [6, 8]. Nemalinic myopathy (NM) with mutations in the *ACTA1* gene has also been associated with both central core and minicores [10].

144.2.2 Nemaline Myopathies (NM)

144.2.2.1 Etiology and Pathogenesis

NM is genetically heterogeneous: both autosomal dominant and recessive models of inheritance have been observed. Mutations in five different genes have been detected. ACTA1 gene changes account for the 60–75% of cases with severe congenital nemaline myopathy and are related to the aggregation of actin filaments and the presence of rods within the nuclei of muscle fibers (the so-called intranuclear rod myopathy) [4–6, 11, 12].

144.2.2.2 Clinical Aspects

Six different clinical forms of NM have been described. Three present during the neonatal period. They include:

1. Typical congenital NM, which presents with hypotonia and weakness.
2. Severe congenital NM, which is characterized by lack of muscular movements, respiratory insufficiency, severe contractures, arthrogryposis multiplex and, sometimes fractures. Polyhydramnios, decreased fetal movements, and abnormal fetal presentation or fetal distress can also occur.
3. Intermediate congenital NM, which is a variant in which, as in the severe form, neonatal hypotonia and weakness are present but the child is able to perform spontaneous movements and no severe contractures or respiratory insufficiency are observed. Facial weakness occurs in almost all patients. Ophthalmoplegia is lacking [3, 13, 14].

The severe and the intermediate forms of NM have a poor prognosis. Mortality within the first year of life is directly related to respiratory insufficiency at delivery and the presence of arthrogryposis multiplex congenital. A stormy early course characterized by severe weakness and impaired feeding at birth with the need of mechanical ventilation and frequent respiratory tract infections may be followed by clinical stabilization and, in some, ability to stand or walk [3, 13, 14].

144.2.2.3 Laboratory Studies and Pathology

CK serum levels are either normal or mildly increased. EMG shows evidence of a myopathy. Muscle biopsy shows threads-like inclusions on modified Gomori trichrome (MGT) staining (Fig. 144.1). There is predominance of type I fibers. Ultrastructural studies show rod bodies, which are derived from the lateral expansion of the Z-band and mainly contain alpha-actinin and tropomyosin [3, 14–16].

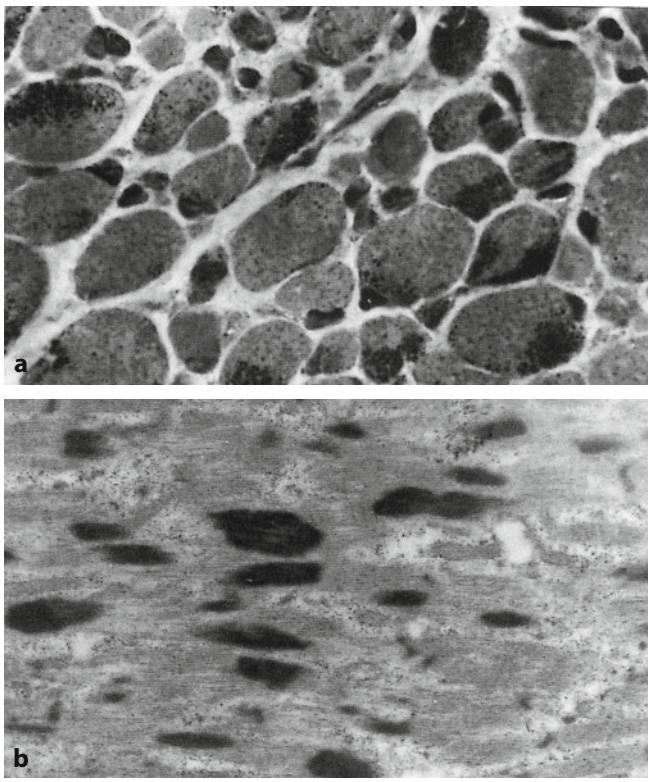

Fig. 144.1 **a** Gomori's trichrome reaction, transverse section (900×). Presence of numerous typical rod-shaped bodies. **b** Longitudinal view of a fiber with several nemaline bodies measuring 3–5 μm in length and 1–2 μm in width (14,000×). Reproduced from [15] with permission

144.2.2.4 Treatment

Therapy includes aggressive management of pulmonary infections and feeding difficulties.

144.2.3 Myotubular Myopathy

Autosomal dominant, autosomal recessive and X-linked recessive forms of myotubular myopathy (MM) have been recognized. The term MM, which refers to muscle fiber resembling fetal myotubules, continues to be used to indicate the X-linked variant with neonatal onset [3, 5, 17].

144.2.3.1 Etiology and Pathogenesis

Neonatal MM is caused by mutations in the XLMTM gene located at Xq28, encoding a protein, called myotubularin, which belongs to the family of tyrosine phosphatase. The reasons why this enzyme defect induces muscle fiber immaturity remain to be elucidated.

144.2.3.2 Clinical Aspects

Neonatal MM has a severe phenotype. Males present at birth with marked weakness and hypotonia, external ophthalmoplegia and respiratory failure [17]. The majority of patients die within the first months of life. A positive family history of either male neonatal deaths or miscarriages is common. Reduced fetal movements and polyhydramnios are common. Marked facial weakness, ptosis, ophthalmoplegia, joint contractures, high-arched palate, club feet, micrognathia, and arthrogryposis multiplex are also present, as well as macrosomia and cryptorchidism. Thinning of the ribs on chest radiographs, rarely observed in other congenital myopathies, has been reported.

Birth asphyxia, often misinterpreted as an hypoxic-ischemic encephalopathy, may be the presenting feature. Only a proportion of affected males survive into their teens or beyond. In these cases, motor outcome is poor as many of them are bedridden or wheelchair-bound [18].

144.2.3.3 Laboratory Study and Pathology

CK serum levels are either normal or mildly increased. EMG shows evidence of a myopathy. Muscle pathology shows fibers containing central nuclei. Immunohistochemical studies demonstrate increased signal from myofibers with antibodies to proteins such as vimentin, desmin, neural cell adhesion molecule, and utrophin, probably related to the immaturity of myofibers [18, 19].

144.2.4 Congenital Fiber Type Disproportion

Congenital fiber type disproportion (CFTD) is a rare type of congenital myopathy which may be sporadic or familial. Mutation in genes such as ACTA1, SEPN1, and TPM3 have been detected.

144.2.4.1 Clinical Aspects

CFTD is characterized by hypotonia and mild-to-severe generalized muscle weakness of limbs, neck, and face. The onset is at birth or within the first year of life. There are also bulbar signs, extraocular muscle involvement and respiratory failure, which can occur at any age. Neonatal disability may be severe with contractures of the hips, knees, ankles, elbows, and fingers.

The course of the disorder is variable and some individuals may be able to walk.

144.2.4.2 Laboratory Study and Pathology

CK serum levels are mildly increased. Histopathology shows type 1 fiber predominance and hypoplasia. Fiber type disproportion can also occur in neurogenic atrophy and in many other muscle disorders. Its existence as an independent entity has therefore been questioned [3–6, 19].

144.2.5 Multi-Minicore Disease

Multi-minicore disease (MMD) has a wide clinical spectrum with four distinct phenotypes.

144.2.5.1 Etiology and Pathogenesis

Sporadic and autosomal recessive cases have been linked to mutations in both SEPN1 and RYR1 genes. Multiple minicores, small zones of sarcomeric disorganization lacking mitochondria in muscle fibers, affect both type I and type II fibers.

144.2.5.2 Clinical Aspects

The onset of classical MMD is during the neonatal period or within the first year of life with a peculiarly slow course. Clinical features are hypotonia, generalized weakness mostly affecting proximal muscles, spinal rigidity, scoliosis, and respiratory impairment.

Arthrogryposis can be observed in MMD patients carrying RYR1 mutations (3-6, 19).

144.3 Congenital Muscular Dystrophies

Congenital muscular dystrophies (CMD) are a group of genetically and clinically heterogeneous hereditary myopathies with a predominantly autosomal recessive model of inheritance. Striking myopathological findings include great variability in the size of muscle fibers, marked endomysial and perimysial proliferation, and later increase of adipose tissue. Internal nuclei and necrotic as well as regenerating fibers can be observed during the early stages. The clinical course is widely variable. CMD patients may have central nervous system (CNS) and ocular changes and may not exhibit a progressive course.

A classification of CMDs based on biochemical and genetics defects has been proposed and continuously up-dated. Most of the various genes involved in the pathogenesis of the CMDs are related to the function of the dystrophin-glycoproteins associated complex (DAG) in the sarcolemma and may lead to abnormalities of either extracellular matrix proteins or glycosylation of alpha-DG. A single gene may be related to diverse clinical phenotypes. For the clinician, it may be more practical to define CMDs according to the involvement of the CNS and the presence or absence of merosin (i.e., merosin-positive and merosine-negative CMD) [19–22].

144.3.1 Merosin-Negative CMD

144.3.1.1 Etiology and Pathogenesis

Merosin is the critical alpha-dystroglycan-binding, basement membrane protein of the muscle extracellular matrix. Merosin defects are linked to LAMA2 gene mutations. White matter anomalies are consistently present in merosin-genative CMD.

144.3.1.2 Clinical Aspects

CMD caused by a primary deficiency of merosin accounts for up to 50% of CMD and differs from the classic merosin-positive CMD.

The clinical picture of CMD with total absence of merosin expression is homogeneous: there is a severe phenotype characterized by marked muscle weakness, atrophy, and facial weakness with impaired chewing and swallowing. Diffuse joint contractures are common. Patients are unable to achieve independent ambulation. In one third, death supervenes during the first year of life because of cardiopulmonary complications. Serum CK levels are markedly raised and white matter changes represent a consistent finding on brain MR imaging.

Cognitive impairment, seizures, and neuronal migration defects, mainly in the occipital cortex, have been reported in a few patients [3, 19–21].

144.3.1.3 Investigations and Pathology

Serum CK levels are markedly elevated. EMG shows evidence of a myopathy. Muscle biopsy demonstrates a classic dystrophic process with fiber necrosis and regeneration [19–22].

144.3.2 Congenital Muscular Dystrophies with Structural Anomalies of the CNS

These dystrophies are mainly represented by Fukuyama congenital muscular dystrophy (FCMD), Muscle-Eye-Brain (MEB) disease, and Walker-Warburg syndrome (WWS). Ocular anomalies and severe brain changes such as disorders of neuronal migration, cerebral white matter abnormalities, and hindbrain anomalies can be present. The pathogenesis of CMD is through abnormalities of glycosylation of alpha-dystroglycan (alpha-DG) and therefore grouped under the name of dystroglycanopathies.

144.3.2.1 Etiology and Pathogenesis

They show an autosomal recessive inheritance with mutations in at least six genes (POMT1, POMT2, POMGnT, fukutin, FKRP, and LARGE), which encode specific or putative glycosyltransferases involved in the glycosylation of alpha-DG. It was earlier suggested that each CMD form was caused by mutations in a distinct gene. It is now clear that WWS and MEB are linked to mutations in all the genes involved in the glycosylation of alpha-DG. Conversely, mutations in one gene may give origin to variable clinical features, with diverse CNS and ocular patterns of anomalies.

144.3.2.2 Investigations and Pathology

CK serum levels are increased. Normal CK values do not exclude the diagnosis. EMG may show evidence of a myopathy sign. Muscle biopsy changes, compatible with a dystrophic process, may also appear late during the clinical course. Brain imaging and ophthalmologic examination are necessary to define CNS and ocular anomalies [3, 19–23].

144.3.2.3 Clinical Aspects

Fukuyama Congenital Muscular Dystrophy (FCMD)

FCMD mostly occurs in Japan. There is variable severity even in the same family. Clinical features include poor fetal movements, impaired respiration, generalized weakness, hypotonia, and facial weakness. Joint contractures, hypertrophy of the calves, quadriceps and tongue muscles; a cardiomyopathy

may develop later. Mental retardation and seizures are cardinal features. CNS anomalies are represented by cerebral and cerebellar micropolygyria, obstructive hydrocephalus, occipital cobblestone cortex, hypoplasia of the pons and cerebellar vermis, and cerebellar cysts. Ocular changes include retina anomalies with folding, fusion, focal dysplasia, and detachment, abnormal eye movements, strabismus, myopia and microphthalmos [3, 19, 21, 24].

Walker-Warburg Syndrome

This is the most severe of CMDs. Neonatal generalized weakness and severe hypotonia are associated with brain malformations (lissencephaly type II, prenatal obstructive hydrocephalus, neuronal heterotopias, corpus callosum agenesis, pontocerebellar hypoplasia, and sporadically occipital encephalocele and Dandy-Walker cyst). Ocular changes involve both anterior and posterior eye chambers (retinal detachment, blindness, microphthalmia, optic nerves hyploplasia, colobomas, congenital glaucoma, cataract, megalocornea). Genital anomalies in males, and facial dysmorphisms with cleft lip or palate have been reported [3, 19–21, 25].

Muscle-Eye-Brain Disease (MEB)

Initially reported in Finland, MEB is now recognized worldwide. Although it is less severe than WWS, the spectrum of clinical severity is broad with patients presenting a WWS-like phenotype. Ocular defects include high myopia, congenital glaucoma, retinal dysplasia, coloboma of the optic nerve, and cataracts. CNS abnormalities are represented by cortical malformations variable in severity within the spectrum of pachygyria/polymicrogyria/agyria associated to flat brainstem and cerebellar hypoplasia, and white matter abnormality. Hydrocephalus, seizures and facial dysmorphisms (short nasal bridge, micrognathia, and midface hypoplasia) may also be observed. The clinical course is variable with some patients able to walk and speech, while others present with severe motor and cognitive delay [21, 22].

144.3.3 Congenital Myotonic Dystrophy

In the congenital form of myotonic dystrophy muscle weakness predominates and may be so severe as to lead to neonatal death [19].

144.3.3.1 Etiology and Pathogenesis

Congenital myotonic dystrophy is caused by mutations in the DMPK gene which contains an unstable CTG trinucleotide. CTG repeats range from 5 to 34 in normal people. These patients have very large CTG repeats, which number up to several thousands. The mother is almost always the parent who transmits the larger repeat, but transmission by the father has been recorded [26].

144.3.3.2 Clinical Aspects

The clinical picture include polyhydramnios, reduced fetal movements, severe generalized weakness, hypotonia, arthrogryposis (especially of the lower extremities), feeding difficulties, and respiratory insufficiency with mechanical ventilatory support needed for most of affected children. Facial diplegia, with a classical inverted V-shaped upper lip, is constant. Areflexia and atrophy are common. In neonates, percussion myotonia, where percussion of a muscle evokes a mytonic phenomenon, is elicited only sporadically. Mortality from respiratory failure is high [19, 21].

Severity of the clinical course is consistent with the clinical picture at onset. Neonatal mortality can be up to 40% in severely affected children. In the post-neonatal period most patients survive but few become independent [27]. A careful examination of the mother may show a typical myotonic facies with ptosis, atrophy of the masseter and temporalis muscles, and percussion myotonia. Presenile cataract, frontal baldness, and gonadal atrophy may also be seen in affected family members.

144.3.3.3 Laboratory and Pathology

Serum CK level is normal. EMG leads to the diagnosis with myotonic discharges. Muscle pathology features are not diagnostic [3].

144.4 Metabolic Myopathies

Disorders with prominent involvement of muscle at neonatal onset mainly include defects of glycogen metabolism and respiratory chain.

144.4.1 Pompe Disease (PD)

PD is a lysosomal storage disorder that leads to accumulation of glycogen with muscle weakness, organ damage and death. It is detectable by screening during the newborn period, and treatment has become available. The clinical picture is characterized by early onset severe weakness and hypotonia, mimicking SMA1. The diagnosis is suggested by the observation of cardiomyopthy, macroglossia and hepatomegaly, which are lacking in SMA1 [2, 3]. Enzyme replacement therapy with recombinant human precursor acid α-glucosidase is available.

144.4.2 Mytochondrial Myopathies (MM)

MM are highly heterogeneous conditions related to mitochondrial DNA or nuclear DNA mutations with defects of oxidative phosphorylation. They are generally multi-system and affect highly aerobic post-mitotic tissues, such as muscle and nerve. Autosomal recessive inherited defects of cytocrome C oxidase may present with a neonatal myopathy syndrome. Cardinal clinical features are axial and facial weakness, hypotonia, hypo/areflexia. Systemic involvement is also common with hepatomegaly, cardiomyopathy and renal dysfunctions. Lactic acidosis and the presence on muscle biopsy of ragged red fibers with cytocrome C oxidase deficiency are diagnostic [3].

144.5 Myasthenia

144.5.1 Neonatal Mysthenia Gravis

Neonatal myasthenia gravis (NMG) is a transient disorder of neuromuscular transmission that occurs in 12% of newborns born to women with myasthenia gravis [28].

144.5.1.1 Etiology and Pathogenesis

NMG is related to the passive transfer of antibodies against acetyl-choline receptor (AChR) across the placenta, which it is thought to be followed by decreasing AChR at the postsynaptic muscle membrane.

144.5.1.2 Clinical Aspects

Clinical onset usually occurs within a few hours of birth or during the first 72 hours. There may be facial diplegia with feeding, sucking and swallowing difficulties, generalized weakness, hypotonia, respiratory insufficiency and inability to handle pharyngeal secretions. Ptosis and oculomotor dysfunctions occur in a minority of patients. The most severely affected infants may show arthrogryphosis, polyhydramnios, pulmonary hypoplasia and death.

144.5.1.3 Investigations

Repetitive nerve stimulation, at 5-20 Hz, typically shows a decrement in the amplitude of the motor action potential.

144.5.1.4 Treatment

Neostigmine, an anticholinesterase, is the drug of choice. Initial doses of 0.04 mg/kg intramuscularly, are followed by 0.4 mg/kg given by gastric tube. Exchange transfusion is ineffective. Few data are available on the efficacy of intravenous immunoglobulins [2, 19].

144.5.2 Non-Autoimmune Congenital Myasthenic Syndromes (CMSs)

These syndromes are inherited heterogeneous disorders affecting the neuromuscular junction. In most patients clinical onset is during infancy. The number of recognized CMSs has increased dramatically over the past few decades. They are classified by the site of neuromuscular transmission defect (presynaptic, synaptic or postsynaptic), but accurate identification of the site of the defect is not always possible.

144.5.2.1 Etiology and Pathogenesis

In some patients a deficiency of endplate acetyl-choline receptor (AChR), and referred to as "Endplate Acetylcholine Receptor Deficiency", can be identified. Autosomal recessive inherited mutations in genes coding for both AChR subunits and for rapsyn, a protein able to cluster the receptors, have been reported. CMSs with presynaptic dysfunctions, referred to as congenital myasthenic syndrome with apnea are linked to a gene encoding choline acetyltransferase, a rate-limiting enzyme involved in resynthesis of acetylcholine.

144.5.2.2 Clinical Aspects

Although phenotypic variability exists among CMSs, several clinical features are shared by these disorders. Ptosis, ophthalmoplegia, early facial and bulbar involvement with feeding difficulties and respiratory failure, hypotonia, and weakness are common. Reduced fetal movements, arthrogryposis and polyhydramnios may be observed. Peculiar clinical findings may occur in specific CMS syndromes (i.e., pupillary dysfunction is typical of endplate AChE deficiency).

144.5.2.3 Investigations

Investigations include single fiber-EMG, specific staining for AChR, electron microscopy of motor endplate, and molecular genetic studies.

144.5.2.4 Treatment

Anticolinesterase drugs are crucial in the therapeutic strategy. 3,4-Diaminopyridine is effective in combination with anticolinesterase. Steroids and thymectomy are ineffective. Medication should be protracted: an interruption may lead to apnea and sudden death [2, 19, 28–31].

144.6 Spinal Muscular Atrophy (SMA)

The spinal muscular atrophies (SMAs) comprise a group of autosomal-recessive disorders characterized by progressive weakness linked to loss of the lower motor neuron in the anterior horn cells in the spinal cord and cranial nerve nuclei. Several types of SMAs have been defined by their age at onset. A neonatal onset occurs in the acute, severe infantile variant (SMA type 1; Werdnig-Hoffman disease) [32].

144.6.1 Etiology and Pathogenesis

The gene for the autosomal recessive SMA1 is located on 5qll-ql3 and termed survival motor neuron (SMN). Each individual has two SMN genes, SMN1 and SMN2. More than 95% of patients with SMA1 have a homozygous mutation in the SMN1 gene [33].

144.6.2 Clinical Aspects

SMA1 present with axial and limb weakness and hypotonia at birth or in the first weeks of life. Legs are more affected than arms and proximal muscles more than distal. There is little spontaneous activity, which is limited to the feet and hands. Facial muscles are spared and the infants show a normal bright expression. Bulbar dysfunction includes an impaired ability to suck, reduced swallowing, and respiratory failure. The intercostal muscles are always affected but the diaphragm is spared. The extraocular muscles are not involved and there is normal brain anatomy. Almost all patients die from complications of the disease within 18 months. At physical examination the extensive paralysis of the limbs and distinctive breathing pattern are associated with the characteristic jug-handle posturing of the upper limbs with internal rotation of the shoulders and pronation of the forearms. Deep tendon reflexes are absent and fasciculations are often restricted to the tongue. Findings on sensory examination are normal. Arthrogryposis or deformities of the limbs and joints at birth can be observed as a result of utero hypotonia [2, 32, 34].

144.6.3 Investigations

Serum CK levels are normal. Electrophysiologic studies help to differentiate SMA1 from other neurogenic and myopathic diseases. The SMN1 gene should be screened for mutation. Muscle biopsy should be considered in the diagnostic workup when genetic analysis is normal.

144.6.4 Spinal Muscular Atrophy Variants

Among variants of SMA, those with a potential neonatal onset include the spinal muscular atrophy with respiratory distress type 1 (SMARD1) and pontocerebellar hypoplasia type 1 (PCH1).

SMARD1 is a clinically and genetically heterogeneous condition resulting from mutations in the gene coding for the immunoglobulin-binding protein 2 (IGHMBP2), located on chromosome 11ql3. The clinical mimics, in part, that of SMA1 with associated diaphragmatic weakness leading to acute life-threatening respiratory failure. Intrauterine growth restriction, mild hypotonia, weak cry and, in contrast to SMA1, a prominent distal muscles involvement are also present. Peculiarly, respiratory distress in SMARD1 is the consequence of the severe diaphragmatic paralysis with elevation of both hemidiaphragms on chest X-ray, rather than the severe intercostal muscle impairment of SMA1 [35].

PCH1 is a disorder which is not allelic to SMA1 and the pathogenetic mechanism of which is still unknown. Clinical features include arthrogryposis, severe weakness, hypotonia, bulbar signs, severe microcephaly, mental retardation, classically associated with hypoplasia of the cerebellar vermis and, in some cases, cerebellar hemispheres, thin brainstem and pons. The clinical course is progressive [36].

Ocular Malformations

Elena Piozzi and Alessandra Del Longo

145.1 Introduction

There are multiple ocular malformations: some are evident at birth or during the first few months of life, others are revealed at a later stage.

Ocular malformations can be a sign of more complex and general pathology. The importance of early recognition is particularly important for those that can damage vision and/or cause amblyopia (interruption of the development of visual function).

Ocular malformations of the anterior segment are recognised at examination. Malformations of the posterior segment may present either because of their frequent association with anterior malformations or, more often, as a constant or intermittent strabismus.

It is important to be aware that possible serious ocular malformations may be indicated by asymmetry of the eyes, as well as by differences in their color and the sizes of the globes, irises and palpebral fissures. Thus, the role of the pediatrician is crucial in the timely diagnosis of congenital eye pathologies and an appropriate specialist referral [1, 2].

145.2 Eyelid Malformations

Eyelid development occurs during the second month of fetal life. Eyelid opening occurs after about 25 weeks gestation as the development of the eyelid is completed.

Abnormal development may cause anomalies of eyelid position and lid margin.

E. Piozzi (✉)
Department of Pediatric Ophthalmology
Niguarda Ca' Granda Hospital, Milan, Italy

145.2.1 Developmental Anomalies

145.2.1.1 Coloboma

Lack of tissue causes a defect of the lid margin, the severity of which is proportional to the size of the defect (Fig. 145.1). It generally affects the nasal half of the superior eyelid and can be isolated or associated with other pathologies (Tessier syndrome, Goldenhar syndrome). Lack of protection by the eyelid and consequent corneal exposure may cause keratitis.

145.2.1.2 Epicanthus

Semi-lunar skin fold with a downwards orientation at the nasal margin (canthus), simulating a convergent strabismus (Fig. 145.2). The recognition of an actual strabismus may be difficult and requires extra care.

Fig. 145.1 Eyelid coloboma

Fig. 145.2 Epicanthus

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

145.2.2 Anomalies of the Rima (Palpebral Fissure)

145.2.2.1 Distichiasis

This condition is characterized by the growth of a second row of eyelashes. It mostly affects the lower lid. It can be isolated or hereditary (autosomal dominant). If the inner part of the lid margin is affected, distichiasis may cause corneal ulceration, lachrymation and photophobia.

145.2.2.2 Blepharophimosis

This is a complex autosomal dominant syndrome, characterized by a narrow palpebral fissure and inverted epicanthus (Fig. 145.3). It can be associated with strabismus and nystagmus. Treatment is by surgery.

145.2.2.3 Angiomas

Benign vascular tumor that becomes evident a few days after birth and which, depending on their extension and location, may be a cause of total or partial palpebral ptosis with consequent amblyopia if the visual axis is disturbed (Fig. 145.4). Ultrasonography may be useful to establish the degree of extension within the orbit. Generally angiomas are self-limiting processes and resolve spontaneously. Therapy is only indicated when amblyopia is suspected. Therapy is medical (cortisone and beta blockers). Surgery is only indicated for non responsive forms or when vision, including the integrity of the visual axis, is threatened.

145.2.3 Position Anomalies

145.2.3.1 Palpebral Ptosis

Also known as a drooping eyelid (Fig. 145.5). Severe cases can cause a visual disturbance (amblyopia) and abnormal head position. Ptosis may be unilateral or bilateral. Manifests as a difficulty in opening the eyelid from the first days of life. Surgery is reserved for total ptosis. In other cases, therapy is aimed at cure of the amblyopia and surgery, which is done for esthetic reasons, is delayed until children are over 5 years old [3, 4].

145.3 Ocular Bulb Malformations

145.3.1 Anophthalmia

Total absence of the eye (Fig. 145.6).

145.3.2 Microphthalmia

This is a reduced volume of the eye (the normal length of the eye at birth is approximately 17 mm) (Fig. 145.7). The diagnosis is straightforward in monolateral forms because of the inter-ocular difference, more complicated in bi-ocular forms. Microphthalmia is associated with a small eyelid, drooping of the lid and enophthalmos (sunken eye).

If there is anophthalmia and microphthalmia, a prosthesis must be inserted to promote orbital growth [5].

Fig. 145.3 Blepharophimosis

Fig. 145.5 Eyelid ptosis

Fig. 145.4 Angiomas

Fig. 145.6 Anophthalmia

Fig. 145.7 Left eye microphthalmia without and with prothesis

Fig. 145.8 Congenital naso-lacrimal-duct obstruction

145.4 Naso-Lacrimal-Duct Malformation

145.4.1 Congenital Naso-Lacrimal-Duct Obstruction

Epiphora is present from the first days of life. By applying pressure near the lacrimal sac, mucous and purulent material may be discharged from the inferior lacrimal point.

Therapy consists of massage of the lacrimal sac region, cleaning the nose with physiological saline and local antibiotics when needed.

Surgery for cases that do not respond to therapy probing of the lacrimal ducts (Fig. 145.8).

145.5 Corneal Malformations

145.5.1 Size Anomalies

145.5.1.1 Megalocornea

Simple megalocornea is isolated and autosomal dominant. Associated anomalies (megalophthalmos) are X-linked and it is associated with congenital glaucoma (buphthalmos).

Congenital glaucoma is an important differential diagnosis and if enlargement of the eye is suspected, it is important for an ophthalmologist to measure corneal diameter and ocular pressure. Possible watering and photophobia may manifest as a consequence of increased eye pressure.

145.5.1.2 Microcornea

It is a small corneal diameter (normally 9.5-10 mm in the newborn) (Fig. 145.9). May be associated with microphthalmos and other anterior segment abnormalities.

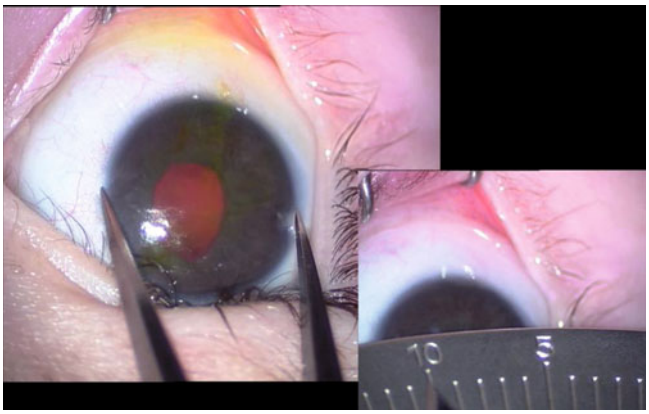

Fig. 145.9 Microcornea

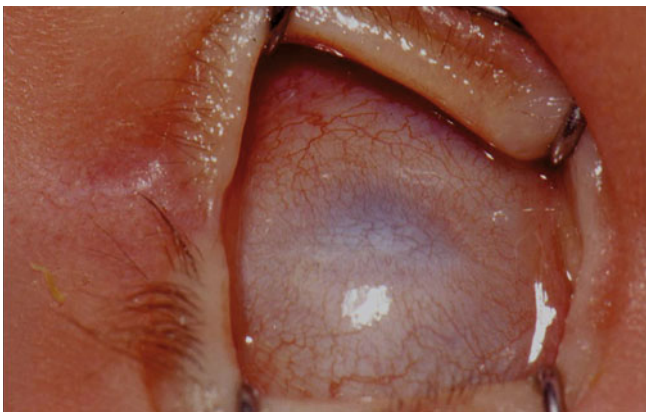

Fig. 145.10 Sclerocornea

Fig. 145.11 Peter's anomaly

145.5.2 Anomalies of Transparency

These are anomalies of transparency (congenital corneal opacity, sclerocornea (Fig. 145.10), Peter's anomaly (Fig. 145.11), corneal dystrophy and corneal opacifications) and may be associated with metabolic illnesses or congenital infections. Corneal opacifications may be isolated or widespread. Often associated with poor eye opening. May be an indication of serious metabolic illnesses.

145.5.3 Epibulbar Dermoids

Their appearance is similar to a solid white mass in the limbus, or more frequently in the inferior-temporal region (Fig. 145.12). Often associated with the Goldenhar syndrome, tend to involve the cornea causing astigmatism. As they develop, they may involve the optic axis with consequent damage to normal vision. Treatment is by surgery [6].

145.6 Crystalline Lens Anomalies

145.6.1 Epipupillary Membrane Persistence

This is a failure of reabsorption of the epipupillary membrane during normal fetal development.

A veil-like membrane formed by thin vessels and residual mesodermic tissue, partially or totally occluding the pupil, leading to impaired pupillary dilatation and interfering with the visual axis. Treatment is initially medical with the administration of mydriatics. If the membrane is thicker, treatment is by surgery.

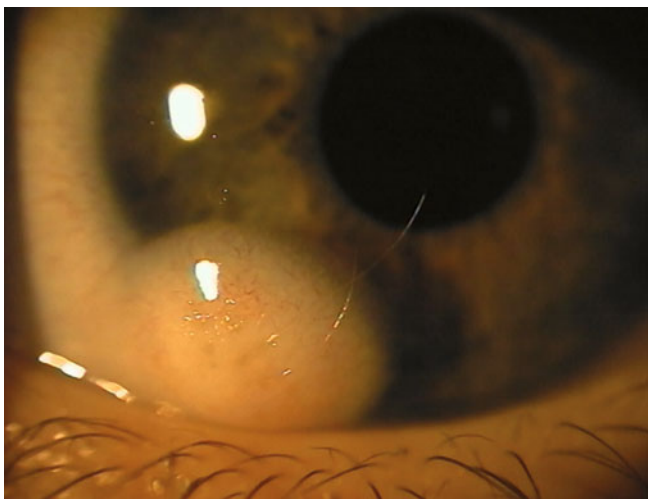

Fig. 145.12 Epibulbar dermoid

145.6.2 Position Anomalies

Dislocation of the crystalline lens from its normal position as a consequence of malformation of zonular fibres of the lens is associated with more generalized syndromes, e.g. Marfan syndrome and Marchesani syndrome. The dislocation can be partial (subdislocation, Fig. 145.13) or complete (dislocation, Fig. 145.14). Since the lens is not in the correct position with respect to the pupil, serious refractive defects and amblyopia may ensue. Subluxation can cause the crystalline lens to fall to the back of the eye (into the vitreous), which results in retinal damage, or to the front (towards the cornea) with endothelial damage. Treatment is surgical.

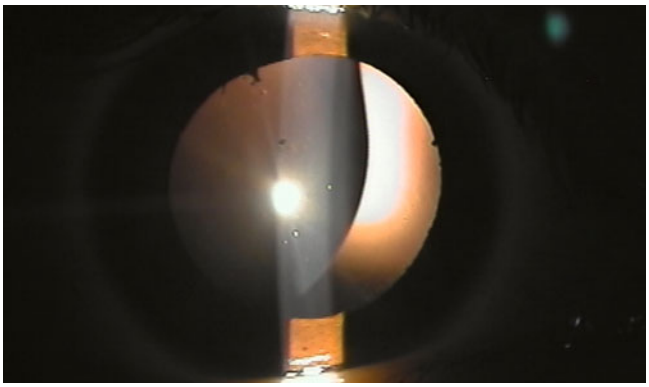

Fig. 145.13 Subdislocation of lens

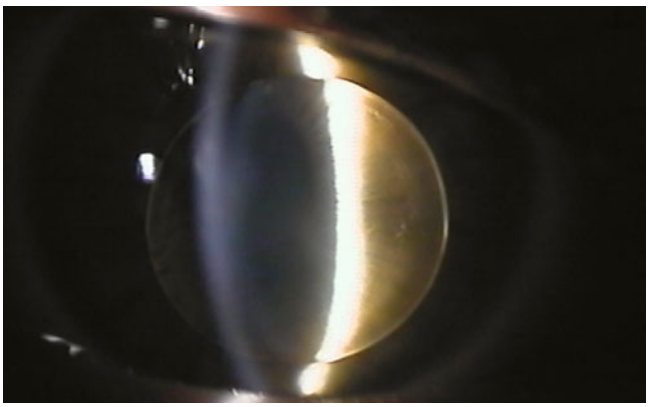

Fig. 145.14 Complete dislocation of lens

145.6.3 Transparency Anomalies

Congenital cataracts can be unilateral or bilateral, isolated or associated with general pathologies, including intrauterine infections (rubella, cytomegalovirus, toxoplasmosis) or metabolic diseases (galactosemia). The lens can be more or less opaque (Fig. 145.15). Total opacification results in the pupil having a characteristic white color (leukokoria) [7].

Treatment depends on the density of the opacification and the degree to which vision is affected. If the cataract is dense, especially if unilateral, surgery should be performed as soon as possible. The operation is aimed at removal of the opaque lens with the possible implantation of an intraocular lens. Treatment aimed at preventing amblyopia is important after surgery.

145.6.4 Malformative Glaucoma

This is a developmental abnormality of drainage, causing increased intraocular pressure and an enlarged eye (buphthalmos) (Fig. 145.16). Alterations of the anterior segment (corneal edema, striated lines) may be present at birth or manifest later. Physical signs include severe photophobia and watering of the eye.

Early diagnosis is essential for a good outcome.

Glaucoma is an hereditary disease. Nowadays a study to discover the gene mutation (CYP1B1, MIOC) is being undertaken in children affected by congenital glaucoma.

Treatment can be medical or surgical.

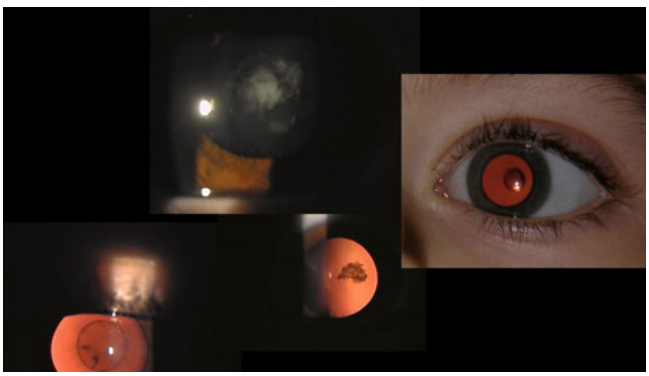

Fig. 145.15 Congenital cataracts

Fig. 145.16 Buphthalmos

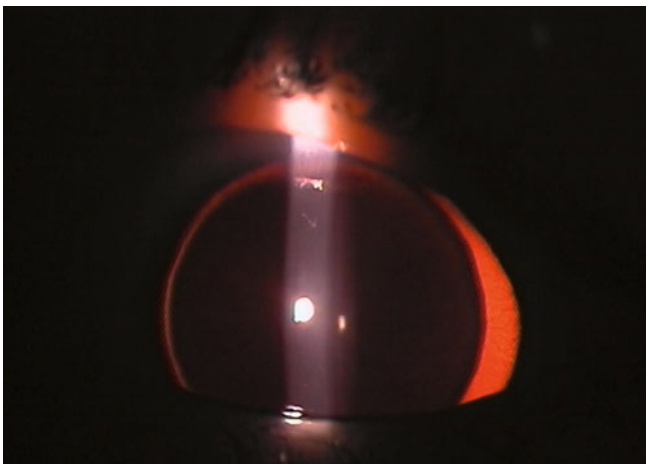

Fig. 145.17 Aniridia

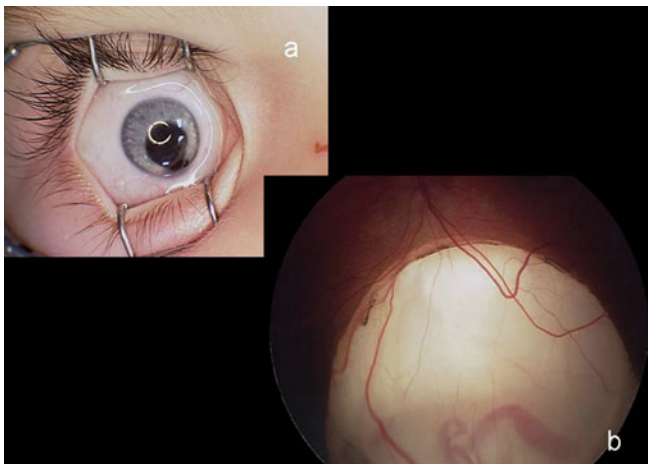

Fig. 145.18 Iris and retinochoroidal coloboma

145.7 Congenital Anomalies of the Iris and Pupil

145.7.1 Aniridia

This is a total or partial absence of the iris, normally bilateral (Fig. 145.17). It is associated with nystagmus and photophobia. It may be inherited with dominant autosomal transmission. Aniridia can be associated with glaucoma.

An eye test for aniridia always includes measurement of intraocular pressure. In isolated forms it is frequently associated with nephroblastoma or Wilms' tumor (abdominal ultrasonography is mandatory).

Vision correction and the use of tinted lenses can improve vision for those patients [8].

145.7.2 Iris Coloboma

Coloboma of the iris is a deficiency of part of the iris (normally in the inferior sector) (Fig. 145.18). It is due to abnormal closure of the fetal fissure. Close to the coloboma, the pupil is irregular with an elongated oval appearance. The malformation is normally reported by the mother who notices that "the pupil looks strange" whilst she is breast-feeding. This anomaly may be associated with colobomas of the posterior segment of the eye (choroid-retina).

145.7.3 Leukokoria

A white pupillary reflex signifies a cataract or malformation and congenital vitreoretinal disease.

145.7.4 Malformations of the Posterior Segment

Malformations of the posterior segment such as a coloboma (Fig. 145.18), congenital malformations of the optic nerve and of the vitreo-retina can manifest mainly because of constant or intermittent strabismus. If parents report repeated strabismus, the pediatrician should refer the patient for ophthalmological review.

Retinopathy of Prematurity

José Carlos Rivera, Elsa Duchemin-Kermorvant, Allison Dorfman, Luis M. Ospina and Sylvain Chemtob

146.1 Introduction

Retinopathy of prematurity (ROP) is an ocular disease that occurs in premature infants and affects the blood vessels of the developing retina. It is characterized by the onset of visible vascular abnormalities in the second or third month after birth. The pathogenesis of ROP is related to many causative factors, like low birth weight, low gestational age, supplemental oxygen therapy, and some lines of evidence suggest the role of a genetic component. ROP is mild and undergoes spontaneous regression with no visual sequels in the majority of affected infants. However, progression to advanced ROP does occur in a significant number of infants and can lead to severe visual impairment and even complete unilateral or bilateral blindness in some cases. In general, more than 50% of premature infants weighing less than 1250 g at birth show evidence of ROP, and in approximately 3% of children it undergoes abnormal retinal vascular development, neovascularization, and, in its more severe forms, traction retinal detachment [1]. These injuries may occur despite the aggressive interventions currently available, such as cryotherapy or laser photocoagulation for this sight-threatening disease.

ROP has been recognized since 1942 as a blinding disease of the very premature infant [2] and the incidence of blinding forms of retinopathy has varied greatly over the intervening decades. Over more than half a century of intense clinical and laboratory research great efforts have been made in developing effective therapies for severe stages of ROP, and the understanding of the nature of this disease has improved tremendously. But modest progress has been made in truly understanding the cellular and molecular mechanisms causing this pathology and even less in developing effective prophylactic treatments. At present, the problem increases worldwide with the technological advances in neonatology leading not only to an increased survival rate of very low birth weight infants, but also to a correspondingly increased incidence of ROP. This, in turn, has provided a major challenge to all physicians treating the premature infant and has created renewed interest in the pathogenesis, prevention, and treatment of ROP. However, the central mysteries of this disease have not been adequately unraveled to effectively eradicate unfavorable visual outcomes and the efforts continue. The purpose of this chapter is to present current knowledge about ROP, demographic incidence, risk factors and its more recent treatment strategies, as well the possible promising future therapies against this serious disease.

146.2 Historical Background

Prior to the 1940s, ROP was an unknown disease because severe prematurity was often fatal. The first case of ROP was described in Boston by Dr TL Terry in 1942 [2]. His initial report referred to this new disease as possible fibroblastic overgrowth of the persistent tunica vasculosa lentis. In a second report [3], containing several pathological specimens in the cicatricial end stages of the disease with multiples complications, Terry clearly misinterpreted the involved pathophysiology. He did not recognize the retina as the source of the problem and still linked it to the rare congenital birth defect of persistence of hyaloid artery and tunica vasculosa lentis. However, he did recognize the salient epidemiology and showed that the disease occurred much more frequently in infants born extremely prematurely [3]. In this same report Dr Harry K Messenger, a colleague of Terry, suggested the term "retrolental fibroplasia" that was used for about 40 years and that described the end-stage of the disease in which a white, vascularized plaque could be seen behind the lens in an eye that was often completely blind. At that time, there was inadequate technology to carefully monitor oxygen levels

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

in neonatal intensive care units and high doses of oxygen were being administered to premature infants without monitoring; the pulse oximeter was not yet available. In fact, during the next 12 years following the first report, more than 10,000 premature infants in North America were blinded before it became appreciated that the outbreak was related to the use of supplemental oxygen [4]. Much of our understanding of ROP can be credited to Kate Campbell from Melbourne, Australia who compared the incidence of ROP at hospitals that charged for oxygen use and hospitals that did not [5]. This investigator found that the incidence of ROP was higher at those hospitals where the oxygen was free and use was unrestricted. Furthermore, with the advent of pulse oximetry in the 1970s and beyond, oxygen administration became more controlled, and it was thought that ROP would disappear. Unfortunately, this proved to be untrue. As neonatologists got better at saving tinier and sicker babies, the rate of ROP rose again to frighteningly high levels. Soon, small gestational age and very low birth weight correlated more strongly with occurrence of ROP than did oxygen administration. During the 1980s and early 1990s a major understanding in the physiopathology disease progressed with the use of animal models [6, 7], suggesting that the degree of prematurity of the eye at birth was the critical and necessary risk factor for the disorder and that ROP goes through several well-defined stages before getting to the irreversible retrolental fibroplasia. During the early 1980s the term of retrolental fibroplasia was renamed to retinopathy of prematurity, and with new knowledge of ROP pediatrics, ophthalmologists and neonatologists united to find a treatment. The first step was the development of a common nomenclature, followed by a natural history study and a treatment protocol. In 1984, the International Classification of Retinopathy of Prematurity (ICROP) was developed [8]. Despite the efforts, no treatment for ROP was available for several years. Major advances in ROP treatment came in the 1980s and 1990s, when cryotherapy and laser photocoagulation, which consists of destroying the portion of the retina that is unvascularized in order to preserve the rest of it, showed to be partially effective in preventing blindness in ROP infants. However, these surgical procedures are sometimes uncomfortable or painful and can only reduce the incidence of blindness by 25% in infants with late-stage disease, moreover these patients often still have poor visual acuity after treatment [9]. Nowadays, the fight against ROP continues generating new information including possible genetic predisposition [10] and the role of angiogenic growth factors, such as insulin-like growth factor (IGF-1) [11], or vascular endothelial growth factor (VEGF) [12], that are involved in the development of pathological retinal neovascularization. Over this decade new agents targeting VEGF have become commercially available for intraocular use. Development of pharmacological strategies for treating ocular neovascularization has revolutionized the care of some neovascular ocular diseases and has great potential for ROP. The use of preventive and less destructive therapies for this pathology such as nutritional supplements, including forms of vitamin E [13], amino acids [14], or omega 3 fatty acids [15], would be much more desirable, however, understanding the molecular basis of the disease is important to the development of new medical interventions or therapeutic treatments.

146.3 Epidemiology

It is estimated that of the 45 million people who are blind worldwide in the 2000s, 1.4 million are children from middle income and low-income countries, the majority of whom live in the poorest regions of Africa and Asia [16]. In 1995, ROP accounted for 10.6% of cases of blindness in children in schools for the blind in South Africa [17]. However, ROP is not considered a significant cause of childhood blindness in very poor countries due to the low survival rate of premature infants [18]. Yet, ROP is emerging as a major cause of childhood blindness in middle-income countries. For example, a study from 1997 through 2005 showed that of the 34 million live births analyzed in the United States, 58,722 newborns were identified with ROP. This study showed that the incidence of ROP has increased from 0.12% to 0.17%, and that in the patient population at risk for ROP, it has doubled from 7.35% to 15% [19]. Furthermore, almost half of the world's 50,000 children who are blind from ROP live in Latin America [20]. The World Health Organization estimates that 24,000 of the 100,000 visually impaired infants in Latin America are attributable to ROP [21, 22]. An observational study [23] comparing characteristics of infants who develop severe ROP from countries with low, moderate and high levels of development showed that larger, more mature infants are at risk in the less developed countries. In the developing countries, the mean birth weight of infants with severe ROP ranged from 903–1527 g, compared with 737–763 g in the highly developed countries. The mean gestational age of infants with severe ROP from the developing countries was 26.3–33.5 weeks, compared with 25.3–25.6 weeks in highly developed countries. In nearly all of the middle-income countries, infants who developed severe ROP had a gestational age of more than 32 weeks and weighed more than 1500 g. This fact demonstrates the inadequacy of the current screening guidelines used in developed countries when evaluating infants from middle-income countries [24, 25].

While exposure to an oxygen-rich extrauterine environment is clearly identified as a major factor in the genesis of ROP (see below), it is not the only predisposing factor. Interestingly, there are many premature infants that are treated with supplemental oxygen who will never end up developing ROP, while other children that are nearly full-term who receive little or no treatment will eventually present with the disease [26]. Not only are low birth weight and low gestational age correlated with the incidence of ROP but ethnicity is also a factor that has been reported to significantly influence its epidemiology [27]. Findings by some have suggested that fundus pigmentation might play a protective role against the progression

to severe ROP given the greater incidence of threshold ROP in Caucasian infants compared to African-American infants [27, 28]. However, others have reported an even greater incidence in the onset of threshold ROP exists in Alaskan natives, a darkly pigmented race, when compared to other racial subgroups [29, 30]. There are also many indications that the patient's genetic make-up plays a role in whether ROP develops, and how severe it will be. Although ROP occurs in all populations, it long has been noted to occur in its most severe form less frequently in blacks than in whites. In the CRYO-ROP study, 3.2% of black infants developed threshold ROP compared with 7.4% of white infants. In black South African infants, a similar rate of 3.2% in infants born at less than 1251 g was found [31]. This is unlikely to be caused by environment, because it is constant across continents. It could be a protective effect of increased retinal pigment, but it also could be because of differential genetic effects, more common in one population than another. Males also were found to have a higher risk than females in the CRYO-ROP study. And in several studies, variations in the Norrie disease gene, a gene responsible for an X-linked form of congenital retinal detachment or dysgenesis were more common in infants with severe ROP than in those in whom the disease resolved on its own [10, 32]. Each person carries genetic predispositions to certain disorders, but less widely understood are genetic proclivities toward outside effects, trauma, hypoxia, premature birth among them. Further investigation into the potential factors that might contribute to these discrepancies, including genetics, socio-economic status and dietary intake, is warranted.

146.4 General Definition

Retinopathy of prematurity (ROP) is a blinding eye disease of premature infants that affects more than 80% of babies born with birth weight less than 1000 g. It is a disease confined to the immature retinal vascular system and it is characterized by disorganized growth of retinal blood vessels, which may result in scarring and retinal detachment. ROP can be mild and undergoes spontaneous regression with no visual sequelae in the majority of affected infants. However, progression to advanced ROP does occur in a significant number of infants and can lead to severe visual impairment and even complete unilateral or bilateral blindness in some cases. Many causative factors can contribute to the development of ROP including low birth weight, low gestational age, supplemental oxygen therapy and some lines of evidence suggest the role of a genetic component.

146.4.1 Progression of ROP

Retinal blood vessel development commences around 16 weeks of gestation. The nasal retina is vascularized by 36 weeks gestation and the temporal retina by 40–45 weeks [33]. Therefore, the retinas of premature infants are incompletely vascularized. Two phases of ROP are characterized [34]. The first phase begins when retinal vascular growth ceases after premature birth. The relative hyperoxic environment causes downregulation of the major hypoxia-triggered vascular endothelial growth factor (VEGF) resulting in vaso-obliteration of the developing retinal capillaries. The ensued relatively vascular-depleted retina becomes increasingly hypoxic and a second phase begins. In this phase VEGF and other growth factors are upregulated, leading to a proliferation of abnormal neovascularisation with the development of stage 3 ROP. VEGF is an important hypoxia regulated factor in the development of ROP. Studies have shown that serum levels of VEGF are higher in infants with stage 3 and threshold ROP compared to those with less severe disease [35].

The time of the appearance of ROP is determined both by the immaturity of the child at birth and by perinatal events that are associated with increased incidence of ROP. In full-term infants, ROP almost never develops when oxygen is delivered in high concentration. Also, when oxygen is monitored carefully and controlled in mildly preterm infants with zone II or III disease, the retinal vasculopathy is usually mild; this inference has been corroborated by a number of human studies wherein lower O_2 saturation revealed decreased rates of ROP, without causing increased neurologic complications (see § 146.5). Conversely, the risk of ROP rises in very premature infants whose eyes have large areas of avascular retina.

146.5 Pathogenesis

The vasculature of the human retina begins to develop by approximately 16 weeks gestation and reaches the periphery at near-term gestation; accordingly, in the premature infant retinal vascularization is incomplete. The endothelial cells committed from angioblasts lead the way in response to increasing metabolic demands of the developing retina [36]. Pericytes develop later and their absence facilitates angiogenic stimuli to induce endothelial cell proliferation [37]. This process of angiogenesis occurs as expected in part through expression and actions of VEGF [38].

Increased retinal oxygenation is an important factor in the pathogenesis of ROP [39–41]; in utero the immature subject is exposed to much lower levels of O_2 than postnatally. Recent studies [42–48] have concluded that the rate of ROP can be reduced by limiting O_2 administration (Table 146.1); this of course needs to be done cautiously. In contrast to the adult [49, 50] the immature newborn is unable to regulate O_2 delivery (principally from the highly perfused choroid) to the inner retina [51–54]. In response to the ensued retinal hyperoxia, not only the particularly vulnerable endothelial cells at the vascular front degenerate, but also a marked involution

Table 146.1 Rate of ROP in infants exposed to different hemoglobin O_2 saturations (Data collection: retrospective)

Reference	BW	O_2 sat (>90%)	O_2 sat (82–90%)
Tin et al, 2001 [42]	<1500 g (n = 210)	13.5% (threshold)	6.3% (threshold)*
Chow et al, 2003 [43]	<1500 g (n = 447)	4.5% (threshold)	1.3% (threshold)*
Wright et al, 2006 [44]	<1500 g (n = 350)	7.3% (threshold)	1.3% (threshold)*
VanderVeen et al, 2006 [45]	<1250 g (n = 323)	16.7% (threshold)	4.2% (threshold)*
Deulofeut et al, 2006 [46]	<1250 g (n = 502)	36% (ROP = 2)	25% (ROP = 2)*
Wallace et al, 2007 [47]	<1250 g (n = 89)	18% (ROP < 2) 25% (ROP > 3)	14% (ROP < 2) 22% (ROP > 3)

of the choriocapillaris in the central choroid was recently reported as an important contributor to central photoreceptor compromise in the OIR/ROP [35, 55, 56]. This endothelial cytotoxicity embodies the vaso-obliterative phase of ROP [57], and impacts on neovascularization (as well as on retinal function secondary to the ensued ischemia [58, 59]).

A number of factors participate in the vaso-obliteration that precedes the pre-retinal neovascular phase: a) O_2-dependent suppression of the important endothelial growth/survival factor VEGF through stabilization of hypoxia-inducible factor (HIF) [60, 61]. b) Decreased expression of the nutrition-dependent factor insulin-like growth factor (IGF-1). c) Inability of the newborn to autoregulate oxygen delivery compared to the adult. d) Increased generation of reactive species of oxygen and their products, notably thromboxane A_2, platelet-activating factor (PAF), lysophosphatidic acid (LPA) and trans-arachidonic acids [62]. e) Increased vulnerability of the neuroretinal endothelium to oxidant stress (more so than neurons and glia).

The increased generation of reactive oxygen species is the result of an incompletely developed anti-oxidant potential in the immature subject and a tissue (the retina) highly prone to peroxidation due to a high content of polyunsaturated fatty acids; in fact the retina contains the highest concentration of long-chain fatty acids in the organism. Antioxidants are molecules that can safely interact with ROS and terminate the chain reaction before vital molecules are damaged. The concentration of all the major components of the antioxidant systems in neonates, which include heme oxygenase-1, metallothionein, Cu-Zn superoxide dismutase, catalase, vitamins C and E, and glutathione peroxidase, are reduced in retinal tissues. Hence, a limited ability of the newborn to autoregulate oxygen delivery, the abundant unsaturated fatty acids in retina, and the reduced antioxidant systems, renders the ocular vasculature of the newborn more vulnerable to oxidative damage.

146.5.1 Oxygen-Independent Factors and ROP

146.5.1.1 Hypercapnia

In addition to hyperoxia, other factors regularly encountered in neonates with bronchopulmonary dysplasia, such as high carbon dioxide (CO_2) tension (hypercapnia) and associated acidosis, have also been shown to play a role in the development of ROP [63]. Interestingly, ischemia also results in a concomitant elevation in CO_2 [64]. This local tissue hypercapnia arises as a consequence of 1) decreased waste removal, 2) continued aerobic CO_2 production until O_2 stores are depleted, and 3) increased anaerobic CO_2 generation from the bicarbonate buffering of hydrogen ions (derived from lactic acid breakdown and high-energy phosphate hydrolysis). The specific consequences of hypercapnia have generally been overlooked with respect to neovascularization.

Exposure of endothelial cells to hypercapnia has been shown to inhibit their proliferation, migration and differentiation into capillary-like structures and to decrease their viability, apparently through cytotoxic nitration [65]. Hypercapnia also attenuates developmental retinal neovascularization with acute and prolonged exposure. Likewise, in a mouse model of O_2-induced retinopathy, retinas are unable to revascularize as efficiently when CO_2 levels are concomitantly elevated [65].

146.5.1.2 Insulin-like Growth Factor-1 (IGF-1)

Of all contributors, prematurity remains the greatest risk for ROP, suggesting that certain key factors present in utero that partake in normal fetal development are lacking in preterm infants. This hypothesis was explored in the seminal works of Lois Smith on the role of deficiency of the major growth factor, IGF-1 in premature subjects [9]. Plasma levels of IGF-1 rise with gestational age and considerably augment during the third trimester of pregnancy (when premature infants predisposed to ROP are born). Importantly, IGF-1 decreases postnatally, thus underscoring the placental and amniotic source of the factor. In human subjects, low IGF-1 serum levels directly correlate with the severity of ROP, and interestingly may also account for abnormal brain development where retinal vessel growth was retarded, akin to patterns noted in premature babies with ROP [66]; interestingly, IGF-1 binding protein, IGFB3, was also found to be decreased in premature infants, and may also contribute to retinal vessel depletion. It was also found that IGF-1 modulates VEGF actions. On one hand, IGF-1 curtails protective actions of VEGF during the vaso-obliterative phase. Subsequently, when retinal ischemia develops and VEGF levels rise, IGF-1 plays an essential role as a permissive factor allowing VEGF to exert its vasoproliferative actions. Hence, early on IGF-1 depletion participates in vaso-obliteration and later IGF-1 repletion contributes to the aberrant pre-retinal neovascularization. Accordingly, clinical

trials are being undertaken to address the merits of treatment with IGF-1 at an early stage to prevent the vaso-obliteration in the premature infants [9]. Based on these and animal observations the question of poor weight gain in premature infants at risk of ROP has been raised. In this context, it was recently found that inadequate weight gain during the first few weeks of postnatal life is associated with more severe ROP. Accordingly, an algorithm based on weight gain and IGF-1 was developed as a predictor of ROP (WINROP). Using serial weight and IGF-1 measurements in a cohort of 50 premature babies, WINROP predicted all infants who later developed ROP by a mean age of 10 weeks [67]. Moreover, measurements of weight gain (and exclusion of IGF-1) was sufficient to demonstrate in a cohort of 351 patients that insufficient weight gain could predict all infants who required treatment and 75% of babies who did not develop ROP [68].

146.6 Classification

Prior to the early of 1980s, most ophthalmologists recorded observations about the natural course of ROP using different classification systems. Though these systems were similar in the extreme degrees of ROP, moderately severe grades of retinopathy had different emphases that made discussion of ocular findings and comparison of treatment effects difficult. This situation was radically altered with the introduction of the International Classification of Retinopathy of Prematurity (ICROP) in 1984 [8]. This classification was a group effort of 23 ophthalmologists and ophthalmic pathologists from 11 countries. The ICROP group suggested four major components for an international classification, including: 1) localization (Zones I, II and III) of the retinopathy between the ora serrata and the optic disc, 2) severity (Stages 0-5) of disease at the junction between the vascularized and non-vascularized retina, 3) extent of involvement of disease (given in clock hours 0 through 12) at the junction, and 4) presence or absence of plus disease, defined as abnormal dilatation and tortuosity of the vessels of the posterior pole of the eye. The major theme of the classification was that the more posterior, the more severe and more extensive retinopathy was the most likely to have the worst long-term outcome for the child. All these components have greatly enhanced the study of the course and the treatment of both the acute and cicatricial phases of the disease.

146.6.1 Zones in ROP

The area of the retina affected by ROP is divided into three zones (Fig. 146.1). Zone I, the most posterior, is the area bound by a circle that has the disc at its center and a radius of twice the disc to foveal region distance. ROP develops in this zone if the retina in this area is most underdeveloped. Zone II is concentric around Zone I and having a radius defined from the disc to the nasal ora serrata. Zone III is the crescent of peripheral retina from the edge of Zone II to the ora serrata. Thus, ROP that extends for 12 clocks hours (360°) must occur in Zone I or II. Disease in Zone I is more severe compared with disease limited to Zones II or III.

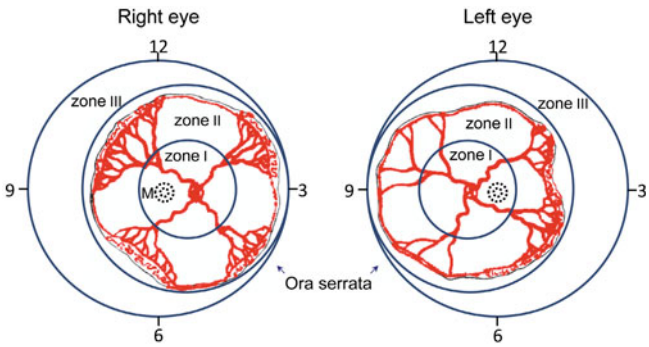

Fig. 146.1 International Classification of Retinopathy of Prematurity Zones and Stages. This figure shows threshold disease in both eyes, with dilation and tortuosity of the posterior pole vessels. Modified from [73]

146.6.2 Stages in ROP

ROP is divided into stages 0 to 5.

- *Stage 0* is the first stage of this disease characterized by an incomplete vascularization of the retina, leaving avascular tissue in a doughnut shape, or a temporal ellipse, around the optic nerve.
- *Stage 1* is uniformly recognizable as a white line develops at the junction between the vascularized and non-neovascularized retina.

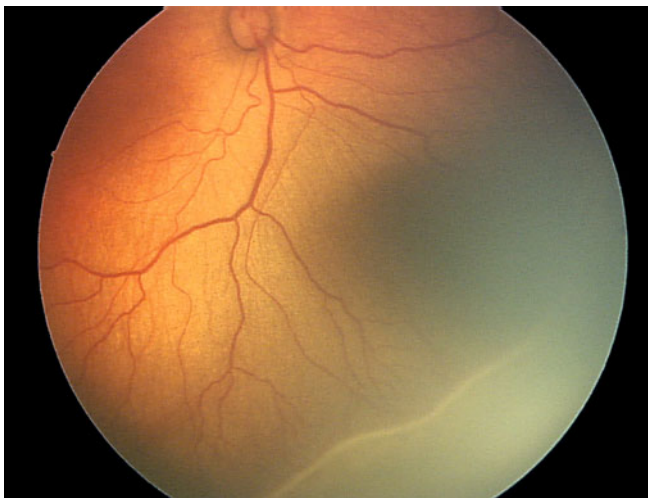

Fig. 146.2 ROP stage 2, the vascular and avascular retina are separated by thick ridge

- *Stage 2* occurs when the line develops height and width. Stages 1 and 2 do not usually require treatment in the majority of the cases (Fig. 146.2).
- *Stage 3* is characterized by extension of fibrovascular proliferation into the vitreous cavity (Fig. 146.3). The presence of neovascular tufts, called "popcorn" were described as being present in active disease [69]. Some cases can present an ominous sign called plus, in which the retinal vessels around the optic nerve and in severe cases on the iris also, become engorged and tortuous. The natural history study showed that if an eye developed five contiguous or eight cumulative clock hours of stage 3 in zones I or II in the presence of plus, there is a 50% chance of retinal detachment with a poor visual outcome [70]. This point in the disease was termed threshold. Approximately 95% of the babies who require laser or cryotherapy develop threshold disease between 32 and 42 weeks after conception. Lower zone and higher stage correlates in general with younger and smaller premature birth and higher risk (e.g., zone I stage 3 is more ominous than zone III stage 1).
- *Stage 4* ROP is the beginning of the blinding consequences of ROP. The neovascular ridge contracts, pulling the retina up with it and causing partial retinal detachment. This stage is divided in Stage 4A if there is a partial retinal detachment not involving the macular region or Stage 4B (Fig. 146.4) if the partial retinal detachment involves the macula. At this stage, the retina may sometimes reattach spontaneously, however, in many cases the retinal detachment, which is unlikely to regress, requires treatment. Treatment modalities are cryopexy for shallow retinal detachment, or scleral buckling for more advanced cases. Stage 4 may progress quickly in some babies and its treatment has frequently been unsuccessful leading to stage 5 ROP.
- *Stage 5* ROP shows a total retinal detachment and is the end stage of the disease. Stage 5 in its most severe form shows a dense white membrane or scar behind the lens of the eye. The detached retina is adherent to this scar tissue. The condition was previously called retrolental fibroplasia (RLF), because the scar is white and visible through the pupil [3]. Spontaneous reattachment of the retina rarely happens in stage 5 ROP. If the eye is left alone at this stage, the baby becomes permanently and often totally blind in both eyes. In addition, some babies develop high intraocular pressure, causing glaucoma. Others develop problems leading to clouding of the cornea.

146.6.3 Severe ROP

146.6.3.1 Plus Disease

Abnormal dilatation of retinal veins with florid abnormal new vessels is called Plus disease, a sign of very poor prognosis in ROP. It is characterized by progressive vascular incompetence

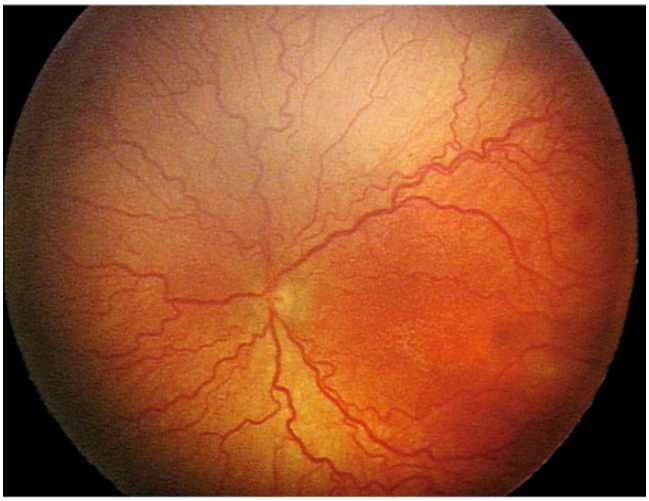

Fig. 146.5 Plus disease, increasing dilatation and tortuosity of veins and arteries of the posterior pole

with increasing dilatation and tortuosity of veins and arteries of the posterior pole, as shown in Fig. 146.5. Also, frequently seen in moderate to severe plus disease are iris vascular engorgement, pupillary rigidity, vitreous haze, and increasing dilatation and tortuosity of the peripheral retinal vessels [71].

146.6.3.2 Rush Disease

Timing is one of the important factors that makes treatment successful in ROP, because the disease can advance very quickly and delayed treatment often reduces the chances of success. The rapidly progressing ROP is called Rush disease, and it is usually associated with very extensive or aggressive growth of abnormal blood vessels [72].

146.6.4 New Classification

The Revised International Classification [73] introduced the new form which concerns premature infants with extremely low GA, defined as aggressive posterior ROP (AP-ROP) and a description of an intermediate level of plus disease: pre-plus

The criterias that characterize AP-ROP are the same: posterior location (zone I), increasing dilatation and tortuosity of the posterior arteries and veins in all four quadrants and shunting from vessel to vessel, within the retina and not solely at the junction between the vascularized and non vascularized retina and a flat network of neo-vascularization. Timing is one of the important factors that make the treatment successful in ROP, because the disease can advance very quickly and delayed treatment often reduces the chances of success. The rapidly progressing ROP is usually associated with very extensive or aggressive growth of abnormal blood vessels [74].

The pre-plus disease indicates vascular abnormalities of the posterior pole that are insufficient for the diagnosis of plus disease, but that demonstrate more arterial tortuosity and more venous dilatation than normal. This situation requires attention to progress a frank plus.

146.6.5 Diagnostic Examination

Indirect ophthalmoscopy with 25–28 D lens is the correct modality to observe the premature retina. This examination is fundamental, it needs papillary dilatation with eye drops which combines 2.5% phenileprine and 1% tropicamid, 3 times in each eye one hour before examination.

In the last years, RETCAM is a new device, which permits the taking of pictures of the retina and allows comparisons between experts.

The fluorescein angiography is important to complete the ROP valuation especially in forms that need treatment. After treatment RETCAM examination and fluorescein angiography help to determine if treatment is complete or not.

146.7 Clinical Presentation

Much of our knowledge regarding the clinical presentation of ROP has been obtained from follow-up data from infants enrolled in the no-treatment arm of prospective randomized trials (natural-history cohorts), mainly the CRYO-ROP and ETROP studies. The CRYO-ROP Study was a multi-center randomized blinded trial designed to evaluate the risks and benefits of trans-scleral cryotherapy [74]. It enrolled 4099 infants weighing less than 1250 g at birth who were born between January 1986 and November 1987. The ETROP Study was a multi-center, randomized trial conducted 15 years later and designed to investigate the potential benefits of early (prethreshold) treatment versus conventional (threshold) treatment in high-risk prethreshold eyes [75] during which 6998 infants born between October 2000 and September 2002 with a birth weight of less than 1251 g were screened for ROP.

146.7.1 Onset

146.7.1.1 Age at Onset

While the risk of developing ROP is influenced by several factors including gestational age and neonatal events, the time at which ROP develops appears to be rather constant and closely related to postmenstrual age [76, 77]. Data from the CRYO-ROP study showed that retinal conditions indicating a risk of poor outcome are not observed before 31 weeks'

postmenstrual age (PMA) or 4 weeks' chronologic age in 99% of infants [78]. In the ETROP and CRYO-ROP studies, the median PMA at first identification of any ROP was 34.1 weeks and 34.3 weeks, respectively [79]. However, a study by Subhani et al suggests that ROP onset is slightly accelerated in the most immature infants thus occurring at a slightly earlier postmenstrual age [77]. ROP can also develop after 37 weeks; it is then most unlikely to develop into disease requiring treatment [78].

146.7.1.2 Site of Onset

ROP develops initially within the peripheral retina, more frequently in the nasal retina in the most immature infants [76]. However, over time location of disease can change [80], maybe due to ocular growth. The risk of developing significant ROP depends on the location of incomplete vascularization by zone. Zone I ROP is high-risk disease, while zone III has very low risk and zone II is intermediate.

146.7.2 Natural Evolution

Despite advances in neonatal care, the CRYO-ROP and the ETROP natural-history studies have shown little change in the natural evolution of ROP [79].

146.7.2.1 Regression

In the CRYO-ROP study, ROP was found to regress with vascularization of the retina growing into zone III in 80% of cases [74]. The mean age at which ROP began to involute was 38.6 weeks PMA [80]. Involution was observed in 90% of infants before 44 weeks PMA, but in 3% of eyes, regression had still not occurred by 3 months corrected age [79]. In the conventional treatment arm of the ETROP study, ROP regressed without reaching threshold in 33.6% of high-risk eyes. The other 66.4% underwent peripheral retinal ablation for progression to threshold [81].

146.7.2.2 Timing and Rate of Progression

The median age at onset of prethreshold ROP was 36.1 PMA in the CRYO-ROP as well as in the ETROP study [79], occurring before 32.1 weeks PMA in 5% of infants enrolled in the ETROP trial [78], and before 30.9 weeks PMA in 1% of babies in the CRYO-ROP study [78]. In the ETROP trial, 95% of babies developed prethreshold at 7 postnatal weeks or more [79] and in the CRYO-ROP study 99% of eyes were free of prethreshold ROP before 4.7 weeks postnatal age [77]. Subhani et al [77] reported earlier onset of prethreshold disease with 3.2% of babies developing prethreshold before 30 weeks PMA in the most premature infants, but the definition of prethreshold in this study differed from that used in the ETROP trial and CRYO-ROP studies.

The earliest onset of threshold ROP is reported between 31.0–32.6 weeks PMA and 6.6–8.0 weeks postnatal age [77, 80]. The earliest age of onset of stage 3 disease is reported between 30.3–35.6 weeks PMA, and 3.8–6.7 weeks postnatal age [76, 79, 82].

In the CRYO-ROP study, threshold ROP developed in 6% of infants, at a mean PMA of 37.7 weeks. The median time from prethreshold to threshold disease did not exceed 1 week [75]. Of note, aggressive posterior ROP progressing from onset to stage 4 in less than a week has also been reported.

146.7.2.3 Risk Factors for Progression and Unfavorable Outcome

Lower birth weights and younger gestational age carry an increased risk of reaching threshold ROP. Eyes in which vascularization has grown only into zone I before 35 weeks PMA have a 30% risk of developing threshold ROP compared to eyes in which vascularization have reached zone III. At fundus examination, risk factors for progression and unfavorable structural outcome include the presence of plus disease, zone I or posterior zone II ROP, increased circumferential involvement and stage 3 ROP [75]. A faster rate of progression to prethreshold disease is also associated with an unfavorable outcome [83]. Conversely, infants with zone II ROP without plus disease or with zone III ROP are at very low risk (<1%) of developing sight-threatening ROP and unfavorable outcome [78, 80, 83]. The risk to the baby's sight appears to be minimal in infants with acute ROP that demonstrated involution by moving from zone II to zone III with moderate ROP [78, 80].

146.7.3 Complications

Unfavorable visual outcome may be observed in up to 40–50% of severe ROP at one year follow-up compared to less than 1% in infants with no or less severe ROP. Prior to the introduction of retinal ablation to stop the progression of ROP, infants with prethreshold disease were predicted to have a 50% risk of blindness [74].

146.7.3.1 Anatomical Abnormalities

Apart from retinal detachment (stage 4 ROP), the main retinal and vitreal complications of ROP include retinal folds, foveal heterotopia, preretinal membranes and hemorrhages. In the CRYO-ROP study, eyes with zone I ROP or with zone II, stage 3+ were reported to have a higher risk of retinal and vitreous damage than eyes with less severe ROP [83].

Serious anatomical damage of the anterior segment can also occur in infants with severe ROP. Synechiae were observed

in 37.4% of eyes with stage 3–5 ROP, and cataract was diagnosed in 6.3% of cases in the CRYO-ROP study [83].

146.7.3.2 Refractive Errors

Twenty percent of children enrolled in the CRYO-ROP study were found to be myopic at one year of age [84]. Approximately 70% of eyes with high-risk prethreshold ROP during the neonatal period were myopic in early childhood in a follow-up report from the ETROP Study Group [85, 86]. The proportion of eyes with high myopia increased steadily between 6 months and 3 years [86]. Prevalence of myopia increased with increasing severity of cicatricial ROP, but was not related to severity of acute-phase ROP (zone of disease, presence of plus disease) [85, 86].

Prevalence of astigmatism in preterm children who participated in the ETROP Study was similar in either arm of treatment (early or conservative). By 3 years of age, astigmatism ≥ 1.00 diopters occurred in 43% of eyes treated at high-risk prethreshold ROP; 20% of eyes had astigmatism ≥ 2.00 diopters [87].

146.7.3.3 Loss of Visual Field

Visual field was shown to be reduced by approximately 30% in children with ROP, whether they underwent retinal ablation or not, compared with infants without ROP [88].

146.7.3.4 Strabismus

The prevalence of strabismus in the first year of life was 14.7% and was correlated with ROP severity in the CRYO-ROP study [89].

146.7.3.5 Late Sequelae

The percentage of eyes with unfavorable outcome increases over time. In the CRYO-ROP study, nearly half of eyes developed unfavorable outcomes at ten years [90]. Unfavorable visual outcome (vision ≤ 20/200) and unfavorable structural outcome (posterior retinal folds or worse) were reported in 62.1% and 47.9% of untreated eyes, respectively [90]. Compared to outcome at 5 years, total retinal detachments had continued to occur in control eyes, increasing from 38.6%–41.4% at ten years [90].

Although surgical treatment of severe ROP is associated with better long-term visual and structural outcomes, it still carries a risk of both short- and long-term ophthalmic morbidities, including retinal detachment and blindness. Laser-treated severe ROP remained associated with unfavorable visual outcome in 11% of cases at 3 months of age [91]. Total retinal detachment was observed in 22% of treated eyes in the CRYO-ROP 10-year follow-up study [90]. Iris atrophy and cataracts have also been reported following peripheral retinal ablation [92].

146.7.3.6 Functional Changes

While ROP is often considered to be primarily a disease of the developing retinal vasculature, the vasculopathy phase has been shown to resolve itself in some cases [93]. In contrast, despite the vascular repair, functional sequelae as revealed with the flash electroretinogram (ERG) and multifocal electroretinogram (mfERG), for example, have been shown to carry on into adulthood. In patients with a history of ROP, significant abnormalities in the a- and b-waves of the ERG have been shown to persist in the absence of any abnormal retinal vasculature [94, 95]. Furthermore, elevations of the scotopic visual thresholds in children with a history of resolved, mild ROP in addition to the slower maturation of the rod-mediated thresholds in the central retina are also suggestive of photoreceptor involvement [96–98]. Interestingly, a differential susceptibility between cone and rod function has been suggested in subjects with a history of preterm birth, where higher cone sensitivity and minimal cone dysfunction could be observed compared to that of rods [96]. While this discrepancy requires further elucidation, it has been postulated that the earlier maturation of the cones might carry out a beneficial protective effect with respect to their function in comparison with the relative immaturity of the rods that might render them more susceptible to oxidative stress [96].

Significant deficits in amplitude and implicit time of the mfERG, a central retinal response, have also been shown in subjects whose clinical features of ROP had completely resolved more than 10–20 years earlier [98]. These findings suggest that a history of ROP can carry out lasting consequences on central retinal development as revealed with the mfERG. ON- and OFF-bipolar cells contribute to this central response, and therefore amplitude attenuation might occur should ROP specifically target these cells, thereby resulting in an altered summation of depolarization and hyperpolarization in these subjects [98]. More recently, the morphologic changes of the macular structure have also been studied in formerly preterm children with mild or no sequelae of regressed ROP using optical coherence tomography (OCT). Findings in formerly preterm infants revealed a larger central retinal region in addition to a decreased foveal depression compared to children born at full term, which was suggested to result from problematic centrifugal movement of foveal cones as well as inner retinal cells throughout retinal maturation [99]. Overall, despite the resolution of vascular abnormalities that are commonly reported in ROP patients, careful consideration and monitoring of structural changes and neural dysfunction in the retina that can carry on throughout adulthood is warranted.

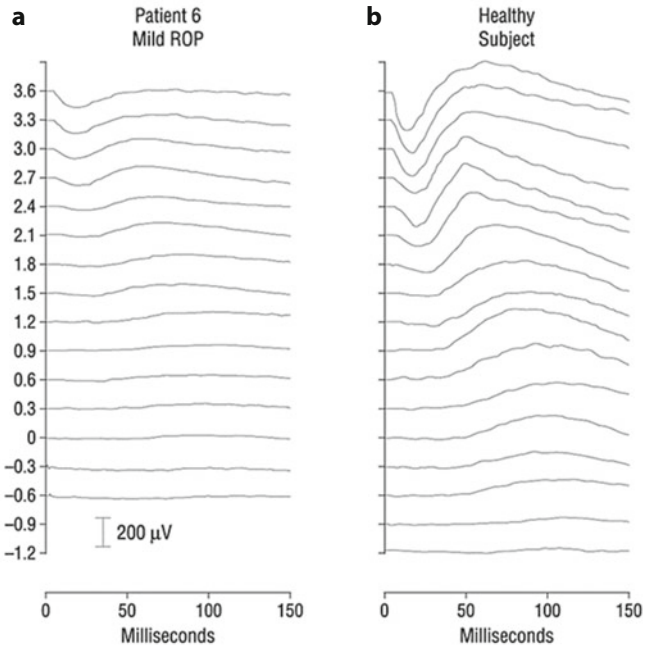

Fig. 146.6 **a** Sample electroretinographic record at 2.5 months post term in patient 6 with mild retinopathy of prematurity (ROP). **b** Electroretinographic record of a healthy, term born infant. The numbers to the left of each trace indicate the stimulus in log scotopic troland seconds. Adapted from [94]

Several other types of visual manifestations, in addition to ROP, have been thought to result from the challenges of premature birth on the developing ocular system. For example, an increased incidence in refractive errors such as myopia, astigmatism and anisometropia has been noted, in addition to an increased incidence in strabismus [100–102]. An association between the oscillatory potentials (OPs) of the ERG and ametropias has also been reported in patients with a history of ROP. For example, while a stronger ON signal and lower OFF signal (as revealed by an increase in OP_3 and a decrease in OP_4, respectively) was found in myopic patients, the reverse was documented in hyperopic patients, and thus it could be concluded that the ON and OFF pathways might play a role in determining refractive development in these patients [103]. Similar to the manifestations of ROP on eye growth and movement, visual functions including visual acuity, contrast sensitivity, color vision and visual fields may also be significantly altered and can consequently impact psychological and educational development [100, 102].

146.7.4 Surveillance of ROP and Follow-up

146.7.4.1 Screening

Based on published data regarding evolution of ROP, screening guidelines to identify infants requiring treatment for ROP while minimizing the number of stressful examinations have been established in many countries [104, 105]. In industrialized countries, they vary little, with respect to the gestational age and birth weight of screened infants, timing of first examination and frequency of subsequent examinations. Screened infants are born between 1250 and 1500 g and between 30 and 32 weeks PMA. Screening recommendations also generally include selected larger or more mature infants with unstable clinical course who are considered at high risk by the attending neonatologist [104]. In countries with low/moderate level of development, where larger and more mature infants develop severe ROP [23, 82], ROP screening programs include infants up to 1750 g and 33 weeks PMA [82]. Timing of first examination range between 4 and 6 weeks of life or 31 and 33 weeks PMA, whichever is later [82]. Subsequent follow-up examinations are recommended biweekly when examination is normal, or at least once a week in other cases. In the absence of any ROP, screening can be stopped when the retinal vascularization is completed, i.e., when retinal capillaries have grown into zone III. Screening by an experienced ophthalmologist is recommended, using binocular indirect ophthalmoscopy after pupillary dilation (Box 146.1).

As an example, the recently updated screening recommendations for ROP published jointly by the American Academy of Pediatrics (AAP), the American Academy of Ophthalmology (AAO) and the American Academy for Pediatric Ophthalmology and Strabismus (AAPOS) are summarized in Box 146.2 [104].

Telemedicine Approach to Screening for ROP

Technical advances have permitted an innovative approach to remote ROP evaluation, using digital retinal imaging systems. Theoretical advantages of this technique include, for NICUs with poor access to experienced ophthalmologists, a

Box 146.1 Pain prevention during screening for ROP

Screening examination is performed using indirect ophthalmoscopy after pupils dilation. In some cases, an eyelid speculum and a scleral depressor are used to rotate the eye in the appropriate position, making the examination stressful and painful for the baby. ROP screening examinations can have short-term effects on blood pressure, heart rate and respiratory function in the premature baby. The baby should therefore be clinically stable at the time of the examination, which should be kept as short as possible. Nesting, use of oral sucrose and use of a topical anesthetic are recommended prior to screening of babies for ROP.

BOX 146.2 Screening guidelines from the AAP/AAPOS and AAO

Infants to be screened
- infants with a birth weight < 1500 g, or
- with a gestational age < 30 weeks
- selected infants with a birth weight between 1500 and 2000 g or gestational age of more than 30 weeks with an unstable clinical course, including those requiring cardiorespiratory support and who are believed by their attending pediatrician or neonatologist to be at high risk.

Timing of initial examination

GA (wks)	Postmenstrual age at first examination (wks)	Chronologic age (wks)
22	31	9
23	31	8
24	31	7
25	31	6
26	31	5
27	31	4
28	32	4
29	33	4
30	34	4
31	35	4
32	36	4

Frequency of subsequent examinations
- 1-week or less follow-up:
  - stage 1 or 2 ROP: zone I
  - stage 3 ROP: zone II
- 1 to 2-week follow-up
  - immature vascularization: zone I – no ROP
  - stage 2 ROP: zone II
  - regressing ROP: zone I
- 2-week follow-up
  - stage 1 ROP: zone II
  - regressing ROP: zone II
- 2 to 3-week follow-up
  - immature vascularization: zone II – no ROP
  - stage 1 or 2 ROP: zone III
  - regressing ROP: zone III

Termination of screening criteria

a. zone III retinal vascularization attained without previous zone I or II ROP (if there is examiner doubt about the zone or if the postmenstrual age is less than 35 weeks, confirmatory examinations may be warranted)
b. full retinal vascularization
c. postmenstrual age of 45 weeks and no prethreshold disease (defined as stage 3 ROP in zone II, any ROP in zone I) or worse ROP is present; or
d. regression of ROP (care must be taken to be sure that there is no abnormal vascular tissue present that is capable of reactivation and progression).

decrease in the number of eye examinations that would require an evaluation by an ophthalmologist. Although recent studies have shown promising results [106], evidence base for digital imaging remains scarce, and clinical examinations by an experienced ophthalmologist remains the standard for identifying ROP [107].

146.7.4.2 Ophthalmologic Follow-up Beyond the Neonatal Period

Although the risk of long-term visual disorders, such as refractive errors, strabismus or amblyopia is well recognized in ROP, there is little consensus regarding when, how frequent and forhow long ophthalmologic follow-up should take place [108]. Eye examination is indicated after discharge [104], even in case of ROP regression. An early first post-discharge examination, for example within 6 months of expected full-term birth, could help detect amblyogenic factors and reduce the risk of later visual impairment.

146.8 Treatment

146.8.1 Cryotheraphy

Cryotherapy to the vascular peripheral retina of eyes with severe forms of active ROP had been used in Japan since the early 1970s [109] and gradually gained advocates in several countries. Many ophthalmologists were reluctant to employ this treatment modality because of untoward or unexpected results. In the CRYO-ROP study, the method used to ablate

avascular retina was cryotherapy. This treatment is still used in some hospitals, but it largely has been supplanted by diode laser in many countries. The cryotherapy probe is a long, thin, curved metal hand piece with a slightly rounded tip. It is applied to the external eyeball transconjunctival or trans-scleral in forms more posterior using the indent of the wall of the eye. This indentation can be seen using the indirect ophthalmoscope. A foot pedal attached to the probe is depressed when it is seen to be in proper position. The retina blanches as it freezes, and leaves a treated spot. The probe is removed and moved to the next spot, either contiguous with or leaving a small space next to the previous treatment. The process is repeated over and over until the entire unvascularized retina has been treated. Cryotherapy is a painful and inflammatory procedure and needs general anesthesia. Adverse effects include conjunctivitis, eyelid swelling, hypotony, infection, retinal detachment, and glaucoma. Pressing on the eye with the cryoprobe may elicit the oculocardiac reflex, a sudden bradycardia. Infants are usually put on topical antibiotics and steroids for a week or so after cryotherapy [70].

146.8.2 Photocoagulation

The treatment of ROP has evolved significantly since the advent of the CRYO-ROP study, the trial that proved the benefit of ablating the peripheral avascular retina in ROP [110]. A fifteen year follow-up of this study, published in 2005, describes a decrease of over 40% and 30% in unfavorable structural and visual outcomes respectively, in treated versus observed eyes [110]. Easier to administrate, and with less adverse effects than cryotherapy, laser photocoagulation soon became the modality of choice to treat ROP. The treatment ablates the peripheral avascular retina (Fig. 146.7), which causes the stimulus for neovascularisation to decrease, probably through decline of angiogenic factors. Many studies demonstrated that laser was at least as effective as cryotherapy in preventing unfavorable outcomes. The use of cryotherapy is now restricted to particular cases in which fundus visualization is poor (i.e., vitreous hemorrhage), thus preventing laser administration.

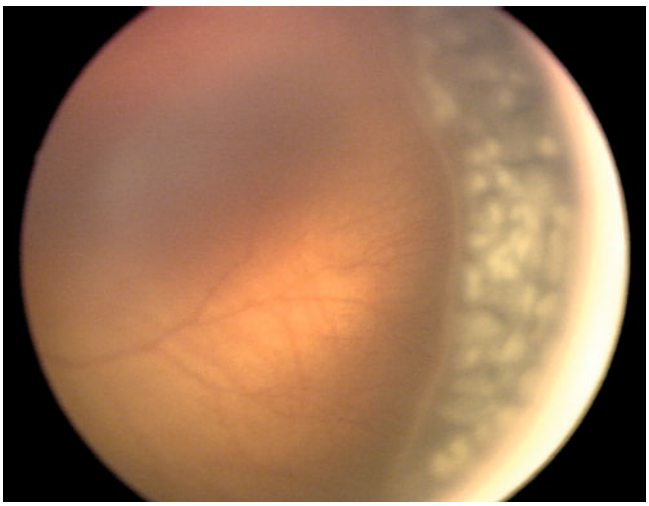

Fig. 146.7 Diode laser photocoagulation of the peripheral avascular retina

Table 146.2 Treatment strategies based on stage and location (zone) of ROP

Consider early treatment of eyes with pre-threshold-type 1 disease: – Zone 1, any stage of ROP with plus disease – Zone 1, stage 3 with or without plus disease or – Zone 2, stage 2 or 3 with plus disease
Observe closely eyes with pre-threshold-type 2 disease (Consider treating when progression to type 1 or threshold ROP): – Zone 1, stage 1 or 2 with no plus disease or – Zone 2, stage 3 with no plus disease

Laser photocoagulation was used for years following the CRYO-ROP recommendation: to treat threshold ROP, a point in the progression of the disease at which the risk of retinal detachment approached 50% [110]. Nonetheless, poor visual results remained common with such treatment criteria. The CRYO-ROP study demonstrated at 10 year follow-up that 44.4% of eyes with severe ROP had vision of 20/200 or worse [111]. The need for earlier intervention became evident and the Early Treatment for ROP study (ETROP), published in 2003, provides our current treatment guidelines (Table 146.2) [75]. In that trial, infants with high-risk pre-threshold ROP had one eye randomized to early intervention and the contralateral-control eye to conventional treatment. Unfavorable visual and structural outcomes were reduced from 19.8% to 14.3% and 15.6% to 9%, respectively. Some recent laser treatment long-term outcome studies report best mean corrected visual acuities between 20/46 and 20/98 [112–114]. Over 65% of the eyes from those series had vision of 20/40 or better.

Laser photocoagulation, applied transpupillary through an indirect ophthalmoscope can be performed in the nursery or operating room. Argon laser was used initially but is now widely replaced by Diode laser, which requires less power. Many studies described placement of laser burns 0.5–1 burn width apart. We favor a more confluent pattern of treatment. Laser burns were applied in the area of the avascular retina extending from the ridge of extraretinal fibrovascular proliferation to the ora serrata for 360°. More continous treatment may not only reduce the rate of progression [115, 116] but also the need for retreatment [115]. Generally, regression can be seen 5–7 days after treatment. Retreatment must be considered when retinopathy continues to progress and there are skipped areas that can be treated.

Laser treatment needs topical anesthetic and intravenous sedation in spontaneous respiration. Complications from indirect laser photocoagulation include cataract, corneal or iris burns, choroidal or vitreous hemorrhage, hyphema, choroidal

rupture and phthisis bulbi [117]. Reduction of the visual field is minimal and not felt to impact visual function [113].

The refractive status of treated eyes deserves special mention, since myopia remains a significant and very common finding in all series of patients treated with laser. In a randomized bilateral treatment study, Connolly et al [118] found that laser treated eyes were less myopic than those treated with cryotherapy (mean spherical equivalent –4.48 and –7.65 diopters, respectively). Other authors have found similar results [119, 120]. The problem of myopia is compounded by the fact that prematurity, ROP itself and the treatment predispose to this refractive error [84, 121–123].

146.8.3 Anti-VEGF

Anti-VEGF treatment is reserved for premature infants affected by AP-ROP.

VEGF is a dominant factor that contributes to the neovascular phase of ROP. Accordingly the potential use of anti-VEGF therapy during this phase has been proposed. bevacizumab is a monoclonal antibody against VEGF that has been approved for use in colorectal, breast and lung cancer; this antibody has also been widely used for proliferative macular degeneration and diabetic retinopathy. Since the cryotherapy and early treatment ROP trials detected an unfavorable visual outcome in relatively advanced proliferative retinopathy in 78% and 55% of infants respectively, it was reasonable for practitioners to attempt using anti-VEGF therapy with the hope of improving outcome. Until 2009, nine reports (including 6 case reports, 2 retrospective studies, and 1 prospective study) had documented results of anti-VEGF therapy in ROP [124]. A generally favorable outcome (controlled progressive neovascularization) was detected in 6 of the 9 small reports [125–130] (Table 146.3). However, timing (stage/zone of ROP), dose (range: 0.4–12.5 mg iv), and frequency of administration of bevacizumab, as well as co-treatment with photocoagulation, varied tremendously between reports. Recently, in a multi-center randomized prospective trial patients treated with bevacizumad had significantly less recurrence of neovascularisation requiring treatment than eyes treated with diode laser for zone 1, stage 3 ROP plus. No statistical difference between the two treatment modalities was identified for zone 2, stage 3 ROP plus [131]. The interpretation of the results of the trial has not escaped controversy [132]. The unknown possible deleterious effects that blocking VEGF may have on the developing brain constitutes the principal concern over the incorporation of a new promising treatment for ROP [133]. A number of issues need to be addressed in future well-conducted randomized trials: a) adjunct photocoagulation therapy with anti-VEGF treatment; b) impact on retinal ganglion cell integrity, since these neurons express the receptor for VEGF and are cytoprotected by VEGF; c) timing of anti-VEGF therapy; d) systemic effects of larger doses (1.25 mg) of bevacizumab, notably on cerebral vasculature; e) long-term impact on visual acuity and visual fields; f) cost-benefit versus currently available treatment.

146.8.4 Scleral Buckling and Vitrectomy

Almost one in 10 infants will develop unfavorable structural outcomes despite appropriate laser treatment [123]. Stages 4 and 5 of ROP will often require surgical treatment. It is however, possible to observe a small, localized and shallow retinal detachment which may not progress or can even reattach, especially in the absence of active neovascularization and plus disease [134]. Examinations and treatment decisions must be done by an experienced ophthalmologist.

Acute ROP related retinal detachments result from contraction of neovascularization along the ridge and growth of vessels into the overlying vitreous leading to traction on the retina. Exudation causing subretinal accumulation of fluid is a much less common mechanism. Available techniques to treat retinal detachments from ROP include scleral buckling and different modalities of vitrectomy. The latter has become more frequently utilized by vitreoretinal surgeons and in a comparative nonrandomized study Hartnett et al found it superior to scleral buckling to treat stage 4 retinal detachment [135]. The choice between the two procedures is, nonetheless, controversial and scleral buckling is still used when the retinal traction is located near the equator of the eye or anterior to it [134, 136, 137].

Scleral buckling (encircling the eye at the equator or anteriorly with a silicone band) intends to correct the retinal detachment mechanically by moving the wall of the eye closer to the detached retina, thus counteracting the forces that exert traction on it. In a recent study using fundus fluorescein angiography Yokoi et al [138] have suggested that scleral buckling may also reduce the neovascular activity in eyes with peripheral proliferation. They speculated that retinal reattachment may improve the vascular supply from the choroid to the retina, therefore decreasing the stimulus for VEGF expression. Buckling is not useful to treat posterior detachments in zone 1 or posterior zone 2, in which the ridge is located behind the equator and there is a large anteriorly attached retina. Buckling has a success rate of retinal reattachment in stage 4A ROP of around 70% [139]. A major disadvantage of buckling is that the indentation caused by the silicone band elongates the eye inducing myopia of up to –9 or –11 dioptres [140, 141], thus increasing the risk of amblyopia, a significant concern given the age group. Furthermore, a second operation is required later to divide or remove the buckle to promote normal growth of the eye, improve its anterior circulation and correct the refractive error.

Vitrectomy works through direct release of vitreoretinal traction forces. The removal of angiogenic factors like VEGF and vasodilators during vitrectomy may constitute an additional mechanism of action [137]. In the past it was necessary

Table 146.3 Case reports on use of bevacizumab for severe ROP

Authors, Year	No. of patients (eyes treated with bevacizumab)	GA (wks)	BW (g)	State before use of bevacizumab (as described)	Previous therapy for bevacizumab-treated eye(s)?	Treatment use in conjunction with bevacizumab	Dose of bevacizumab used (mg)	Favorable outcome with bevacizumab?

to remove the lens in order to access the vitreous cavity. Nowadays lens-sparing vitrectomy has become the preferred technique of many vitreoretinal surgeons to treat stage 4 ROP [131]. Early vitreous surgery is advised when the laser fails and the signs of progression are evident: vitreous torbidity, pupillary rigidity, persistent plus disease. The recently introduced vitrectomy 25 G, is an approach suited to the small eye of premature baby. The eye is entered through the pars plicata and the procedure allows treatment of retinal detachments resulting from the posterior zone of ROP, in which operating posterior to the equator is necessary [134]. When more anterior disease causes retrolental membranes, removal of the lens may be necessary (vitrectomy and lensectomy) [131]. The response to vitrectomy is unfavorable when done in eyes with active neovascularization. Unfortunately sometimes a retinal detachment can progress rapidly in an eye that is still vascularly active; bleeding, continued proliferation and contraction can occur with the surgery [134, 135]. Other complications of lens sparing vitrectomy are cataract, infection and retinal breaks [135]. Combining buckling was not found to add any benefit to lens-sparing vitrectomy [137]. Capone and Trese found reattachment of the retina in 90% of the eyes with Stage 4A ROP treated with lens-sparing vitrectomy [142].

Stage 5 ROP is more often treated with vitrectomy. The results are, however, poor. Cusick et al reported reattachment of the retina in 28% of their cases [143]. The use of coadjuvant intravitreal triamcinolone [144] and more recently autologous plasmin [145] has been reported to improve the anatomical results of vitrectomy for ROP stage 5. No data was presented on vision in those studies.

Despite improved anatomical results over the past years, there remains an important disparity between structural and visual outcomes of surgery for ROP related retinal detachment. Poor vision is common in eyes with affected maculas (stage 4A) and stage 5. Cusick et al found vision better than 5/200 in only 8 of 183 eyes treated for Stage 5 ROP [143]. Among 12 eyes from the ETROP treated for Stage 5, 6 had no light perception, 4 had light perception only and 2 eyes had detection only of the low vision card [146]. Unfortunately, poor visual outcome occurs in less severe retinal detachments as well; in the ETROP study, only 21% of eyes treated for stage 4A maintained normal acuity 9 months after surgical repair [146]. Even though the trial may have involved eyes with inherently more severe disease, its results show that further investigation is still needed in order to improve the modest successes of surgery for ROP retinal detachment. The

use of anti-VEGF drugs may show promise in decreasing the progression of ROP to retinal detachment and is currently being investigated at some centers. In the mean time the surgical developments are likely to continue evolving.

146.8.5 Prevention

The development of preventive and less destructive therapies for ROP such as nutritional supplements, including forms of vitamins E and C, and omega 3 fatty acids, would be much more desirable, however, despite numerous trials, prophylactic supplementation with these components remains controversial; limitation of oxygenation has already been addressed above as an effective means of reducing ROP incidence and will not be repeated in this section.

146.8.5.1 Vitamin E

The most extensively studied medical treatment of ROP is the use of antioxidant vitamin E (alpha tocopherol). Vitamin E is a naturally occurring potent, free radical scavenger that decreases lipid peroxidation and helps maintain membrane integrity [147]. The retinal cells of the premature infant who has these clinical complications have their antioxidant defense system severely compromised, and they may be particularly vulnerable to the deleterious effects of oxygen derived free radicals. It is known that premature infants are born with only 10% of adult levels of retinal vitamin E [148]. The rationale for using vitamin E as a treatment for ROP stems from the idea that peroxidative damage to cells is a causal factor and that vitamin E supplements may prevent this damage. The first reports of its use in the 1940s [149] provide encouraging preliminary results of possible benefits of vitamin E prophylaxis in preventing ROP. However, this study was soon followed by the observation that oxygen therapy had a close link with ROP [150, 151], and investigations into the effect of vitamin E were abandoned until the 1970s. In 1974 Johnson et al [152] reported a randomized clinical trial using oral and parenteral alpha tocopherol acetate supplements to achieve physiological serum levels (1–3 mg/dL) in premature infants. Subsequent work showed a beneficial effect on incidence and severity of ROP associated with vitamin E prophylaxis that yielded physiologic serum levels of the antioxidants [13]. Three clinical trials enrolling 418 infants (less than or equal to 1500 g birth weight) elucidated the efficacy of vitamin E in suppressing the development of severe ROP. In this study only continuous vitamin E supplementation to adult physiologic levels from the first hours of life suppressed the development of severe ROP [153]. Other randomized clinical trials with increasing serum concentrations of vitamin E at a physiologic range, reduced by 52% the incidence of severe threshold (Stage 3+) ROP in the very low birth weight infant [154]. Despite several clinical trials showing the effectiveness of vitamin E in preventing ROP, prophylactic supplementation with vitamin E remains controversial [155]. Subsequent trials have shown no effect and questions revolve around the route of administration (oral versus intramuscular versus intravenous), dose, timing of therapy, appropriate plasma levels, and trends towards higher plasma tocopherol levels in control groups [156, 157]. The protection mechanism of vitamin E in suppressing the development of severe ROP is not well known. A report proposed that spindle cells, mesenchymal precursors of the inner retinal capillaries, are the primary inducers of the neovascularization associated with ROP and the exposure of spindle cells to elevated oxygen tension increases their gap junction area. This early morphologic event immediately halts the normal vasoformative process and eventually triggers the neovascularization that is observed clinically 8–12 weeks later. Vitamin E supplementation above the deficient plasma levels of these infants suppresses gap junction formation and clinically reduces the severity without altering the total incidence of ROP [158].

146.8.5.2 Vitamin C

Vitamin C (ascorbic acid) is an important aqueous phase antioxidant in cells and plasma [159]. Vitamin C has a number of important metabolic functions and is actively transported across the placenta [160]. Vitamin C concentrations in cord plasma are higher than the mother's and, in term infants, plasma concentrations fall considerably over the first 24 hours of life [161]. Preterm infants generally have higher cord Vitamin C concentrations than term infants, and concentrations then decline over a few days [162]. Most preterm infants receive vitamin C as part of a multivitamin supplement, but there are few data on which to base optimum concentrations [163]. One recommendation derives from the concentrations found in healthy breast fed term infants, with an adequate vitamin C concentration stated at approximately 34 mmol/L [164]. Breast milk contains 3.5–5.5 mg vitamin C per 100 mL [165, 166] so that an average infant having 150 mL/kg/day of milk will receive 5.2–8 mg/kg/day. The alternative view is that preterm infants should receive higher doses of vitamin C (25–31 mg/kg/day), to achieve concentrations closer to those in utero in the third trimester [164].

Vitamin C also has shown to have pro-oxidant activity [167, 168], and the few studies of the relation between vitamin C concentration and morbidity in very preterm infants remain controversial. Silvers et al [169] reported that plasma vitamin C concentrations within 2 hours of birth were significantly higher in infants who died compared with survivors. These researchers also observed that higher vitamin C concentrations on day 2 were associated with a greater risk of developing bronchopulmonary dysplasia [170]. In contrast, Moison et al [171] reported lower plasma vitamin C concentrations on day 10 in preterm infants who developed

bronchopulmonary dysplasia compared with those who did not. In a pilot observational study of very low birth weight infants, an increased risk of retinopathy of prematurity (ROP) with higher plasma vitamin C concentrations at day 7 and an increased risk of bronchopulmonary dysplasia with lower concentrations at 28 days was found [172]. In another study, Darlow et al [14] hypothesized that maintaining a lower plasma vitamin C concentration (target 35–50 mmol/L) in the first week of life and a higher concentration (target 90 mmol/L) in weeks 3–4 would be accompanied by improved clinical outcome and less morbidity (chronic lung disease and ROP) in very low birth weight infants.

146.9 Future Directions

Some advances have been made in reducing severe retinal damage due to aberrant pre-retinal neovascularization with the use of cryo- and photocoagulation therapy. Likewise, preventive measures to diminish adverse consequences of relative hyperoxia have also started to be tackled by reducing oxygen administration to premature infants. Yet, a number of issues require future investigations. These can be divided along the following lines: genetic predisposition; improved inhibition of pre-retinal neovascularization; and most importantly, preservation of retinal microvasculature (and parenchyma).

146.9.1 Genetic Predisposition

Despite the widespread exposure of premature infants to adverse risk factors, notably hyperoxia, relatively few babies develop severe forms of ROP; this infers genetic predisposition to advanced forms of ROP. So far only the Norrin gene and Frizzled-4 have been clearly associated with an increased risk for ROP [10, 173]. There is a need to identify other genetic susceptibility determinants.

146.9.2 Inhibition of Pre-retinal Neovascularization

In addition to anti-VEGF therapy, other solutions to neovascularization can be envisaged to affect vascular development and factors that trigger expression of angiogenic factors; along these lines, the role of anti-inflammatory agents and modulators of carbohydrate metabolite receptors [174], are also worth exploring.

146.9.3 Preservation of Retinal Microvasculature

Finally, it is paramount to preserve retinal microvasculature since its integrity prevents not only aberrant pre-retinal neovascularization but also retinal function. Hence, strategies suggested above regarding growth infer that IGF-1 may be an interesting potential avenue to pursue. Along the same lines, countering pro-inflammatory lipids using omega-3 fatty acids may also turn out to be effective [175]. In addition, acceleration of normal revascularization may also be a worthy approach. Finally, prevention of prematurity is a long-term goal.

Acknowledgments

Neonatal Orthopedic Surgery

Peter D. Pizzutillo and Martin J. Herman

147.1 Introduction

The physical examination of the neonate is unique and reflects stages of development. While the examination may suggest deformities of the spine and extremities, it is important to recognize physiologic variations of anatomy and growth that are characteristic of the neonate and distinguish them from pathologic anatomy. Timely recognition of clinical problems is especially important for prompt and appropriate interventions in this population. Delay in treatment of acute problems may interfere with normal limb growth and function or survival of the neonate.

147.2 Clinical Findings

While congenital anomalies of the spine or limb may not require urgent attention, they are associated with a host of anomalies involving other organ systems, such as renal, cardiovascular or spinal cord, which may require immediate evaluation and interventions. Fractures and infections are the most common clinical problems that demand early diagnosis and treatment.

In the absence of bone dysplasias, such as osteogenesis imperfecta, vaginal delivery or difficult cesarean section are associated with fractures of the clavicle, humerus, femur and injury of the cervical spine. When the infant presents with a flail upper limb, fracture of the clavicle, fracture of the proximal or distal humeral physes, brachial plexus injury or septic arthritis of the shoulder must be considered. Radiographs of the injured area may or may not confirm injury due to skeletal immaturity and incomplete ossification. Ultrasonographic evaluation of the proximal or distal humerus or proximal femur may document pathologic motion of the unossified epiphysis to confirm the diagnosis of a transphyseal fracture. Radiographs of long bones may reveal periosteal reaction that is a normal finding in 35% of infants older than 1 month and younger than 4 months of age. The periosteal reaction is characterized as regular and less than 2 mm in thickness. In the neonate, a periosteal reaction thicker than 2 mm may be associated with infection, syphilis, prostaglandin infusion, ECMO or Caffey disease. In infants older than 4 months of age, child abuse must be considered.

When more than one limb is flaccid, neonatal cervical spinal cord injury may be responsible. Injury of the cord may occur with distraction forces applied to the head. Due to the differential in plasticity of the vertebral column and the spinal cord, neurologic injury may occur without injury to the vertebral column. Radiographs of the cervical spine may appear normal and MRI would be required to diagnose injury of the cord. Complete or incomplete injury of the cervical spinal cord may present as a stillborn infant or an infant with significant neurologic deficits and delays that suggest the diagnosis of cerebral palsy. Early diagnosis is important since incomplete injury of the cord requires immobilization of the spine to prevent increasing injury.

Infection of the musculoskeletal system is of special concern in the neonate since the immature immune system may not express the expected findings of fever or abnormal laboratory studies, such as white blood cell count, ESR and CRP. Early examination of an infected joint may not reveal any signs of inflammation and may create a false sense of security that will delay diagnosis. A more common presentation of infection in the neonate includes diminished interest in feeding, irritability and decreased motion of an affected limb. Common sites of infection involve the hip, knee and shoulder joints with associated osteomyelitis. Ultrasonographic evaluation of suspected joints will confirm the presence of fluid and can guide aspiration of the joint. MRI of an infected joint is helpful to determine the coexistence of osteomyelitis. Multiple sites of infection are the rule in the neonate and effective treatment includes not only appropriate antibiotic coverage of

Table 147.1 Common musculoskeletal findings and diagnoses

Neck	Head tilted with contralateral rotation, mass in sternocleidomastoid muscle Limited neck motion, short neck (Klippel-Feil syndrome)
Arm	Swelling, tenderness clavicle (fracture) Flail arm (brachial plexus injury) Swelling, diminished movement (infection, fracture) Radial deviation of hand (TAR syndrome) Polydactyly, syndactyly
Spine	Curvature (scoliosis) Rib abnormalities (congenital scoliosis, spondylocostal dysplasia) Midline defects (myelomeningocele, spinal cord anomalies)
Hip	Positive Ortolani/Barlow (DDH) Short femur (DDH, congenital anomalies of the femur, skeletal dysplasia)
Leg	Tibial bowing Posterior apex (calcaneovalgus foot) Anterolateral apex (congenital pseudoarthrosis of tibia, fibular hemimelia) Hyperextended knee (congenital knee dislocation)
Foot	Medial midfoot crease, forefoot inward (metatarsus adductus) Fixed ankle equinus with forefoot down and inward, heel inward (clubfoot) Rocker bottom foot (congenital vertical talus) Foot dorsiflexed and touching shin (calcaneovalgus foot)

Table 147.2 Common traumatic birth injuries and their associated physical findings

Fractures	
– Clavicle	Tenderness and swelling over mid-clavicle, diminished spontaneous arm movement (pseudoparalysis) Consider congenital pseudarthrosis if right-sided
– Humerus	Upper arm swelling, crepitus, diminished spontaneous arm movement (pseudoparalysis)
– Elbow	Elbow swelling, deformity, painful and limited elbow ROM
– Femur	Thigh swelling, pain with diaper changes, limited hip ROM
Brachial plexus	
– Erb's palsy	Shoulder internal rotation, elbow extension, wrist flexion Diminished spontaneous arm movement proximal to hand
– Complete plexus injury	Flail arm without spontaneous movement Ptosis of the ipsilateral eye (Horner's syndrome)
Spinal cord injury	
– Apnea	
– No spontaneous bilateral extremity movement	
– Progressive increase in extremity tone with truncal hypotonia	
Cephalohematoma	
– Focal area of head swelling, ecchymosis	

Table 147.3 Important orthopedic diagnoses and syndromes in the NICU

Achondroplasia
- Frontal bossing, depressed nasal bridge, midface hypoplasia
- Global hypotonia
- Joint laxity
- Apnea, foramen magnum stenosis
- Thoracolumbar kyphosis
- Hip flexion contracture
- Rhizomelic short limbs

Spondylocostal Dysplasia (Jarcot-Levin syndrome)
- Prominent occiput
- Short neck
- Thoracic hypoplasia and insufficiency
- Chest wall defects, rib fusions
- Congenital scoliosis

Down syndrome
- Depressed nasal bridge, medial epicanthal folds, hypertelorism
- Simian crease
- Global hypotonia
- Joint hyperlaxity
- Hip dysplasia

Arthrogryposis
- Severe joint stiffness
- Elbow extension, wrist flexed and in ulnar deviation, fingers flexed with thumb in palm deformity
- No skin creases in antecubital fossa or palm
- Hip and knee flexion contractures
- Hip dislocations
- Severe, rigid clubfeet

Myelomeningocele
- Midline low thoracic or lumbar spine skin defects with exposed meninges
- Limited or no spontaneous movement of lower extremities
- Exaggerated reflex response in lower extremities
- Hip dislocation
- Clubfeet or congenital vertical talus

Caffey's Disease
- Diminished spontaneous arm movement (pseudoparalysis)
- Swelling of mandible or extremity, especially the ulna
- Exuberant periosteal reaction by radiographs
- Evaluation inconsistent with infection or trauma

Table 147.4 Hallmarks of musculoskeletal infection in the newborn

- Irritability, poor feeding, focal limb swelling and diminished spontaneous limb movement (pseudoparalysis)
- Most common sites: hip, knee, and shoulder
- Most common diagnoses: osteoarticular infections and cellulitis with soft tissue abscesses of the extremities
- Most common infectious agents: *Staphylococcus aureus* and gram negative bacteria
- Most common complication: joint and angular deformities and leg-length inequality

Pitfalls
1. Immature immune response may delay diagnosis and treatment
2. Osteomyelitis and septic arthritis often occur concurrently and at multiple sites
3. Bone scan is less sensitive than other imaging modalities for identifying infection; ultrasound and MRI most useful

Staphylococcus aureus and Gram negative organisms but also surgical drainage of septic joints. Repeated daily aspiration of the septic hip joint is not capable of complete evacuation of harmful inflammatory elements and is painful. Repeated aspiration of the knee or ankle may be effective, but surgical drainage of the involved hip joint is the standard of care.

147.3 Diagnosis and Syndromes

Delay in diagnosis and treatment of septic arthritis of the hip results in impaired physeal function, progressive angular deformity of the limb, limb length discrepancy and permanent destruction of the hip joint.

Developmental dysplasia of the hip (DDH) joint responds well to nonoperative intervention when treatment is initiated in infancy. Fixed dislocation of the hip, the so-called teratologic dislocation, is rare and associated with more generalized disorders, such as arthrogryposis and Larsen syndrome. DDH is associated with breech presentation and delivery, congenital muscular torticollis, foot deformities and congenital dislocation of the knee.

There are a host of musculoskeletal conditions that may be diagnosed in the neonate. Tables 147.1–147.4 provide a menu of commonly occurring problems. A high index of suspicion for occult acute clinical problems will serve the clinician well in the care of these unique patients. Specific information of each of these conditions may be readily found in textbooks of pediatric orthopedics.

Neonatal Skin Disorders

Michele Fimiani, Roberta Bilenchi, Filomena Mandato, Stefania Mei, Niccolò Nami and Rosa Maria Strangi

148.1 Neonatal Skin Structure and Functions

By the end of pregnancy, fetal skin anatomy and composition are similar to those of adults. By 22–24 weeks all anatomical elements are present, while functional and biochemical maturity takes several years to achieve (Table 148.1). There are structural differences between the skin of the preterm neonate, term neonate and adult that have significant physiological and clinical consequences [1].

The primary functions of neonatal skin are mechanical protection, thermoregulation, prevention of insensible fluid loss and immune surveillance. The skin of premature infants is thinner and much less effective in these functions. It is subject to fissuring from use of adhesives and their removal. Chemical burns from topical alcohol swabs or disinfectants, and thermal burns from transcutaneous oxygen monitoring are well-recognized problems in neonatal intensive care. Neonatal skin has increased permeability that reflects the reduced water-holding capacity of the stratum corneum. Transcutaneous absorption is increased in neonates, especially premature infants, and may lead to local and systemic side effects from topical agents such as iodine soap, hexachlorophene, benzyl alcohol and steroids (Table 148.2 and Fig. 148.1) [2]. The increased permeability of neonatal skin can also be an alternative method of drug administration. Other structural parameters that affect neonatal skin permeability are low surface lipid production, epidermal and dermal thickness due to incomplete development, and an under-developed basement membrane and papillar vasculature. Altered permeability of neonatal skin also permits transepidermal water loss from the internal environment, which can lead to extreme dehydration, and poor autonomic control of skin vessels and reduced sweating contribute to poor thermal regulation in preterm infants.

148.2 The Physical Dermatological Examination of the Newborn

It is important in the newborn, to evaluate the total skin surface including the adnexa, the oral mucosa and the genitoanal region. Dermatological examination is primarily morphologically and descriptively oriented. A good knowledge of elementary skin lesions is essential for a reliable description of dermatoses (Table 148.3).

148.3 Transient Physiologic Disorders in the Newborn

Normal physiological characteristics of newborns that reflect immaturity and transition from life in utero should be recognized and differentiated from true disease.

148.3.1 Vernix Caseosa (VC)

VC is a white waxy or cheese-like substance coating the skin of newborns. It is composed of sebum, shed lanugo and sloughed off fetal skin cells. VC is secreted by sebaceous glands around the 20th week of gestation, and decreases in amount toward the end of gestation. It is thought to protect the baby's skin from dehydration in the womb. Vernix colour and odour can reflect intrauterine problems as in hemolytic diseases (yellow-brown discoloration) or infections.

148.3.2 Rubor and Acrocyanosis (RaA)

RaA are manifestations of vasomotor instability, frequent in neonatal life. Generalized redness, reflecting vasodilatation,

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

Table 148.1 Structural differences between preterm neonate, term neonate and adult skin

	Adult	Term infant	Preterm infant (30–32 weeks)
Skin surface	Dry	Vernix	Vernix (gelatinous)
Skin thickness	2.1 mm (media)	1.2 mm	0.9 mm
Epidermal thickness	50 μm	50 μm	27.4 μm
Stratum corneum thickness	9–15 μm	9–10 μm	4–5 μm
Melanocytes	Number decreases with ageing	Number as in young adults, fewer melanosomes and low melanin production	Number as in term infants, few mature melanosomes
Dermal epidermal junction	Ridged; Antigen expressed	Flat but ridged; Antigen expressed	Flat but ridged; Antigen expressed
Anchoring filaments, fibrils and hemidesmosomes	All normal	All normal	All fewer and smaller
Papillary dermal collagen	Normal	Normal	Edematous
Reticular dermal collagen	Normal	Smaller-intermediate boundless with the hypodermis	Much smaller boundless with the hypodermis
Reticular dermal elastic fibers	Normal	Smaller in size and immature in structure	Finer than in term infants, immature in structure
Reticular dermal cell count	Fibroblasts +	Fibroblasts ++	Fibroblasts +++
Hypodermis	Well developed	Well developed	Well developed

Table 148.2 Potential dermatological and/or side/untoward effects from topical application of some skin care applied substances in newborns

Agent	Vehicle/Use	Neurologic side/Untoward effect(s)	Dermatologic side/Untoward effect(s)
Adhesives	Adhesives removal	–	Toxic epidermal necrolysis
Adhesive monitoring leads	Adhesives devices	–	Anethoderma of prematurity, skin breakdown
Alcohols	Topical antiseptic	–	Skin necrosis (expecially in immature occluded skin)
Boric acid	Diaper powder	Seizures	Erythrodermia
Corticosteroids	Topical anti-inflammatory agent	–	Skin atrophy, striae distensae
Glycerin	Emollient	Seizures	–
Hexachlorophene	Antiseptic cleanser	Vacuolar encephalopathy, seizures	–
Lidocaine	Local anesthetic	Seizures	–
Lindane	Scabicide lotion	Seizures	Rash
Neomicin	Local antibiotic	Ototoxicity, neural deafness	Conctact dermatitis
Pentachlorophenol	Laundry detergent	–	Sweating
Propylene glycol	Excipient	Seizures	–
Salicylates	Keratolytic ointment	Encephalopathy	–
Silver sufadiazine	Topical antibacterial	Kernicterus	Argyria
Tincture of benzoine	Antiseptic	–	Skin breakdown
Triclosan	Topical antibacterial	–	Conctact dermatitis

Fig. 148.1 Severe acute irritant dermatitis in a newborn, with erosive lesions of the perianal zone

is often present at the birth, associated with peripheral acrocyanosis. Acrocyanosis has no pathologic significance and gradually disappears after several weeks. It presents as bilateral, symmetric, intermittent bluish discoloration of the hands and feet.

148.3.3 Cutis Marmorata (CM)

CM is a transient benign reticulate bluish discoloration of the skin occurring in preterm and full-term infants, due to an exaggerated vasomotor response to hypothermic stress. It disappears after warming the infant and resolves after a few weeks. Profound or persistent CM has been reported in

Table 148.3 Lesions in dermatological semeiology

Type	Description or definition
Erythema (P)	Redness of the skin caused by dilatation and congestion of the capillaries
Wheal (P)	Skin elevation caused by swelling that can be itchy and usually disappears soon after erupting
Papule (P)	Circumscribed solid, raised lesion less than in 1 cm across A patch of closely grouped papules more than in 1 cm across is called a plaque
Nodule (P)	Circumscribed solid lesion with distinct edges usually more deeply rooted than a papule
Vesicle (P)	Circumscribed raised lesion less than 5 mm across filled with a clear fluid
Bulla (P)	Circumscribed raised lesion more than 5 mm across and filled with a clear fluid
Pustule (P/S)	Circumscribed raised lesion filled with purulent fluid
Macule (P/S)	Not palpable small, usually circumscribed brown, white, or red flat spot less than in 1 cm in diameter
Erosion (S)	Lesion that involves loss of the epidermis healing without scarring
Ulcer (S)	Lesion that involves loss of the upper portion of the skin (epidermis) and part of the lower portion (dermis) healing with scarring
Crust (S)	Dried collection of blood, serum, or pus overlying an impaired epidermis
Fissure (S)	Linear painful loss of skin
Lichenification (P/S)	Rough, thick epidermis with exaggerated skin lines
Atrophy (S)	Area of very thin and wrinkled skin
Scar (S)	Discolored, permanent fibrous tissue that replaces normal skin after destruction of the dermis

P primary, *S* secondary.

trisomy 21, trisomy 18, hypothyroidism, Cornelia de Lange syndrome and neonatal lupus. Differential diagnosis includes cutis marmorata telangiectatica congenita, a persistent vascular anomaly that presents at birth with marked purple reticular discoloration that may be segmental or diffuse. Associated features are skin atrophy, telangectasias, phlebectasias and ulcerations (Fig. 148.2).

Fig. 148.2 Cutis marmorata of the lower limbs

148.3.4 Harlequin Color Change (HCC)

HCC is a harmless vascular phenomenon characterized by a transient pink to reddish discoloration that occurs in a symmetric half of an infant's body shortly after birth. Due to immaturity of the hypothalamus and inconsistent regulation of peripheral vessels, it affects 10% of newborns. It is most common in low birthweight infants. It appears as an episodic skin color change after lying on the side: a sharp line from the forehead to the pubis divides the neonate body into two vertical halves. One side turns dark red (dependent side), the other quite pale [3]. Episodes last for up to 20 minutes and disappear with movement or crying. No intervention or investigation is required.

148.3.5 Linea Nigra and Genital Hyperpigmentation (LNGH)

LNGH is a common finding in newborns, especially those with pigmented skin. The presence of linea nigra seems to be influenced by maternal hormone levels. It disappears gradually over several weeks.

148.3.6 Physiological Lanugo

Lanugo is the first body hair formed in the embryo. It is fine and soft without pigment and is usually shed in utero at 28–32 weeks of gestation. Preterm infants may show profuse lanugo on the face, limbs and trunk that is shed in the first few months of life. Congenital hypertrichosis lanuginosa (ChL) is a very rare inherited syndrome characterised by confluent, generalized overgrowth of silvery blonde to grey lanugo at birth or in early infancy. ChL continues to grow and persists throughout life. Differential diagnosis of increased neonatal hair includes several rare genetically determined disorders.

148.3.7 Transient Neonatal Conditions (Miscellaneous)

148.3.7.1 Milia

Milia are tiny keratin-filled lesions due to retention cysts of pilosebaceous follicles. Common in newborn babies, they manifest as uniform, superficial, pearly white to yellowish

domed lesions measuring 1–2 mm in diameter, usually situated around the nose and eyes and sometimes on the genitalia. Milia may also be a feature of a number of very rare genodermatoses (e.g., Bazex-Dupré-Christol syndrome). In neonatesm milia often disappear within 2–4 weeks. Persistent milia have been reported as familial disorders with autosomal dominant inheritance (Fig. 148.3).

148.3.7.2 Sebaceous Hyperplasia (SH)

SH is a common, transient, benign condition of the sebaceous glands, caused by exposure to maternal androgens in uterus. The lesions may appear as small (1–3 mm), superficial yellow-pink papules with a central pore almost always located on the tip of the nose (Fig. 148.4).

148.3.7.3 Sucking Blisters (SB)

Neonatal SB appear as unilateral or symmetrical bullae or erosions involving the upper extremities. They are self-inflicted trauma due to intrauterine sucking. The lesions are present at birth, most often on the dorsal and lateral aspects of the wrist or forearm. The infant exhibits excessive sucking. The number and the location of the lesions are diagnostic.

148.3.7.4 Subcutaneous Fat Necrosis of the Newborn (SCFN)

SCFN is an uncommon disorder characterized by firm, erythematous, painless nodules and plaques over the trunk, arms, buttocks, thighs and cheeks, manifest in full-term newborns in the first few weeks of life. SCFN is usually self-limiting, but may be complicated by hypercalcemia and other metabolic abnormalities. The pathogenesis is not known. Cold or stress-induced injury of immature fat is thought to lead to solidification and necrosis. No other organ systems are involved, unless hypercalcemia develops. Differential diagnosis is from a deep hemangioma, lipogranulomatosis, plexiform neurofibroma, and sarcoma.

148.4 Neonatal Disorders with Pustules, Blisters, Erosions and Scaly-Crusts

Vesicular and pustular disorders are common during the first months of life. Most are benign, often transient, but several serious infectious and non-infectious diseases can present in neonates. They can be diagnosed clinically because of their distinctive appearances; some cases may require simple investigations including microscopic examination of the pustule content, culture and skin biopsy.

148.4.1 Transient Sterile Pustular Disorders in Newborns

148.4.1.1 Toxic Erythema of the Newborn

This is a benign, asymptomatic skin condition occurring within 24–48 hours after birth and disappearing spontaneously after several days. It affects 30–70% of newborns. The eruption, generally starting on the trunk, is characterized by small erythematous papules, vesicles and occasionally pustules, usually surrounded by a distinctive, diffuse, blotchy, erythematous halo (Fig. 148.5). Individual lesions disappear within hours and then appear elsewhere on the body. Wright-Giemsa (WG) staining of the pustular smear reveals eosinophils. The etiology is unknown [4].

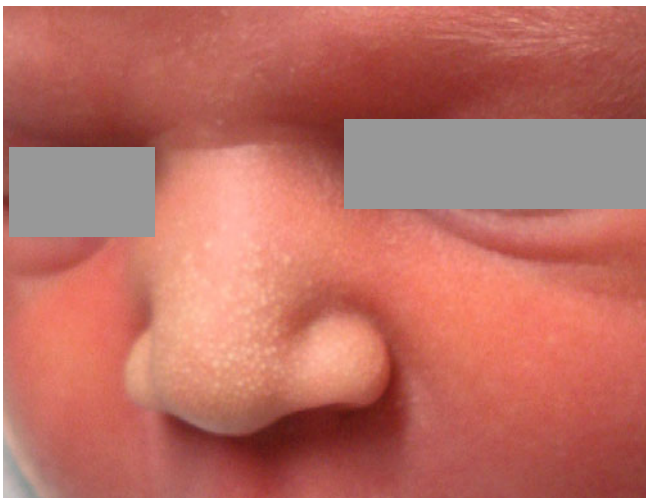

Fig. 148.4 Sebaceous hyperplasia of the nose

Fig. 148.3 Milia on the cheek of a newborn

Fig. 148.5 Erythema patches and small pustular lesions of the trunk in a 3 days old newborn affected by toxic erythema

148.4.1.2 Transient Neonatal Pustular Melanosis (TNPM)

TNPM is a benign, asymptomatic, self-limiting skin condition with distinctive features characterized by vesicles, superficial pustules and pigmented macules. The lesions are generally present at birth on the chin, neck, forehead, chest and back especially in black neonates. The palms and soles are seldom involved. No systemic signs are associated with the skin eruptions. The vesicles and pustules clear up within 48 hours, while the brown macules persist for several months. Etiology is unknown. WG staining of a smear reveals many neutrophils without evidence of changes due to bacteria, yeast or viruses.

148.4.1.3 Infantile Acropustulosis (IA)

IA is a rare benign idiopathic disorder characterized by recurrent crops of 1–2 mm intensely itchy vesiculo-pustules found on the distal extremities of newborns or early infants. It is more common in black infants. Permanent recovery occurs around 2–3 years. WG staining of a smear reveals polymorphonuclear and eosinophilic leucocytes. The duration of recurrent crops is shortened by topical steroids.

148.4.1.4 Eosinophilic Pustulosis

This relatively rare disorder is characterised by recurrent crops of itchy follicular papulo-pustules located primarily on the scalp but also on the face, trunk and extremities. The pustules may be present at birth or may occur during the first few months of life and show peripheral extension with crusts and central clearing. The disorder may last days to weeks or relapse over years. WG staining of a pustular smear shows polymorphonuclear and eosinophilic leucocytes without evidence of changes due to bacteria, yeast or viruses. There may be a peripheral leukocytosis and eosinophilia. Most cases respond to topical corticosteroids.

148.4.1.5 Miliaria (M)

M is a disorder of the eccrine sweat glands that often occurs under hot humid conditions. Although it affects people of all ages, it is especially common in children and infants due to underdevelopment of their sweat glands. M is caused by blockage of the sweat glands and can be classified according to the level at which obstruction occurs: M cristallina, M rubra and M profunda. The most common form in newborns is M rubra provoking a local inflammatory reaction and the typical redness and blister-like lesions. When pustules develop in lesions of M rubra, the term miliaria pustulosa is used. M usually affects neonates aged 1–3 weeks. Superficial clear vesicles of M cristallina occurs in often confluent crops, without any surrounding erythema. Lesions tend to occur on the head, neck and upper trunk. The disorder clears up spontaneously in few days with superficial branny desquamation.

148.4.1.6 Neonatal Cephalic Pustulosis (NCP) and Neonatal Acne (NA)

NA is a true comedonal and papulopustular acne induced by maternal hormones that cause excessive facial sebum production in infants. NCP is a newer entity, consisting of a pustular condition of the head (face and/or scalp) without comedones, often occurring during the third week of life, thought to be caused by overgrowth of various *Malassezia*. NCP usually clears up without treatment in a few weeks [5].

148.5 Infective Diseases Characterized by Pustules, Blisters, Erosions and Crusts

148.5.1 Varicella (Chickenpox)

Infections due to Varicella-zoster virus (VZV) are rare before 6 months of age. Varicella of newborns is serious and potentially fatal, manifesting with disseminated red spots developing into papules and then rapidly into vesicles and pustules that finally form a scab after a few days. Congenital varicella can present with erosive lesions, but often typical depressed, pigmented or hypopigmented, cicatrized lesions are evident (Table 148.4). When varicella occurs from 8 days before delivery to 2 days after delivery, the baby may develop diffuse skin eruptions with necrotic ulcerated or hemorrhagic lesions [6].

148.5.2 Herpes Simplex

Neonatal Herpes simplex virus (HSV) infection occurs in 0.1–0.5% of live births. HSV-2 is responsible for about 70%

Table 148.4 Clinical manifestations of congenital varicella syndrome

Skin (76%)
- Dermatomal scarring
- Cutaneous defects
- Hypopigmentation

Nervous system (60%)
- Intrauterine encephalitis
- Cortical atrophy/porencephaly
- Seizures
- Mental retardation
- Autonomic instability

Eyes (51%)
- Chorioretinitis
- Cataracts
- Microphthalmia
- Horner syndrome
- Nystagmus
- Anisocoria

Musculoskeletal (49%)
- Limb/muscle hypoplasia

Other
- Intrauterine growth restriction
- Developmental delay
- Cardiovascular defects
- Gastrointestinal reflux
- Hydroureter
- Hydronephrosis
- Neurogenic bladder
- Early death

of cases and the rest are caused by HSV-1. HSV-2 infections generally result from contact with maternal genital secretions during delivery and are mostly due to primary genital infection acquired by the mother in late pregnancy. Transplacental transmission of the virus has been documented less often and may result in miscarriage or premature birth of a severely ill baby [7].

The symptoms in neonates have been classified into three forms. The classification has predictive value for outcome.

1. Skin-eye-mouth (SEM) manifestations without visceral or CNS involvement
2. Disseminated form (DISS) with sepsis-like symptoms, DIC and visceral involvement with or without CNS symptoms
3. CNS form without involvement of other visceral organs.

A fourth form, asymptomatic infection, can be added. The various forms are summarized in Table 148.5.

Skin lesions manifest at birth or within 24 hours in the case of infection in utero, and appear at about 7–14 days in babies who contracted the infection during delivery. Initial lesions are usually manifest on the head. Sometimes they become pustular but soon transform into erosions, which may be deep and hemorrhagic. On the palm or sole, vesicles or pustules tend to remain integral. Prognosis of disseminated forms is poor. Neurological sequelae are also frequent.

Differential diagnosis is seldom necessary (Table 148.6). The diagnosis can be confirmed by cytodiagnosis, immunofluorescence or viral culture. The treatment of choice is high-dose, prolonged acyclovir therapy.

148.5.3 Staphylococcal Scalded-Skin Syndrome (SSSS)

Staphylococcus aureus can cause a spectrum of exfoliative skin conditions ranging from localized bullous impetigo to generalised cutaneous involvement with systemic illness. SSSS generally affects neonates, infants and children under 5 years of age [8]. Skin manifestations appear several days after a local and often unapparent staphylococcus infection. Macular erythema first appears in periorificial patches, spreading to the whole skin surface in 12–24 h. The body becomes covered in large flaccid blisters that are easily ruptured. There is widespread epidermal lifting revealing large areas of red, shiny, exudative skin, resembling burns. The mucous membranes are spared. The child has edema, fever, weakness and altered general state and may die if antibiotic therapy (penicillinase-resistant semisynthetic penicillin) and fluid and electrolyte replacement are not begun immediately. When patients respond to treatment, recovery is achieved in 1–2 weeks without scarring. Pathogenesis is linked to entry of epidermolytic

Table 148.5 Herpes simplex virus infection in neonates: clinical presentation, mortality and morbidity. Modified from [8] and [9]

Neonatal disease	Cutaneous lesions	Visceral involvement	Vesicles at onset	Age of onset	Mortality	Disability
Skin-eye-mouth disease	Vesicles in skin, mouth or conjunctive, cornea	None	All cases	5–11 days	0%	0%
Disseminated disease	Vesicles	Sepsis-like jaundice, clotting disorders, pneumonia, hepatomegaly, DIC (meningoencephalitis)	20%	5–11 days	29%	13%
CNS disease	Vesicles	Seizures, Lethargy, Fever	50%	2–4 weeks	4%	70%
Congenital	Vesicles, scarring of skin	Brain damage, microcephaly, low birthweight	Vesicles or scars	At delivery	?	100%
Asymptomatic infection	–	–	–	–	–	–

Table 148.6 Differential diagnosis of herpes simplex virus infections in newborns

– Mechanobullous disease

toxins (ET-A and ET-B) of *S. aureus* into the bloodstream [9]. Diagnosis is generally helped by the typical appearance of the syndrome, but in newborns it is necessary to distinguish scaly and eczematous erythrodermal syndromes.

148.5.4 Cutaneous Fungal Infection

Cutaneous fungal infections are quite common in newborns. The more premature the newborn, the greater the risk [10]. Clinical manifestations can be the result of infection with *Candida* species or of skin colonization with *Malassezia* species; cutaneous infection with other fungal pathogens is rare (Table 148.7). Immunocompromised and premature neonates, however, are susceptible to infection with opportunistic pathogens such as *Mucor* and *Aspergillus* species and are at higher risk of invasive infection by common pathogens such as *Candida*.

148.5.4.1 *Candida* spp

Candida albicans accounts for the majority of Candida infections in neonates.

Congenital candidiasis is acquired in utero from previous candida chorioamnionitis and generally presents at birth or in the first 2 days of life with a variety of clinical features, ranging from monilial diaper dermatitis, diffuse eruption of pustules and papulovesicles on an erythematous and scaling base with widespread erosions, to a burn-like dermatitis followed by peeling. It is generally not accompanied by thrush. The palms and soles may be involved, and onychomycosis and paronychia have been reported. In healthy full-term infants, congenital candidiasis is a benign condition that can be treated with topical antifungal agents or no therapy at all. Premature infants may present with systemic infections and widespread dermatitis. In such cases, systemic therapy is required (Amphotericin B, fluconazole or itraconazole) [11].

Neonatal candidiasis is acquired during delivery or later from nursery contacts. It usually appears after the fifth day of life and commonly manifests as oral thrush or diaper dermatitis. The typical presentation is erythematous patches with satellite papules and pustules, and scaling in intertriginous areas. Invasive fungal dermatitis presents predominantly in very low birth-weight infants as diffuse erosive, crusted and sometimes necrotic dermatitis. This condition is often fatal [12].

Table 148.7 Clinical presentation of uncommon fungal infections in neonates

Dermatophytes (*Tricophyton rubrum*, *T. tonsurans*, *T. mentagrophytes*, *Microsporum canis*, *Epidermophyton floccosum*)	Tinea corporis (scaly erythematous annular patches, with papulopustular component), tinea facei, tinea capitis (scaling erythematous scalp eruption with or without alopecia), tinea diaper dermatitis
Malassezia species (*M. furfur*, *M. sympodialis*)	Neonatal cephalic pustulosis (self limiting eruption characterized by scattered erythematous papules and pustules on the face, scalp and neck, without comedos or follicular localization) or invasive fungal disease (septicaemia and pneumonia)
Aspergillus species	Primary cutaneous infection (erythematous papules or plaques, evolving to necrotic skin lesions) or systemic infection (often fatal, may involve gastrointestinal, pulmonary and central nervous system), especially in VLBW and immuno compromised neonates
Zygomycetes (*Rhizopus*, *Mucor*, *Rhizomucor*, *Absidia*)	Primary cutaneous infection (erythematous papules, nodules or plaques, progressing to necrosis and crusted eschars) or systemic infection (often fatal, may involve gastrointestinal, pulmonary and central nervous system), especially in VLBW and immunocompromised neonates

148.5.5 Scabies

The pathognomonic skin lesion of scabies is the burrow, a white-greyish linear or tortuous ridge, with a small vesicle at the end. Several non-pathognomonic lesions can also be observed: 1–2 mm inflammatory papules, vesicles, pustules, crusts and, if the patient is not treated, red-brown nodules. These last lesions may persist for several weeks after successful therapy and represent a hypersensitivity reaction to the mite and its products. Neonatal scabies, is often characterized by a more or less diffuse and polymorphic eruption of inflammatory papules, vesicles, pustules, crusts and nodules also involving areas normally spared in adults and older children, such as the face, scalp, palms and soles [13]. Pruritus is usually absent. The nails may be involved. A frequent complication is impetiginization of lesions. The demonstration of *Sarcoptes*

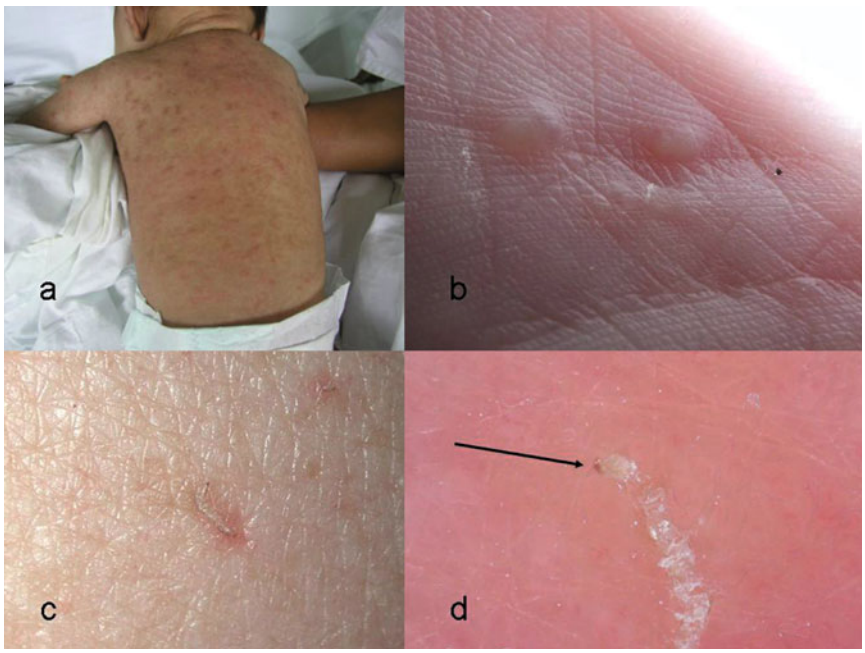

Fig. 148.6 **a** Neonatal scabies diffuse to the trunk. **b** Vesicles and scales of the palm. **c** A detail of a burrow. **d** Dermoscopic features of burrow, note the mite at the end of the burrow (*arrow)*

scabiei mites, eggs, or fecal pellets is diagnostic. A superficial scraping followed by microscopic observation of the skin samples after application of potassium hydroxide preparation seems to be the most sensible method. Dermoscopy, a new non-invasive technique is very useful in newborns, because it allows, if well performed, rapid identification of the burrows and the mite at the end of it (Fig. 148.6).

Permetrin 5% cream is regarded as a safe drug which is recommended for scabies therapy of newborn and preterm infants [14]. The parents must be treated too.

Table 148.8 Differential diagnosis of impetigo in newborns

- Neonatal syphilis
- Bullous epidermolysis
- Incontinentia pigmenti
- Neonatal pustulosis (congenital candidiasis, toxic erythema, transient pustular melanosis)
- Infantile acropustulosis
- Profuse scabies of unweaned babies
- Sweat retention syndromes

148.5.6 Bullous Impetigo

This is the most superficial form of pyoderma. In newborns and nursing babies *Staphylococcus* infection is common, manifesting with vesicobullous lesions containing serum, germs and polymorphonuclear neutrophils, which soon become pustules that erode and form yellowish brown crusts. Lesions generally start from the periumbilical regions, spreading to the trunk, scalp and exposed skin due to frequent self-inoculation from the hands. Diagnosis is generally straightforward, though in newborns various diagnoses must be considered (Table 148.8).

148.5.7 Congenital Syphilis (CS)

Syphilis is a sexually transmitted infection, caused by the bacterium *Treponema pallidum*. Vertical transmission is usually transplacental and can occur at any time during pregnancy and at any stage of disease. It is particularly likely during the first two years of the mother's infection. Pregnancies complicated by syphilis may result in intrauterine growth restriction, non-immune hydrops fetalis, stillbirth, preterm delivery, and CS.

CS occurs in over 60% of infants born to untreated infected mothers. The timing of infection in utero impacts whether early signs are present at birth. For live-born infants, CS is divided into early or late disease depending on whether it presents before or after 2 years of age. Two-thirds of infants with CS are asymptomatic at birth, but signs appear within 3–8 weeks after birth. Neonates born with overt manifestations of infection at delivery are usually severely affected and with a poor prognosis. Lesions are usually inflammatory and exudative. Early manifestations of CS involving multiple organ systems are described in Tables 148.9 and 148.10. Neonates show irritability, failure to gain weight or failure to thrive and nonspecific fever. The most striking lesions affect the mucocutaneous tissues and bones [15]. Dermatological findings are quite variable, although palmar/plantar, perioral, and anogenital regions are classically involved. Mucous

Table 148.9 Clinical manifestations in early congenital syphilis (presentation before 2 years of age)

Manifestations	Incidence %
Prematurity	Depends on whether vertical transmission occurred
Jaundice	15
Hepatosplenomegaly	33–100
Generalized lymphadenopathy	20–50
Skeletal involvement (osteochondritis, epiphysitis and periostitis)	70
Neurological symptoms and signs (hydrocephalous, cranial nerve palsies)	40–60
Meningitis	10
Muco-cutaneous lesions	30–60

Table 148.10 Cutaneous lesions in early congenital syphilis (presentation before 2 years of age)

Lesions	Distribution
Ragadized mucous patches	Mouth and perianal area
Snuffles	Nose
Condilomata lata	Intertriginous and periorificial areas
Maculopapular desquamative rash	First palms and soles; then extremities, face, diaper area and trunk
Vesicular-bullous rash	Palms and soles

patches, rhinitis, and warty lesions are highly characteristic features of tegumental involvement in early CS. Smooth, round, moist mucous patches involve the mouth and perianal area. Rhinitis with profuse and occasionally bloody rhinorrhea, is invariably present in symptomatic babies. The infant may have a characteristic "old man" look with fissured lesions around the mouth. Moist, flat warty lesions (condilomata lata) may develop in intertriginous and periorificial areas. Mucocutaneous lesions usually appear between 2 and 6 weeks of age. Snuffles are followed quickly by a diffuse maculo-papular desquamative rash that involves extensive sloughing of the epithelium and begins on the palms and soles and spreads over the extremities, face, diaper area and trunk. In contrast to acquired syphilis, a vesicular rash and bullae may develop. All these lesions are highly infective. The rash appears over seven days and may remain for several months as copper-colored lesions. Screening of neonates at risk of syphilis include specific treponemal and non-treponemal studies. Serological tests that detect IgG may be positive due to passive transfer of maternal antibodies. A positive anti-treponemal EIA IgM is indicative of congenital infection. Diagnosis of CS is made when the mother of an infant has a reactive treponemal and non-treponemal serologic test with characteristic clinical findings in the infant or when *T. pallidum* is demonstrated by dark-field microscopy or immunoflorescence from placental, skin or umbilical lesions. Infants with clinical signs of illness or suggestive serologic test results also should have lumbar puncture with CSF specific analysis and long-bone X-rays. Serological tests may be negative in infants infected in late pregnancy and should be repeated. Early diagnosis and treatment with high-dose penicillin prevents late complications of syphilis.

148.6 Non-Infective Blistering and Pustular Conditions

148.6.1 Inherited Blistering Diseases

148.6.1.1 Epidermolysis Bullosa (EB)

This is a group of rare inherited disorders characterized by blister formation caused by minor frictional trauma [16]. These diseases are the result of various genetic defects in essential dermal-epidermal adhesion molecules, which anchor basal keratinocytes to the underlying papillary dermis. Thirty subtypes of EB are described and have been divided into four major forms: simplex (EBS), junctional (JEB), dystrophic (DEB) and Kindler syndrome, based on clinical findings, pattern of inheritance, presence or absence of scarring and particularly the level within which blisters arise (Table 148.11) [17, 18].

In all twelve subtypes of EBS, blistering, often congenital from passage through the birth canal, is superficial and heals without scarring. The most common subtypes are inherited in an autosomal dominant pattern. In newborns, blistering and

Table 148.11 Major EB types and subtypes

Histopathology	Major EB type	Major EB subtypes	Targeted protein(s)
Intraepidermal cleavage	EBS	Suprabasal EBS	Placophilin-1; desmoplakin; others
		Basal EBS	Keratins 5,14; plectin; α6β4 integrin
Intra-lamina lucida cleavage	JEB	Herlitz-JEB	Laminin-332 (laminin-5)
		JEB, other	Laminin-332; type XVII collagen; α6β4 integrin
Sub-lamina densa cleavage	DEB	Dominant DEB	Type VII collagen
		Recessive DEB	Type VII collagen
Mixed	Kindler syndrome	–	Kindlin-1

EB epidermolysis bullosa, *EBS* epidermolysis bullosa simplex, *JEB* junctional epidermolysis bullosa, *DEB* dystrophic epidermolysis bullosa.

Fig.148.7 A blister of the big toe in a newborn affected by epidermolysis bullosa. Orange colour is due to topical antiseptics

large erosions primarily affect the feet, hands, neck and lower legs (Fig. 148.7). The severity of phenotypes varies greatly.

Junctional EB is an autosomal recessive disorder with seven subtypes, the most common of which is called Herlitz-JEB. This very severe variant of EB is associated with 50–80% mortality in the first two years of life. These infants have massive erosions that heal very slowly, often forming thick granulation tissue. The nail plates are often absent at birth, replaced by abundant granulation tissue. These infants are prone to infection, electrolyte imbalance, temperature instability, and high metabolic demand. Airway disease, growth retardation, eye problems and gastrointestinal diseases are often associated [19].

Dystrophic EB is an inherited autosomal dominant and recessive. In the latter form, much more severe, widespread blistering begins at birth and results in contractures with severe scarring and milia formation due to split trough pilosebaceous or sweat ducts. Fusion of digits and autoamputations lead to classic "mitten deformities". Systemic involvement may be severe, with gastrointestinal complications being the most common. Nail changes are invariable in all forms of DEB.

Diagnosis may be established by electron microscopic examination of a new blister, immunofluorescence mapping and mutational analysis. Management of all forms of EB consists of good wound care with antibacterial creams and non-adherent dressings, prevention of trauma and prevention and treatment of infection. In severe forms, newborns should initially be nursed naked in a humified crib on non-adherent material and with barrier nursing. Nasogastric tubes, tourniquets, adhesive urine collection bags, identification bands and pacifiers should all be avoided. Some evidence of phenotypic reversion of JEB keratinocytes by somatic gene therapy has been reported recently.

148.6.1.2 Mastocytosis

The term mastocytosis denotes a heterogeneous group of disorders characterized by abnormal growth and accumulation of mast cells (MC) in one or more organ systems [20]. The diagnosis of cutaneous mastocytosis (CM) is based on typical clinical and histological skin lesions and absence of definitive criteria of systemic involvement. Most patients with CM are children and have maculopapular cutaneous mastocytosis/urticaria pigmentosa (UP) [21]. In UP, rarely present at birth, the skin shows a maculopapular rash, often with pigmented lesions, wheal and flare phenomenon with stroking and a positive "Darier's sign" (Fig. 148.8 and Tables 148.12, 148.13)

Fig. 148.8 Diffuse cutaneous mastocytosis

Table 148.12 Classification of cutaneous mastocytosis

Variants	Criteria	MC burden	Grade	Typical findings
Urticaria pigmentosa (UP) Maculopapular cutaneous mastocytosis (MPCM)	Maculopapular lesions	Low	Low	–
Subvariants:				
Typical UP	Maculopapular	Low	Low	Vast majority of cases
Plaque-form	Plaques	Low	Low	Often found in infants
Nodular	Mastocytoma-like lesions (≥2)	Low (rarely high)	Low	Rare
Telangiectasia macularis eruptiva perstans (TEMP)	Telangectasias, macules	Low	Low	Rare
Diffuse cutaneous mastocytosis (DCM)	Erythrodermic rash	Low or high	Low	More diffuse patterns
Mastocytoma of skin	Unifocal (local) tumor	Low	Low	–

Table 148.13 Proposed criteria to diagnose mastocytosis

Cutaneous mastocytosis	Typical skin lesions, typical clinical signs (UP/MPCM, DCM, mastocytoma) and positive histology with typical infiltrates of MC (diagnostic infiltrate-pattern: multi/focal or diffuse)
Systemic mast cell disease "SM criteria"	Diagnosis may be rendered if one major plus one minor or three minor criteria are fullfilled
Major criterion	Multifocal dense infiltrates of MC (>15 MC aggregating) detected in sections of bone marrow and/or of other extracutaneous organ(s) by tryptase-immunochemistry or other special stains
Minor citeria	a. In biopsy sections (of bm or other extracutaneous organs), more than 25% of the MC in the infiltrate have atypical morphology or more than 25% of MC in the aspirate smear are immature or atypical b. Mast cells co-express CD117 with CD2 and/or CD25 c. Detection of a c-kit point mutation at codon 816 in bone marrow or blood or other extracutaneous organ(s) d. Serum total tryptase persistently >20 ng/mL (not valid in case of an associated hematologic clonal non-MC lineage disease, AHNMD)

MC mast cells, *UP* urticaria pigmentosa, *MPCM* maculopapular cutaneous mastocytosis, *DCM* diffuse cutaneous mastocytoses.

[22]. Other less frequent forms of CM, diffuse cutaneous mastocytosis (DCM) and mastocytoma of the skin, are usually congenital [23, 24]. Mastocytomas appear as one or several, isolated, skin-coloured to light yellow-brown, 1–5 cm macules, nodules, or plaques, typically on the trunk or extremities (Fig. 148.9). Spontaneous or friction-induced blistering is common and bullous lesions may also develop. In diffuse cutaneous mastocytosis, a more diffuse erythtrodermic rash is found and some patients may show generalized thickening of the skin, often described as "doughy", or additional nodular lesions. Sometimes, rubbing, bullous lesions may develop. All forms of cutaneous mastocytosis improve with time, sometimes healing completely at puberty. The major mediators secreted by mast cells are histamine, heparin and prostaglandins, the effects of which account for many of the clinical features of mastocytosis. The predominant symptom in all is pruritus. Additional mediator-related symptoms include flushing, hypotension, fatigue, diarrhea, vomiting and abdominal pain.

Fig. 148.9 Solitary mastocytoma of the trunk

148.6.1.3 Incontinentia Pigmenti (IP)

IP is a rare, X-linked dominant genodermatosis, usually lethal in males. It affects the skin and its appendages, bones, eyes and central nervous system [25, 26]. Cutaneous lesions usually appear at birth or in the first days of life and have three distinct morphological stages (vesiculopustular, verrucous and pigmented) with stage one occurring in the neonatal period [27]. Initially, there are clear-to-yellow vesicles, measuring 2–4 mm, clustered in a linear configuration, mostly on the trunk and distal limbs. They may sometimes be pustular or crusted. At this stage, peripheral blood eosinophilia is often associated. Vesicular and pustular lesions are replaced within several weeks by grey to brown, linear and swirled verrucous papules and plaques, the second stage of the disease, and after years by brown to grey macular hyperpigmentation in streaks and whorls.

The diagnosis of IP is based on clinical findings [28]. It should be considered when inflammatory linear groups of vesicles are seen in a newborn female infant. Biopsy of a blister reveals a subcorneal vesicle filled with eosinophils. Lyonisation accounts for the linear pattern of this disease, typical of mosaic disorders [29]. Ocular, skin appendage, dental and skeletal abnormalities may also occur [30]. No specific treatment is required for the skin lesions, as spontaneous healing usually occurs.

148.6.1.4 Neonatal Pemphigus Vulgaris (NPV)

The term pemphigus refers to a group of diseases characterized by cutaneous or mucosal blisters and erosions, and antiepidermal autoantibodies against desmoglein 1 and desmoglein 3 [31, 32]. NPV is caused by passive transfer of maternal IgG antibodies across the placenta in pregnancy from mothers with PV or pemphigus foliaceus [33]. Lesions are usually present at birth, ranging from flaccid bullae and/or vesicles to large erosions on the whole body. Mucous membranes are rarely involved. Histopathological findings include intraepithelial blisters and acantholytic cells. Direct immunofluorescence is always positive, and indirect immunofluorescence almost always positive. Neonatal prognosis is excellent: non-corticosteroid ointments usually produce prompt epithelization of the erosive lesions and skin eruptions generally disappear within 3 weeks.

148.6.1.5 Herpes Gestationis (HG)

HG is an uncommon, autoimmune, bullous disease that appears during the second or third trimester of pregnancy [34]. It almost invariably recurs in subsequent pregnancies. Anti-180 kDa bullous pemphigoid autoantibodies are the cause. The disorder may be evident at birth or within several hours in neonates from mothers affected by HG. The skin eruption consists of red macules or papules, often progressing to vesicles or bullae. The typical rash usually starts around the umbilicus and spreads over the trunk and extremities. Rapid improvement occurs over few days with spontaneous recovery by one month of age.

148.7 Disease with Systemic Involement Presenting with Pustulas, Blistering and Erosions

148.7.1 Acrodermatitis Enteropathica (AE)

This rare autosomal recessive disease is caused by the impaired absorption of zinc in the gastrointestinal tract. Signs and symptoms of AE may be neurological-behavioral, gastrointestinal (diarrhea), ophthalmologic, infectious or dermatological. Cutaneous manifestations of zinc deficiency are obligatory and diagnostic. Skin lesions are erythematous with peripheral crusting. Margins are well defined, progressing to vesicobullous, erosive or pustular lesions. The typical distribution is periorificial and acral (Fig. 148.10). AE patients need zinc supplementation for life.

The main differential diagnoses are diaper dermatitis, chronic mucocutaneous candidiasis, atopic dermatitis, impetigo, epidermolysis bullosa, psoriasis and seborrhoeic dermatitis.

Fig. 148.10 Acrodermatitis enterophatica with perianal and genital lesions

Table 148.14 Clinical characteristics of hyper IgE syndrome

- Pustular and eczematoid rash
- Blisters
- "Cold" abscesses
- Pyogenic pneumonia
- Pneumatocoele
- Bronchiectasis
- Eczema
- Mucocutaneous candidiasis, disseminated *Cryptococcus* and *Histoplasma* infection
- Peak serum IgE > 2000 IU/mL
- Eosinophilia
- Increased incidence of lymphoma (both Hodgkin and non Hodgkin)
- Scoliosis, osteopenia, minimal trauma fractures, hyperextensibility
- Cranyosynostosis
- Arterial aneurisms
- Facial asymmetry, deep-set eyes, prominent forehead
- Retained primary dentition
- High arched palate
- Alteration of oral mucosa and tongue

148.7.2 Hyper-Immunoglobulin-E Syndrome (HIES)

Hyper-immunoglobulin-E syndrome, also called Job's syndrome, is a very rare primary immunodeficiencies , characterized by chronic eczematous dermatitis, recurrent skin and respiratory tract infections, markedly elevated serum IgE (>2000 IU/mL), and a variety of connective tissue and skeletal abnormalities (Table 148.14) [35]. In almost all cases, an eczematoid rash, first affecting the face, scalp and upper trunk and later progressing over the whole body, with papules or pustules, usually due to *S. aureus* infection, manifests in the first month of life. Blistering is a classic finding in this disease. To control the rash antibiotic prophylaxis is indicated.

148.7.3 Langerhans Cell Histiocytosis (LCH)

LCH is a rare group of disorders of the monophagocytic system, with a peak incidence at 1–4 years of age, characterized by proliferation of a distinct cell type that is CD1a, S100, CD207 positive and contains Birbeck granules in various organs. Cutaneous involvement is encountered in 50% of the cases. It includes four main clinical forms: Letterer–Siwe disease, Hand–Schuller–Christian disease, eosinophilic granuloma and congenital self-healing Langerhans-cell histiocytosis (CSHLCH). CSHLCH is the most frequent found in newborns. It presents at birth or in the neonatal period with papulonodules or less commonly with vesiculopustules and blisters. It usually affects otherwise healthy infants. Systemic involvment must be excluded anyway [36].

148.7.4 Porphyrias

The porphyrias are a group of metabolic disorders of heme biosynthesis that may present with acute neurovisceral symptoms, skin lesions or both [37]. Of the cutaneous porphyrias, erythropoietic protoporphyria (EPP), congenital erythropoietic porphyria (CEP), hepatoerythropoietic porphyria (HEP), and the hereditary form of porphyria cutanea tarda can present in infancy.

148.7.4.1 Erythropoietic Protoporphyria EPP

EPP is characterized by acute photosensitivity, with rare subepidermal bullae in exposed areas. It may occur in neonates during phototherapy. Liver disease is an uncommon, potentially fatal, complication of EPP.

148.7.4.2 Congenital Erythropoietic Porphyria (CEP)

CEP presents soon after birth with typical reddish urine, severe photosensitivity, hypertrichosis of the face and extremities, mechanical fragility leading to formation of bullae, erythrodontia and hemolytic anemia. The blisters cause scarring, dyschromia and deformations.

148.7.4.3 Hepatoerythropoietic Porphyria (HEP)

HEP appears at birth or in the first years of life. It is characterized by early severe photosensitivity resulting in bullae, erosions, crusts in sun areas and severe hypertrichosis. Patients must be protected from light by clothing, sunscreen and beta-carotene. Whenever photosensitivity is observed in a neonate, porphyrin levels in red cells, plasma, urine and faeces should be measured.

148.7.5 Skin Manifestation in Down Syndrome

Skin manifestations are rare but characteristic. There have been few reports in the literature describing crusted, erythematous, vesiculopustular eruptions associated with trisomy 21 concentrated on the face, and spreading to the trunk and extremities.

148.8 Red Scaly Skin in the Newborn

The term neonatal or infantile erythroderma denotes diffuse erythema with variable scaliness affecting more than 90% of the body surface. A number of major conditions can present with erythroderma in the neonate or young baby (Table 148.15) [38–39]. Prognosis is poor, especially in babies with immune deficiency or chronic disease (mortality 26.2%). Severe skin diseases persist in 60% of survivors [40].

148.8.1 Immunodeficiencies (ID)

Because of the protective effect of maternal immunity, congenital ID syndromes are rarely symptomatic at birth. It is now clear that what was described in the past as Leiner's disease is a phenotype of non-congenital early-onset erythroderma, diarrhea and failure to thrive.

148.8.1.1 Omenn's Syndrome

Omenn's syndrome is an autosomal recessive form of severe combined ID characterized by exfoliative erythroderma that occurs at birth or in the early neonatal period in association with diffuse alopecia, lymphadenopathy, hepatosplenomegaly, recurrent infections and failure to thrive.

148.8.1.2 Graft Versus Host Reaction

Graft versus host reaction from maternal engraftment can occur as a result of the transplacental passage of maternal lymphocytes during intrauterine or postnatal transfusions. In immunocompetent newborns, clinical manifestations are minimal, often resulting in only a transient macular rash. In contrast, in newborns with congenital ID, GVH reaction occurs within the first two or three weeks of life with fever, eosinophilia, lymphocytosis, lymphadenopathy and hepatosplenomegaly, but may be present at birth as a morbilliform rash which evolves into erythroderma [41].

In the first weeks of life, ID should be suspected in cases in which the presenting features include pruritic erythroderma combined with skin induration, nondysplastic alopecia of hair, eyelashes, and eyebrows, widespread lymphadenopathy, and deep systemic infection. Skin infiltration is strongly indicative of Omenn's syndrome or ID, although true atopic dermatitis with marked lichenification can have a similar appearance. An association with diarrhea and extreme failure to thrive should also suggest the diagnosis. Histological findings in these cases are helpful.

148.8.2 Ichthyoses

Congenital ichthyoses are a large and heterogeneous group of monogenic disorders of cornification, sometimes associated

Table 148.15 Neonatal erythroderma: more common causes and management

Disease	Clinical features	Etiology	Treatment
Infections			
SSSS	Preceding purulent infection; skin tenderness; superficial blisters; positive Nikolsky sign	Bacterial infection	Antibiotic, contact tracing
Toxic shock syndrome	Concomitant maternal infection; skin tenderness; hypotension/shock	Bacterial infection	Antibiotic, intravenous Ig
Congenital cutaneous Candidiasis	Maternal vaginal candida infection; oral cavity spared; may have paronychia and nail dystrophy	Mycological infection	Antimycotics
Ichthyoses			
Non-bullous ichthyosiform erythroderma	Collodion baby; when shed leaves disseminated ichthyosiform scaling	Transglutaminase 1 gene defect and other genetic defects	Emollients, bland keratolytic creams
Bullous ichthyosiform erythroderma	Superficial blistering and erosions; ichthyosiform erythroderma; family history; linear epidermal nevus parents or sibling	Keratine gene 1,2,10 defects	Emollients, bland keratolytic creams
Netherton's syndrome	Diarrhea; failure to thrive; atopy; sparse hair, trichorrhexis invaginata (bamboo hair)	Genetic defects	Emollients; adequate hydration
Conradi-Hunermann syndrome	Linear and swirled patterns	Genetic defects	Emollients
Drugs			
Ceftriaxone	Infection for which it was prescribed	Allergic reaction	Reversible on discontinuation
Vancomycin	"The red man syndrome" sudden hypotension and erythema	Allergic reaction	Reversible on discontinuation
Others			
Seborrhoeic dermatitis	Cradle cap, accentuation in skin folds of neck, axilla and nappy area	Multifactorial	Moisturising agents; miconazole-hydrocortisone ointment; protective cream nappy area
Atopic dermatitis	Encrusted eczema on the scalp and face; generalized eczematous skin; family history for atopy	Allergy	Weak topical steroid; systemic antibiotics if skin infected
Psoriasis	Erythematosquamous patches; can be pustular; may have positive family history	Multifactorial	Bland emollient creams, wet dressing helpful
Pityriasis rubra pilaris	Similar to psoriasis; follicular accentuation; skin thickening of palms and soles; may have positive family history	Corneification disorder	Along same lines as psoriasis
Diffuse mastocytosis	Darier's sign often with blistering	Abnormal proliferation of mastocytes	H1 and H2 antagonists; oral sodium cromoglycate; avoidance of substances with potential for mast cell degranulation

Modified from [42].

Table 148.16 Common versus rare forms of non-syndromic ichthyosis

	X-linked ichthyosis	Lamellar ichthyosis (or CIE)	Bullous ichthyosis (or EHK)
Inheritance	XR	AR	AD
First appearance	Infancy (at birth?)	At birth	At birth
Affected gene(s)	STS	TGM1, Ichthyin, ALOXE3/12B, etc	KRT 1,2,10
Histopathology	Retention hyperkeratosis	Hyperproliferative hyperkeratosis	Hyperproliferative hyperkeratosis
Cutaneous clinical features	Brown scales also on the trunk	Collodion baby; dry, scaly skin; ectropion; hypohidrosis, erythema	Intense blistering at birth, verrucous hyperkeratosis and erythema

CIE congenital ichthyosiform erythroderma, *EHK* epidemolytic hyperkeratosis, *STS* steroid sulphatase gene, *TGM1* transglutaminase 1 gene, *ALOX* lipoxygenase gene, *KRT* keratin gene.

with systemic symptoms (Table 148.16). A common feature is rough, dry scaly skin. Some patients have complex ichthyoses, with systemic manifestations, mainly involving the CNS, immune system and skeleton.

The two most common forms of ichthyosis, autosomal dominant ichthyosis vulgaris (IVU) and X-linked recessive ichthyosis (XRI) start early in life, but are not present at birth. Lamellar ichthyosis, with its variants non-bullous icthyosiform erythroderma and bullous icthyosiform erythroderma, are invariably present at birth with variable degrees of erythroderma [43].

148.8.2.1 Non-Bullous Ichthyosiform Erythroderma

Non-bullous icthyosiform erythroderma, an autosomal recessive congenital ichthyosis, is characterized by fine white-greyish scales and erythroderma. Many patients suffer from deep skin fissures, and some develop flexion contractures. About 90% of patients with non-bullous ichthyosiform erythroderma present as "collodion babies" enveloped in a glistening membrane resembling sausage skin that may produce ectropion, lip eversion, nasal obstruction, temperature instability and fluid loss. The membrane peels off in days or weeks and this may be a presentation of various forms of ichthyosis besides congenital icthyosiform erythroderma. The most severe phenotype of autosomal recessive congenital ichthyosis is "harlequin ichthyosis", in which neonates are covered with plate-like scales and massive hyperkeratosis, leading to severe disfigurement, particularly of the face. The skin soon splits forming bleeding fissures, and then peels-off leaving red scaly skin.

148.8.2.2 Bullous Ichthyosiform Erythroderma

Bullous ichthyosiform erythroderma, presents with generalised erythema and superficial blisters. Bullous lesions become less prominent as the infant grows, and may eventually disappear completely. These children later develop typical ichthyosiform hyperkeratosis, with hyperkeratosis more pronounced in the flexural areas, in which the dark, warty scales often acquire a ridged pattern with frequent maceration that causes a strong unpleasant odor.

148.8.2.3 Netherton's Syndrome

Netherton's syndrome is a complex ichthyosis with high mortality (30–40%) characterized by a triad of generalized exfoliative dermatitis, sparse hair with trichorrhexis invaginata (bamboo hair), and atopic features. It usually presents at birth as erythroderma. Patients are atopic and suffer from recurrent angio-edema and urticaria.

148.8.3 Drugs

Although many drugs can determine an erythematous maculo-papular rash, erythroderma has only been described in neonates treated with ceftriaxone and vancomycin.

148.8.4 Seborrhoeic Dermatitis (SB)

Infantile SB is a papulosquamous eruption that typically develops during the first 12 weeks of life. The characteristic feature is yellowish, inflammatory, scaling of the scalp (cradle cap), which spreads over the face, including the forehead, eyebrows, ear, and nose (Fig. 148.11). Lesions often involve skin folds of the neck, postauricular regions, midtrunk, umbilicus, axilla, and groin. The scales may be absent in the flexures, and secondary candidiasis is common.

Other forms of presentation include a psoriasiform variant or rarely erythroderma. Pityrosporum ovale is usually found in this disorder. SD is often asymptomatic and self-limiting after the early months of life. Scales on the scalp may be treated with mild baby shampoo, and a soft-bristled toothbrush.

148.8.5 Atopic Dermatitis

Although about 18% of all children develop skin symptoms within the first 4 weeks of life, this condition rarely presents in the neonatal period with an erythrodermic rash. These patients are likely to go on to difficult long-term disease. In young infants, the primary lesion of atopic eczema is

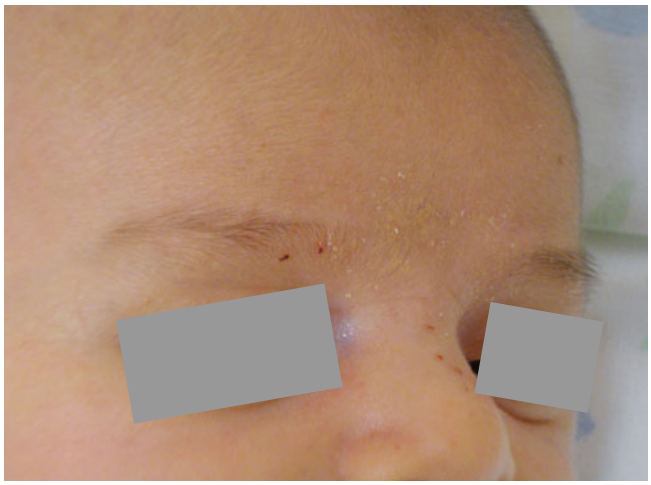

Fig. 148.11 Seborrhoeic dermatitis of the glabella in a 10 day old baby

Fig. 148.12 Flexural lesion of the upper limb in a 30 day old boy affected by atopic dermatitis

frequently vesicular and exudation is common. Atopic dermatitis more often involves the face, especially the cheeks, flexural creases of the limbs, and usually spares the nappy area (Fig. 148.12). In atopic dermatitis, itching is usually not apparent until 2–3 months of age. The total IgE and eosinophil count, usually considered to be markers of atopy, are neither constant nor specific. Management involves emollients and careful use of weak topical steroids, sometimes with wet dressing.

148.8.6 Psoriasis

Psoriasis may rarely present at birth or shortly after as generalized erythroderma, sometimes evolving into pustular psoriasis. A dramatic form of psoriasis seen in babies is napkin (diaper) psoriasis with dissemination. Starting with a bright-red napkin rash, this form of the disease later develops with small scaly patches beyond the margins. An explosive psoriasic eruption develops on the scalp and face and all over the trunk, self-limiting in a few weeks.

148.8.7 Pityriasis Rubra Pilaris (PRP)

This disease is characterized by scaly erythematous plaques similar to psoriasis and follicular hyperkeratosis. They may coalesce to larger plaques and become generalized as erythroderma. Palmoplantar keratoderma is frequently associated. Congenital erythrodermic PRP is inherited as an autosomal dominant trait and, unlike the acquired forms of PRP, tends to last a lifetime.

148.9 Neonatal Lupus Erythematosus (NLE)

NLE is a rare condition caused by transplacental passage of maternal antibodies against SS-A/Ro and SS-B/La [44]. Only 1% of infants with positive maternal autoantibodies develop NLE, when the mothers have clinical or subclinical LES, LECS or Sjogren syndrome. Most infants have heart and skin manifestations, but some may also have blood and liver involvement (Table 148.17). Skin lesions occur in the first month of life or may be present at birth. Cutaneous findings usually disappear at about the sixth month of life. Lesions resemble those of subacute cutaneous lupus erythematosus (SCLE): mild scaling erythematous plaques with well-defined margins, often annular, predominately affecting the scalp, neck and face [45]. The plaques are typically periorbital, but may appear on the trunk or extremities. In male babies they are more often crusted. Solar exposure can precipitate the eruption. In some cases, erythema spreads over the entire body. Thrombocytopenia and hepatic disease may also be common. Healing tends to be associated with mild cutaneous atrophy, with or without teleangectasia. The histologic aspect of the cutaneous lesions is similar to that of SCL. NLE is the most common cause of congenital complete heart block and is associated with significant morbidity and mortality. Treatment of the mother with corticosteroids early in pregnancy may prevent heart block.

Table 148.17 Clinical manifestations of neonatal lupus erythematosus

Organ	Clinical manifestations
Skin	– Annular-polycyclic erythematous plaques – Persistent telangiectasias, atrophy or pigmentation (less frequent) – Confluent erythema around the eyes, giving an "owl eye" or "eye mask" appearance
Heart	– Congenital heart block with or without NLE Cardiac blocks usually develop in utero between weeks 18–20 of pregnancy. Once established it is irreversible. Most surviving children require permanent pacemaker implantation – Cardiomyopathy, present in some cases usually in association with heart block, is evident at or prior to birth and is often life threatening
Blood	– Thrombocytopenia – Pancytopenia – Anemia – Neutropenia – Hypocomplementemia
Liver	– Hepatomegaly with mild elevation of aminotransferase levels – Neonatal hemochromatosis – Cholestasis with conjugated hyperbilirubinemia and minimal elevation of transaminase
Others	– Macrocephaly – Hydrocephalus – Gastrointestinal bleeding

148.10 Congenital Disorders of Melanin Pigmentation

Depigmented nevi simplex type 1 (DNS type 1) is the most frequently found white spot on newborns and infants [46]. Up to 1 in 130 otherwise healthy newborns have at least one depigmented nevus present at birth, most commonly on the trunk, usually measuring 2–3 cm. The lesions are well circumscribed with irregular borders, non-progressive, lighter than the surrounding skin but seldom white. Depigmented nevi simplex type 2 (DNS type 2) are larger than 10 cm, block-like or linear lesions, with or without whorls. They may or may not follow Blaschko lines, are usually present at birth, involve one or several body segments. There is no associated pathology.

Metameric or segmental nevi have also been described. In such cases, the main differential diagnosis is metameric or segmental vitiligo, but this condition does not occur at birth. Rarely depigmented maculae are a part of multisystemic disorders (e.g., Ito's hypomelanosis or neurocutaneous melanosis).

148.10.1 Nevus Anemicus

Nevus anemicus resemble an achromic nevus, 1–3 cm in diameter, round, slightly hypochromic and with a ragged outline. If pressure is applied with a convex glass, the nevus disappears, and if stroked, no flare is elicited.

148.10.2 Neurofibromatosis

Neurofibromatosis 1 (NF1) is a common neurocutaneous condition with autosomal dominant inheritance [47]. Some cutaneous features of NF are present at birth, others are age-related. Café-au-lait spots are usually the initial clinical manifestation of NF1 and may be present at birth or appear in infancy. They may be found anywhere on the skin but rarely on the face and scalp. They tend to increase in number and size throughout early childhood. Plexiform neurofibromas, found in at least 25% of patients with NF1 are also congenital. They feel like a bag of worms and cause gross disfigurement. They may also affect deep structures and cause pulmonary or vascular involvement. Early in life, the lesions may only be recognized as soft tissue enlargement or a patch of cutaneous hyperpigmentation with or without hypertrichosis. The other typical cutaneous findings of NF appear later.

148.10.3 Tuberous Sclerosis (TS)

The TS complex is an autosomal dominant multisystem neurocutaneous disorder characterised by widespread hamartomas in several organs, including the brain, heart, skin, eyes, kidney, lung and liver [48]. Most features of tuberous sclerosis only become evident after 3 years of age. The earliest cutaneous lesion to appear in TS is the hypopigmented macule, also called an "ash leaf" macule, frequently present at birth. These lesions often come in other shapes: they may be round, but most are polygonal, usually 0.5–2.0 cm in diameter, resembling a thumbprint. Another manifestation of TS that may be seen at birth is a hypopigmented tuft of hair. However, these findings are not pathognomonic of TS. Any newborn with a hypopigmented macule or white tuft of hair should be followed for development of the other manifestations of TS.

148.10.4 Ito's Hypomelanosis (IH)

Initially described as incontinentia pigmenti achromians, IH is a congenital multisystemic neurocutaneous disorder often characterized by neurological, musculoskeletal and eye abnormalities [49]. The disease is characterized by depigmented maculae on the limbs, where they appear as lines, and on the trunk where they appear as whorls or have a mottled appearance. These maculae appear at birth or during the first year of life. They may be asymmetric, unilateral or bilateral and may occur anywhere, except on the palms, soles and mucous membranes. No bullous or verrucous stages are seen. The skin returns to its normal colour late in childhood or early adulthood.

The most severe complications affect the central nervous system (CNS), causing mental retardation and epilepsy, which are both present in more than 50% of cases and are the two most severe and frequent disorders.

148.10.5 Piebaldism

Piebaldism is a rare autosomal dominant disorder. It is due to a defect in migration and maturation of melanoblasts from the neural crest. It is characterized by congenital, extensive and symmetrical white patches on the forehead, anterior thorax and limbs, and a tuft of white hair on the forehead. Small patches of normally pigmented skin are characteristically observed inside depigmented areas. In stable piebaldism, cutaneous depigmentation remains unchanged through life [50].

148.10.6 Albinism

Genetic abnormalities of the melanin pigment system in which the synthesis of melanin is reduced or absent are called albinism. Oculocutaneous albinism (OCA) is a group of inherited disorders of melanin biosynthesis characterized by a

generalized reduction in pigmentation of hair, skin and eyes [51]. The reduction in melanin synthesis can also be localized primarily to the eye, resulting in ocular albinism. The clinical spectrum of OCA ranges with OCA1A being the most severe type with a complete lack of melanin production throughout life. Foveal hypoplasia is invariably present and individuals with albinism often have other characteristic ocular symptoms. The degree of skin and hair hypopigmentation varies with the type of OCA but is generally reduced. The incidence of skin cancer may be increased. All four types of OCA are inherited as autosomal recessive disorders. The diagnosis is based on finding hypopigmentation of the skin and hair, in addition to ocular symptoms. Strabismus and nystagmus should be corrected and sunscreens are recommended. Regular skin checks for early detection of skin cancer should be offered. Persons with OCA have normal lifespan, development, intelligence and fertility.

148.10.7 Waardenburg Syndrom (WS)

WS is an autosomal dominant disorder classified into four types. WS type 1 is clinically characterized by dystopia canthorum, sensorineural hearing loss, congenital patches of achromic skin, white forelock, broad nasal root, synophrys, and heterochromia of irides.

148.10.8 Chediak-Higashi Syndrome (CHS)

This autosomal recessive condition is due to a gene defect localized in chromosome 1q. CHS is clinically characterized by lighter skin than parents and siblings in sunprotected skin areas, slate-gray hair, and periodic, life-threatening "accelerated phase" of systemic involvement, with fever, hepatic, splenic and lymph-node enlargement. Epstein-Barr induced malignant lymphoma is usually fatal.

148.10.9 Xeroderma Pigmentosum (XP)

XP is a rare, recessive disorder based on a deficiency in nucleotide excision repair (NER) or postreplication repair (PRR) [52]. The earliest manifestation of the disease is recognized as acute sun sensitivity. This is noted as irritability followed by prolonged erythema, edema and blistering. The severe actinic changes lead to early onset of skin cancers. Most patients do not reach adulthood, but die from metastatic cutaneous malignancies. Diagnosis can be confirmed by unscheduled DNA synthesis. XP must be distinguished from other so-called DNA repair deficiency syndromes, including Cockayne syndrome and trichothiodystrophy.

148.10.10 Neurocutaneous Melanosis (NCM)

NCM is a rare congenital phakomatosis characterized by a focal or diffuse proliferation of melanin-producing cells in both the skin and the leptomeninges [53]. This syndrome is believed to result from an error in the morphogenesis of embryonal neuroectoderm. Two-thirds of patients with NCM have giant congenital melanocytic nevi, and the remaining one-third have numerous lesions but no giant lesions. Patients may present with neurologic manifestations early in life secondary to intracranial hemorrhages, impairment of cerebrospinal fluid circulation, or malignant transformation of the melanocytes.

The prognosis of patients with symptomatic NCM is poor. In their follow-up of patients with large or multiple congenital melanocytic nevi, physicians should be aware of this condition, to aid in prompt diagnosis and treatment.

148.11 Birthmarks

148.11.1 Pigmented Birthmarks

148.11.1.1 Congenital Melanocytic Nevi (CMN)

CMN are thought to arise from disrupted migration of melanocyte precursors in the neural crest and occur in 0.2–2.1% of infants at birth. CMN have been arbitrarily divided into three size ranges, small, intermediate and giant with diameters of less than 1.5 cm (Fig. 148.13), 1.5–20 cm (Fig. 148.14) and over 20 cm, respectively. Colors range from brown to black and the commonest site is the lower back and thigh area. At birth they are often flat and pink or pale brown and most are small.

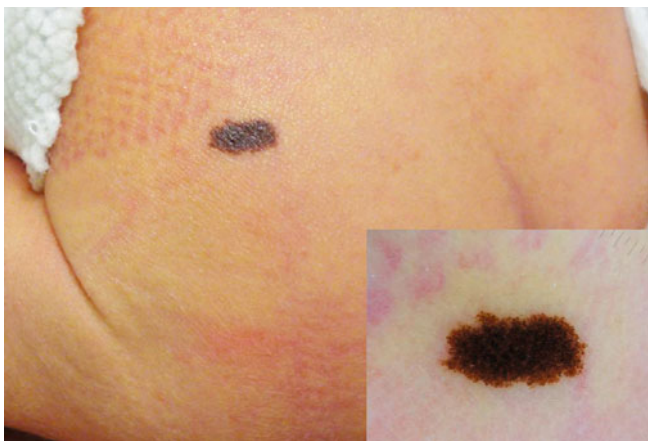

Fig. 148.13 A small (less than 1.5 cm) congenital nevus of the buttock, showing on dermoscopic evaluation an homogeneous distribution of globules (globular pattern)

Fig. 148.14 An intermediate (1.5–20 cm) congenital nevus of the cheek, showing on dermoscopic evaluation a diffuse homogeneous pattern

Giant CMN are immediately obvious at birth. They are extremely rare and darken as the infant grows, the surface often becoming rugose or warty with nodules developing within it. The hairy component, typical of 95% of lesions, tends to become more prominent at puberty. Giant CMN of the head, neck or posterior midline area may be associated with underlying neurocutaneous melanosis. Malignant potential increases with the size of lesion and the numbers of satellite nevi near the large lesion [54]. Smaller nevi are not well studied, but malignant changes in lesions projected to grow to less than 1.5 cm in adulthood, appear to occur rarely and only after puberty. There are various treatment options for the management of giant CMN: surgical excision (total or staged), exploiting grafts, tissue expanders, dermabrasion and curettage. Curettage is best performed before 2 weeks of age [55].

148.11.1.2 Use of Dermoscopy in Management of Congenital Melanocytic Nevi

Dermoscopy is a noninvasive technique that allows visualization of structures that are not visible by clinical examination. If expertly performed, it has been shown to increase diagnostic accuracy for pigmented skin lesions, especially for malignant melanoma. Dermoscopic features of congenital nevi are equally distributed between reticular, globular (Fig. 148.13) and homogeneous patterns (Fig. 148.14).

148.11.1.3 Dermal Melanocytosis (DM)

DM includes Mongolian spots, nevi of Ota and Ito and the blue nevi.

Mongolian spots are flat, blue-gray or brown lesions with poorly defined margins, that arise when melanocytes are trapped deep in the skin. These lesions may be single or multiple and generally occur on the back or buttocks, although other areas may be involved. They may easily be mistaken for bruises. They are more common in black, native American, Asian and Hispanic populations. Most lesions fade by two years of age and do not require treatment.

Nevus of Ota, a persistent patchy blue-gray discoloration of the face, is usually unilateral and often accompanied by an ipsilateral patchy blue discoloration of sclera, conjuntiva, cornea, retina or oral mucosa. It is most common in Asians and is present at birth in more than 50% of cases of associated glaucoma. Very rarely, melanoma may occur in adult life [56].

Nevi of Ito are distinguished from those of Ota for their location in the supraclavicular, scapular or deltoid regions. It may be associated with an Ota nevus with ipsilateral or bilateral distribution.

Common blue nevi are acquired dome-shaped blue-black papules measuring less than 1 cm in diameter. They are often located on the backs of the hands or feet or nearly.

148.11.1.4 Epidermal Nevi (EN)

EN are hamartomas characterized by epidermal and adnexal hyperplasia. They may be classified into distinct variants (Table 148.18). The lesions may be deeply or slightly pigmented, have unilateral or bilateral distribution and involve any area of the skin, though they are usually located on the extremities along Blaschko lines. On the face and scalp EN

Table 148.18 Epidermal nevi

Verrucous epidermal nevus	Consists of hyperplasia of the surface epidermis and typically appear as verrucous papules that coalesce to form well-demarcated, skin colored to brown, papillomatous plaques
Sebaceous nevus	Includes many of the surface findings of verrucous epidermal nevus, but also contains malformations of the dermis, most prominently, hyperplasia and malpositioning of the sebaceous glands
Nevus comedonicus	Manifests as groups of closely set, dilated follicular openings with dark keratin plugs resembling comedones
Eccrine nevus	Is a rare cutaneous condition histologically characterized by an increase in size or number of eccrine secretory coils
Apocrine nevus	Is an extremely rare cutaneous condition found more often on upper chest and axilla histologically composed of hyperplastic mature apocrine glands
Becker's nevus	First appears as an irregular pigmentation (melanosis or hyperpigmentation) on the trunk or upper arm and gradually enlarges irregularly, becoming thickened and often hairy
White sponge nevus	Consists of bilateral white keratotic macules and plaques found especially on the buccal mucosae, but labial, lingual, vaginal and rectal mucosa may be involved

Table 148.19 Types of epidermal nevus syndromes

Well-defined syndromes, based on histopathology, extracutaneous manifestations and genetic features	– Sebaceous nevus syndrome (SNS) – Nevus comedonicus syndrome (NCS) – Becker nevus syndrome (BNS) – Phakomatosis pigmentokeratotica (PPK) – Proteus syndrome – Congenital hemidysplasia with ichthyosiform nevus and limb defects (CHILD)

are yellowish due to prominent sebaceous glands and devoid of hair. They often have a linear distribution. In infancy they are flat, tending to become warty and papillomatous in puberty in response to androgens. Most EN remain stable. However, benign or malignant tumors can arise within them.

Sebaceous nevi of Jadassohn (SNJ) are a well-known congenital hamartoma of the skin and its adnexa. They can present as isolated lesions or as rare, more complex syndrome. Sebaceous nevus syndrome (SNS) is characterized by a sebaceous nevus and extracutaneous abnormalities, usually involving organs derived from the neuroectoderm. At least six different types of epidermal naevi syndromes (ENS) have been identified (Table 148.19) [57].

148.11.2 Vascular Birthmarks

Vascular birthmarks are divided into vascular tumors and vascular malformations on the basis of their cellular features, clinical characteristics and natural history. Vascular tumors, also called hemangioma, are associated with vascular proliferation and can be infantile or congenital. Vascular malformations have an initial rapid proliferative phase followed by an involutional phase and they are developmental anomalies classified according to the type of vessel involved: capillary, vein, lymphatic vessel, artery or mixed malformations. They are present at birth, grow proportionally with the child and do not spontaneously involute [58].

148.11.2.1 Vascular Tumors

Hemangiomas (Strawberry Nevi)

Hemangiomas are the most common benign vascular tumors of infancy, occurring in 1.1–2.6 % of newborns (Fig. 148.15). Females are three times more likely to have hemangiomas than male infants, and prematurity increases the risk. At birth, the lesions may vary from bright strawberry-red coloured lesions to pale patches or telangiectasiae surrounded by a blanched halo maculae. Hemangiomas may proliferate for 18 months and then begin to involute. Approximately 50% of hemangiomas disappear by five years of age, and 90% by 10 years of age. After spontaneous disappearance, there may be residual epidermal atrophy, telangiectasia, hypopigmentation or scarring [59]. Despite their benign nature, hemangiomas can be complicated by ulceration, pain, infections, hemorrhage and scarring (Fig. 148.16).

Fig. 148.15 A bright strawberry-red color hemangioma of abdomen

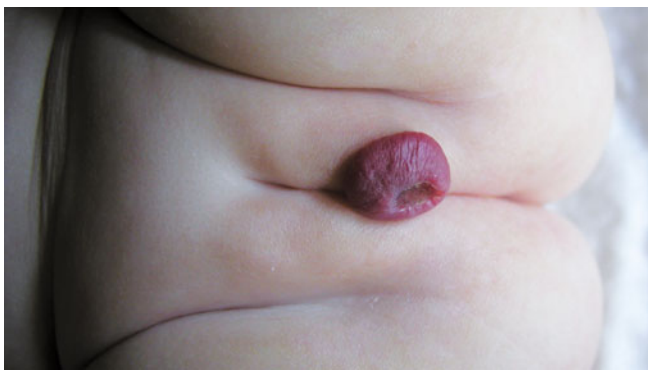

Fig. 148.16 Ulceration of a genital hemangioma

Hemangiomas that compress the eye, nose, mouth, auditory canal, or vital organs require immediate referral in the neonatal period. Uncomplicated hemangiomas should be observed with reassurance. Systemic steroids are the elective treatment for problematic proliferating hemangiomas. Propranolol may be a promising new treatment for life-threatening hemangiomas [60]. Laser treatment is also an option if the lesion threatens to interfere with the airway or the ocular axis.

Kasabach-Merritt Syndrome (KMS)

KMS is a form of consumptive coagulopathy in patients with rapidly spreading hemangiomas, vascular tumors and other malformations. It consists of thrombocytopenia, which is secondary to platelet trapping within the lesions, microangiopathic hemolytic anemia and localized consumptive coagulopathy. In some cases there is a true disseminated intravascular coagulation (DIC) [61]. KMS is not associated with classical hemangiomas, but rather kaposiform hemangioendotheliomas or

tufted hemangiomas. They are usually deep red/blue and firm and have an equal male:female distribution. If untreated, KMS can be life threatening. It requires aggressive therapy, including corticosteroids, interferon-alpha, vincristine, radiation therapy and surgery. Antiplatelet drugs and transfusion of blood products can be required too.

148.11.2.2 Vascular Malformations

Capillary Malformation (Port-Wine Stains or Nevus Flammeus)

Capillary malformation is a vascular birthmark, occurring in 0.3% of newborns, composed of mature dilated capillaries in the dermis, that appear as variably sized pink to dark red maculae. The face is most frequently affected, often unilaterally (Fig. 148.17) [62]. The lesions grow proportionally with the child and tend to darken with age. Port-wine stains in the ophthalmic distribution of the trigeminal nerve are associated with ipsilateral glaucoma.

The Sturge-Weber Syndrome

The syndrome is classically defined by the triad of glaucoma, convulsions, and port-wine stains and involves angiomas of the brain and meninges. Port-wine stains in the ophthalmic branch of the trigeminal nerve distribution (V1) are a strong indication of underlying neurological and/or ocular lesions that require on-going ophthalmologic surveillance and/or neurological or neurosurgical management [63].

Nevus Simplex

Nevus simplex is a vascular birthmark that occurs in 33% of newborns. These flat, salmon-colored lesions are caused by telangiectasias in the dermis. They occur over the eyes, scalp, and neck, with a symmetric pattern and fade when compressed.

Fig. 148.17 Capillary malformation (port-wine stains or nevus flammeus) of the face in a newborn

Venous Malformations (VM)

VM are always present at birth, but they may manifest clinically later in life depending on their location. Appearances vary from a vague blue patch to a soft blue mass. When venous pressure increases, for example during crying, they usually swell, though some may remain asymptomatic throughout life. Episodic thromboses are common occur in VM, even in infants under two years of age.

Arteriovenous Malformation (AVM)

AVM is a congenital defect in which arteries and veins are tangled and not connected by capillaries. In early developmental stages, large shunts exist between future arteries and veins and a defect or arrest occurring at this stage may allow some of these connections, to persist. AVM manifests as a skin-colored mass with warm overlying skin that pulsates on auscultation. It is often asymptomatic, but symptoms depend on site. Localization in the CNS is not rare and may be associated with major neurological symptoms.

Lymphatic Malformations (LM)

LM are considered rare. There are two main types: lymphangioma and cystic hygroma. The former manifest as a group of lymphatic vessels forming a mass or lump, the latter as a large cyst or pocket of lymphatic fluid resulting from blocked lymphatic vessels. Both usually present as slowly enlarging, non-tender masses. Frequent sites are the head and neck followed by the trunk, axilla and extremities. There is a predominance of right-sided lesions. Laryngeal and oral involvement is not uncommon. In such cases and when other vital structures are involved, surgical extirpation is usually the treatment of choice [64].

148.12 Adnexal Congenital Disorders

148.12.1 Congenital Nail Disorders

The most common nail disorders in newborns and infants are listed in Table 148.20. A number of genodermatoses primarily involving the skin and mucosa are associated with more or less characteristic nail changes [65].

In epidermolysis bullosa (EB, 148.6.1.1), nail changes are seen especially in junctional and dystrophic types.

In X-linked dyskeratosis congenita, the nail plate is completely absent or hypoplastic. A pterygium formation may also be present.

Table 148.20 Nail disorders in newborns

Nail disorder	Description
Anonychia	Absence of nails; rare; may be the result of a congenital ectodermal defect or anomalies like epidermolysis bullosa, severe exfoliative diseases or infections
Micronychia	Small nail plate, shorter or narrower than normal; unusual; it is associated with syndromes or toxin exposure
Onychoschizia	Splitting of the distal nail plate into layers of the free edge. It is most noted on the big toes and thumbs, with thumb sucking being an exacerbating factor
Infantile ingrowing toenails	The thin, sharp edge of the big toenail implants into the hypertrophic lateral nail folds of the hallux. Often bilaterally, this condition improves spontaneously with age
Racket nails or brachyonychia	Nails are broad and shortened and reflect an underlying disturbance in the formation of distal phalanx
Polyonychia	Rare; several nails on the same digit due to bifurcation of the distal phalanx. A history of maternal teratogen exposure should be searched
Congenital malalignment of the great toenail	Lateral deviation of the nail plate from the longitudinal axis of the distal phalanx Spontaneous improvement occurs in approximately 50% of patients

Table 148.21 Congenital alopecia

Circumscribed alopecia	Diffuse alopecia
– Neonatal telogen effluvium – Neonatal occipital alopecia – Tinea capitis – Alopecia areata – Congenital triangular alopecia – Congenital aplasia cutis – Underlying meningocele or cystic lesion – Congenital nevi	– Alopecia areata – Marie Unna hypotrichosis – Rothmund-Thompson syndrome – Ectodermal Dysplasia – Epidermolysis bullosa

Fig. 148.18 Congenital triangular alopecia of the temporal zone

Pachyonychia congenita (PC) is a rare, autosomal dominant genodermatosis, characterized by symmetrical thickening and discoloration of the nails with a wedge-shaped, pinched-up, or claw-like appearance. Cutaneous cysts, hair abnormalities and presence of teeth at birth can be observed [66].

Nail-patella syndrome is a genodermatosis with autosomal dominant transmission associated with bone and renal disorders. The nail abnormalities recognized at birth include micronychia or anonychia, especially on the thumbs. The lunula can be triangular or V-shaped.

148.12.2 Main Causes of Alopecia in Newborns

Alopecia in newborn can be classified in circumscribed and diffuse as shown in Table 148.21. Some manifestations as neonatal occipital alopecia and telogen effluvium may be observed frequently and are considered as physiological skin changes, others are rare.

148.12.2.1 Alopecia Areata (AA)

AA is a form of non-scarring hair loss, rarely reported in the neonatal period [67].

148.12.2.2 Congenital Triangular Alopecia (CTA)

CTA is a triangular, lancet, or oval-shaped area of hair loss usually behind the fronto temporal hairline (Fig. 148.18). It may be congenital but usually appears in childhood. The hair loss may be uni- or bilateral, complete or fine vellus hairs may remain. CTA may occur as a paradominant trait.

148.12.2.3 Maria Unna Hypotrichosis (MUH)

MUH is a rare autosomal dominant pilar dysplasia, which can be seen at birth as progressive hair loss.

148.13 More Common Congenital Tumors

148.13.1 Dermoid Cyst (DC)

DC is a benign, congenital, solitary or occasionally multiple, hamartomatous tumor. It is covered in a thick dermis-like wall that contains multiple sebaceous glands and almost all skin adnexa. Hair and abundant fatty masses cover poorly to fully differentiated structures derived from the ectoderm. These growths are usually located at the midline and commonly have a deep sinus that connects to the epidermis. Common

sites include forehead, lateral eye and neck [68]. A superficial DC on the dorsal nose is referred to as a fistula and is characterized by a central tuft of hair or intracranial communication. DC can be located deep in the subcutaneous tissue, intracranially or intraorbitally. Infections, rupture and abscess formation from manipulation of DC are possible serious complications. Surgical excision is the treatment of choice in any localization.

148.13.2 Congenital Leukemia (CL)

CL associated with skin infiltration occurs in 25–30% of patients and usually presents as firm blue, red or purple nodules in a generalized distribution. CL cutis may precede other manifestations of leukemia by as much as 4 months.

148.13.3 Meningocele

Meningocele is a developmental defect related to abnormal attachment and closure of the neural tube during embryogenesis. It typically presents as a skin-coloured nodule on the scalp over the midline or along the spine. The treatment of choice is surgical excision.

148.13.4 Granuloma Gluteale Infantum (GGI)

GGI is a benign granulomatous eruption involving the gluteal region that may simulate a neoplastic process. It arises as a complication of primary irritant diaper dermatitis and typically resolves without treatment.

148.14 Other Skin Malformations

148.14.1 Congenital Aplasia Cutis (CAC)

CAC is a rare anomaly presenting with localized or widespread absence of skin at birth (Fig. 148.19). Lesions are commonly present as non-inflammatory ulcerated or membranous defects with well-defined borders of variable size, near the midline of the scalp vertex. Absent hair is a constant feature. Most single defects are oval-shaped and small (0.5–3 cm) and heal gradually during the first week after birth, leaving a residual atrophic or hypertrophic scar with alopecia [69].

For extensive scalp defects, which may extend to and involve the dura mater, differential diagnoses include: scalp infection, small meningocele, heterotopic brain or glial tissue, traumatic lesions, "en coup de sabre" morphea, sebaceous nevus, herpes simplex type 2, incontinentia pigmenti and epidermolysis bullosa. The condition may be associated with specific teratogens, intrauterine infections, epidermolysis bullosa, chromosomal abnormalities, ectodermal dysplasia, or other syndromes of malformation (Table 148.22) [70].

Fig. 148.19 Congenital aplasia cutis (courtesy of Dr. MC Muraca)

Table 148.22 Systemic distribution of associated findings of aplasia cutis congenita

Central nervous system	– Hydrocephaly – Meningocele – Spastic paralysis and mental retardation – Occult spinal dysraphism
Cardiovascular System	– Arterovenous malformation – Coarctation of aorta – Congenital heart defects
Gastrointestinal System	– Cleft lip- palate – Intestinal lymphangiectasia – Omphalocele
Eyes	– Myopia and cone-rod dysfunction – Oculo-ectodermal syndrome
Miscellaneous	– Ventral body wall and/or neural tube closure defects – Cutis marmorata – Piebaldism

148.14.2 Supernumerary Nipples (SN)

SN are a common congenital malformation with male predominance, consisting of extra nipples and/or related tissue besides the two nipples normally appearing on the chest. They are usually located along the embryonic milk line. Sometimes pigmented, they may be mistaken for congenital melanocytic nevi.

148.14.3 Accessory Tragus (AT)

AT is a common congenital defect linked to maldevelopment of the first and second branchial arches, which appears as a

small skin-colored tag or nodule arising near the tragus. It is composed of normal epidermis with dermal adipose tissue, pilosebaceous units, eccrine glands, elastic fibers, and cartilage.

148.14.4 Branchial Cleft Cysts (BCC)

BCC are congenital epithelial cysts, which arise on the lateral part of the neck, usually near the front edge of the sternocleidomastoid muscle, from a failure of obliteration of branchial cleft in embryonic development [71]. BCC are the most common of congenital neck masses and they are bilateral in about 2–3% of the cases. Usually asymptomatic, but, if infected, they may form a deep neck abscess or a draining fistula. Depending on the size and the anatomical extension of the mass dysphagia, dysphonia, dyspnea, and stridor, may occur.

Surgery is indicated for branchial anomalies because of lack of spontaneous regression, a high rate of recurrent infection and rare malignant degeneration.

Fig. 148.20 Amniotic band syndrome (ABS) caused by entrapment of lower limb in fibrous amniotic bands during intrauterine life

148.14.5 Amniotic Band Syndrome (ABS)

ABS is a rare congenital disorder caused by entrapment of fetal parts (usually a limb or digits) in fibrous amniotic bands during intrauterine life [72]. Prognosis depends on the location and severity of the constricting bands. In mild cases, a band may result in amputations of the fingers or toes, or syndactyly (Fig. 148.20). In more severe cases, an amniotic band can become extremely constrictive leading to decreased blood supply and possible amputation of the limb. The most severe, and life-threatening complication of amniotic band syndrome is fetal death, if a band becomes wrapped around vital areas such as the head or umbilical cord.

Appendix B C reactive protein and procalcitonin: Reference intervals for preterm and term newborns during the early neonatal period

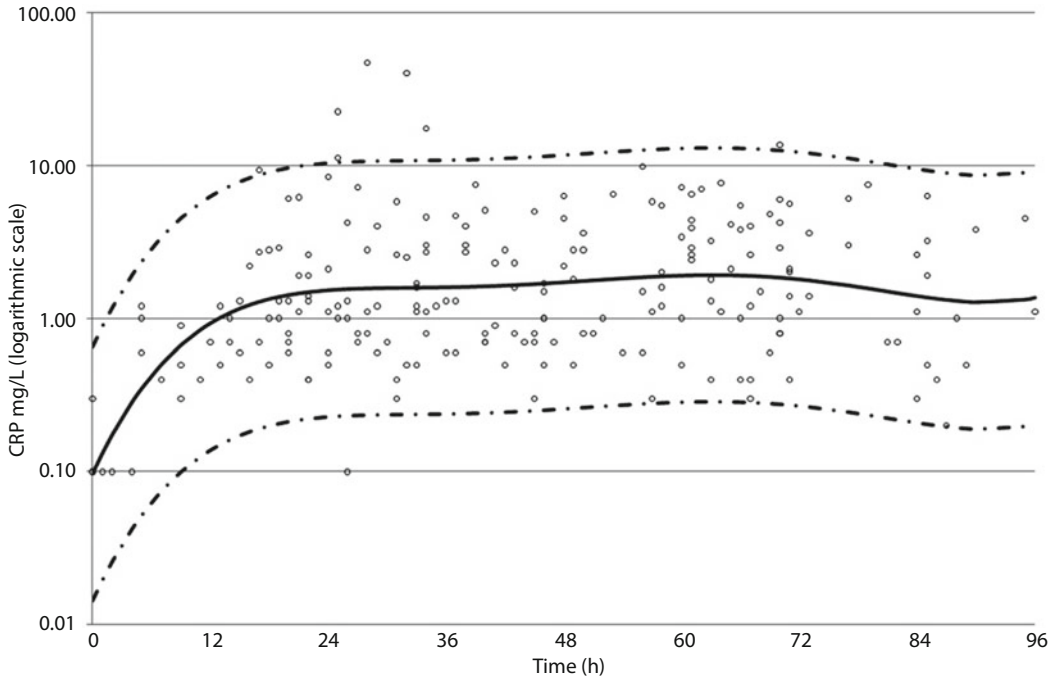

Figure B1 Age-specific 95% reference intervals for C reactive protein (CRP) in healthy term neonates from birth to 96 h of life. The circles represent single values; the dotted lines represent lower and upper limits; the bold line represents the predicted geometric mean

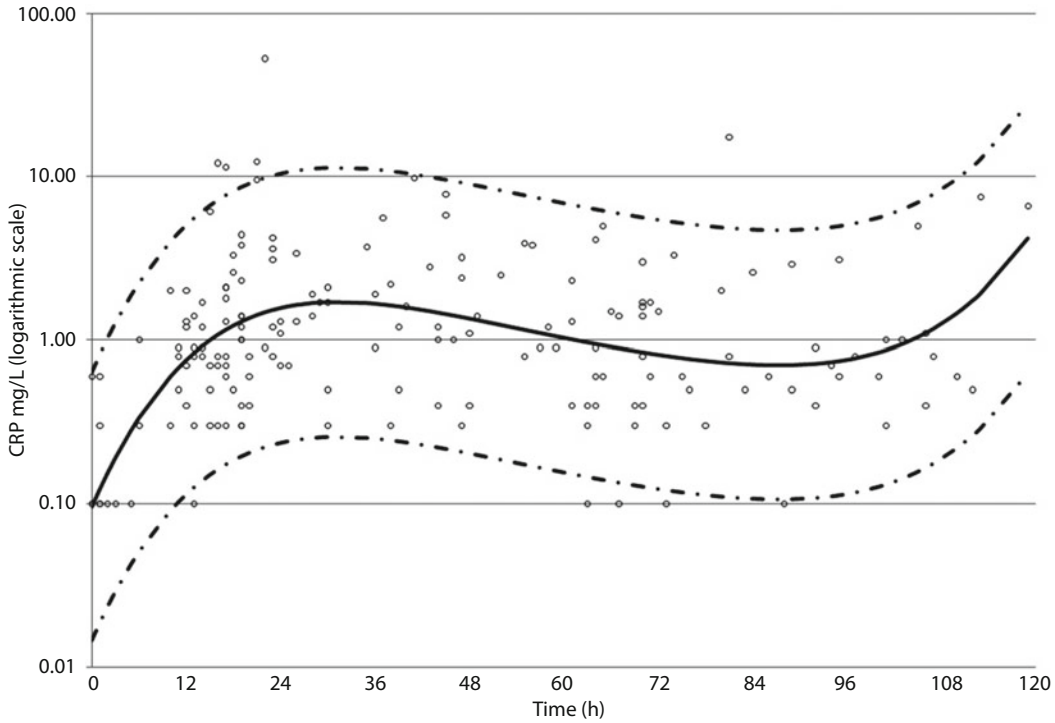

Figure B2 Age-specific 95% reference intervals for C reactive protein (CRP) in healthy preterm neonates from birth to 120 h of life. The circles represent single values; the dotted lines represent lower and upper limits; the bold line represents the predicted geometric mean

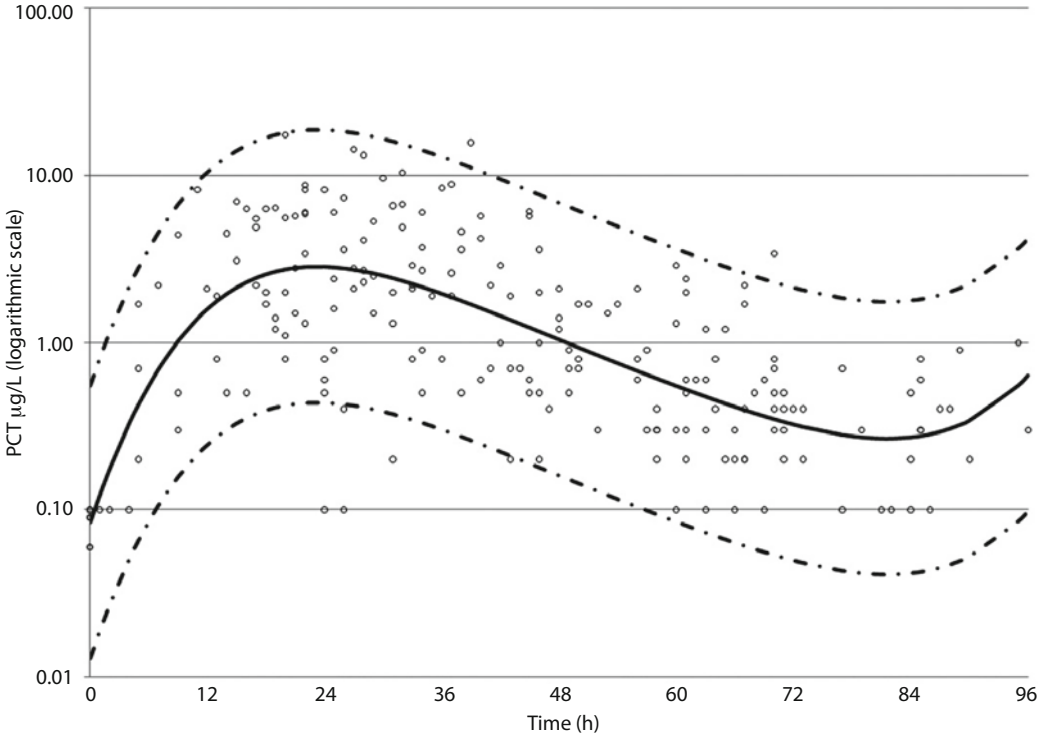

Figure B3 Age-specific 95% reference intervals for procalcitonin (PCT) in healthy term neonates from birth to 96 h of life. The circles represent single values; the dotted lines represent lower and upper limits; the bold line represents the predicted geometric mean

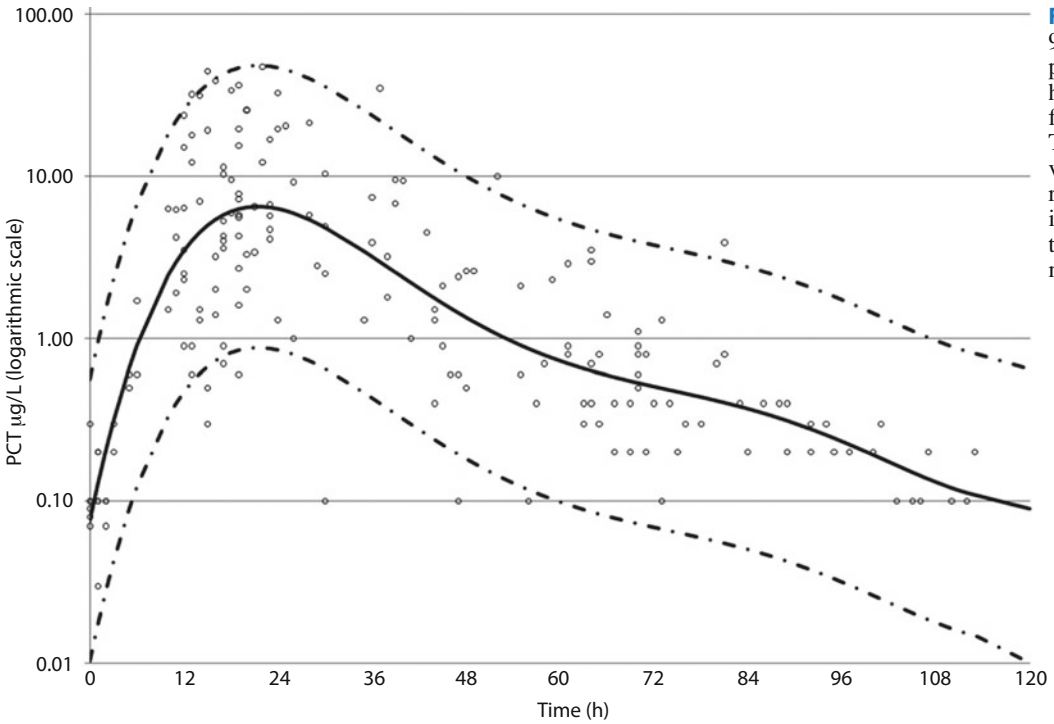

Figure B4 Age-specific 95% reference intervals for procalcitonin (PCT) in healthy preterm neonates from birth to 120 h of life. The circles represent single values; the dotted lines represent lower and upper limits; the bold line represents the predicted geometric mean

Appendix C Distribution of neonatal birth weight, body lenght and head circumference

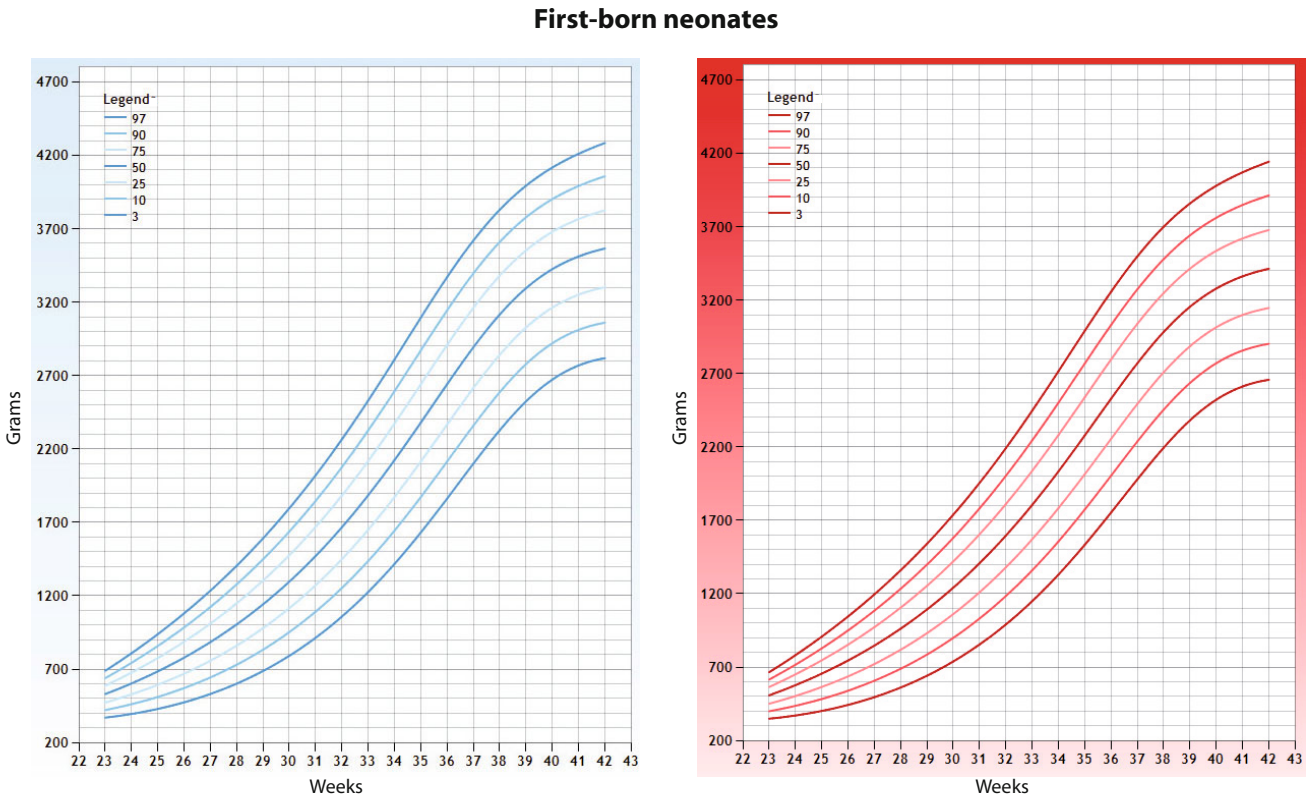

Figure C1 Distribution of birth weight in first-born neonates (*left* boys, *right* girls) for 3rd to 97th centiles (see legend)

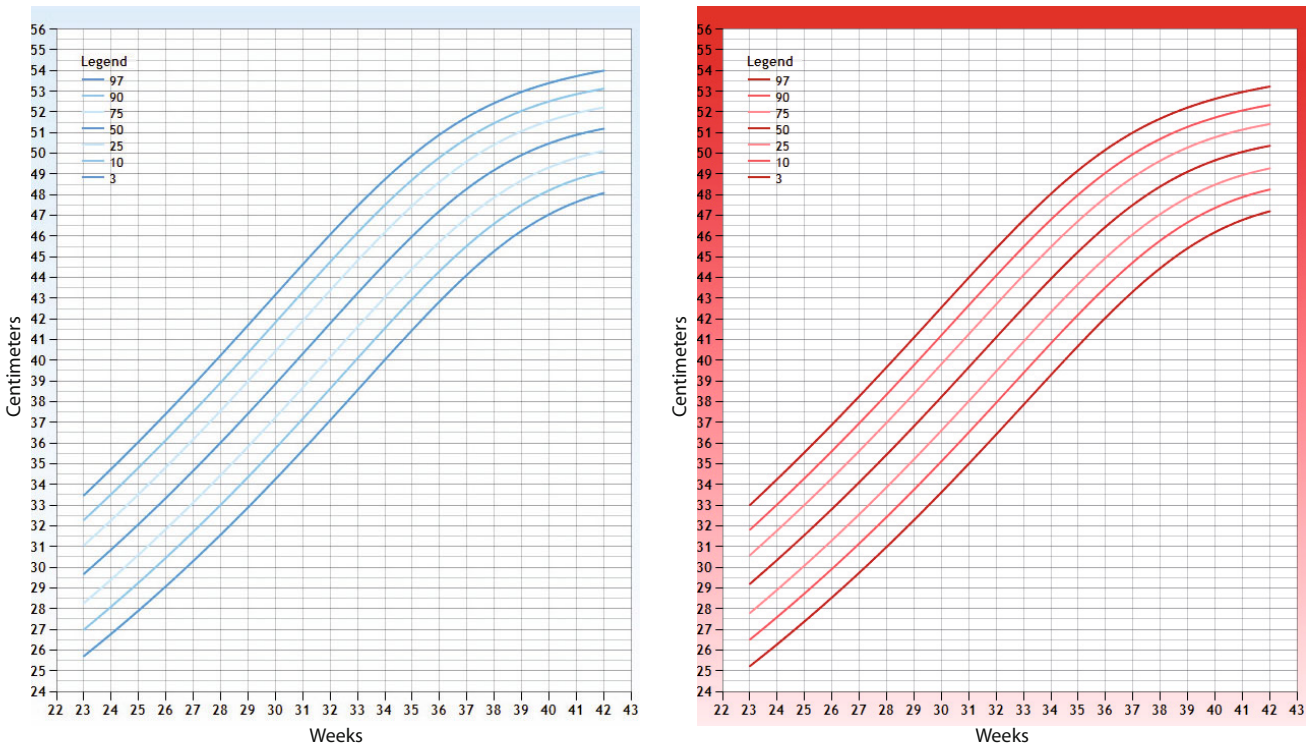

Figure C2 Distribution of body lenght in first-born neonates (*left* boys, *right* girls) for 3rd to 97th centiles (see legend)

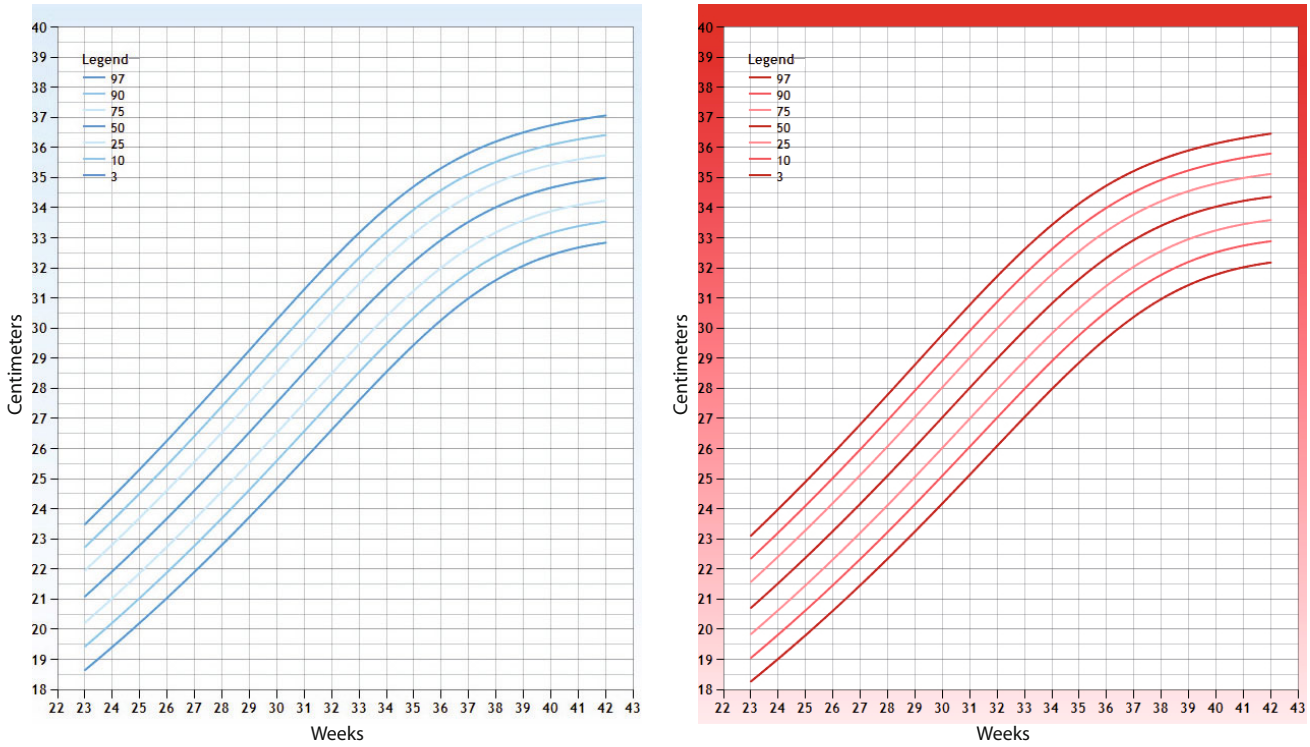

Figure C3 Distribution of head circumference in first-born neonates (*left* boys, *right* girls) for 3rd to 97th centiles (see legend)

Later-born neonates

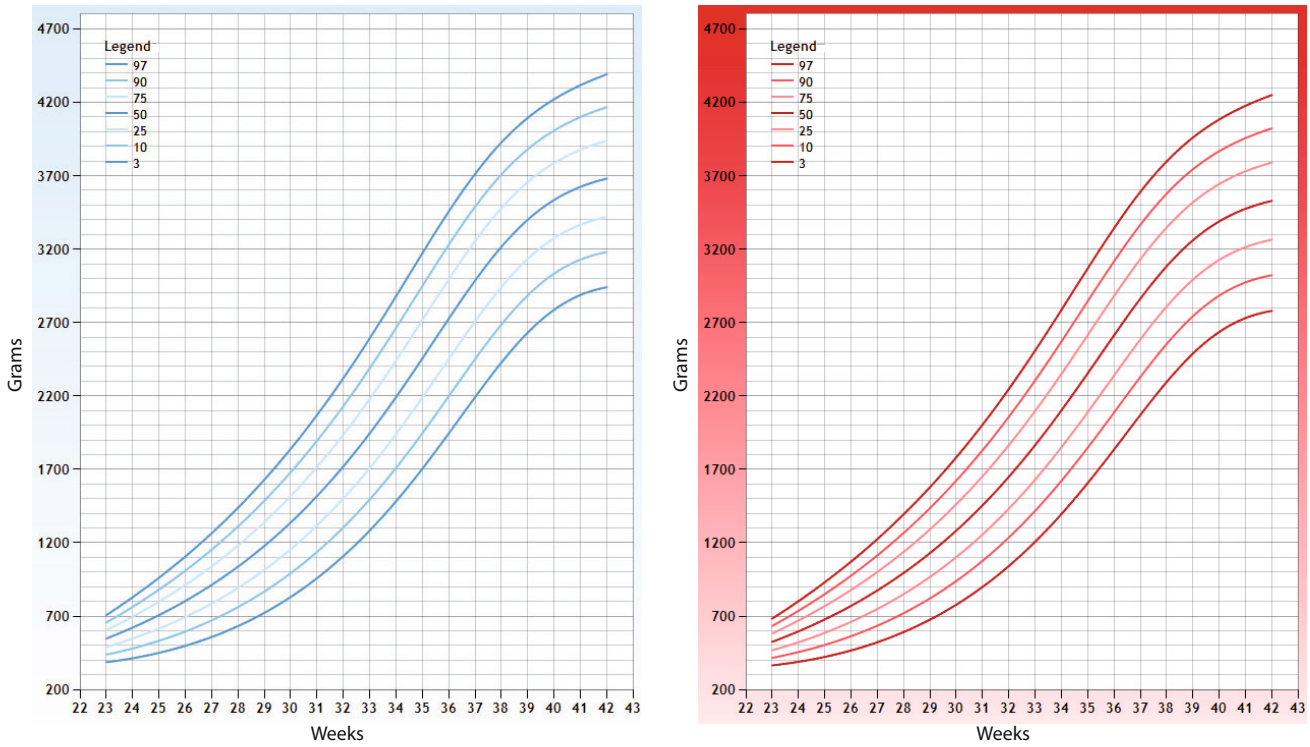

Figure C4 Distribution of birth weight in later-born neonates (*left* boys, *right* girls) for 3rd to 97th centiles (see legend)

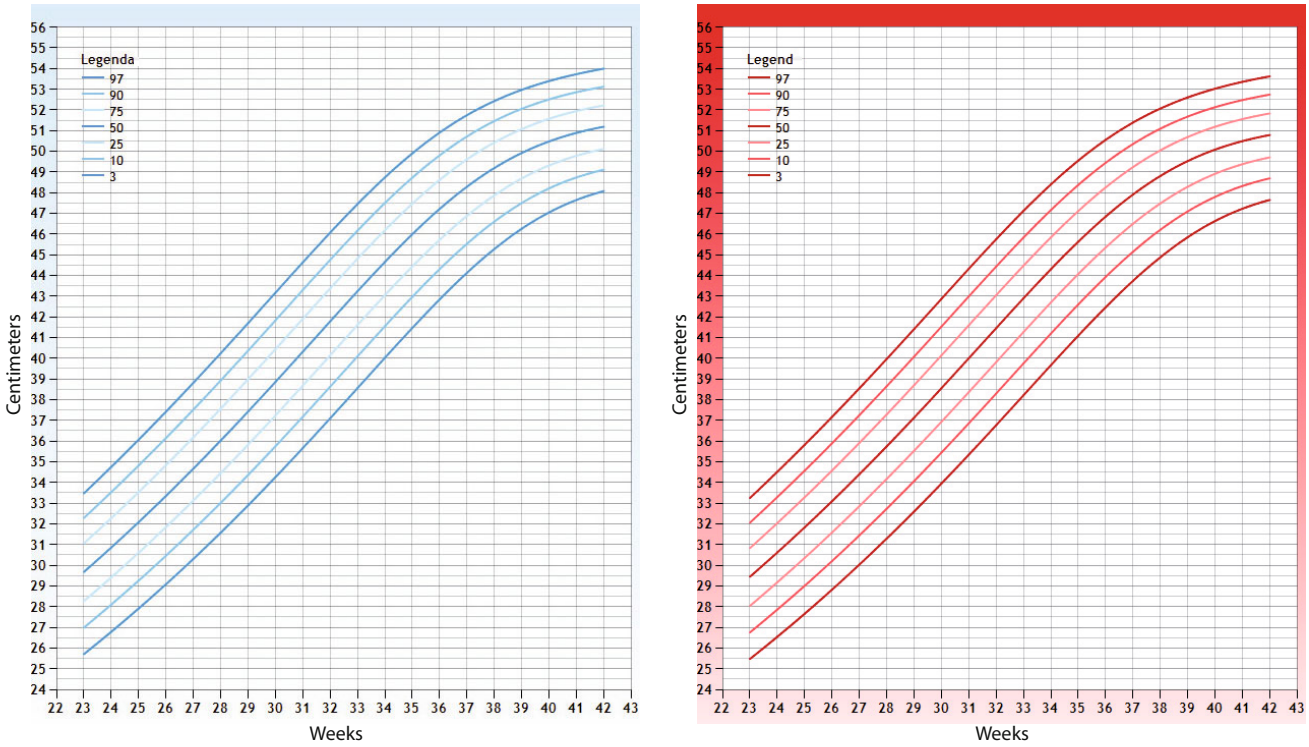

Figure C5 Distribution of body lenght in later-born neonates (*left* boys, *right* girls) for 3rd to 97th centiles (see legend)

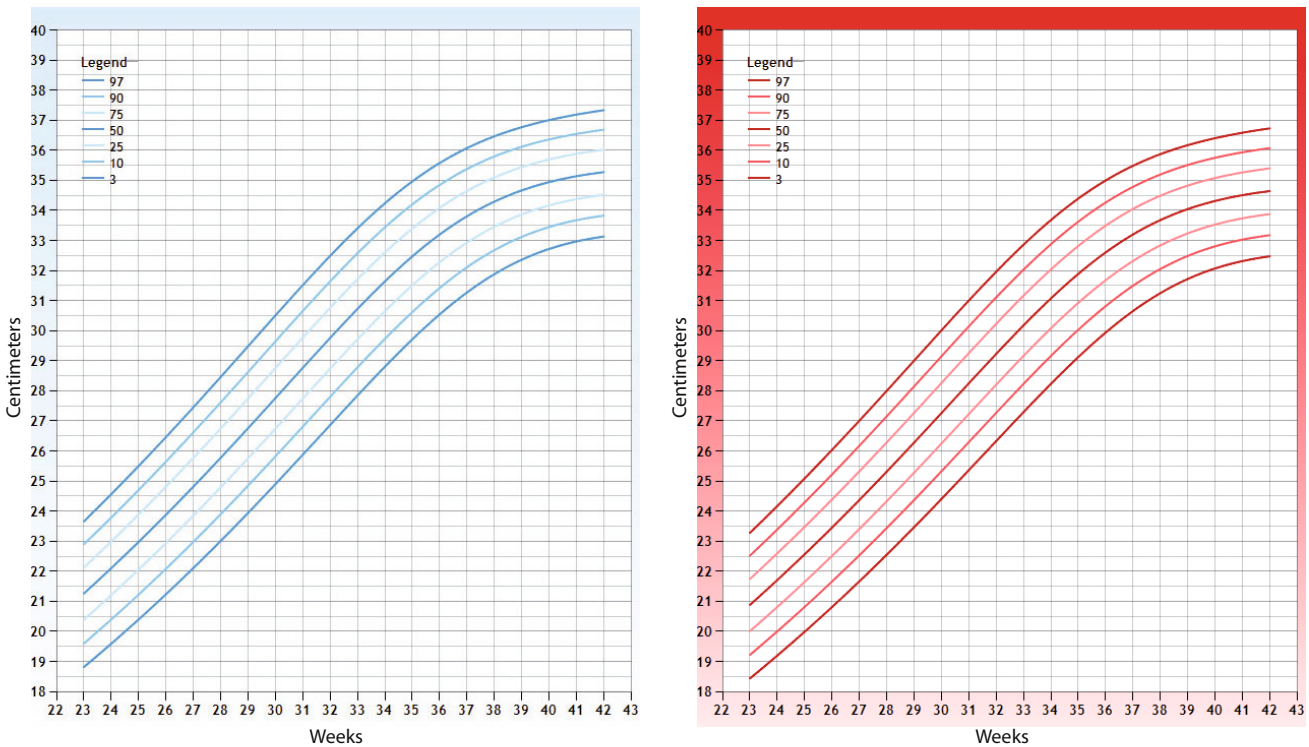

Figure C6 Distribution of head circumference in later-born neonates (*left* boys, *right* girls) for 3rd to 97th centiles (see legend)

Data of charts from Bertino E, Spada E, Occhi L et al. Neonatal anthropometric charts: the Italian neonatal study compared with other European studies. *J Pediatr Gastroenterol Nutr* 2010;51:353–361. Charts reproduced by courtesy of the Authors.
