During fetal development the lung is a secretory organ that exhibits breathing-like movements without contributing to respiratory gas exchange. The lung fluid is produced by epithelial cells, especially those in the distal airways, through chloride secretion, and it flows to the upper airway where it is either swallowed or released into the amniotic space. The fluid is rich in chloride and low in bicarbonate and proteins. The rate of fluid production increases in fetal lambs from approximately 5 mL/kg at mid-gestation to more than 20 mL/kg near term, with hourly rates increasing from 2 mL/kg/h to 5 mL/kg/h, respectively [12]. This increase mirrors the progressive expansion of the contact surface between alveolar epithelium and microcirculation, due to the proliferation of pulmonary capillaries and to the growth of the terminal saccules.

The production of pulmonary fluid is essential for the normal development of the respiratory apparatus since it determines the form and volume of its peripheral units; experimental evidence shows that extended drainage of tracheal fluid causes pulmonary hypoplasia. The amount of pulmonary fluid that is present inside the respiratory tree depends on the balance between production at the level of the alveolar epithelium and resistance to its outflow exerted by the upper airway [13]; its volume at the end of gestation is around 20–30 mL/kg, a value that is comparable to that of the functional residual capacity (FRC) of a normal lung.

The other physical factor that is critical for normal lung development is FBM, periodic rhythmic contractions of the diaphragm that maintain adequate fluid volume and lung distension. During pregnancy, the fetus spends most of its time, around 30–40% during the third quarter, performing breathing movements even though ventilation is exclusively a placental function [14]. Fetal breathing appears to be related to the behavioral state of the fetus. As the fetus approaches term, the incidence of these movements is considerably greater during active periods than during periods of quiet activity [15].

Observations of human fetuses with congenital anomalies and of experimental animals show that the breathing movements of the fetus produce distension forces that stimulate cell multiplication [16] and are necessary to ensure an adequate development of the muscular and respiratory apparatus for postnatal life. Pulmonary hypoplasia is a disorder that is frequently associated with oligohydramnios and experimentally it can be determined in the uterus through bilateral phrenectomy. These observations seem to confirm the importance of fetal respiratory activity for the development of the lung, which could undergo alterations when this activity is prevented or when there are obstacles [17]. The physiological fluctuations of PaO_2 and of $PaCO_2$ do not influence the respiratory activity of the fetus, which stops if the PaO_2 drops to a level of 16–18 mmHg. Hypoxia therefore has an inhibiting effect on breathing movements, which is not to be interpreted as a sign of neuronal immaturity but rather as a response aimed at reducing the consumption of O_2 by the fetus. In fact, intrauterine respiratory

activity demands up to 15–30% of the total O_2 available. By contrast, the fetus responds to an increase in $PaCO_2$ with a corresponding increase in respiratory activity and the opposite occurs in the case of hypocapnia. These observations suggest that the central chemoreceptors are active in fetal life. Maternal ingestion of alcohol or sedatives has been shown to decrease breathing movements, but drugs such as caffeine increase them. Maternal smoking also decreases fetal breathing movements through several mechanisms including decreased uterine blood flow and hypoxia [18].

The pressure inside the fetal respiratory system varies depending on the presence or absence of breathing movements. During the periods in which the fetus does not practice breathing, pressure remains constant [19]: if the amniotic pressure is considered to be zero, the pressure inside the trachea is around 1–2 mmHg greater, while the intrapleural pressure is about 0.7 mmHg lower. The positive pressure inside the respiratory tree is modulated mainly by the degree of resistance of the larynx. Similarly, the negative endopleural pressure is the product of the balance between elastic return of the lungs and of the thoracic cage. The resulting force between endotracheal positive pressure and endopleural negative pressure is a transpulmonary positive pressure of around 2.5 mmHg, a force that keeps the lungs expanded hence stimulating their growth. During the periods when the fetus performs FBM, the glottis dilates and resistance decreases at the larynx, but the rhythmic contractions of the diaphragm attenuate the outflow of fluid from the trachea and restrict the reduction of pulmonary volume [20].

56.4 Pulmonary Malformations

Knowledge of the various phases of pulmonary development allows us to understand the pathophysiology of the various congenital malformations of this organ, many of which, thanks to the considerable development of prenatal ultrasonography, may be diagnosed as early as between the 18th and 20th weeks of gestation.

56.4.1 Intrapulmonary Cystic Malformations

Intrapulmonary cystic malformations comprise a spectrum of congenital malformations of the lower respiratory tract that have in common the fact that cysts may represent (but not always) a prominent part of the anomaly; these include congenital cystic adenomatoid malformation (CCAM), bronchopulmonary sequestration (BPS), congenital lobar emphysemas (CLE), and bronchogenic cysts.

Intrapulmonary cystic malformations have been increasingly detected at midgestation due to improvements in ultrasound technology and the routine use of ultrasound as a screening test. The different postnatal diagnostic entities are difficult to differentiate prenatally and there is confusion in terms of how these malformations should be described; recently a new nomenclature using the terms "congenital thoracic malformation" (CTM) and "congenital large hyperlucent lobe" have been proposed [21]. It has been suggested that many, if not all of these defects, may represent a continuum of anomalies of fetal lung development, despite some diversity in morphology. Fetal airway obstruction probably plays a prominent role in their pathogenesis [22], but the mechanism by which bronchial athresia might lead to different fetal chest masses remains unknown.

The widespread use of antenatal ultrasound with Doppler studies has led to a better understanding of the development of some of these anomalies and to an improvement in their management. Antenatal fast magnetic resonance imaging is also an important adjunct to prenatal ultrasound in the evaluation of CTM: it may provide further information on the nature of the lung anomaly, it may help to differentiate lung lesions from extrathoracic abnormalities such as congenital diaphragmatic hernia, and it may be useful in planning pre- or postnatal surgery.

Large congenital malformations may compress the ipsilateral lung or even the contralateral lung via mediastinal shift thus causing lung hypoplasia. Compression of the esophagus may result in polyhydramnios; the resulting uterine distension may induce premature labor. Impairment of cardiac return due to the vena cava and to cardiac compression is responsible for fetal hydrops with ascites, pleural and pericardial effusions, and skin and scalp edema.

CTM may change in size and/or appearance during pregnancy, but the growth pattern is rather unpredictable. There is a wide spectrum of clinical severity, with a relationship between size of the malformation, concomitant lung hypoplasia and the occurrence of pulmonary hypertension in the newborn period. Most fetuses with CTM have a good outcome, and an initially large lesion does not necessarily correlate with a poor prognosis [23, 24]. In fact, many lesions (both CAM and BPS) decrease in size over time [23, 25–28], and some even disappear completely on serial prenatal ultrasound scans toward the end of pregnancy [23, 25, 29–31]. However, although these lesions are often undetectable on postnatal ultrasound and chest X-ray examination, in the vast majority of cases they can be detected by computed tomography (CT) scans or magnetic resonance imaging [26, 32–35]. Thus all patients with prenatally detected CTM require postnatal evaluation, and documentation of true resolution must be confirmed, preferably by CT scans. It is also important in the postnatal period to seek an anomalous blood supply in patients who have CTM, even if prenatally color flow Doppler studies fail to identify a systemic arterial blood supply.

Therefore, most fetuses with a CTM will do well during pregnancy. However, if hydrops develops, the risk of fetal or neonatal death is extremely high [23, 25, 36]: most current reports suggest that a large cystic mass volume (specifically when measured as a ratio of normal lung to thorax) and

hydrops are the only indications for fetal intervention [27, 37]. In intrathoracic lesions with cystic parts, prenatal needle aspiration of the fluid has been performed but often leads to rapid re-accumulation. Therefore, fetal surgery with the implantation of shunts between the cyst and the amniotic space has successfully reduced the size of the lesion and improved hydrops fetalis; however, this intervention may cause fetal death [30, 38].

After 32 weeks of gestation, early delivery should be considered in hydropic fetuses and, furthermore, when severe RDS is expected, the ex-utero intrapartum therapy (EXIT) procedure may be considered to allow interventions such as drainage of large pleural effusions or even resection of an affected lobe [39]. A recent paper has reported 100% survival in children with large intrathoracic cystic masses causing hydrops fetalis after maternal betamethasone therapy [40]. Although the effect of steroid treatment on CCAM growth was variable, resolution of hydrops was seen in 80% of steroid-treated patients.

The postnatal clinical appearance of CTMs may vary from immediate respiratory distress at birth to an incidental finding on a chest radiograph at any age. In the neonatal period a small number of patients with large lesions require surgery, which is the accepted standard of care for all symptomatic lesions. Many children, however, will be asymptomatic at birth and in the neonatal period, and there is controversy about the management of these newborns: most authors would recommend resection of CAMs, cysts and BPSs if the lesions can be detected postnatally, because of complications such as infections, hemorrhage, pneumothorax, sudden respiratory failure, and malignant transformation [41–43]. Moreover, conservative management of these lesions with repeated CT scans causes significant radiation exposure. Successful expectant long-term management has been reported particularly for late presenting asymptomatic or oligosymptomatic lobar emphysema [44].

CAMs, BPSs and cystic malformations can be removed surgically before 6 months of age [27, 45] with excellent results, either by open thoracotomy or, more recently, by using the minimally invasive video-assisted thoracoscopic approach [46, 47].

56.4.2 Congenital Cystic Adenomatoid Malformation

CCAM is characterized by an adenomatoid proliferation of terminal bronchioles with the formation of solid, cystic or mixed masses inside the pulmonary parenchyma without subsequent alveolar differentiation [48]. This lesion is usually unilateral, without a right or left prevalence, and it affects a single lobe; vascularization originates from the bronchial circulation, but in rare cases it may depend on an anomalous systemic vessel.

56.4.2.1 Etiology and Pathogenesis

The pathogenesis of CCAM is still unclear, but it is likely to be due to a failure of normal interaction between the mesenchymal tissue and epithelial cells during early fetal life.

56.4.2.2 Clinical Aspects

The congenital cystic adenomatoid malformation was originally classified by Stocker into three distinct histological subtypes, and recently expanded to five [49]:

- type 0: involvement of all lung lobes, incompatible with life (<2%);
- type 1: single or multiple cysts, size >2 cm, lined by pseudostratified columnar epithelium; wall of fibromuscular and cartilaginous tissue (60–70%);
- type 2: single or multiple cysts (<2 cm) lined by cuboidal or columnar epithelium (15–20%);
- type 3: predominantly solid lesions, with small (<0.5 cm) cysts, lined by cuboidal epithelium (5–10%). On the whole, this constitutes a solid mass and is the form that has the worst prognosis;
- type 4: large air-filled cysts, lined by flattened epithelial cells (<10%).

This classification can obviously only be applied to resected lung specimens and it is inappropriate for describing fetal lung lesions. The emerging consensus is that imaging findings should simply describe without attempting to make a pathological diagnosis, as done by Adzick in his classification [50] in which he simply differentiated prenatally detected cystic lesions into two types:

- macrocystic (single or multiple echogenic cysts >5mm)
- microcystic (smaller echogenic cysts <5 mm).

56.4.2.3 Differential Diagnosis

The chest radiograph and clinical symptoms of CCAM may be easily confused with those of a diaphragmatic hernia: the insertion of a nasogastric tube and instilling a few mL of barium may help locate the stomach and hence facilitate differential diagnosis (Fig. 56.5). Ultrasound and CT scans are also useful in determining the size of normal lung and the position of the diaphragm.

56.4.2.4 Therapy and Treatments

The risk of infections, associated with the risk of malignant degeneration of the adenomatoid tissue into rhabdomyosarcoma or into bronchioloalveolar carcinoma or into other mesenchymal malignancies, a complication described both in children and in adults [41, 43], is to be considered when deciding on surgery in an asymptomatic patient. Also, in asymptomatic cases, a chest CT scan within one month of birth is mandatory, even if resolution is noted on prenatal scanning

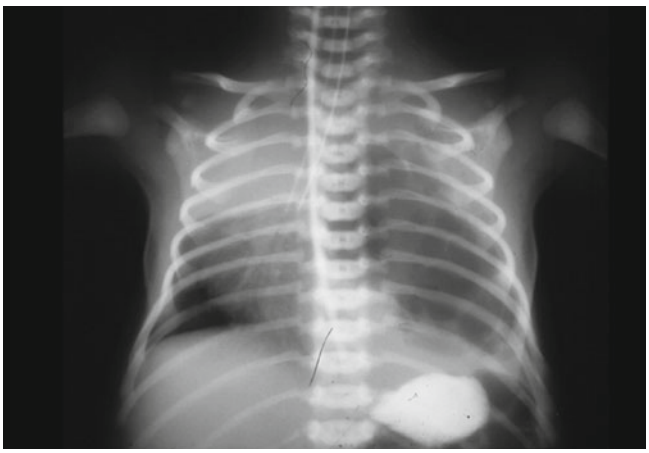

Fig. 56.5 Left lower lobe CCAM with mediastinal shift to the contralateral side

[41] and bearing in mind that a true resolution of these lesions is exceptional.

When needed, assisted ventilation in these patients may determine a progressive distension of the cysts with a life-threatening mediastinal shift: one-lung ventilation may be carried out in order to achieve perioperative stabilization (Fig. 56.5). High-frequency oscillatory ventilation may also be successfully used in patients with pulmonary hypertension [51].

56.4.3 Bronchopulmonary Sequestration

The term bronchopulmonary sequestration (BPS) was introduced by Pryce in 1946, who took the term from the Latin word sequestrate which means "to separate". He used it to define a portion of the pulmonary tissue that does not work and is not linked to the bronchial tree.

56.4.3.1 Etiology and Pathogenesis

The pathogenesis may be referred to an anomaly in the development of the primitive lung bud with the formation of an ancillary structure that has preserved the original arterial supply and that grows inside the pleural cavity in close contact with the normal lung (intralobular sequestration), or it may remain separate and be wrapped in its own visceral pleura (extralobular sequestration).

56.4.3.2 Clinical Aspects

Intralobular sequestration is the form most frequently found and is usually located in the lower lobes; extralobular sequestration is located almost constantly on the right, between the diaphragm and the lower lobe, and is often associated with other congenital malformations, in particular diaphragmatic hernia. This malformation has its own vascular supply that usually originates from the lower chest or upper abdominal aorta or one of its major branches, rather than from the pulmonary artery. Usually the venous blood is normally drained into the right atrium, but occasionally the venous blood may also drain abnormally into the left atrium, the vena cava (the so called Scimitar syndrome for its characteristic chest radiograph appearance), or into the azygos system [52]. The size of abnormal arteries and veins and consequently the blood flow through the malformation is considerable and may cause heart failure and massive arteriovenous shunting [53]. Recently many papers have described cystic lung lesions, defined "hybrid lesions", with coexisting features of both CCAM (the histological features are mostly Stocker type 2 lesions) and BPS, suggesting that they may represent the two ends of a broad spectrum of disorders [27, 51].

Only a small percentage of children with intralobular sequestration have a symptomatology characterized by respiratory distress in the neonatal period. In most cases the malformation is asymptomatic for a long time and then it appears later in life with localized recurrent pneumonias, fever and occasionally hemoptysis. By contrast, extralobular sequestration rarely presents respiratory symptoms and may also be found incidentally on routine chest radiography. BPSs have rarely been linked with malignancy and most likely these tumors develop in hybrid lesions [54].

56.4.3.3 Differential Diagnosis

The initial detection of BPSs is currently obtained by intrauterine sonography (Fig. 56.6) and Doppler ultrasound is useful as it shows the characteristic vascular abnormality. Postnatally, intralobular sequestration should be suspected when the chest radiograph shows a dense lesion on the posteromedial part of the left or, less frequently, right lower zone of the lung. Multi-detector CT evaluation with intravenous

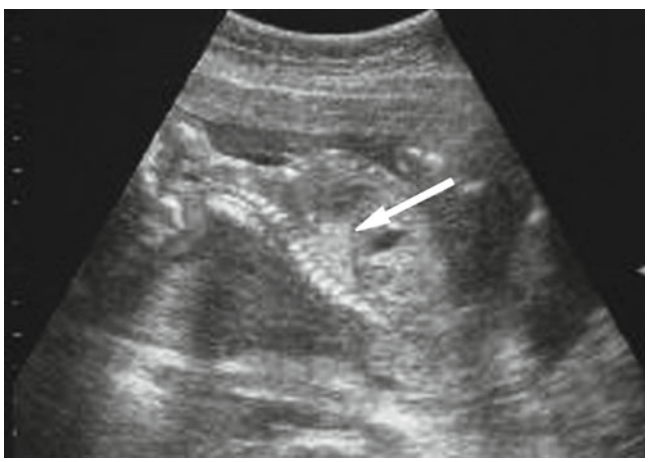

Fig. 56.6 Pulmonary sequestration: midtrimester fetal sonogram shows a triangular echogenic mass astride the left diaphragm

contrast for CT angiogram is useful in establishing the diagnosis: this study provides the best evaluation of the vascular anatomy of the lesion, of the appearance of the lesion itself, of the diaphragm and of the remainder of the lung [55].

56.4.3.4 Therapy and Treatments

Surgery is recommended once the infant becomes symptomatic and should be undertaken only after assessing the characteristics of the arterial supply and of the venous drainage.

56.4.4 Congenital Lung Cysts

Congenital lung cysts are divided into bronchogenic, alveolar and combined forms. They may lie outside the normal lung structure (extrapulmonary), or within it (intrapulmonary). The cysts tend to be limited to one lung and are not associated with cystic disease elsewhere in the body. Bronchogenic cysts may vary notably in size and are rare in the newborn period.

56.4.4.1 Etiology and Pathogenesis

Congenital lung cysts result from abnormal budding of the foregut; the position within the branching pattern indicates when the cyst developed.

56.4.4.2 Clinical Aspects

Such lesions are found in the mediastinum in over 2/3 of cases. They are usually located in the right para-tracheal or carinal regions, but can also be found within the parenchyma of the lung. The cysts contain a lining of respiratory epithelium and have cartilage, smooth muscle and glands in the wall [48]. They are usually unilocular, filled with fluid or mucus and generally do not communicate with airways. Location of the cyst is important in determining the clinical presentation: a bronchogenic cyst may cause airway compression resulting in cough, wheeze, dyspnoea, or even respiratory distress and those located in the region of the carina may determine lobar emphysema. Secondary infection of the cyst is also a very frequent complication and may cause acute distension with exacerbation of symptoms. In addition, peptic ulceration may develop in cysts containing gastric mucosa [56].

56.4.4.3 Differential Diagnosis

Radiographic findings are variable and range from a rounded mass to atelectasis or hyperinflation of a lobe or an entire lung (Fig. 56.7). The diagnosis is usually established from the chest X-ray, but the lesion must be differentiated from congenital lobar emphysema (CLE), acquired cysts complicating pulmonary interstitial emphysema (PIE) and bronchopulmonary dysplasia (BPD). Usually the latter two conditions can easily be differentiated through patient history.

56.4.4.4 Therapy and Treatments

All congenital lung cysts require surgical resection because they do not spontaneously regress, and even those that are asymptomatic may cause problems as a result of compression or infection [43].

56.4.5 Congenital Lobar Emphysema

Congenital lobar emphysema (CLE), defined as a postnatal overdistension of one or more lobes of a histologically normal lung, is a rare cause of respiratory failure in the newborn, but in most patients the diagnosis is made before six months of life [57].

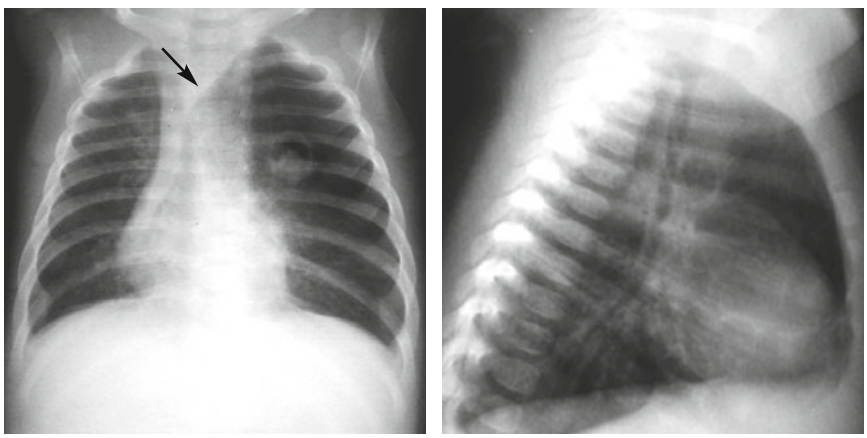

Fig. 56.7 Left bronchogenic cyst. The *arrow* shows upper lobe emphysema

56.4.5.1 Etiology and Pathogenesis

CLE may result from a malformation in the bronchial cartilage, with no or incomplete rings. It also may result from extrinsic bronchial obstruction caused by anomalous vessels or from intrathoracic masses such as bronchogenic cysts. The etiology of the intrinsic bronchial obstruction is thought to be a localized interruption of the blood supply to an already formed bronchus, resulting in bronchial infarction and luminal obstruction or developmental abnormalities of the bronchial cartilage after completion of bronchial branching [58].

56.4.5.2 Clinical Aspects

The left upper lobe is most often involved (Fig. 56.8), followed by the right middle lobe; involvement of the lower lobes is very rare. Dyspnea, tachypnea, wheezing, tachycardia and cyanosis are among the most common presenting symptoms. Chest radiograph, computed tomography (CT), ventilation scintigraphy and bronchoscopy are usually sufficient for diagnosis. The chest radiograph will demonstrate marked hyperinflation of the affected lobe with the adjacent lobe collapsing down or up and mediastinal shift to the controlateral side.

56.4.5.3 Differential Diagnosis

CLE can easily be confused with pneumothorax, but in the latter there are no bronchovascular markings in the radiolucent area [43]. A CT scan is useful in the differential diagnosis of a mediastinal mass.

56.4.5.4 Therapy and Treatments

The traditional treatment for most cases of CLE with respiratory distress is lobectomy. Conservative treatment is possible in asymptomatic or mildly symptomatic cases [59].

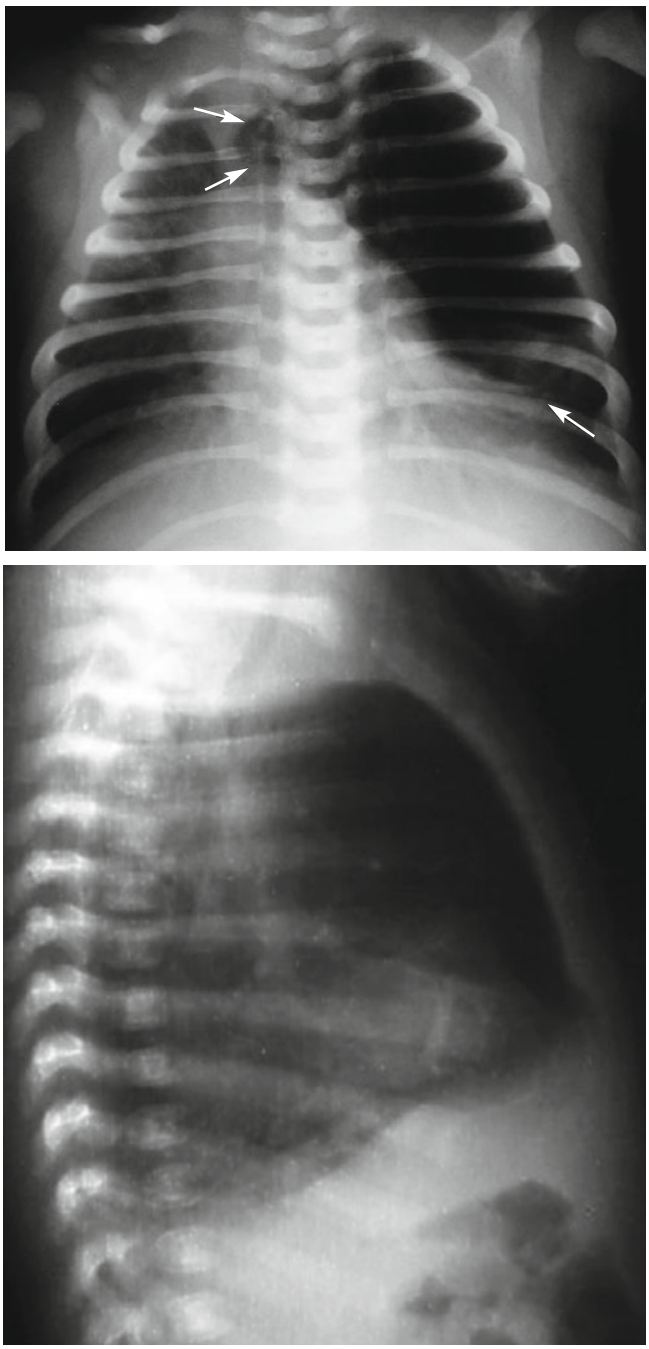

Fig. 56.8 Congenital left upper lobar emphysema. The *upper arrows* show retrosternal hernia. The *lower arrow* shows the collapse of the lower lobe

56.4.6 Pulmonary Agenesis

Pulmonary agenesis may be classified morphologically by the extent to which bronchopulmonary tissue is absent [48]. Pulmonary agenesis is divided into (1) bilateral complete agenesis, (2) unilateral agenesis with (a) complete absence of lung and bronchus and no vascular supply to the affected side (agenesis), (b) rudimentary bronchus with complete absence of pulmonary parenchyma (aplasia), (c) presence of variable amounts of bronchial tree, pulmonary parenchyma and supporting vasculature (hypoplasia), and (3) lobar agenesis. The incidence may range between 0.0034 and 0.0097% [60]. The left lung is slightly more affected than the right. Isolated agenesis of a lobe or lobes is more common than total unilateral lung agenesis. This abnormality occurs more often on the right than on the left, involving the upper and middle lobes.

56.4.6.1 Clinical Aspects

Unilateral pulmonary agenesis may present with severe respiratory distress at birth or may be asymptomatic. In this latter

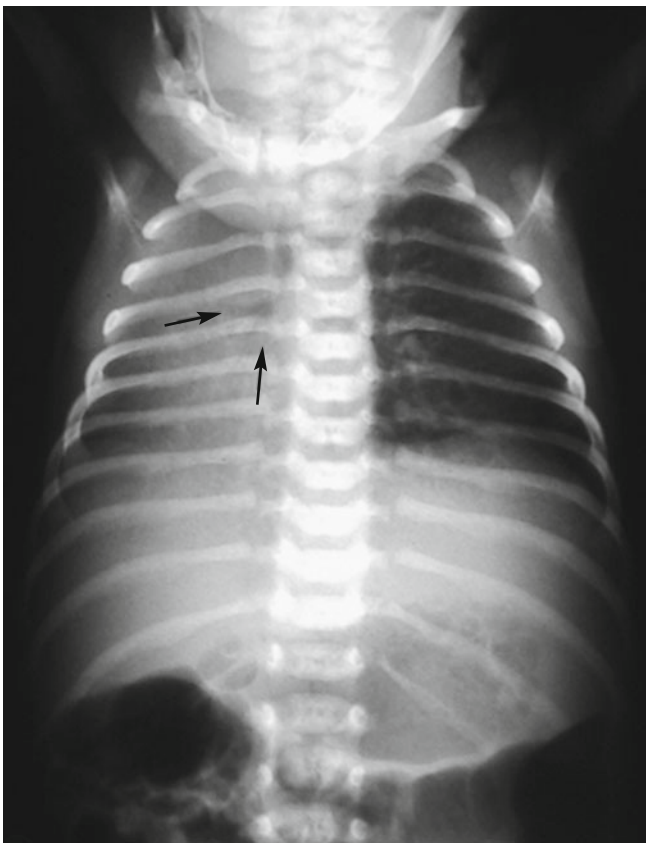

Fig. 56.9 Chest X-ray of a neonate with agenesis of the right lung. *Black arrows* show the right lobar bronchi ending blindly. Mediastinum shifts to the right side

occurrence, recurrent respiratory symptoms secondary to respiratory tract infections may appear later in life. On auscultation, mediastinal shift and hyperresonance of the contralateral hemithorax side are usually present. Asymmetry of the chest becomes more noticeable in the adult patient [61].

With postnatal compensatory growth the remaining lung often herniates into the contralateral chest. Chest X-ray shows a mediastinal shift towards the affected side (Fig. 56.9), and skeletal abnomalities may be present. Absent or incomplete lung development may be associated with abnormalities of the trachea, absence of one or both kidneys, cardiac defects (patent ductus arteriosus, patent foramen ovale, ventricular defects, pulmonary veins entering the azygos vein), gastrointestinal malformations (atresia ani, esophageal atresia, short bowel), skeletal anomalies (spina bifida, wedge-shaped vertebrae, hemivertebra, deformed ribs, absent left hand, absence of right radius, rudimentary atlas) deformed external ear, and many others. Differential diagnosis should be made with lung atelectasis, congenital diaphragmatic hernia, cystic adenomatoid malformation and pulmonary sequestration [62]. The difficulty of diagnosis depends on the side of the absent lung, the apparent dextrocardia induced by absence of the right lung being a striking clinical finding. Bronchoscopy has been used to establish the diagnosis of pulmonary agenesis. Typical findings include bronchus/i narrow ending blindly.

56.4.6.2 Prognosis

About 50% of patients survive; the mortality rate is higher with agenesis of the right lung than of the left lung.

56.4.7 Pulmonary Hypoplasia

Pulmonary hypoplasia (PH) is a common and serious problem in the perinatal period with a significant mortality rate. Premature rupture of membranes at less than 25 weeks' gestation, severe oligohydramnios (amniotic fluid index <4) for more than 2 weeks and earlier delivery are known risk factors for mortality [63]. Pulmonary hypoplasia is defined as a defective or incomplete development of lung tissue characterized by a reduction in the number of lung cells, airways and alveoli, resulting in a lower organ size and weight. It encompasses a wide spectrum of anatomic malformations ranging from total bronchial and parenchymal agenesis to mild pulmonary parenchymal hypoplasia. The lesions may be lobar, unilateral, or bilateral. Cases of isolated lobar defects have only been rarely reported. PH may be an isolated entity (primary PH) or be secondary to lesions restricting lung growth [64].

56.4.7.1 Etiology and Pathogenesis

Primary PH includes pulmonary agenesis (unilateral) [65] with or without associated malformations and idiopathic PH (bilateral). The causes of primary PH have not been identified. However, experimental models suggest that deficiencies in certain growth factors (e.g., epidermal growth factor and its receptor; mitogen-activated protein kinase, connective tissue growth factor) can result in disordered lung growth.

Nakamura and colleagues [66] revealed five statistically significant risk factors associated with secondary PH from a large series of autopsy cases: (1) hydrops fetalis; (2) renal anomalies; (3) diaphragmatic hernia; (4) skeletal anomalies; (5) oligohydramnios and polyhydramnios (Table 56.2).

Pathologically, the hypoplastic lung shows a low ratio of lung to body weight, low DNA content, or a decreased radial alveolar count [67]. Epithelial differentiation is delayed, and surfactant deficiency is associated [68]. Both pulmonary arterioles and bronchioles are decreased in size. Hypertrophy of the medial smooth muscle is a common finding in peripheral pulmonary blood vessels.

56.4.7.2 Clinical Aspects

In patients with PH, the clinical profile and the time of presentation vary depending on the extent of hypoplasia and other

Table 56.2 Causes of secondary pulmonary hypoplasia

Small fetal thoracic volume
- CDH
- Eventration of the diaphragm
- Abdominal mass lesions
- Exomphalos
- Pleural effusions with fetal hydrops
- Hydrothorax
- CAM
- Sequestration
- Malformations of the thorax (eg, asphyxiating thoracic dystrophy)
- Achondroplasia
- Thanatophoric dwarfism
- Osteogenesis imperfecta
- Thoracic neuroblastomas

Prolonged oligohydramnios
- Fetal renal agenesis
- Urinary tract obstruction
- Bilateral renal dysplasia
- Bilateral cystic kidneys
- Prolonged rupture of membranes

Early rupture of membranes
- More severe oligohydramnios (amniotic fluid index <4)
- Longer latent period before delivery

Decreased fetal breathing
- CNS lesions
- Lesions of the spinal cord, brain stem, and phrenic nerve
- Neuromuscular diseases (eg., myotonic dystrophy, spinal muscular atrophy)
- Arthrogryposis multiplex congenital
- Maternal depressant drugs

Congenital heart diseases with poor pulmonary blood flow
- Tetralogy of Fallot
- Hypoplastic right heart
- Pulmonary artery hypoplasia
- Scimitar syndrome causing a unilateral right-sided pulmonary hypoplasia

anomalies. Severe respiratory insufficiency resulting in a fatal outcome is the presenting symptom in a vast majority of preterm infants with severe bilateral PH. The history may include poor fetal movement or amniotic fluid leakage and oligohydramnios. In more mature neonates, mild to moderate hypoplasia or unilateral PH may be asymptomatic or may present with respiratory distress that requires mechanical ventilation. Newborn infants with moderate to severe PH often present with persistent pulmonary hypertension responding to inhaled nitric oxide [69] as a result of reduced vascular bed and secondary arterial muscular hypertrophy. Pneumothorax, spontaneous or associated with mechanical ventilation, may occur [70]. Compression deformities due to prolonged oligohydramnios, contractures, and arthrogryposis may be present when PH is associated with oligohydramnios. The Potter facies (hypertelorism, epicanthus, retrognathia, depressed nasal bridge, low set ears) suggest lung hypoplasia caused by the associated renal defects [71]. When the etiology of the hypoplasia is a neuromuscular disease, the patient may have myopathic facies, with a V-shaped mouth, muscle weakness, and growth retardation.

A number of studies have described associated anomalies with PH including heart defects (e.g., anomalous venous return to the right atrium or the inferior vena cava or scimitar syndrome, absence of the ipsilateral pulmonary artery), skeletal and vertebral anomalies (metacarpal and radial anomalies, failure of segmentation of thoracic or other vertebrae, rib abnormalities), abdominal defects (diaphragm, abdominal wall defects), facial abnormalities, as well as numerous lung and tracheo-bronchial tree defects. There have been a number of case reports of PH and tracheoesophageal fistula and a number of reports of an association of tracheal stenosis with pulmonary agenesis. Similar to patients with more severe degrees of PH, neonates with isolated lobar hypoplasia may demonstrate other congenital malformations.

In infants with unilateral pulmonary agenesis the diagnosis may be suspected by unilaterally decreased breath sounds and displacement of the mediastinum to the affected side. In right-sided hypoplasia, the heart is displaced to the right, which may lead to a mistaken diagnosis of dextrocardia. The external chest may appear normal or may be small and bell shaped, with or without scoliosis. In PH associated with congenital diaphragmatic hernia signs of respiratory distress are associated with scaphoid abdomen and bowel sounds upon chest auscultation. In older children, dyspnea and cyanosis may be present upon exertion, or a history of repeated respiratory infections may be noted.

56.4.7.3 Diagnostic Methods

The diagnosis of PH can be made with certainty only at autopsy by measurement of total lung DNA content. Because of this, the incidence of PH is probably underestimated. The diagnosis should be suspected in the presence of perinatal factors suggestive of PH, unexpected respiratory distress, specific findings at clinical examination.

Diagnosis of unilateral lobar PH requires a high index of clinical suspicion and experience with reading neonatal and infant radiographs. Chest CT or MRI may be needed to better delineate the defect and to detect possible associated defects (accessory diaphragm, pulmonary sequestration adjacent to a small diaphragmatic hernia). Unilateral PH should be suspected in the presence of hyperlucency and smallness of one lung. Hyperdistention of the contralateral lung can be seen.

The diagnosis of primary PH implies a lack of any specific pathophysiologic process that could cause fetal lung compression. For the diagnosis of secondary PH abdominal masses, such as cystic renal diseases and an enlarged bladder, must be sought. Associated anomalies of the cardiovascular, gastrointestinal (e.g., tracheoesophageal fistula, imperforate anus, communicating bronchopulmonary foregut malformation), and genitourinary systems, as well as skeletal anomalies of the vertebrae, thoracic cage, and upper limbs, may be found upon examination.

Echocardiography is fundamental to reveal possible cardiac defects. Prenatal ultrasound [72] and, more recently, fetal MRI constitute the methods of choice to investigate the fetal lung development throughout pregnancy [73].

Basically, the MR assessment of the fetal lung growth and the maturation consists of three diagnostic elements. First, fetal MR volumetry is used to identify restricted and insufficient lung growth. Second, the evaluation of signal intensities using different MR sequences provides information about the maturation of the fetal lung. Third, the high resolution and tissue contrast of MR allows us to examine the structure of the fetal lung and to offer a more detailed diagnosis of fetal pulmonary pathologies [74].

56.4.7.4 Differential Diagnosis

The differential diagnosis of respiratory distress in the newborn associated with marked opacification of one side of the thorax on radiograph includes atelectasis, congenital diaphragmatic hernia, congenital cystic adenomatoid malformation, pulmonary sequestration, chylothorax, PH, bronchogenic cyst, and a chest tumor (e.g., neuroblastoma, teratoma, fibrosarcoma). In a right-sided CDH, there may be opacification of the right hemithorax if the liver is occupying that space. A left-sided CDH will have air-filled loops of bowel in the chest except possibly in a chest radiograph taken shortly after birth or following bowel decompression. Congenital cystic adenomatoid malformation will usually appear as a cystic mass rather than a homogenous opacification. Obstruction of the bronchus with resultant opacification of the hemithorax may occur with a bronchogenic cyst or a vascular sling. Neonatal chest tumors are very rare and may present as a focal abnormality on chest X-ray.

In cases of bilateral PH with hyperlucent lungs idiopathic persistent pulmonary hypertension should be considered in the differential diagnosis, whereas the presence of small lungs may suggest spinal thoracic dysplasia or neuromuscolar disesases.

56.4.7.5 Therapy and Treatments

Treatment is largely supportive, and prognosis will depend on the presence or absence of the other anomalies. Inhaled nitric oxide (iNO) administered to preterm infants with prolonged premature rupture of membranes (PPROM), oligohydramnios, and PH improves oxygenation, survival, or other clinical outcomes [75]. Because of the surfactant deficiency a significant number of infants with PH require surfactant replacement therapy and high-frequency ventilation [76].

Conventional therapies may fail in these infants who then become candidates for ECMO [77]. The eventual survival is limited by the underlying degree of the PH.

Fetoscopic temporary tracheal occlusion (FETO) may improve outcome in poor-prognosis fetuses with CDH [78].

56.4.7.6 Prognosis

Long-term consequences of PH include: reduced exercise tolerance, even in mild cases, scoliosis in adolescent years, recurrent respiratory infections, chronic pulmonary insufficiency. Right-sided hypoplasia has a worse prognosis than left-sided hypoplasia, probably because of the loss of the bigger right lung mass and more severe mediastinal shift and great vessel displacement [79].

During the first 48 hours of life, the best oxygenation index above 13 and the best $PaCO_2$ above 45 mmHg were predictive of poor outcome [80].

56.4.8 Oligohydramnios Syndrome

Bilateral PH commonly occurs in association with oligohydramnios caused by either renal disease in the fetus or chronic leakage of amniotic fluid as a consequence of PPROM.

For the fetal lung to develop normally, the fetal airways must be filled with fluid [81]. Active chloride transport by epithelial cells results in passive water movement into the fetal airspaces, with a net production rate of lung fluid of about 4–5 mL/kg/h.

The pressure in the fetal trachea exceeds that in the amniotic fluid by about 2 mmHg, generating an outflow resistance that maintains the fetal lung fluid in the fetal lung. Several factors affect the volume and composition of the amniotic fluid, including amount of fetal urine and chronic leakage of amniotic fluid secondary to premature rupture of membranes at 15–28 weeks' gestation.

Any alteration in the critical volume and pressure relationships of amniotic fluid and fetal lung fluid during the canalicular stage of fetal lung development can induce hypoplasia [82].

Infants subject to oligohydramnios resulting from chronic leakage of amniotic fluid over many weeks may exhibit a varying degree of PH. Oligohydramnios may act by compressing the fetal thorax or altering the dynamics of lung fluid so that full expansion of the lungs cannot be maintained. The severity of the PH is directly proportional to rupture of the membranes early in gestation, longer duration of rupture, and the presence of the oligohydramnios during the period of rupture. Oligohydramnios can be associated with a spectrum of a fetal positional and compression abnormalities, such as pes equinovarus and a bell-shaped thorax.

The presence of PH in infants with bilateral renal agenesis was first recognized by Potter in 1946. It has since become apparent that a similar picture of the lethal PH is seen in conjunction with bilaterally dysplastic kidneys with or

without cyst formation and in infants with congenital obstructive uropathy. In the cases of renal agenesis the reduction in lung volume and number of the alveoli is greater than in renal dysplasia, where these changes are more variable in their severity [83].

Despite attempts at in utero decompression of the urinary system, fetal surgery in this disease remains controversial and has met with limited success.

56.4.9 Congenital Pulmonary Lymphangiectasia

Congenital pulmonary lymphangiectasia (CPL) is a rare developmental disorder involving the lung and is characterized by pulmonary subpleural, interlobar, perivascular, and peribronchial lymphatic dilatation.

Reports of occurrence in siblings suggest a genetic inheritance in some families and possibly an autosomal recessive mode of transmission [84]; however most cases occur sporadically [85]. Male are more frequently affected than females (ratio 2:1). The incidence of CPL is not clearly defined. Autopsy studies suggest that approximately 0.5–1% of infants who are stillborn or die in the neonatal period have CPL [86].

56.4.9.1 Etiology and Pathogenesis

Noonan and colleagues classified CPL into three patho-physiological groups [87]:

- Type 1 - Generalized lymphangiectasis with thoracic and extrathoracic involvement.
- Type 2 - Lymphangiectasis secondary to pulmonary venous obstruction due to congenital heart disease.
- Type 3 - Primary pulmonary developmental defect of the lung.

Clinically, two forms of CLP have been recognized: primary or congenital (type 1 and 3) and secondary (type 2), which occurs as a result of injury to the lymphatic vessels. The primary type has a neonatal onset and is often fatal [88]. It may be caused by a congenital defect in the primary development of the lung, or may represent the localized expression of more generalized lymphatic involvement (non immune hydrops).

The pulmonary lymphatic system is normally well developed by the end of the 14th week of gestation. Initially, large lymph channels are present in the normal fetal lungs, which later undergo spontaneous regression. It is believed that failure of these channels to undergo the normal regression leads to primary pulmonary lymphangiectasia.

The secondary form results from impaired lymphatic drainage and increased lymphatic production as a consequence of increased venous and lymphatic hydrostatic pressure; it may also be due to cardiac lesions, which have been hypothesized to interfere with the normal regression of the lymphatic tissue elements after the 16th week of fetal life [88]. Hypoplastic left heart syndrome, pulmonary vein atresia, congenital mitral stenosis, cor triatum, and thoracic duct agenesis are the most likely causes of secondary CPL.

Congenital PL may be associated with non-immune hydrops fetalis and with congenital chylothorax [89].

56.4.9.2 Clinical Aspects

Clinical diagnosis of CPL can be strongly suspected in neonates who present severe respiratory distress with or without generalized or localized lymphedema, and with pleural effusion (especially if chylous) either monolateral or bilateral although the disease affects both lungs.

In the post-neonatal period, CPL can occur any time in childhood or even adult life. During both the neonatal and post-neonatal period, CPL may be associated with chylothorax, chylopericardium, and chylous ascites [90]. In older children it is frequently associated with recurrent cough, wheeze, increased respiratory effort with inspiratory crackle, and even congestive heart failure [91].

CPL has been described in patients with 46,XY/46,XX mosaicism, ichthyosis congenita, Noonan syndrome, Turner syndrome, Fryns syndrome, Down syndrome, and other syndromes that suggest genetic predisposition [88].

Diagnostic Methods

During the prenatal period, all causes leading to hydrops fetalis have to be taken into consideration. The diagnostic approach includes the following: complete family and obstetric history, laboratory investigations including blood type, Rhesus factor (Rh), antibody screening, TORCHES-CLAP titer (*Toxoplasma gondii*; Rubella virus; Cytomegalovirus; Herpes simplex virus; Enterovirus; Syphilis; Varicella-zoster virus; Lyme disease; AIDS; Parvovirus B19), metabolic studies, and hemoglobin (Hb) electrophoresis [92]. An instrumental evaluation is needed to rule out various conditions possibly related to CPL and to establish whether CPL is primary or secondary.

Diagnostic methods that may be useful in evaluating CPL include conventional radiologic studies, echocardiography, high-resolution CT [93] and MR imaging [94], lymphoscintigraphy [95], lung functionality tests [96], lung biopsy [97], bronchoscopy, and pleural effusion examination [98].

Chest X-rays usually show hyperinflation with interstitial markings. CT demonstrates diffuse thickening of the interstitium, both of the peribronchovascular interstitium and the septa surrounding the lobules. Coronal MRI T1 may show thickening of the interstitium, pleural fluid effusion, and atelectasia, if present. Axial MRI T2 usually shows high-signal material within the pulmonary interstitium, which is very often associated with pleural effusion. Despite the greater

dose of radiation that is given during CT as compared to chest radiography, CT is preferable for the diagnosis of CPL and, more generally, for the diagnosis of pediatric interstitial lung disease. Lymphoscintigraphy is a mildly invasive technique that provides valuable morpho-functional information regarding the lymphatic system [99]. It highlights the accumulation of lymphatic fluid in the interstitial tissue that causes swelling, which is most evident in the limbs.

In the few cases in which lung function tests were performed, they showed various patterns including restrictive, obstructive, and normal values. It is noteworthy that pulmonary function tests were stable over time in the patients who obtained multiple values.

Bronchoscopic evaluation, while not specifically indicated in CPL, may be useful for ruling out other pulmonary pathologies. No tracheo-bronchial anatomical abnormalities were reported in CPL patients who were evaluated by bronchoscopy.

Lung biopsy may be useful to demonstrate the presence of dilated lymphatic spaces in the sub-pleural connective tissue, along the thickened interlobar septa, and around the bronchovascular axes. Great care must be taken when interpreting lung biopsies. In fact, the pathological findings in CPL patients may change a great deal over time, especially in case of viral infection, and, more generally, may range from initial recognition of minimal evidence of lymphatic dilatation to proof of severe lymphangiectasia. In this case, the lymphatic vessels are characterized by a thin wall, devoid of smooth muscle, and with slightly dilated lumen, lined by flattened endothelial cells.

56.4.9.3 Differential Diagnosis

During the neonatal period, transient tachypnea of the newborn, pulmonary aspiration syndrome and interstitial pulmonary infection are well known and are usually taken into consideration in the differential diagnosis of respiratory distress syndrome in the neonate.

Rarer conditions must also be considered in the differential diagnosis of chronic interstitial lung disease in infants, and include surfactant protein B deficiency, desquamative interstitial pneumonitis (familial and non-familial forms), pulmonary alveolar proteinosis, idiopathic pulmonary fibrosis, lymphoid interstitial pneumonitis, cellular interstitial pneumonitis, and chronic pneumonitis of infancy. Moreover, other conditions that can mimic interstitial lung disease in infants and children should be considered. These include neuroendocrine cell hyperplasia of infancy, acute pulmonary hemorrhage of infancy, follicular bronchiolitis, pulmonary vascular disorders (obstructive pulmonary venous disease, i.e., total and partial anomalous pulmonary venous return, pulmonary vein atresia or stenosis), hereditary hemorrhagic teleangiectasia, pulmonary hemangiomatosis, various systemic diseases, and metabolic lipid storage disorders.

56.4.9.4 Therapy and Treatments

Delivery room management could be a challenge in the presence of severe respiratory distress associated with pleural effusion, and multiple procedures might be required. Tracheal intubation and assisted ventilation are usually necessary. Infants with persistent pulmonary hypertension and difficulties oxygenating should be ventilated with high-frequency oscillation. This type of ventilation could be useful in recruitment of alveoli and will decrease barotrauma and volutrauma. Higher sustained mean airway pressure may also favor alveolar lymph drainage. Thoracentesis is useful in cases with conspicuous pleural effusion. Some patients with CPL could benefit from inhaled nitric oxide (iNO). Patients with acute respiratory failure who are refractory to maximal conservative treatment might be considered candidates for ECMO [100].

56.4.9.5 Prognosis

Recent advances in neonatal intensive care have changed the previously nearly fatal outcome of PL at birth. However, contradictory data have been reported regarding the outcome and do not allow a consistent prognosis to be established. The outcome is more likely to be favorable if there are no associated defects. Respiratory problems can continue over the first years of life and often require home supplemental oxygen and symptomatic treatment for recurrent cough and wheeze.

56.4.10 Chylothorax

Chylothorax is an unusual entity in the neonate that commonly is associated with respiratory symptoms in the first day of life and may be expression of CPL. The incidence of congenital chylothorax is about 1:10,000–15,000 pregnancies, with a male-female ratio of 2:1. Chylothorax presenting at birth may be associated with cardiac anomalies, various syndromes, thoracic ductal or venous thrombosis, birth trauma or local compression of the thoracic duct, congenital malformation of the lymphatic system (lymphangiomatosis) [86, 101, 102]. Chylothorax has been described as a complication of Down syndrome, in which there is presumably a significant maldevelopment of the lymphatic system. Other patients may have Turner or Noonan syndrome. Infants may have cystic hygroma malformations [86, 103]. Acquired chylothorax results from damage to the thoracic duct. It has been reported as a surgical complication in the repair of congenital diaphragmatic hernia, tracheoesophageal fistula, and a variety of congenital heart disorder (e.g., PDA ligation). Acquired chylothorax may also be the consequence of drainage of pneumothorax when the tube is inserted too far [104]. In many cases, however, no underlying cause for the chylothorax is found. Chylothorax is

more common on the right side: Chernick and Reed said that 53% of the cases were on the right side, 35% on the left side, and 12% were bilateral [104]. If the problem occurs early in the fetal life, infants may have significant pulmonary hypoplasia [105]. Since chylothorax is typically unilateral, there may be decreased breath sounds over the side of the effusion and mediastinal shift to the contralateral side. Bilateral chylothoraces should be considered in the differential diagnosis for any infant who cannot be ventilated in the delivery room. The characteristic roentgenographic appearance is similar to that of a large pleural effusion depressing the adjacent diaphragm and displacing the mediastinum.

The evaluation of the pleural effusion is essential for the diagnosis of chylothorax. Chylothorax is usually diagnosed in the presence of "milky" pleural effusion with a triglyceride level >1.1 mmol/L and a cell count >1000 cells/μL, with a predominance of lymphocytes (approximately 80%), according to the criteria drawn up in previous reports (Table 56.3) [98]. However, this is an unreliable diagnostic test in malnourished patients and in patients not receiving enteral nutrition, including the fetus and occasionally the neonate. Without enteral feeding, not enough chylomicron (the main triglyceride carrier) is produced to raise chyle triglyceride levels. In these patients, a diagnosis of chylothorax may easily be made by detecting lymphocytes in the pleural fluid.

Treatment of chylothorax may require repeated thoracenteses or even thoracostomy tube drainage to prevent respiratory failure. The large amount of fluid that is drained over days and weeks leads to the loss of great quantities of albumin, immunoglobulin, and many other plasma factors that must be replaced, in some cases even on a daily basis. Once drainage is accomplished, these infants are placed on formulas containing medium-chain triglycerides (MCTs) to reduce thoracic duct lymph flow. Oral intake of protein and water also stimulates thoracic duct lymph flow, so in resistant cases the infant is managed with nothing by mouth, with nutritional support through a central line [106].

Octreotide and antiplasmin have been used in CPL and chylothorax [107].

A variety of approaches have been used with some success to treat the infant with persistent chylothorax, including direct attempts at repair, patching with fibrin glue, and obliteration of the pleural space with sclerosing agents [108]. Congenital chylothorax also has been managed successfully using a pleuroperitoneal shunt [109]. Finally some reports suggest that ligation of the thoracic duct below the area of leakage is highly effective; this procedure is well tolerated without accumulation of fluid in the peripheral tissues or in the peritoneum [110].

Table 56.3 Composition of chyle [99]

Measurement	Mean	Range
Total protein (g/dL)	3.56	1.89–6.17
Albumin (g/dL)	2.24	1.26–3.0
Total lipids (mg/dL)	1180	56–3500
Cholesterol (mg/dL)	81	48–200
Triglycerids (mg/dL)	197	123–234
White blood cells (/mm^3)	15.200	0–29.000
Lymphocytes (%)	90	70–100
pH	7.5	7.4–7.8
Specific gravity	1.013	1.008–1.027

56.4.11 Misalignment of Pulmonary Veins with Alveolar Capillary Dysplasia

Alveolar capillary dysplasia (ACD) is a rare disorder typically presenting at birth with severe hypoxemia, although an unusual late onset has been reported at 6 weeks of life in an infant with a patchy distribution of disease [111]. No sex predilection has been identified. While the cause is unknown, there have been six cases reported in siblings, indicating that in some cases this may be a familial disorder with autosomal recessive inheritance [112].

56.4.11.1 Etiology and Pathogenesis

Pathological features include a paucity of alveolar capillaries, widened alveolar septae, and increased muscularization of pulmonary arterioles [113]. There is usually malpositioning ("misalignment") of pulmonary veins in the bronchovascular bundle, but this is not required for the diagnosis. A focal distribution of disease has been described, which makes it necessary to examine multiple lung sections if ACD is suspected [114]. ACD is characterized by failure of formation of alveolar capillaries, poor capillary apposition and density, together with medial arterial hypertrophy and misalignment of pulmonary vessels. Airspaces are lined by simple cuboidal cells, and there is a striking lack of proximity of capillaries and pneumocytes. Pulmonary veins are present in the bronchovascular bundle rather than in their normal position in the interlobular septa.

56.4.11.2 Clinical Aspects

The initial presentation is identical to severe idiopathic pulmonary hypertension of the newborn [115]. However, infants with ACD do not respond, or respond only transiently to therapies that are usually effective in reversing pulmonary hypertension.

The diagnosis of ACD should be considered in infants who present with severe hypoxemia and idiopathic pulmonary hypertension, and who do not respond appropriately after 7–10 days of standard treatment as described below. The majority of patients with ACD (approximately 75%) will have other associated anomalies of the cardiovascular,

gastrointestinal, urogenital, or musculoskeletal systems [116–118]. The initial chest radiograph is usually normal. The diagnosis can only be confirmed by lung biopsy or autopsy.

56.4.11.3 Differential Diagnosis

Conditions that must considered in the differential diagnosis of ACD are idiopathic persistent pulmonary hypertension of the newborn and surfactant protein B deficiency [119].

56.4.11.4 Therapy and Treatments

Standard therapies include mechanical ventilation, high concentrations of inspired oxygen, iNO and ECMO support [120]. These therapies prolong life by days to weeks, but have not led to long-term survival [121]. Theoretically, ACD could be treated by lung transplantation. However, successful transplantation has not yet been reported. Donor availability continues to limit the utilization of lung transplantation for neonatal diseases.

Neonatal Pulmonary Physiology of Term and Preterm Newborns

Corrado Moretti and Paola Papoff

57.1 Introduction

The transfer of O_2 to the tissues and the removal of CO_2 are guaranteed by the simultaneous activity of the respiratory apparatus and of the cardio-circulatory system which ensures that O_2 reaches the tissues and that the CO_2 produced by cell metabolism is removed [1].

The main steps in this process are:

- pulmonary ventilation, which consists in the rhythmic introduction of fresh gases into the alveolus; tidal volume is a term deriving from "tide" which offers an excellent representation of the flow and reflow of the gases;
- the diffusion of O_2 and CO_2 at the alveolus-capillary interface;
- capillary perfusion, whereby O_2 and CO_2 are transported into and out of the tissues.

Unlike the respiratory apparatus, the cardio-circulatory system is a closed-loop system with a one-way flow.

57.2 Lung Mechanics

Alveolar ventilation is obtained through pulmonary expansion, which in turn occurs through dilatation of the ribcage. At rest, the lungs and ribcage are in a situation of equilibrium determined by the resultant of two contrasting forces: elastic inward recoil of the pulmonary parenchyma and outward elastic traction of the ribcage. The pulmonary volume that results from this equilibrium is defined as functional residual capacity (FRC).

The consequence of this interaction in opposite directions is the presence of a negative pressure of around –3, –5 cm H_2O in the intra-pleural space, which is a virtual cavity. During normal breathing, most of the tidal volume is ensured by the diaphragm, a muscle supplied by the phrenic nerves, whose contraction causes an increase in the vertical diameter of the ribcage; the increase in the antero-posterior diameter is due to the contraction of the internal intercostal muscles whereby the ribs rotate upwards along their axis.

Dilatation of the ribcage during inspiration causes a reduction in intra-pleural pressure, and the lungs – hence the alveoli – undergo passive expansion [2]. The decrease in intra-alveolar pressure produces an air flow in the respiratory system; the flow stops at the end of inspiration when the alveolar pressure returns to a state of equilibrium with atmospheric pressure (Fig. 57.1).

In newborns, chest stability is facilitated by a relatively horizontal position of the ribs so that the intercostal muscles, which contract simultaneously with the diaphragm, can provide structural stiffness for the ribcage rather than expanding it during inspiration. Inspiration and expiration are therefore ensured above all by the activity of the diaphragm, which is less efficient in newborns compared to adults due both to its rather flat conformation that reduces its excursion and to its histological characteristics. In premature infants, in particular, the proportion of diaphragmatic slow-twitch muscle fibers that are resistant to oxidation and fatigue (Type I) is much smaller (10%) than the fast-twitch fibers which tire more easily (Type II); the proportion of Type I fibers increases progressively with age (about 25% in a term infant and 55% at eight months) [3].

Moreover, the chest of a premature infant is subject to distortion owing to the poor ossification of the ribs and sternum and because the intercostal muscles are not fully functional. The inward distortion of the chest during inspiration compels the diaphragm to do more work: indeed, in order to maintain the tidal volume constant, the excursion of the diaphragm must increase so as to offset the paradoxical movement of the ribcage. This phenomenon contributes to accelerating the respiratory functional exhaustion to which low birth-weight infants with respiratory distress are subject to.

The expiratory phase, by contrast, is usually a passive phenomenon determined by the forces of elastic recoil of

distended tissues: the greater the expansion of the lungs during inspiration, the greater its elastic recoil. The intervention of expiration muscles, the most important ones being the muscles of the abdominal wall, occurs only in some physiological situations such as coughing and sneezing or in some pathological conditions.

57.3 Elastic Properties of the Lungs

Compliance (C) is a value that expresses the elasticity of the lung or, rather, its capacity to be distended. It is defined by correlating the pressure applied to the alveoli (P) to the ensuing volume variations (V):

$$C = V/P$$

Compliance is usually represented through pressure/volume curves (Fig. 57.2): the higher its value the greater the variation of the amount of gas in the lung per unit pressure and the steeper the slope of the curve. A peculiar characteristic of lung pressure/volume curves is that inflation and deflation have different pressure curves, a phenomenon that is called hysteresis.

The factors determining the degree of elasticity of the lung are the presence of elastic fibers in the parenchyma, and the surface tension forces of the liquid that wets the alveoli walls [5]. Surface tension forces are generated by the cohesion between the molecules making up the liquid: these forces are balanced in the liquid phase but not at the air-liquid interface; the result is that the molecules on the surface exercise greater attraction towards the surrounding molecules. The importance of the role of the surface tension forces may be demonstrated through a simple experiment: by expanding an isolated lung with saline solution, and then with air, two different pressure/volume curves are obtained. In the first case the recoil forces are entirely due to the elastic properties of the lung tissue because there is no air-liquid interface; by contrast, when the lung is expanded with gas, the surface tension forces require a greater pressure to obtain the same expansion; moreover, it must be pointed out that when the lungs are filled with saline solution the hysteresis disappears.

The presence on the surface of the alveoli of a tensioactive factor or surfactant, consisting of various phospholipids, has the function of reducing the superficial tension forces and of stabilizing the size of the alveoli.

According to Laplace's law

$$\text{Pressure} = 2 \times (\text{surface tension})/\text{radius}$$

the pressure required to maintain the alveoli expanded increases proportionally to the decrease in its radius: the consequence should be that the smaller alveoli empty out into the larger ones, but the action of the surfactant, i.e., decreasing surface tension, is more effective as the alveolus decreases its size as a result of the greater concentration of surfactant molecules. The intra-alveolar pressure is thus uniformly maintained in the pulmonary parenchyma and the size of the alveolus is kept stable.

The effects of the surfactant on lung mechanics can be easily understood from the analysis of Fig. 57.3, which shows two pressure/volume curves obtained by inflating a lung affected by respiratory distress syndrome (RDS), before and after treatment with surfactant.

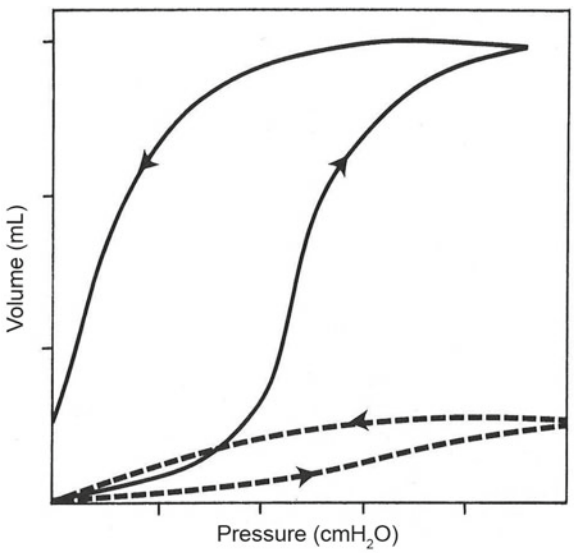

Fig. 57.2 Pressure/volume diagram in a neonate with RDS (*dashed line*) and in a normal neonate (*solid line*)

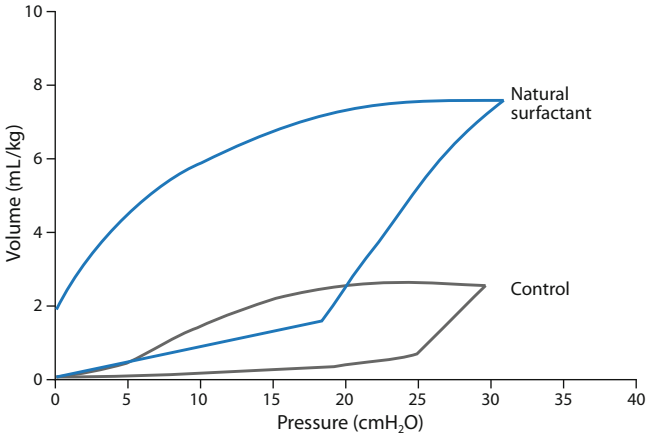

Fig. 57.3 Pressure-volume relationships for the inflation and deflation of surfactant-deficient and surfactant-treated preterm rabbit lungs. Modified from [6]

The fundamental differences between the two curves are:

- the opening pressure, i.e., the pressure at which the alveoli begin to expand, is higher before being treated with surfactant;
- lung expansion at the same peak pressure value is better after treatment with surfactant;
- before treatment with surfactant the lung does not have stability in the expiratory phase and has a tendency to collapse and to lose FRC.

In summary, the surfactant has the following functions:

- it reduces the respiratory workload since the lung is more prone to distension;
- it increases the FRC given the lesser tendency of the lung to collapse;
- it has an anti-edema role since the increase in surface tension facilitates the attraction of liquids from the capillaries into the alveoli;
- it stabilizes the sizes of the alveoli.

A further factor that contributes to stabilizing the sizes of the alveoli is their mechanical interdependence: if an alveolus tends to collapse, the stress on the walls of the adjacent alveoli increases and this helps it remain expanded. The alveoli support each other thus contrasting any tendency towards a reduction or increase in volume of any single alveolus.

57.4 Airway Resistance

The forces that have to be overcome in order to ventilate the air inside and outside the respiratory system are not only the forces of elastic recoil of the lungs and chest but also the airway resistance.

The forces required to ensure breathing, whether the energy spent is stored and retrieved thereafter, or whether it is lost by the system in the form of heat, are defined conservative forces or dissipation forces. Conservative forces are the (volume-dependent) pressures generated by the elastic properties of the lungs and of the rib-cage, forces that tend to cause these structures to return to their initial position after a deformation: the energy spent on overcoming these forces during inspiration is recovered during expiration, which is a passive phenomenon. Conversely, the dissipation forces are the (flow-dependent) energies required to overcome not only the friction of the gases against the airway walls, but also the viscoelastic properties of the respiratory system determined by the molecular movements in the tissues. The dissipation forces are also defined as resistance forces: the energy required to overcome these forces is lost in the form of heat and hence can no longer be used.

In lung physiology the term airway resistance (R) is used to define the ratio between the difference in pressure between the alveoli and the mouth (ΔP) and the resulting flow (V):

$$R\ (cmH_2O/L/sec) = \Delta P\ (cmH_2O)/V\ (L/sec)$$

In the respiratory system some 30–40% of the resistance occurs at the nose, in the oro-pharynx and in the pharynx, while at the level of the trachea and bronchial tree the structures that resist most against the flow are the average sized bronchi and not the smaller sized airways.

The airways can indeed be schematized as a series of successive dichotomies (22 generations or bronchial branching): at each branch division the size of the segments slightly decrease in size, but since the number of elements doubles, the total cross section area increases with respect to the previous level (Fig. 57.4). Thanks to this architecture the resistance of the peripheral airways is very mild even if the flow runs along ducts whose size is truly very small.

The factors that determine the degree of resistance (R) of a duct include its length (l), its radius (r) and type of flow, i.e., laminar or turbulent flow

$$R = l/r^4$$

Turbulent flow, which occurs mainly at the points of branching or when the air flow is high and the radius of the duct is large, generates a larger resistance compared to laminar flow. The pressures in a laminar flow are proportional to the flow rate whereas in a turbulent flow they are proportionate to the square of the flow; in these conditions the energy needed is obviously greater. The progressive increase in total cross section area towards the periphery of the lung implies a progressive reduction in the linear velocity (linear velocity = air flow/cross section area) of the air flow, which is quite low and of the laminar type at the level of the smaller airways, whereas in the trachea and in the larger branches it is essentially turbulent.

Lung volume is another important factor for the resistance of the airways, above all of those with little or no cartilage structure. Indeed the small airways distend and compress very

easily, and the transmural pressure gradient of the walls of the small airways is important in defining their radius: during deep inspiration the intrapleural negative pressure increases thus causing an increase in the transmural pressure gradient and hence an increase in their size. A further factor consists in increasing the elastic tension exercised by the pulmonary parenchyma on the airways during volume expansion in the inspiration phase. The resistance of the airways therefore is less during inspiration as compared to expiration; in addition, during forced expiration, as occurs in the newborn when he cries, resistance is influenced by the dynamic compression of the airways.

Making the intrapleural pressure positive determines changes in transmural pressure whose effects are clearly seen in Fig. 57.5, which represents the pressure values that come into play during normal expiration and forced expiration. During forced expiration the pressure inside the peripheral airways is greater than the intrapleural pressure thanks to the pulmonary elastic recoil forces; in the larger airways by contrast, the pressure comes progressively closer to atmospheric pressure and is hence lower than intrapleural pressure. The point at which the pressure inside and outside the airways is equal is defined as equal pressure point (EPP), situated in normal individuals in the central airways within the first five branchings of the bronchial tree. Downstream from this point the airways are compressed and the compression increases with greater expiration effort, which will thus not be capable of increasing the flow velocity (dynamic flow limitation).

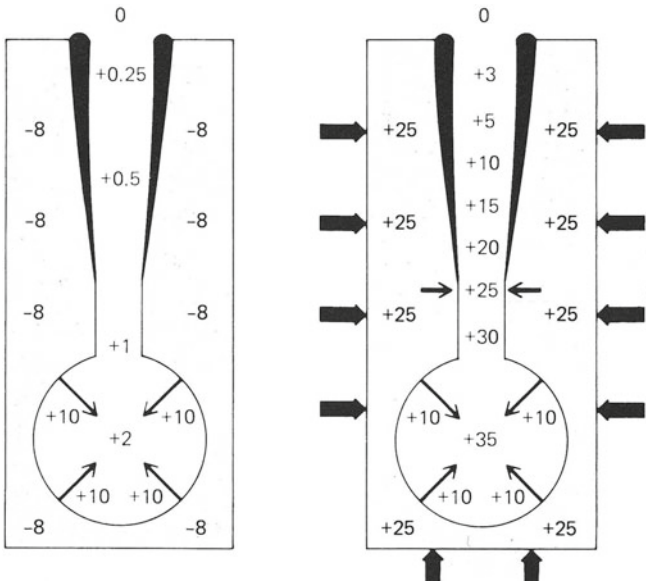

Fig. 57.5 Dynamic compression of airways. On the left, passive expiration: intrapleural pressure is –8 cm H_2O, pulmonary elastic recoil forces pressure is + 10 cm H_2O and alveolar pressure is +2 cm H_2O. On the right, forced expiration: intrapleural pressure is +25 cm H_2O, pulmonary elastic recoil forces pressure is +10 cm H_2O and alveolar pressure is +35 cm H_2O. Reproduced from [4], with permission

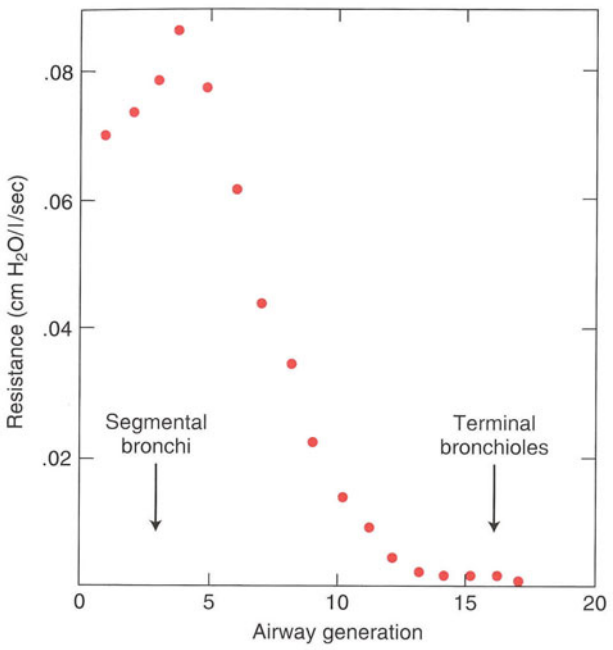

Fig. 57.4 Location of the main site of airway resistance. Note that the intermediate-sized bronchi contribute most of the resistance and that relatively little is located in the very small airways. Reproduced from [7], with permission

The expiratory flow also decreases with the progressive reduction of the pulmonary volume for the attenuation of the elastic recoil forces and for the smaller size of the airways; as expiration proceeds, the EPP moves distally towards the inside of the lung. The flow limiting mechanism is enhanced in some pathologic conditions characterized by an increase in peripheral resistance because the pressure drop is amplified inside the airways, or in others marked by a pressure reduction of the elastic component as occurs in emphysema.

57.5 Alveolar Ventilation

The amount of fresh air ventilated into the airways in one minute, or minute volume $\dot{V}_E$ ($\dot{V}$ = volume/time unit; the minute volume is measured with the amount of expired gas and it is indicated with $\dot{V}_E$), corresponds to the tidal volume (V_T) times the respiratory rate (RR):

$$\dot{V}_E = V_T \times RR$$

The tidal volume, that is to say the inspiration and expiration volume for each normal breathing cycle, measures about 6–8 mL/kg in the newborn, and 4–6 mL/kg in a preterm infant; about 30% of this volume remains inside the airways without taking part in the exchange of gases with the blood (anatomic dead space) and is called the dead space volume ($\dot{V}_D$). Alveolar ventilation ($\dot{V}_A$) is the volume of fresh air that

enters the respiratory zone every minute and is actually available for the exchange of gases; the $\dot{V}_A$ corresponds to:

$$\dot{V}_A = \dot{V}_E - \dot{V}_D$$

A reduction in the expansion of the lung, typical of RDS, causes a drop in V_T and hence in alveolar ventilation since the dead space remains unchanged; this compels the newborn to increase respiratory rate to keep the minute volume constant.

In physiological conditions the amount of air that remains inside the lung at the end of normal expiration, or functional residual capacity, is around 20–30 mL/kg; therefore, for each breathing cycle, only a part of the air in the alveoli (around 1/5–1/6) will be replaced with new air from the atmosphere. This slow renewal of air means that the variation in gas concentration in the alveoli is only 3–4 mmHg for each breathing cycle; relative constancy in gas concentration in arterial blood therefore depends on the buffer action of the FRC.

Let us now analyze the partial gas pressures in an ideal lung, considering that barometric pressure is around 760 mmHg: 20.9% of it is generated by O_2 and 79% by nitrogen; as a consequence, the PO_2 in the air is 20.9% of 760, that is 159 mmHg. The air inspired is saturated with aqueous vapor in amounts proportionate to body temperature; the value of the partial pressure of aqueous vapor at 37°C is 47 mmHg, which is to be subtracted from the relative value at total pressure of unsaturated air. The PO_2 of inspired air is hence 20.9% of 760 – 47 mmHg, therefore around 149 mmHg. The alveolar PO_2 (PAO_2) is less than that of the inspired air because the alveolar air is continuously impoverished of O_2 and enriched with CO_2 and its value is around 100 mmHg (as shown in Fig. 57.10a). The partial pressure values of O_2 and CO_2 at the alveoli are determined by the balance between alveolar ventilation, consumption of O_2 and production of CO_2.

Alveolar ventilation is regulated by the respiratory centers in such a way as to maintain the value of the arterial PCO_2 ($PaCO_2$) around 40 mmHg and the value of the arterial PO_2 (PaO_2) around 100 mmHg [8]. The value of arterial PCO_2, which is normally identical to the alveolar PCO_2 ($PACO_2$), is inversely proportionate to the degree of ventilation and is hence used as an index of alveolar ventilation; if alveolar ventilation is halved, the $PaCO_2$ doubles, if alveolar ventilation doubles, the $PaCO_2$ is halved (Fig. 57.6). Also the PaO_2 variations are proportionate to the degree of ventilation and inversely proportionate to the $PaCO_2$, in that the total sum of the partial pressures of the gases at the alveoli is always 760 mmHg. Actually, the partial pressure of aqueous vapor does not vary, and during ventilation the partial pressure of nitrogen varies slightly. However, the PaO_2 is not used as an index of ventilation because, unlike the $PaCO_2$, its value varies also as a function of the presence of an intra or extrapulmonary shunt [9].

The amount of work that respiratory muscles must do to maintain an optimal level of $PaCO_2$ depends on the type of ventilation. Each individual, depending on the elastic and resistance characteristics of his respiratory system, has an optimal theoretical rate where a reduction in compliance implies that it increases, whereas it is reduced when resistance increases. In clinical practice most patients with a pulmonary disorder use a ventilation mode that requires less respiratory work, and respiratory rate is often close to the optimal hypothetical one. Theoretically it is therefore possible to classify pulmonary diseases as restrictive or obstructive diseases on the basis of high or reduced respiratory rate measurements, but the respiratory centers are regulated also by cortical influences and by mechanical or irritation stimuli coming from the respiratory system that may gain the upper hand over the energy advantage.

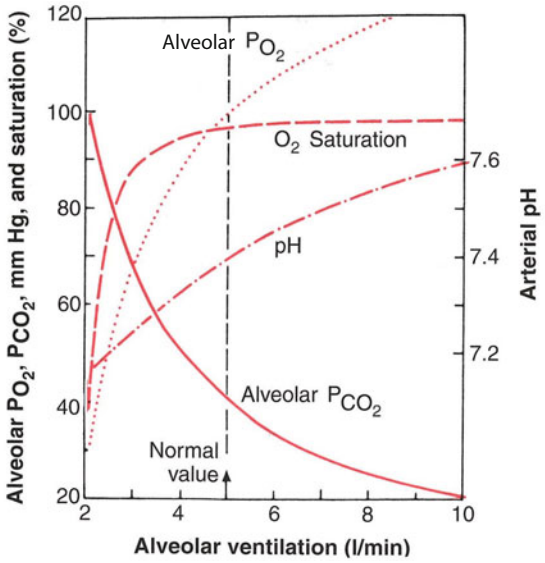

Fig. 57.6 Blood gases analysis variations related to alveolar ventilation (adult). Reproduced from [10], with permission

57.6 Diffusion

The next step after the cyclical renewal of alveolar air is the diffusion of O_2 from the alveoli to the blood, and of the CO_2 in the opposite direction [11]. O_2 and CO_2 move from high partial pressure areas to others where the partial pressure is low as a result of a process of passive physical diffusion. The diffusion of the gases across the alveolar wall is described by Fick's law:

$$\dot{V}\,\text{gas} = A \times K \times (P_1 - P_2)/S$$

This law states that the volume of gas that diffuses per unit of time ($\dot{V}$gas) is proportional to the surface area (A), to a diffusion constant (K) and to the partial pressure difference ($P_1 - P_2$), and it is inversely proportional to the thickness of the alveolar wall (S). The diffusion constant K is, in turn, proportional to the solubility of the gas and inversely pro-

portional to the square root of its molecular weight. The CO_2 has a molecular weight that is not very different from that of the O_2, but it has higher solubility, and so it diffuses about 20 times more rapidly than the O_2 through the blood-gas barrier.

At the blood-gas barrier the flow pressure for the O_2 is around 60 mmHg (100 mmHg alveolar PO_2; 40 mmHg PO_2 capillary venous blood); the O_2 crosses the membrane rapidly and the PO_2 increases just as rapidly in the blood. It must be pointed out that the blood PO_2 reaches the values corresponding to the alveolar air just before the red cells have completed half of their journey inside the lung capillaries, whose overall duration is around 0.75 sec; therefore there are huge possibilities for compensation.

Moreover, thanks to the special form of the Hb dissociation curve, a high partial pressure difference persists between alveolar gas and blood also when the Hb is near total saturation. For instance Hb is saturated at 94% with a PO_2 of 70 mmHg, when there is still a 30 mmHg gradient.

The time it takes the capillary CO_2 to equilibrate against the alveolar CO_2 is more or less the same as the time taken by the O_2 in spite of the fact that the diffusion velocity of the CO_2 is 20 times higher than that of the O_2. In this case, however, we must consider that the partial pressure gradient between capillaries and alveoli is only 5 mmHg.

57.7 Pulmonary Circulation and Ventilation/Perfusion Ratio

The fetal pulmonary arterial muscle thickness increases during the last quarter of pregnancy blocking the perfusion of the lung circulation, which is rapidly developing. Of these two phenomena, the latter is most prevalent and results in a gradual reduction in pulmonary vascular resistances. The degree of development of pulmonary circulation affects the clinical presentation of neonatal cardio-respiratory diseases where the alterations in the ventilation/perfusion ratio are determined by the capacity, or lack thereof, to increase lung vascular resistances following stimuli such as hypoxia and acidosis, with hemodynamic patterns ranging from extrapulmonary shunt to pulmonary overflow.

Let us look at the ventilation/perfusion ratio ($\dot{V}_A/\dot{Q}$) of a term newborn in physiological conditions: their cardiac index (cardiac output referred to body surface) is approximately 3.5 L/min/m^2; since body surface is around 0.25 m^2, the value of the output is 0.8–0.9 L/min. Considering a respiratory rate of around 45 breaths/min, alveolar ventilation is about 700–800 mL/min; the result is a $\dot{V}_A/\dot{Q}$ ratio of 0.8–1 as in the adult. This means that each air volume that arrives at the alveolar surface exchanges with an equal amount of capillary perfusion blood. These values are indicative, but they do give an idea of the order of magnitude of these values.

57.8 Transfer of O_2 and CO_2

In physiological conditions O_2 is transferred to the tissues almost entirely in combination with the Hb of the red cells; only 3% is dissolved in the aqueous phase of the plasma. It must be noted that 1 g of Hb may bind to a maximum of 1.34 mL of O_2 and, since the normal concentration of Hb is about 15 g/100 mL, it may bind 20 mL of O_2 or, to use the generally accepted expression, 20 volumes of O_2 [12].

The amount of O_2 that binds to Hb in the erythrocytes is directly proportional to the PO_2 in the plasma and is plotted graphically as a dissociation curve of hemoglobin (Fig. 57.7). The italics S shape of the Hb dissociation curve is due to the functional interdependence or cooperative effect of its four hemes. As a result of this effect, while the first heme combines slowly with O_2, the second, under the influence of the first that has already been assigned, will combine more rapidly, and so on. Fetal Hb has a greater affinity for O_2 compared to that of the adult; its dissociation curve is shifted to the left and has a greater saturation at the same PaO_2 (the position of the Hb curve is defined by the P_{50}, which is the PaO_2 at which the Hb is 50% saturated; the P_{50} of the HbF is 19 mmHg , that of the HbA 26 mmHg). The shift to the right of the curve, denoting a reduced affinity of the Hb for O_2, is caused by a reduction in pH; this facilitates the transfer of O_2 to the tissues (Bohr effect).

The share of Hb bounded to O_2 is expressed as percentage saturation (SaO_2%); this is equal to the O_2 content in the blood (Cont. O_2) divided by the O_2 transport capacity of the Hb (Cap. O_2), times 100:

$$SaO_2\% = \text{Cont. } O_2/\text{Cap. } O_2 \times 100$$

It must be pointed out that hemoglobin saturation expresses only a percentage and not an amount or volume of O_2.

The special form of the Hb dissociation curve in its upper part means that saturation decreases only slightly with considerable drops in PO_2; for the same reason, considerable increases in alveolar PO_2 do not cause a significant increase in O_2 content since maximum O_2 saturation cannot exceed 100%.

The steepness of the lower part of the curve shows that the peripheral tissues receive large amounts of O_2 with small decreases in capillary PO_2. In venous blood PO_2 is around 40 mmHg, which corresponds to a 75% saturation; this means that during tissue perfusion only 25% of the total content is used; in practice about 5 mL for every 100 mL of blood (Fig. 57.7).

The transport of CO_2 in the blood is not as complex as the transport of O_2 [13]. CO_2 is found in the blood as a free gas in solution (up to 10% since it is 20 times more soluble than O_2 in the plasma) or in a chemical combination with hemoglobin and plasma protein in the form of carbamin-compounds (5–10%) and above all as bicarbonate ions (70–90%). The bicarbonate is formed in the blood by the following reaction:

$$CO_2 + H_2O \rightarrow H_2CO_3 \rightarrow H^+ + HCO_3^-$$

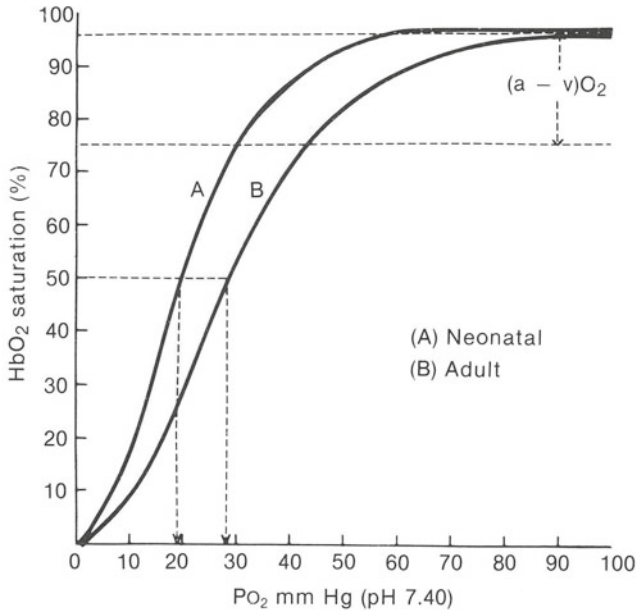

Fig. 57.7 Hb dissociation curve in a neonate (70% HbF) and in an adult in standard conditions (T= 37°C; pH 7.4). Reproduced from [4], with permission

CO_2 combines with water to form carbonic acid, which dissociates into hydrogen ions and bicarbonate ions; carbonic anhydrase, present in high concentrations in red cells, makes the reaction faster. Some of the released H^+ ions bind to the hemoglobin according to the following reaction:

$$H^+ + HbO_2 \rightarrow H^+ Hb + O_2$$

The reduced form of Hb is less acidic than the oxygenated form and it more rapidly accepts the hydrogen ions released by the dissociation reaction of carbonic acid, thus allowing a greater amount of carbon dioxide to be transported by venous blood in the form of bicarbonate ions (Haldane effect). This facilitates the uptake of CO_2 at tissue level and the inverse reaction facilitates its release into the lung capillaries where carbonic acid is converted into gas and removed from alveolar ventilation.

The acid-base status of the blood (pH) results from the ratio between bicarbonate concentration and the CO_2 in solution, and as long as this ratio is 20, the pH is stable at 7.4 [14]. (Normal arterial blood HCO_3^- concentration is 24 mmol/L, at 37°C about 0,03 CO_2 mmol for every PCO_2 mmHg in 1 L of plasma; consequently the amount of CO_2 in the blood is equal to 0,03 × PCO_2. So in normal condition the HCO_3^-/CO_2 ratio is 24/0,03 × 40 = 20.)

The blood concentration of bicarbonate is determined mainly by the kidneys and the PCO_2 by the lungs. An increase in the latter reduces the pH (respiratory acidosis) and the kidneys respond by eliminating a more acid urine, secreting H^+ ions in the tubules as $H_2PO_4^-$ or NH_4^+, while the HCO_3^- ions are reabsorbed. Kidney compensation however is hardly ever accomplished. By contrast, a reduction in PCO_2 determines an increase in pH (respiratory alkalosis) and kidney compensation occurs by eliminating a larger amount of bicarbonate. In the case of acidosis or metabolic alkalosis respiratory compensation mechanisms step in, that is hyperventilation or hypoventilation, so as to maintain the HCO_3^-/CO_2 ratio, and hence the pH, within physiological limits.

The dissociation curve of carbon dioxide shows the relationship between PCO_2 and the total content CO_2 in the blood (Fig. 57.8): at physiological levels of PCO_2 the carbon dioxide content is around 50 mL or volumes per 100 mL, with an oscillation of only 4 volumes per 100 between arterial blood and venous blood (48 mL–52 mL). In practice every 100 mL of blood that go through the lungs release 4 mL of CO_2.

In the normal range of the PCO_2 values the curve approximates a straight line without steep or flat portions; this means that an increase or slowdown in ventilation determines a proportional decrease or increase in arterial CO_2. Furthermore, the lower the PO_2, the greater the CO_2 content for a given PCO_2 (Haldane effect).

The dissociation curve of CO_2 is steeper than that of the O_2, in other words, there is greater variation in gas content for partial pressure variations. Knowing the difference between the dissociation curves of the Hb and CO_2 is essential to understand the pathophysiology of major ventilation alterations.

We have seen how 100 mL of blood transport 5 mL of O_2 from the lungs to the tissues, whereas the same amount of blood transports some 4 mL of CO_2 from the tissues to the lungs. At resting conditions, therefore, for every 100 volumes of O_2 assumed by the lungs only 80 volumes of CO_2 are eliminated, where the ratio between eliminated CO_2 and O_2 uptake is defined as respiratory quotient (RQ) and is expressed by the following formula:

$$RQ = CO_2 \text{ eliminated}/O_2 \text{ uptake} = 0.8$$

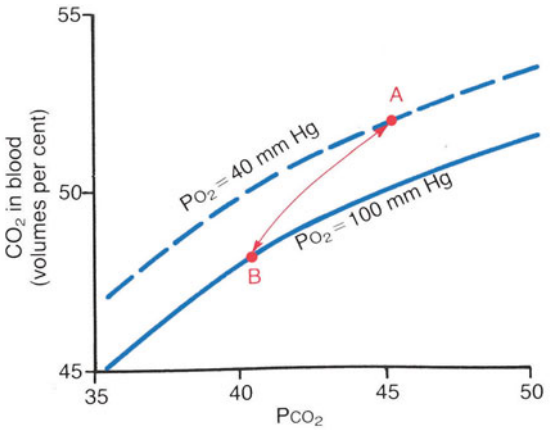

Fig. 57.8 Portions of carbon dioxide dissociation curves when PO_2 is 100 mmHg and 40 mmHg, respectively. Arrows represent the Haldane effect on the transport of carbon dioxide. Modified from [15]

57.9 Causes of Hypoxia

57.9.1 Hypoventilation

We have seen that the alveolar PO_2 and hence the arterial PO_2 is determined by the equilibrium between the speed of CO_2 removal and O_2 supply by alveolar ventilation. If the ventilation is reduced, the alveolar PO_2 drops and for the same reason the $PaCO_2$ rises, and it is the increase in $PaCO_2$ that represents a very important criterion for the diagnosis of hypoventilation because, unlike hypoxia, this is virtually the sole cause for hypercapnia. Hypoventilation is therefore characterized by an inadequate removal of CO_2 compared to its production and the relationship can be written as follows:

$$PaCO_2 = \dot{V}_{CO_2}/\dot{V}_A$$

where $\dot{V}_{CO_2}$ is the production of CO_2 and $\dot{V}_A$ is alveolar ventilation ($\dot{V}_E - \dot{V}_D$).

The gradual reduction in ventilation progressively brings the alveolar gas values closer to the venous blood values. Arterial PO_2 can be easily corrected by increasing the FiO_2, since the larger amount of O_2 that reaches the alveoli through each breath may offset the reduction in ventilation. Conversely, hypercapnia can be corrected only by increasing respiration frequency and/or the tidal volume, and may require a certain amount of time because the CO_2 is stored in large amounts in the form of bicarbonates.

The causes that determine hypoventilation are mostly non-pulmonary; amongst the most frequent causes in newborn we may mention:

- apnea spells in premature infants;
- depression of the CNS due to anesthetics or drugs;
- diseases of the CNS;
- diseases affecting the respiratory muscles (paralysis of the diaphragm, weak respiratory muscles in preterm infants, etc);
- obstruction of the upper airways (choanal atresia, Pierre-Robin syndrome, laryngomalacia, etc.);
- obstruction or mal-positioning of the tracheal tube.

Hypoventilation may also be a symptom of functional exhaustion and it may complicate pulmonary diseases when a considerable increase in work of breathing is required.

57.9.2 Abnormal Diffusion

Normal lungs present extensive compensation possibilities to ensure O_2 diffusion. It was pointed out earlier that blood and alveolar PO_2 and PCO_2 are already in equilibrium even before the blood completes half of its journey along the pulmonary capillaries. It is however possible that in some pathological conditions, like pulmonary edema or interstitial fibrosis, diffusion may be slowed down to such a rate as to make the equilibrium between PO_2 of the alveolar gas and that of the capillary blood incomplete. It is not clear, as yet, what the role of diffusion is in determining hypoxia in these disorders, but it is likely that most of the pathogenic mechanism is due to alterations in the ventilation/perfusion ratio. However hypoxia, secondary to a diffusion defect, may be rapidly redressed by administering O_2; the increase in alveolar PO_2 helps overcome the resistance to diffusion caused by changes in the membrane.

Alterations in diffusion never involve CO_2 given the rapidity with which it diffuses; in such conditions the $PaCO_2$ is often slightly decreased because of the hyperventilation caused by hypoxia.

57.9.3 Extrapulmonary Shunt

The term extrapulmonary shunt refers to the passage of blood from the right sections to the left sections of the heart without crossing the ventilated pulmonary areas. The arterial PO_2 drops when the desaturated blood mixes with the oxygenated blood.

Fig. 57.9 shows the effect of the increase in FiO_2 at various levels of shunting: when the latter exceeds 30%, the O_2 is no longer capable of redressing the hypoxemia and this characteristic makes the difference between an extrapulmonary shunt and the other causes of hypoxia. The mixing of arterial blood and shunt blood causes a considerable drop in PaO_2 because the dissociation curve of the O_2 is flat in its higher portion: it is therefore possible to show up minor shunts by measuring the arterial PO_2 during 100% O_2 inhalation (hyperoxic test). By contrast, if hypoxemia is secondary to other causes (hypoventilation, limitations to diffusion, inhomogeneities in the $\dot{V}_A/\dot{Q}$ ratio), during 100% O_2 inhalation, the

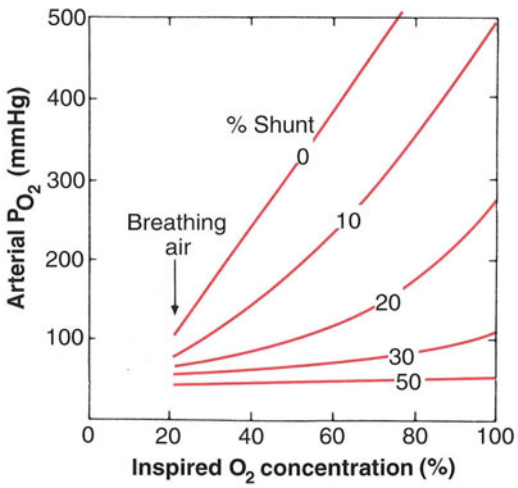

Fig. 57.9 Arterial PO_2 variation with different inhaled O_2 concentrations and different shunt percentage. Reproduced from [10], with permission

PaO_2 reaches levels that are virtually comparable to those observed in normal individuals, albeit over longer time intervals. A healthy individual who inhales 100% O_2 has an ideal PaO_2 of 673 mmHg (760 mmHg – 47 mmHg H_2O – 40 mmHg CO_2 = 673 mmHg).

The $PaCO_2$ is not usually increased in the presence of an extrapulmonary shunt because the hypoxia and hypercapnia of non-oxygenated blood cause an increase in alveolar ventilation; the latter is effective in reducing the $PaCO_2$, but totally ineffective in increasing the PaO_2. As described earlier, the reason is to be found in the shape of the two dissociation curves; the CO_2 curve is virtually straight in the physiological zone, with the result that an increase in ventilation increases the elimination of CO_2. By contrast, the shape of the Hb dissociation curve, which is flat in its upper portion, does not allow the increase in ventilation to bring about an improvement in the O_2 contained in the blood.

During neonatal age, several diseases are characterized by a right-left shunt through fetal channels for the increase of pulmonary resistances; in this case oxygen therapy is a critical element in solving pulmonary vasoconstriction and in reducing the shunt.

57.9.4 Alterations in the Ventilation/Perfusion Ratio

Alterations in the ventilation-perfusion ratio ($\dot{V}_A/\dot{Q}$) are undoubtedly responsible for most of the defects in the exchange of O_2 in pulmonary diseases and rarely for CO_2 defects [16]. The reason hypercapnia rarely occurs with alterations of the $\dot{V}_A/\dot{Q}$ ratio is because the high degree of efficiency of the chemoreceptors that keeps the arterial CO_2 constant by increasing ventilation. As shown earlier, the linear shape of the CO_2 dissociation curve ensures this compensation.

Also in the healthy lung there are regional variations in the $\dot{V}_A/\dot{Q}$ ratio, but the overall effect on the total gas exchange is negligible. The distribution of ventilation in particular is regulated by tissue compliance and by the resistance of the airways; differences in these factors in the pulmonary district cause a non-uniform distribution of ventilation.

Let us now look at the consequences of the two extreme variations of the $\dot{V}_A/\dot{Q}$ ratio, bearing in mind that in practice intermediate degrees of these alterations coexist:

- $\dot{V}_A/\dot{Q} = 0$. In practice the alveoli are not ventilated but perfused (shunt effect). In this case there is no gas exchange between blood and air, but an equilibrium sets in between venous blood and the air in the non-ventilated alveoli; inside the latter the partial pressures will be the same as those of venous blood (Fig. 57.10b). In this way an intrapulmonary shunt is caused because the blood that perfuses the non-ventilated zones is not oxygenated, nor is the CO_2 removed; the consequences are identical to those caused by an extrapulmonary shunt.
  In this case an efficient compensation mechanism intervenes, hypoxic vasoconstriction, which involves the capillaries that perfuse the areas where ventilation is reduced or totally absent; the local blood flow is diverted to the ventilated alveoli and the deleterious effects on the exchange of gases is considerably reduced. It is interesting to point out that when this occlusion of the airways persists, the alveoli end up collapsing because of the diffusion of gas in the blood, and the formation of atelectasis due to reabsorption is more rapid if the patient breathes O_2 at high concentrations. Indeed, nitrogen has a low degree of solubility and its presence provides support for the alveoli and delays their collapse in the case of obstruction of the airways. Oxygen dependence, which is typical of children with bronchopulmonary dysplasia (BPD), is almost certainly due to the presence of multiple shunts having a low $\dot{V}_A/\dot{Q}$ ratio.

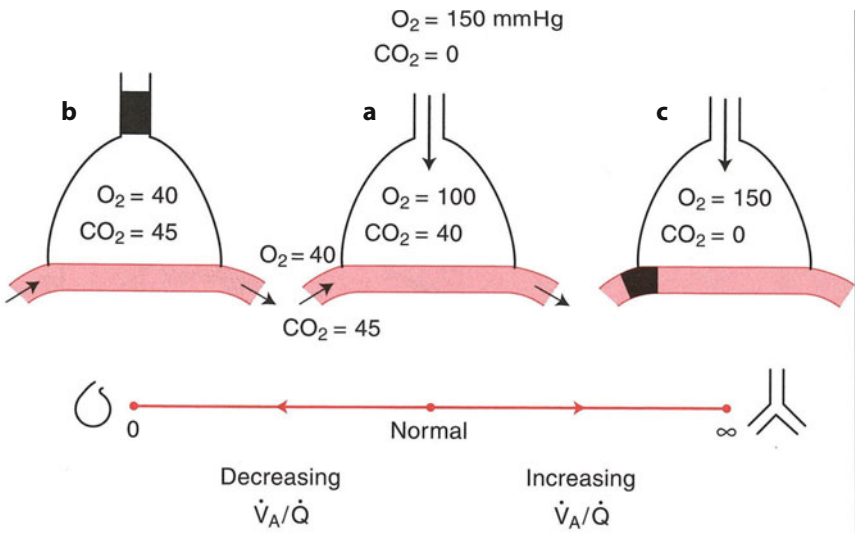

Fig. 57.10 Effects of altering the ventilation-perfusion ratio on the PO_2 and PCO_2 in a lung unit. Reproduced from [17], with permission

- $\dot{V}_A/\dot{Q}$ = infinite. In practice the alveoli are ventilated but not perfused (dead space effect). Also in these conditions there is no blood-air exchange; and indeed, instead of having partial pressures similar to those of venous blood, the air in the alveoli has the same partial pressures as atmospheric air. In other words, O_2 is not transferred to the blood and CO_2 is not removed. This quota of ventilation remains unused (physiological dead space) and increases the respiratory dead space thus causing a reduction in alveolar ventilation (Fig. 57.10c). It is not possible to describe the gas composition of the blood coming from these units because perfusion is totally absent, but clearly the PO_2 and the PCO_2 of the blood will always be closer to those of inspired air as the perfusion is progressively reduced. The units with a high $\dot{V}_A/\dot{Q}$ ratio add little O_2 to the blood compared to the decrease caused by the alveoli with a low $\dot{V}_A/\dot{Q}$ ratio, and the reason is always to be sought in the shape of the Hb dissociation curve.

57.9.5 Hypoxia Due to Anemia and Hypoperfusion

It is worth remembering that to ensure an adequate O_2 supply to the tissues, a normal Hb concentration is required and also the cardiac output must be adequate. The efficacy of the latter may be determined indirectly by assessing skin color and skin temperature, peripheral pulses, gas-analysis values, diuresis and directly by means of color-Doppler echocardiography. And finally, it must be pointed out that a reduction in Hb causes a decrease in the O_2 content without any variation in the PaO_2; an anemic patient may therefore have a good PaO_2, but a low O_2 content.

57.10 Conclusions

After having schematically described the pathophysiology of the possible causes of hypoxia it is worthwhile underlining that in practice these mechanisms often coexist and contribute to determining respiratory failure.

The most typical example in neonatology is RDS, where the lack of surfactant and an alteration in pulmonary compliance cause the formation of atelectasis and the uneven distribution of ventilation; as a consequence the $\dot{V}_A/\dot{Q}$ ratio is altered. The edema and the presence of exudates at the alveoli may have a negative impact also on the diffusion of O_2. The resulting hypoxia, combined with acidosis, further worsens the ratio due to the increase in vascular resistance with the formation of shunts in the fetal channels and hypoperfusion of the pulmonary circulation. Finally, owing to the considerable increase in respiratory work, the patient may present with hypoventilation symptoms after an initial phase characterized by tachypnea.

Control of Breathing in Newborns

Ruben Alvaro and Henrique Rigatto

58.1 Introduction

There are at least three important considerations regarding the study of the control of breathing during the neonatal period. First, the neonates are noncooperative subjects. This means that we must study their respiratory control without their being aware and try to compare the measurements with those of the adult under similar conditions. This is difficult to do. Second, measurements in the neonate are usually made, by necessity, in the decubitus position, whereas those in the adult subject are usually made in the sitting or standing position [1, 2]. Third, babies are usually studied with a nosepiece because they are nose breathers; adults are usually studied using a mouthpiece. These methodological differences have made comparison of breathing in newborns with that in adult subjects difficult to interpret. There is currently a major need for studies to be done using similar methodology. Unless there is some consistency in the methodology, it is hard to define what is actually distinct or unique about the control of breathing in the neonate. In recent years, we have experienced tremendous advances in the field of respiratory control, and we are now witnessing the initial discovery of several of the genes that control the development and maturation of multiple neurally controlled respiratory functions

In this chapter we review some of the concepts and the progress made in the area of control of breathing in the newborn. We also highlight major developments and critically analyze the scientific foundations of our knowledge in this area.

58.2 Breathing Pattern at Rest

The neonate, and particularly the premature infant, breathes irregularly. There is significant breath-to-breath variability and long stretches of periodic breathing in which breathing and apnea alternate [2–4]. Haldane's statement that "the surprising fact is not that we breathe regularly, but that we do not breathe periodically most of the time" applies more at this age than at any other [5]. The resting breathing pattern of the neonate is not sleep-state dependent, although sleep greatly modulates it [6, 7].

Sleep has traditionally been divided into quiet, REM, transitional, and indeterminate states. Twenty-nine percent (29%) of sleep time in neonates is spent in quiet sleep, 33% in REM, 7% in transitional sleep, and 31% in indeterminate sleep. The proportion of quiet sleep increases with age, while the amount of REM decreases with age. The proportion of wakefulness decreases with decreasing gestational age and in very immature infants, it becomes difficult to define wakefulness or arousal [8, 9]. We have shown that periodic breathing, a common breathing pattern in premature infants in which they alternate between breathing intervals and apneas lasting 5–10 seconds, occurs in the three states, wakefulness, REM, and quiet, but its prevalence is increased in REM sleep [6]. It is frequently stated in textbooks that in quiet sleep, in analogy with criteria used for adult subjects, breathing is regular. However, we and Prechtl have clearly shown that periodic breathing is common in quiet sleep [2, 10, 11]. The difference is that periodic breathing in quiet sleep is regular, that is, the breathing and apneic intervals are of similar duration, and very irregular in REM sleep. The most well-defined periodic breathing observable in small babies is in quiet sleep during tracé alternant. Therefore, there are two major differences between neonates and adults regarding staging of sleep state. One difference relates to the patterns of breathing observed in quiet and REM sleep states and the other to the presence of the trace alternant electroencephalogram (EEG) during quiet sleep in the neonate. As this pattern subsides after 44 weeks' postconceptional age, it is not used in adults to characterize quiet sleep. Finally, the overall minute ventilation is increased in REM sleep as compared with quiet sleep, and this is due to a primary increase in respiratory frequency with little change in tidal volume [1, 2, 6].

58.3 Periodic Breathing and Apnea

Periodic breathing, defined as pauses in respiratory movements that last for up to 20 seconds alternating with breathing, is common in preterm infants. When the respiratory pause is longer than 20 seconds, it is called apnea [12]. Although the duration used to distinguish periodic breathing and apnea is arbitrary, it has proved useful and has been widely adopted. Periodic breathing is not as harmful as apnea since the respiratory pause is short and the decrease in heart rate is minor. In contrast, apnea is a more serious condition, the respiratory pause being longer and frequently associated with decreases in heart rate below 80 beats/minute [12, 13]. In very small preterm infants, significant bradycardia and desaturation can occur with very short apneic pauses, likely related to their higher oxygen consumption per unit weight and their relatively smaller lung volumes and oxygen stores than the term infants and adult subjects. In this instance, therefore, the length of the respiratory pause is not a very useful indicator of severity of the disruption in breathing. For this reason, many centers, including ours, have decided to rely on heart rate and oxygen saturation as the primary indicators of severity.

Apneic episodes in the neonate are classified according to the absence or presence of breathing efforts during the period of no airflow [14]. Central apneas are those with no flow and no observable breathing efforts. Obstructive apneas are those with no flow despite breathing efforts. Mixed apneas begin as central and end as obstructive apnea. Breath-holding apneas are those in which flow stops at mid-expiration, and the remaining expiration occurs just before breathing starts again. A new method of classifying apneas, based on a magnified cardiac-induced pulse observed on the respiratory flow tracing, has been recently described by us. This method is able to detect presence and timing of airway obstructions with great precision. Using this method it is obvious that some apneas, previously classified as central because of absence of respiratory efforts, are indeed obstructive (silent obstruction) (Fig. 58.1) [15, 16]. We have been using this method extensively in our experimental studies, but its use in routine clinical care is not yet established.

In preterm infants with underlying disease followed longitudinally over a period of 3 months, central apneas predominated and purely obstructive apneas were rare [14]. Obstructive apneas are more commonly noted as part of a mixed apneic event. Most short apneas are central, whereas long apneas are mixed. The mechanism of obstruction in mixed apneas is unknown and it is not completely clear whether the obstructed respiratory efforts prolong the apnea or whether a longer initial central pause predisposes the airway to collapse at the end of the apnea. We found that airway closure, as measured by the absence of cardiac oscillations on the respiratory flow tracing, was present in about 20% of central apneas and preceded 59% of the obstructed respiratory efforts in mixed apneas. This airway closure during central apneas did not limit the severity of oxygen desaturation or the decrease in heart rate. We also found that although the length of mixed apneas was longer than central apneas, the length of the initial central component of the mixed apneas was significantly shorter than the length of central apneas, suggesting that respiratory efforts against a closed airway prolong apnea. These respiratory efforts against a closed airway also aggravated the oxygen desaturation and the decrease in heart rate that are usually associated with apneas [16]. In preterm infants recovering from respiratory support, with some degree of residual lung disease (bronchopulmonary

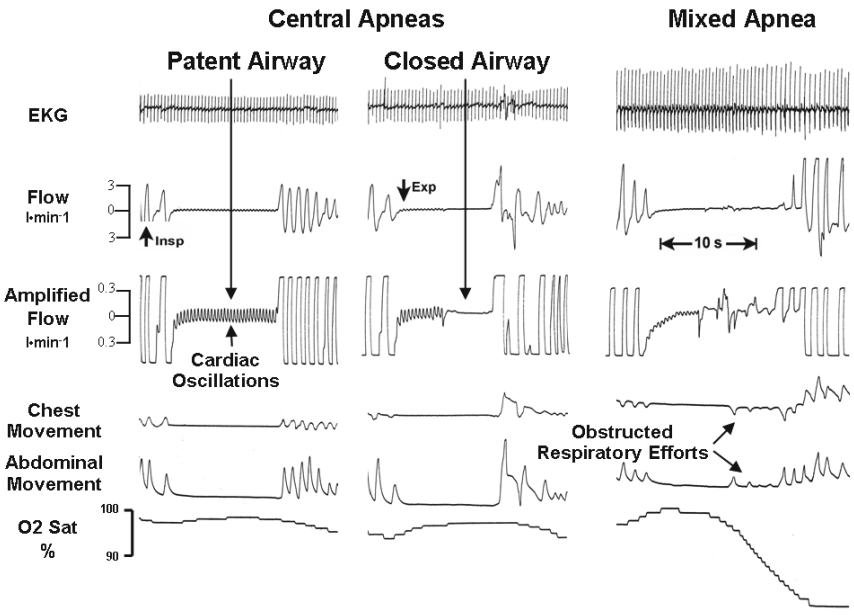

Fig. 58.1 Representative tracing: Examples of three types of apneas diagnosed by absent (central apneas) or present obstructed respiratory efforts (mixed apnea). Central apneas are further classified using the amplified cardiac airflow oscillation into those with open airway (oscillations present) and those with closed airway (oscillations absent). Cardiac oscillations and respiratory effort signals are indicated. The flow channel shows baseline respiratory flow with minor amplification. The amplified flow represents a 10-fold amplification of the flow signal by the chart recorder so that cardiac oscillation may be easily analyzed [16]

dysplasia), the prevalence of obstructive apneas appears to be increased, comprising up to 48% of the apneas in some studies. There is no clear explanation for the obstruction, but it seems to be at the level of the larynx [17].

Periodic breathing and apnea are clearly a consequence of a disturbance of the respiratory control system, but the precise mechanisms are unclear. Investigators in this area tend to believe that the negative feedback loop controlling respiration is affected by multiple factors related primarily to anatomic and physiologic immaturity that affect many levels of the respiratory control system including central and peripheral chemoreceptors. For example, arborization of dendrites at 30 weeks' gestation is meager, and neuroconduction and synaptic relay are impaired [18]. Delays in traffic of neuromessages may then make the system oscillate. Unfortunately, we do not know how much immaturity is needed for a given impairment in neurophysiologic traffic. Oscillation in arterial gas tensions, changes in circulation time, incoordination of the respiratory pump owing to a compliant chest wall, and changes in sleep state may all contribute to this instability of the respiratory control system [12]. Many inhibitory neurotransmitters and neuromodulators, including adenosine, prostaglandins, endorphins and GABA have been also implicated in the pathogenesis of periodic breathing and apnea [19].

There has been controversy in the literature on whether periodic breathing and apnea are mechanistically different or whether long apneas are just a step further in the basic respiratory disturbance that induces the short apneas of periodic breathing. In a study carried out in our laboratory we were able to show that i) a prolonged apnea almost never occurred in the absence of preceding short apneas, and ii) the risk of a prolonged apnea occurring increased significantly when the preceding period contained an increased number of apneic episodes, increased duration of the longest apneic interval, or increased duration of the apneic time [20]. More recently we have shown that the periodic breathing cycles in REM but not in quiet sleep were associated with progressive decrease in minute ventilation and oxygenation likely related to the mechanical and chemoreceptor limitations known to be present in this sleep state. We believe that periodic breathing, especially during REM sleep, is a marker for apnea since apneas almost never occur abruptly in infants breathing regularly, but only in infants whose respiratory pattern is characterized by significant periodicity.

Compared with infants who breathe continuously, neonates breathing periodically have lower arterial PO_2 values and their peripheral chemoreceptors are more hyperactive as reflected by the longer apneic period and more pronounced immediate decrease in ventilation in response to inhalation of high oxygen mixtures [13, 21, 22]. Thus, the basic reason for background instability appears to be the major contribution of the peripheral chemoreceptor drive to normal breathing at this age. Indeed, the arterial PO_2 tension of these infants sits on the steep portion of the minute ventilation-arterial PO_2 regression curve for human adults. This means that small changes in baseline arterial PO_2 produce large changes in baseline ventilation. Hypoxia may be a contributing factor, because inhalation of a low-oxygen mixture easily induces periodic breathing and apnea in these infants.

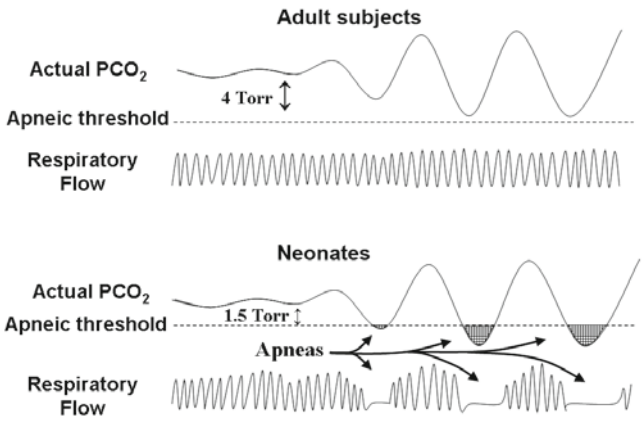

Fig. 58.2 Diagrammatic representation of the relationship between the CO_2 apneic threshold and the baseline or actual PCO_2 levels in neonates and adults. Because of the proximity of these two levels in neonates, PCO_2 is much more likely to dive below the apneic threshold than in the adult

We found that the average CO_2 apneic threshold in preterm infants is only 1.5 Torr lower than the eupneic PCO_2, whereas in adults the average is ~3.5 Torr lower [23]. The closeness of eupneic and threshold $PACO_2$ likely confers a great vulnerability to respiratory stability in these infants. It is not surprising, therefore, that brief startles, movements, or change in sleep state could allow eupneic PCO_2 to dive below the PCO_2 apneic threshold, inducing periodic breathing and apnea in these infants (Fig. 58.2). We believe that the key element responsible for this narrow difference is the well-known hypoxemic status of these infants. Xie and colleagues have recently shown in adults that the time course of the occurrence of apnea after transient hyperapnea was consistent with a peripheral chemoreceptor mechanism. In this study, hypoxia shortened the apnea latency and narrowed the eupneic-apneic $PACO_2$ threshold while hyperoxia delayed the onset of apnea and widened the eupneic-apneic $PACO_2$ threshold [24]. The same group had previously shown that the smaller difference between eupneic and apneic $PACO_2$ during hypoxia was due to a disproportionate reduction in the eupneic $PACO_2$ rather than a higher apneic threshold [25]. The low arterial PO_2 in newborn infants may keep the eupneic PCO_2 relatively low, not by hyperventilation as in adult subjects but by a decrease in metabolism, which parallels the decreased in arterial PO_2.

The sleep state appears also to be a contributing factor, since periodic breathing and apnea are more frequent in REM sleep than in quiet sleep. The neonate sleeps almost uninterruptedly, continuously alternating between REM sleep and quiet sleep. This pattern increases instability in the respiratory control system. Indeed, minor alterations during sleep, such as a startle or a sigh, produce apnea in these infants. The almost

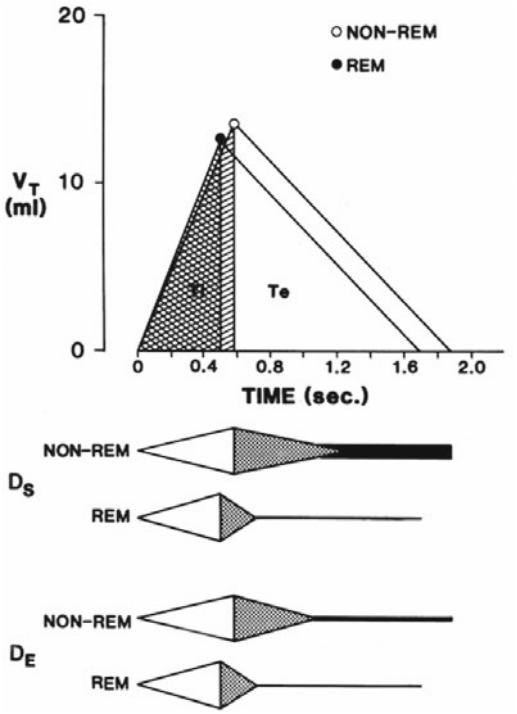

Fig. 58.3 Diagrammatic changes in tidal volume, timing, and diaphragmatic EMG in non–rapid eye movement (REM) (quiet) and REM (active) sleep. Note that total phasic activity diminishes from non-REM to REM sleep. Also, in both sleep states, it is shorter in esophageal (DE) than in surface EMG (DS). Expiratory phase activity as a proportion of total phasic activity decreases significantly from non-REM to REM sleep. From [26]

continuous change in baseline ventilation during sleep is what Haldane called "the hunting of the respiratory centre" [24].

Although sleep modulates breathing, it does not cause apnea; apnea also occurs during wakefulness. The high prevalence of apnea during REM sleep may be related to muscle activity in this stage. During REM sleep, the tone of the intercostal muscles is abolished in conjunction with a decrease in diaphragmatic activity and in the tone of the adductor muscles of the upper airway, a combination of factors likely to induce chest distortion, impairment of the braking mechanism during expiration, pulmonary collapse, and apnea (Fig. 58.3) [12, 26]. When chest distortion occurs, diaphragmatic work increases by about 40%, adding to the mechanical impairment. This observation is compatible with the finding that the application of continuous negative pressure around the chest tends to abolish apnea [27].

58.4 Chemical Regulation

Inhalation of carbon dioxide increases ventilation during REM and quiet sleep in newborn infants. The response to steady-state inhalation of carbon dioxide is the same in these two sleep states, but the response during rebreathing of carbon dioxide is less in REM than in quiet sleep [1, 6, 10, 28] (Fig. 58.4). We postulated that the differences in response with these two techniques relate to the fact that using rebreathing, it is possible to measure the response in "phasic"

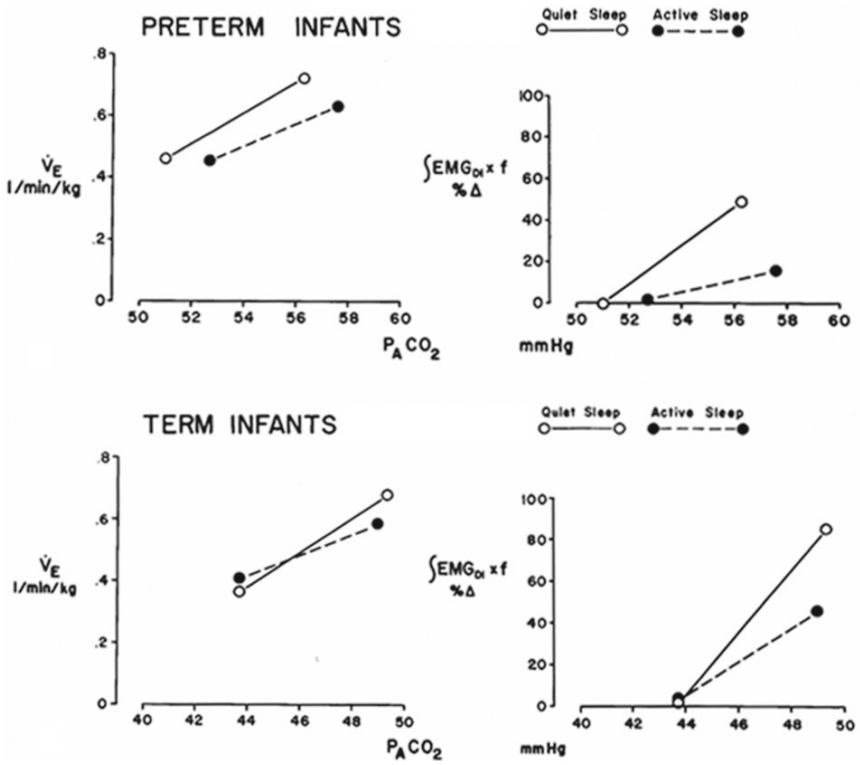

Fig. 58.4 The ventilatory response to CO_2 rebreathing in neonates. Note that (**a**) preterm and (**b**) term infants showed a decreased response to CO_2 in phasic rapid eye movement sleep as compared with quiet sleep [10]

REM only, whereas using the steady-state technique the response always covers both "phasic" and "tonic" REM sleep [10]. As the carbon dioxide response in "tonic" REM is the same as that during quiet sleep, the results using the steady-state method tend to resemble those in quiet sleep [29, 30].

The pattern of breathing observed with inhalation of carbon dioxide varies with the percentage of carbon dioxide inhaled. If the percentage of inhaled carbon dioxide is low (<2%) during steady-state inhalation, the response consists primarily of an increase in tidal volume [2]. If the percentage of inhaled carbon dioxide is high (>2%), the response in both sleep states consists of an increase in respiratory frequency and in tidal volume [10, 21]. Periodic breathing is abolished with a small increase in inhaled carbon dioxide of about 1–2% [2, 21]. This response has been attributed to the increased central drive and increased stores of carbon dioxide, with better buffering capacity for the oscillations in $PaCO_2$.

Inhalation of low oxygen produces an immediate increase in ventilation (1 minute) followed by a later decrease (5 minutes) [4, 31–33]. The response is similar in wakefulness, REM, and quiet sleep, although hyperventilation seems slightly more sustained during late hypoxia in quiet sleep [1]. The more sustained hyperventilation in these infants during quiet sleep reflects the more autonomic control during this sleep state, the system being more responsive to chemical stimuli [29, 30]. The immediate increase in ventilation reflects peripheral chemoreceptor stimulation and is associated with an increase in frequency and in tidal volume. The late response is primarily manifested by a decrease in frequency [13, 31]. The mechanism responsible for this response is still unclear, and may vary according to species. In humans it is likely related to central release of inhibitory neuromodulators [34]. This late hypoxic ventilatory depression is likely mediated through several complex mechanisms. In addition to hypoxic hypometabolism [35], several neuromodulators play a role in the hypoxic ventilatory depression including adenosine [36], γ-aminobutyric acid (GABA) [37], serotonin (5-HT) [38], opioids [39], and platelet-derived growth factor (PDGF-β) receptors [40]. However, experiments in kittens and in newborn monkeys suggest that the late decrease in ventilation may be a mechanical effect rather than a depression of the central respiratory neurons [41, 42]. In these experiments, diaphragmatic activity and frequency remained elevated during hypoxia, but tidal volume decreased below control values during late hypoxia. These experiments were carried out during quiet sleep. The peculiar response of the neonate to low inhaled oxygen is of great clinical significance. Infants who are borderline hypoxic tend to breathe periodically or develop apneic spells. Hypoxia can induce periodic breathing in these infants, as shown previously [43]. The relief of these apneic spells, which are frequently associated with bradycardias, can be obtained by increasing the inspired oxygen concentration [13, 21].

Administration of high concentrations of oxygen, on the other hand, produces an immediate decrease in ventilation followed by hyperventilation, a response that is similar during wakefulness, REM, and quiet sleep. These findings suggest a lack of major differences in the activity of the peripheral chemoreceptors during these sleep states [12, 44]. The immediate decrease in ventilation following the administration of 100% oxygen is related to a decrease in frequency (apnea being common in preterm infants) and a decrease in tidal volume. The late increase in ventilation with oxygen is likely related to cerebral vasoconstriction with increased H^+ concentration at the chemoreceptor site [45].

58.5 Upper Airways and Pulmonary Reflexes

The laryngeal chemoreflexes (LCR) comprise a group of reflexes triggered by the contact between liquids and receptors of the laryngeal mucosa. The receptors involved appear to be unmyelinated nerve fibers located immediately beneath the laryngeal mucosal epithelium [46]. Stimulation of the laryngeal mucosa, either chemically or mechanically, causes laryngospasm, swallowing, central or mixed apnea, oxygen desaturation and bradycardia [47]. This reflex-induced apnea is mediated through superior laryngeal nerve afferents [48]. Immature LCR, characterized by an exaggerated inhibitory cardio-respiratory response, are mainly observed in preterm infants or in conditions where upper airway inflammation is present [49]. Some authors have suggested that up to 70% of apnea of prematurity as well as the apneas associated with respiratory sincitial viral infection are related to LCR reflexes [49–51]. With maturation, the duration and severity of apneas secondary to LCR reflexes decrease. This is in part related to decrease stimulation of the LCR due to improved coordination of upper-airway muscles and to the increase in the excitatory respiratory related neurons within the respiratory network that counterbalance the inhibitory afferent input from the LCR [52, 53].

The inflation reflex of Hering-Breuer is much more active in the newborn period than in adult life [54, 55]. Small increases in lung volume cause apnea. This response is so powerful in the newborn that many have used this inflation to produce apnea and then study the mechanical properties of the respiratory system during the passive expiratory phase following apnea. The action of the stretch receptors is much influenced by sleep, being abolished during REM sleep. The irritant receptors are also poorly developed in preterm infants, and the mediated reflexes are also abolished during REM sleep [56]. Therefore, airway mechanisms responsible for clearing, such as cough, are impaired during REM sleep. The paradoxical reflex of Head is commonly observed in the neonate in the form of a sigh [57]. Many attribute the high prevalence of sighs to the greater need for lung recruitment at this age [58]. Sighs are more frequent in REM than in quiet sleep and are also more frequent during periodic than regular breathing. During periodic breathing, a sigh usually appears during the first or second breath after apnea. When it occurs

during regular breathing, it tends to be followed by short apneas [28]. Efforts to discover the mechanisms triggering sighs have been fruitless. Thach and Tauesch showed that asphyxia does not seem to be a stimulus [58]. Alvarez and colleagues, however, have observed that airway occlusion in the presence of hypoxia predisposes to sighs [59].

When studying the morphology of sighs in infants and adult subjects we have found that the sighs in infants are relatively larger than those in adults and that while post-sigh ventilation is usually increased in adults, it is decreased in infants. Since the drive to breathe early in life is dependent on increased peripheral chemoreceptor activity, it is conceivable that the sudden increase in arterial PO_2 with sighs, could produce a rapid decline in carotid body afferent discharge leading to hypoventilation and apnea. The other almost instantaneous change that occurs with a sigh includes a decrease in PCO_2. Since the CO_2 apneic threshold is much closer to the baseline CO_2 in neonates compared with adults, the decline in CO_2 below the threshold during a sigh, could trigger an apnea or initiate an epoch of periodic breathing in infants with an immature respiratory feedback loop [23, 60]. These findings suggest that although the ability to sigh may be an important mechanism to restore lung volume, sighs have the potential to destabilize breathing and cause hypoventilation and apnea in infants at risk for inadequate control of breathing [61].

58.6 Respiratory Muscles

The activity of the respiratory muscles is much altered by sleep state. Tonic activity of most respiratory muscles is abolished during REM sleep [62–64]. The disappearance of tone in the intercostal muscles has been suggested as a major factor responsible for the increased chest distortion seen during REM sleep in infants with this condition. Lack of tone leads to chest wall collapse during inspiration, and caudal displacement of the diaphragm has to be twice as long to produce the same lung volume displacement [61]. Because of chest wall collapse, functional residual capacity is decreased in these infants during REM sleep [61]. We have found that distorted and nondistorted breaths produce the same instantaneous ventilation as long as they are of the same duration, although the work of the diaphragm is 40% greater when distortion is present.

It has been shown that in newborns, in contrast to adults, expiration is actively terminated at substantial flow rates. The role of this expiratory braking mechanism is to maintain lung volume above FRC. The newborn uses two mechanisms to actively slow expiration. The first one is the postinspiratory activity of the diaphragm [65]. This activity controls, in part, the duration of expiratory time and is also affected by sleep [66, 67]. In neonates, this activity is more pronounced in the lateral than in the crural part of the diaphragm, longer in quiet than in REM sleep, and more prolonged in preterm than in term infants [68]. The length and variability of this activity in preterm infants suggest that because of their highly compliant chest wall, these infants use the postinspiratory diaphragmatic activity as a braking mechanism whose role in maintaining lung volume and controlling expiratory time is much more important than in older children and adult subjects. The second mechanism that the newborn uses to slow expiration is the laryngeal narrowing during expiration [69]. Sleep state profoundly affects the muscular control of upper airway resistance. Studies in fetal and neonatal lambs suggest that the abductor muscles of the larynx—the posterior cricoarytenoid and cricothyroid—have inspiratory activities in parallel with that of the diaphragm, during both quiet and REM sleep. On the other hand, the adductor muscles of the larynx—the thyroarytenoid, lateral cricoarytenoid, and intraarytenoid—have a phasic expiratory activity during quiet sleep. This activity is lost during REM sleep in the fetus and in the newborn lamb [62, 63]. A reduction in adductor activity of the larynx, in conjunction with decreased intercostal and decreased postinspiratory diaphragmatic activity during REM sleep, may cause the decrease in lung volume observed during this sleep state.

58.7 Conclusions

In summary, although the basic mechanisms involved in the control of breathing during neonatal life are similar to those investigated more extensively in adult subjects, there are some unique aspects of this control primarily affecting the preterm infant. First, sleep seems to have a very profound effect during this period of life. REM sleep increases the incidence of periodic breathing and apnea, decreases ventilatory response to CO_2, enhances the late decrease in ventilation with hypoxia, increases chest distortion leading to muscle fatigue, inhibits pulmonary reflexes, and decreases upper airway tone and postinspiratory activity of the diaphragm leading to decrease lung volume during expiration. Second, the highly compliant chest wall, due to lack of mineralization, puts these newborn infants at a mechanical disadvantage which is worsened by the inhibitory effects of REM sleep. These shortcomings favor instability of the respiratory control system. Third, the low FRC of small infants means low O_2 stores with less buffering capacity and increased risk of atelectasis, leading to intrapulmonary right-to-left shunts and reduced arterial O_2 tension. This relatively hypoxic environment increases the activity of the peripheral chemoreptors and narrows the difference between baseline PCO_2 and CO_2 apneic threshold levels favoring the establishment of periodic breathing and apneas. Thus, neonates have some unique features of their respiratory control system, which may at times compromise their health. It is the understanding of these features and their intimate physiologic mechanisms by physicians and other health care workers that represents the best promise for a good quality of medical care at the time of birth.

Meconium Aspiration Syndrome

Simone Pratesi and Carlo Dani

59.1 Introduction

The term meconium is derived from the Greek word *mekoni*, which means poppy juice or opium due to its tarry appearance or to Aristotle's belief that it induced sleep in the fetus. Meconium constitutes the first stool of a newborn infant. The passage of meconium typically occurs within 48 hours after birth, however it can occur in utero.

The optimal care of an infant born through meconium stained amniotic fluid (MSAF) should involve obstetrician and pediatrician together. Indeed, management of a baby at risk of meconium aspiration syndrome (MAS) starts in the delivery room, or even earlier during intrauterine life. MAS is defined as respiratory distress in an infant born through MSAF whose symptoms cannot be otherwise explained; approximately 13% of liveborn infants are born through MSAF, while MAS occurs only in 2–6% of these neonates [1]. A retrospective review of the outcomes and treatment patterns in term neonates admitted for intensive care during a ten-year period indicates an increasing likelihood of MAS with advancing gestational age (from 1.1% at 37 week gestation to 24% at >42 weeks gestation), a quite constant mortality rate of about 1.2% despite changes in care during the last decade, and a higher mortality risk for infants born smaller, outborn, delivered by C-section, who had lower Apgar scores and pulmonary hypertension [2].

Meconium is first noted to be present at 12 wk gestation in the human fetus. It is the by-product of fetal amniotic fluid, lanugo, skin cells, and vernix caseosa swallowing, it also contains cells derived from the gastrointestinal tract. Meconium composition also includes four different biliary acids (cholic, chenodeoxycholic, deoxycholic, and lithocholic) and minerals of which copper, zinc, magnesium, calcium iron, and phosphorus are the most common. In addition, it contains plasmatic proteins such as α1-antitripsin and phospholipase A_2, free fatty acids, bilirubin and enzymes. The passage of meconium from fetus into the amnion at an early stage of gestation is prevented by the lack of intestinal peristalsis due to low motilin levels, tonic contraction of the anal sphincter and a terminal cap of viscous meconium. MSAF in advanced gestation may therefore be a natural phenomenon that reflects a postterm fetus with a mature gastrointestinal tract in which motilin levels have risen. On the other hand, MSAF has been associated with perinatal conditions (such as intrauterine growth restriction, pre-eclampsia, eclampsia, maternal diabetes), which can compromise the uteroplacental circulation with resultant acute or chronic fetal hypoxia and acidosis, in the presence or absence of fetal distress, producing relaxation of the anal sphincter that occurs more easily in term than preterm neonates.

59.2 Pathogenesis

The traditional belief was that meconium aspiration occurs immediately after birth. Several investigators have suggested, however, that most cases of meconium aspiration occur in utero when fetal gasping is initiated before delivery. Thus, it is believed that MAS will sometimes occur despite appropriate airway management at delivery. There is currently no way to distinguish between the infant who has developed MAS by intrauterine respiration or gasping and the infant who has developed MAS by inhalation of meconium at the first breaths after delivery.

But is MAS really caused by a direct injury of meconium on the lung? It is unclear why some infants born through MSAF develop an aspiration syndrome whereas others do not. It is known that meconium presence under the vocal cords is associated with higher risk of MAS, but its absence does not mean the infant will not develop severe respiratory failure. According to Ghidini and Spong there are no correlations between the presence of meconium in the trachea and

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

clinical symptoms, as 2/3 of babies with meconium in the trachea do not develop any respiratory syndrome and a half of those with a respiratory syndrome did not have meconium in the lungs [3]. Thus the correlation, so far considered obvious, between the presence of meconium into the airways and respiratory disease, would be not so obvious. It is suggested that other pathological events such as intrauterine asphyxia could cause the syndrome, while the presence of meconium into the amniotic fluid and the lungs only being an incidental finding or a consequence of the stress insult to the fetus. Intrauterine asphyxia would lead to a remodeling of the pulmonary vascular tree determining a thickening of the pulmonary vascular media and an abnormal vascular reactivity responsible for the persistent pulmonary hypertension associated with persistent hypoxemia frequently seen in newborn with severe MAS [4]. Autopsy data from cases of MAS severe enough to result in neonatal demise within 48 hours of birth show that muscularization of the distal pulmonary arterioles is present in close to 100% of cases. As de novo muscularization requires a minimum of 3–8 days to develop, it may actually precede the aspiration of meconium [5]. Increasing evidence suggests that a chronic in utero insult may be responsible for most cases of severe MAS as opposed to an acute peripartum event. Chronic fetal hypoxia and acidosis may lead to fetal gasping and the subsequent in utero aspiration of meconium. This is supported by autopsy findings of meconium in the alveoli of stillbirths or of infants who died shortly after birth and never developed spontaneous respirations. In contrast to these severe cases, the vigorous infant who aspirates meconium-stained fluid from the nasopharynx at birth usually develops mild to moderate disease. The pathogenic events leading to mild MAS and severe MAS seem to be different, and events antedating labor (such as chronic asphyxia or infection) are predominantly responsible for the lung disease among infants with severe MAS. This is a crucial point as it seems that the only possible prevention of severe MAS could be during intrauterine life. Undoubtedly meconium in the lungs alters the pulmonary physiology but it is not clear how much of the lung injury seen in MAS (inflammation, surfactant dysfunction, vasoconstriction, airway hyperreactivity) is ascribed to a direct toxicity of meconium on lung tissues or partially to other chronic or acute insults begininning before delivery, or even how those injuries could be partially a consequence of the start of therapy (oxygen, ventilatory support, etc.).

Mechanisms of injury in MAS are: (1) meconium mechanical obstruction of airways of variable degree, leading to zones of atelectasis with ventilation/perfusion mismatch or zones of air-trapping at high risk for air leaks; (2) pneumonitis, with an inflammatory response characterized by the presence of an elevated cell count and pro-inflammatory cytokines (IL8, IL6, Il1β, TNFα), that can adversely affect tissues and cause an increase in microvascular permeability leading to hemorrhagic pulmonary edema and exudation of plasma proteins into the alveolar space leading to (3) inactivation of pulmonary surfactant through dilution and direct inhibition, along with damage of type II alveolar pneumocytes; (4) vasoconstriction of pulmonary vessels resulting in pulmonary hypertension and persistence of fetal circulation, that *in vitro* studies indicate are not due to the direct vasoconstrictor effect of meconium but possibly to the release of agonist humoral factors, such as thromboxane or TNFα, by lung parenchyma capable of enhancing the pulmonary arterial constrictor potential [6].

Inflammation plays a major role in the pathogenesis of MAS, and pulmonary function improves concomitantly with resolution of inflammation. Pro-inflammatory substances in meconium can induce lung inflammation in MAS directly via cytokines and heme present in meconium, and indirectly by inducing cytokine release from epithelial cells and alveolar macrophages. IL-1β, IL-6, and IL-8 appear to be expressed at high levels in early postnatal life of infants with MAS, making it highly likely that these cytokines are already expressed in utero before birth supporting the hypothesis of perinatal timing of meconium aspiration in most cases of MAS [7].

59.3 Prevention Strategies

As aforementioned, a reduction of the incidence of MAS over the past 3 decades is probably due to better prenatal care, leading to a reduction of postterm pregnancies and better fetal surveillance before and during labor of high-risk fetuses such as those with intrauterine growth restriction. Interventions of some efficacy to further decrease the incidence of MAS could probably be done only at a prenatal or perinatal stage, removing causes of acute or above all chronic fetal asphyxia. Indeed, the early postnatal management of a MSAF delivered infant has progressively been limited to non "vigorous" babies, assuming that intubation and tracheal suctioning of an already compromised newborn can reduce the incidence or at least the severity of MAS. This point has yet to be demomstrated. It is still unclear whether obstruction of airways caused by aspiration of meconium has a pivotal role in the progress of MAS. Antepartum, peripartum and postpartum interventions to remove meconium from the newborn's airway in order to prevent its aspiration in the presence of MSAF have been evaluated over the past 3 decades, including (1) amnioinfusion, (2) suctioning the infant before the first breath, and (3) intubation and tracheal suctioning of the infant immediately after delivery. Amnioinfusion has been proposed for interventions when monitoring detects variable fetal heart. Potential mechanisms through which amnioinfusion could act include mechanical cushioning of the umbilical cord, which could correct or prevent recurrent umbilical compressions, and dilution of meconium that could reduce its mechanical and inflammatory effects in the pathogenesis of MAS. It would appear that in settings where electronic

fetal monitoring is routinely used, amnioinfusion confers no additional benefit in terms of prevention of MAS while in settings without these capabilities, often in developing countries, amnioinfusion has been protective with improved neonatal outcomes, reduced MAS (4% versus 18%) and improved maternal outcomes [8]. ACOG Committee on Obstetric Practice has recently recommended that "routine prophylactic amnioinfusion for the dilution of MSAF should be done only in the setting of additional clinical trials. However, amnioinfusion remains a reasonable approach in the treatment of repetitive variable decelerations, regardless of amniotic fluid meconium status" [9].

Intrapartum suctioning, combined with intubation after delivery of a newborn from MSAF, has been considered standard procedure for more than 25 years. The aim is to clear as much meconium as possible from the airway before the infant is able to take a breath. Recent evidence has argued against the efficacy of intrapartum oropharyngeal and nasopharyngeal suctioning of meconium using a DeLee suction catheter before delivery of the shoulders (intrapartum suctioning). In a multicenter, randomized controlled trial involving 2,514 full-term women with MSAF, Vain and colleagues failed to show a benefit of intrapartum suctioning on the need for endotracheal intubation, incidence of MAS, need for mechanical ventilation, and neonatal mortality [10]. Based on this evidence, the ACOG Committee on Obstetric Practice recently recommended that "infants with MSAF should no longer receive intrapartum suctioning" [11].

Quite recent evidence has also argued against the efficacy of intubating and suctioning all infants born through MSAF. A number of studies showed no benefit in tracheal suctioning of "vigorous" infants. The largest international prospective randomized controlled trial to assess a selective approach is that conducted by Wiswell and colleagues [4] showing no difference in the rate of MAS in infants who were intubated (3.2%) or not (2.7%). There was no difference between the groups in subanalyses that adjusted for the thickness of the meconium in the amniotic fluid. Subsequent to this publication, the Neonatal Resuscitation Program (NRP) changed its recommendations and advised that apparently "vigorous" meconium-stained infants do not need intubation and intratracheal suctioning. A future question that needs to be answered is whether or not depressed meconium-stained infants actually benefit from having their airways intubated and suctioned. As many clinicians believe that most cases of MAS are due to in utero aspiration of MSAF, the potential efficacy of tracheal cleansing needs to be assessed in a well-conducted randomized, controlled trial, while some have suggested an even more aggressive approach: endoscopic in-utero suctioning of the fetus before delivery [12]. However, this procedure has yet to be tested and proven, and therefore cannot be recommended.

Current recommended delivery room management of the meconium stained newborn is that, if meconium is present, and the newborn is depressed or not "vigorous", the clinician should intubate the trachea and suction meconium from beneath the glottis. Thus, a skilled resuscitation team should be present at all deliveries that involve MSAF. If the delivered infant is judged as "vigorous", that is if he or she has (1) strong respiratory efforts, (2) good muscle tone, and (3) a heart rate more than 100 beats/min, there is generally no need for tracheal suctioning, and the pediatrician may procede with routine management. When an infant is not "vigorous", the goal is to clear the airway as quickly as possible to minimize the amount of meconium aspirated. The infant may be given free-flow oxygen and placed under a radiant heater, but drying and stimulating should be delayed. At this point, direct laryngoscopy should be performed with suctioning of the mouth and hypopharynx (with a 12F or 14F suction catheter) under direct visualization, followed by intubation and then applying suction (approximately 100 mmHg) directly to the endotracheal tube while it is slowly withdrawn. The process is repeated until either "little additional meconium is recovered, or until the baby's heart rate indicates that resuscitation must proceed without delay". Should positive pressure ventilation be required before complete airway clearance, a suction catheter inserted through the tracheal tube may be used to continue meconium removal [13].

59.4 Clinics and Therapy

Most infants born through MSAF require no interventions, however it is important to monitor these infants closely for signs of respiratory distress that possibly develops within the first 12 hours of life.

A severely compromised neonate born with MSAF should not be a priori labeled as a case of MAS until other causes of neonatal compromise have been excluded. Severe MAS should cease to be a diagnosis of inclusion (any respiratory distress in the context of MSAF with any radiologic finding), but rather become a diagnosis of exclusion. Its diagnostic criteria should be strict (i.e., presence of meconium in the mouth or trachea at delivery, early onset of respiratory distress, and chest X-ray evidence of "patchy" areas of opacification or pulmonary air leak) and limited to cases without infection or chronic asphyxia. Infants at risk of MAS who show signa of respiratory distress (tachypnea, cyanosis, retractions, grunting, rales and rhonchi at chest auscultation, barrel shaped chest) must be transferred to the neonatal intensive care unit. An infant developing a severe MAS will require a wide range of intensive therapies to be rapidly available and aimed at increasing oxygenation while minimizing the barotraumas, that may lead to air leak syndromes: intubation and endotracheal suction in the delivery room, mechanical ventilation (conventional or high frequency ventilation) preferably already started in delivery room (to avoid bag ventilation at higher risk of determing air leaks), placement of a central catether in the umbilical vein, sedation with continuous iv infusion of

fentanyl and/or midazolam, administration of endotracheal surfactant as bolus or lavage, inhaled nitric oxide (iNO) if persistent pulmonary hypertension is present, inotropic drugs and/or plasma transfusion to treat hypotension, antibiotic prophylaxis (as sepsis is often in the differential diagnosis), anti-inflammatory drugs to reduce lung inflammation, strict evaluation and management of acidosis, electrolyte imbalance and hypoglycaemia. Severe case of MAS may need for extracorporeal membrane oxygenation (ECMO), even if the percentage of newborns requiring ECMO has decreased since the introduction of treatment of persistent pulmonary hypertension with iNO. A chest X-ray will be performed to evaluate if radiographic features are compatible with the diagnosis of MAS and to exclude the presence of pnemothorax, pneumomediastinum or pulmonary interstitial emphysema, which frequently complicate MAS. Roentgenographic findings may include coarse irregular or nodular pulmonary densities, areas of diminished aeration or consolidation (atelectasis) alternating with areas of hyperinflation and generalized hyperinflation. The classic findings in MAS are described as diffuse, asymmetric patchy infiltrates, but because of the diverse mechanisms that cause disease, various radiographic findings may be present. Radiographic clearing is slow over a period of days or weeks if classic radiographic findings of MAS are present. A two-dimensional echocardiogram will be performed to exclude a congenital heart defect and to assess pulmonary hypertension, myocardial contractility and cardiac output, intracardiac right to left shunts, and shunt through the ductus arteriosus. Usually, in cases of MAS, early blood tests are characterized by hypoxemia, metabolic acidosis, mild to severe hypercarbia, and no signs of infection (C reactive protein negative, no leucocytosis or leucopenia). This kind of biochemical pattern prevents the physiological drop of pulmonary arterial resistance with increase in pulmonary blood flow, resulting in right-to-left shunts at atrial and ductus arteriosus level, thus maintaining and further reducing hypoxemia into a vicious cycle. Leucopenia may present later as a consequence of the accumulation of polymorphonuclear leukocytes into the lung tissues.

Cleary and Wiswell have proposed criteria to define MAS severity: (1) mild MAS is disease that requires less than 40% oxygen for less than 48 hours, (2) moderate MAS is disease that requires more than 40% oxygen for more than 48 hours with no air leak, and (3) severe MAS is disease that requires assisted ventilation for more than 48 hours and is often associated with persistent pulmonary hypertension [1]. Pneumothorax is still a frequent complication of MAS (8–20%), and it is an important indicator of a poorer prognosis. Approximately 40% of the babies with MAS require mechanical ventilation, about 1.4% of ECMO. ECMO use has decreased during the last decade, while high frequency oscillatory ventilation (HFOV) and iNO have been used with increasing frequency [2]. However, no prospective, randomized, controlled trials have compared conventional ventilation versus HFOV in MAS. Theoretically, high-frequency ventilators should reduce airleak syndromes in MAS, but animal and clinical models have yielded conflicting results. High-frequency ventilators may slow the progression of meconium down the tracheobronchial tree and allow more time for meconium removal [14].

Inhibition of surfactant function in the alveolar space is an important element of the pathophysiology of the disease, thus representing the rationale for administration of exogenous surfactant preparations in MAS, initially as standard bolus therapy and, more recently, in association with therapeutic lung lavage. In infants with MAS, surfactant administration may reduce the severity of respiratory illness and decrease the number of infants with progressive respiratory failure requiring support with ECMO [15]. Bolus surfactant should be administered as early as practicable to infants who exhibit significant parenchymal disease, at a phospholipid dose of at least 100 mg/kg, rapidly instilled into the trachea. Lung lavage with dilute surfactant has recently emerged as an alternative to bolus therapy in MAS, which has the advantage of removing surfactant inhibitors (hemoglobin, plasma proteins) from the alveolar space in addition to augmenting surfactant phospholipid concentration. The ideal fluid volume and technique for lavage in MAS are not yet clear; experimental data would suggest a total lavage volume of 30 mL/kg (administered as two 15 mL/kg aliquots) at a 5mg/mL phospholipid concentration (lower concentrations make surfactant more sensitive to inactivation) as most effective in improving oxygenation and pulmonary mechanics, and in attenuating lung injury. Lesser total lavage volumes or smaller aliquot volumes removed meconium less effectively, whereas a greater total lavage volume resulted in unacceptably high deposition of aqueous fluid in the lung. The advised procedure would be the following: a) adequate stabilisation of the newborn, b) sedation and muscle relaxation to minimise bradycardia and maximise fluid recovery, c) perform lavage in a rapid sequence, with instillation and recovery of each lavage aliquot within 60–80s, d) use open suction with the ventilator disconnected and manual vibratory chest squeezing to collect as much fluid as possibile, and e) ventilate with higher mean airway pressure (2–4 cmH_2O more) than the pre-lavage one for 30 minutes to re-recruit lung volume and clear retained lavage fluid. As large-volume lavage procedure is inevitably associated with a fall in oxygenation during and for a short time after lavage, it needs to be included in randomised controlled trial of lavage therapy in ventilated infants with severe MAS in order to assess the real benefits against the potential risk associated with the procedure [16]. Thus, this procedure cannot be routinary recommended.

MAS is frequently accompanied by persistent pulmonary hypertension. iNO causes selective pulmonary vasodilation by acting directly on the vascular smooth muscle. By dilating the blood vessels in well-ventilated areas of lung, iNO decreases the ventilation perfusion ratio mismatch and improves oxygenation in infants with persistent pulmonary hypertension. Proper administration of iNO requires adequate

delivery to the alveoli, thus it may be less effective in patients with MAS, in part because of the physical "barrier" to its diffusion across the alveolar membrane produced by the meconium. Pretreatment with surfactant seems to aid the delivery of iNO to alveoli, with a resultant increase in oxygenation [17]. Kinsella and colleagues showed that the combination of HFOV and iNO may be more successful than either treatment alone in patients with MAS, likely due to improved lung inflation and better delivery of the drug [18]. iNO appears to improve outcome in hypoxemic term and near-term infants by reducing the need for ECMO, but has no apparent effect on mortality [19].

Since the introduction of treatment of persistent pulmonary hypertension with iNO, the need for ECMO has decreased. However, about 40% of infants with MAS treated with iNO fail to respond and require bypass. ECMO is still considered an important tool in treating the newborns with MAS and intractable respiratory failure, with the highest survival rate for any neonatal condition suitable for ECMO (on the order of 93–100%). Despite the evidence pointing to the efficacy of ECMO in severe MAS, without causing excess pulmonary or neurological morbidity (because of prolonged hypoxia), some infants are still referred late for ECMO. Recent introduction of new therapies for respiratory failure in the newborn with MAS such as iNO, surfactant, and HFOV may postpone the use of ECMO. A delay in ECMO initiation longer than 96 hours results in a significant increase in duration of ECMO and length of post-ECMO ventilation, with a significant increase in mortality in this group of infants. Thus, the need of ECMO in severe MAS should be predicted as early as possibile to avoid ventilator-associated lung injury and to improve outcome [20].

Other potential therapeutic interventions for treating MAS have been indicated: synthetic surfactant, captopril, tezosentan, pentoxifylline. Some surfactants may be more resistant to inactivation by meconium [21], however the search for new synthetic surfactant preparations that are highly resistant to inactivation by meconium or other forms of toxic pneumonitis is ongoing.

In MAS inflammation plays an important role in the pathogenesis of lung injury. A number of anti-inflammatory agents have been investigated for their therapeutic values, such as corticosteroids, pentoxifylline, and aminophylline. A Cochrane systematic review of available clinical trials concludes that there is insufficient evidence on the use of systemic steroids in the treatment of MAS [22]. In a recent randomised controlled study, however, both intravenous methylprednisolone and nebulised budecort were able to suppress TNFα level in the tracheal aspirate of infants with MAS. Treated infants also had a shorter hospital stay, shorter duration of oxygen dependency, and earlier radiological clearance of the lung fields [23]. Local corticosteroid administration, both nebulised or intracheally administered (budenoside), resulted in the same benefits with lower adverse effects than systemic corticosteroid; thus further testing of local corticosteroid administration is worthwhile. Pentoxifylline is a methylxanthine derivative and phosphodiesterase inhibitor. It is categorised as an anti-inflammatory agent because of its anti-inflammatory action in lung tissues and its ability in suppressing neutrophil action and proinflammatory cytokines in the injured lung. No study on the use of pentoxifylline in treating MAS in human neonates has been reported. Animal studies indicate that pentoxifylline administration effectively suppresses the meconium-induced increase in alveolar macrophage number and local TNF-α production in the insulted lungs and early treatment of MAS with pentoxifylline could be a new, pathophysiologically plausible therapeutic alternative [24]. Aminophylline, another methylxanthine derivative, has also demonstrated a therapeutic potential in the treatment of MAS in the animal model, effectively decreasing intrapulmonary shunting, lung edema and recruitment of neutrophils, thus enhancing oxygenation in meconium-instilled rabbits [25].

In acute lung injury following meconium aspiration pulmonary hypertension is related to an increase of endothelin (ET)-1 levels. Recently tezosentan, an intravenous dual ETA and ETB receptor antagonist, has been shown to improve pulmonary gas exchange and hemodynamics by decreasing mean arterial pulmonary pressure and pulmonary vascular resistance in experimental meconium aspiration. Tezosentan thus seems to act predominantly in the pulmonary vasculature, the site of turnover of ET-1, and its effect to be enhanced by the combination with an inhalational drug like iloprost [26].

Cell death by apoptosis in the lungs has been demonstrated in MAS. Meconium-induced apoptosis is activated by a strong vasoconstrictor, angiotensin II, which is the product of conversion of angiotensin I by angiotensin-converting enzyme (ACE) within the cell. Pretreatment with captopril, blocking the conversion of angiotensin I to the apoptotic-inducer angiotensin II, significantly inhibits meconium-induced lung apoptosis and also reduces mortality of rabbit pups from meconium. Captopril could represent another potential new therapeutic intervention for MAS [27].

59.5 Conclusions

More efficient modalities of treatment have greatly improved survival rate of MAS infants over the last three decades, but the amount of morbidity among survivors seems unchanged and growing concern exists for long-term poor neurodevelopmental and pulmonary sequelae of infants even asymptomatic at the time of discharge from the nursery.

The American Academy of Pediatrics Neonatal Resuscitation Program Steering Committee has promulgated guidelines for management of the baby exposed to meconium. The guidelines are under continuous review and are revised as new evidence-based research becomes available [13].

Molecular Structure of Surfactant: Biochemical Aspects

Tore Curstedt

60.1 Introduction

Oxygen is needed for energy production in the living organism and is a prerequisite of life. This oxygen, which is taken up from the air during breathing, has to pass from the alveoli to the blood in order to be transported to different organs where it can participate in the metabolic processes in the body. The passage from the alveoli to blood is crucial and is dependent on a barrier composed of the alveolar wall, basal laminae and the endothelial cells. Exposure of a large alveolar surface to the air is required to facilitate an appropriate gas exchange in order to fulfill the energy needs of the living organism.

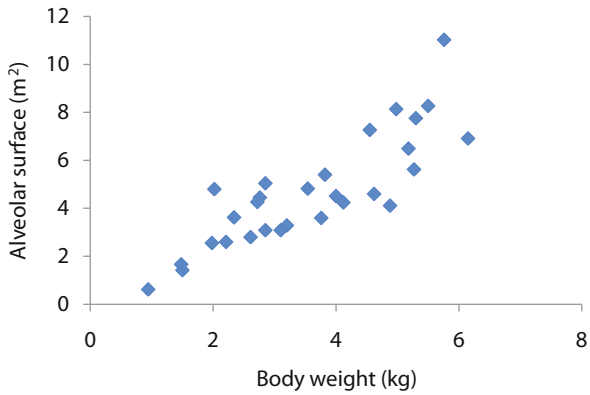

Fig. 60.1 Correlation between body weight and total alveolar surface area. The values are taken from [1]

60.2 Alveolar Surface

The development of the alveoli starts in the weeks before birth and the alveolar area increases roughly linear with body weight (Fig. 60.1). At birth the alveolar area is 3–5 m^2 at end-expiration and about 80 m^2 in adults [1, 2]. Thus, the area is about 1 m^2/kg body weight. The number of alveoli increases in a curvilinear fashion with up to 150 million at birth, which is half to one third of the number in adults.

The alveoli are lined with a surface-active material, called surfactant. This material facilitates alveolar increase during inspiration and prevents alveolar collapse at end-expiration. Thus, pulmonary surfactant is essential for normal lung function and must fulfill properties such as rapid film formation through adsorption from the hypophase, low surface tension at end-expiration and effective replenishment of the surface film during inspiration.

The surfactant lines the alveoli as a monolayer in combination with areas of multilayers [3]. The amount of surfactant needed for formation of a monolayer at end-expiration is about 3 mg/m^2 indicating that a newborn term infant needs 10 mg surfactant for the monolayer. However, during inspiration the alveolar area will increase and some of the surfactant is continuously metabolized. Thus, there must be a surplus of surfactant in the lungs and the pool in newborn full-term animals has been calculated to be about 100 mg/kg body weight [4]. The alveolar subphase beneath the surfactant film has been shown in rat lungs to have an average thickness of about 0.2 μm [5]. If humans have a similar thickness the total aqueous alveolar phase would be about 0.2 mL/m^2 alveolar surface area. This indicates that term infants may have a mean alveolar surfactant concentration of about 500 mg/mL presuming that newborn term infants have about the same surfactant pool size as animals.

60.3 Isolation of Pulmonary Surfactant

The knowledge about the composition of pulmonary surfactant has usually been obtained from lung lavage. The lungs

are lavaged using isotonic sodium chloride solution, followed by fractional centrifugation of the lavage fluid. In the first centrifugation, using 300–400 g for 10 min, cell debris is removed and the supernatant is then centrifuged at 10,000 g for 20 min. The pellets obtained contain a highly surface-active material composed of lipid-protein aggregates that are enriched in tubular myelin and lamellar bodies. Lamellar bodies are stored in type II epithelial cells and are secreted by exocytosis into the alveolar lumen and converted to tubular myelin, which is the source for the surface-active monolayer lining the alveolar surface.

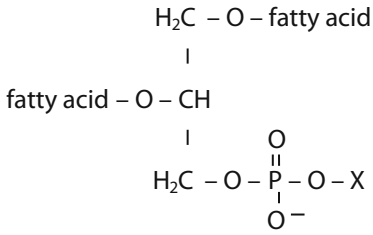

Fig. 60.2 General structure of phospholipids. X: e.g. choline, ethanolamine, glycerol, serine, inositol

60.4 Composition of Surfactant

Pulmonary surfactant lining the alveolar surface is a complex mixture of lipids and proteins. It is composed of about 80–85% phospholipids, 8–10% neutral lipids and 8–10% proteins [6, 7] (Table 60.1). Cholesterol is the main neutral lipid but trace amounts of triglycerides and free fatty acids are also present. Other components such as complex carbohydrates and glycolipids are also found in surfactant.

60.4.1 Phospholipid Composition

The phospholipids are mainly responsible for reducing the surface tension at the air-liquid interface. Its composition is complex and at least fifty different phospholipids may be found in surfactant [8]. The most common structure is a glycerol skeleton with two ester-linked fatty acids and a phosphate group (Fig. 60.2). Different components, e.g., choline, ethanolamine, glycerol, serine or inositol are usually bound to the phosphate group, thus making up the different classes of phospholipids such as phosphatidylcholine, phosphatidylethanolamine, phosphatidylglycerol, phosphatidylserine and phosphatidylinositol. Depending on the fatty acid composition, each phospholipid class is composed of many molecular species. About 80% of the phospholipids consist of phosphatidylcholine with its surface-active disaturated species. These disaturated species, containing 40–60% of total phosphatidylcholines are dominated by dipalmitoylphosphatidylcholine, a phosphatidylcholine containing two palmitic acids. Although phosphatidylcholines predominate among the phospholipids, phosphatidylglycerol is present in amounts up to 10% and smaller amounts of phosphatidylethanolamine, phospatidylserine and phosphatidylinositol are also present.

At the air-liquid interface lining the alveoli the phospholipids are oriented in a monolayer with the hydrophilic head groups towards the aqueous phase and the hydrophobic acyl groups towards the air [9].

A high concentration of phospholipids, mainly dipalmitoylphosphatidylcholine, at the interface diminishes the number of water molecules exposed to the air resulting in a lower alveolar surface tension and less force required to open up the alveoli during inspiration. This saturated phospholipid, in contrast to unsaturated species, can be packed to a very high density at the air-liquid interface and provides a large reduction of surface tension during expiration, thus preventing the alveoli from collapse at end-expiration. However, the melting point of dipalmitoylphosphatidylcholine bilayers is 41°C, which is above the physiological temperature of the human body while that of unsaturated species is much lower. Thus, the presence of significant amounts of unsaturated phospholipids in surfactant reduces the melting temperature of the monolayers to values lower than 37°C, which is important for the physiological properties of pulmonary surfactant. Resent results indicate that cholesterol, which constitutes 5–10% of pulmonary surfactant, may modulate the structure of surfactant membranes by decreasing the packing and increasing the mobility of phospholipids in the monolayer.

Table 60.1 Composition of pulmonary surfactant

Component	%
Dipalmitoylphosphatidylcholine	30–40
Other disaturated phosphatidylcholines	3–5
Unsaturated phosphatidylcholines	35–40
Phosphatidylglycerol	5–10
Other phospholipids	5–10
Neutral lipids (mainly cholesterol)	5–10
Hydrophobic surfactant proteins (SP-B, SP-C)	1–4
Hydrophilic surfactant proteins (SP-A, SP-D)	4–8

60.4.2 Surfactant-Associated Proteins

Proteins represent less than 10% of the total mass of pulmonary surfactant. Four different surfactant-associated proteins have been identified. The two hydrophobic surfactant proteins, SP-B and SP-C, increase the adsorption and spreading of the surfactant film at the alveolar air-liquid interface [7] and are crucial for obtaining a functional surfactant. The two hydrophilic surfactant proteins, SP-A and SP-D, have a primary role in host defense [10].

60.4.2.1 Surfactant Proteins A and D

SP-A and SP-D belong to a larger family of proteins termed collectins containing both collagenous and lectin domains. The lectin domain mediates the calcium-dependent carbohydrate binding and is also called carbohydrate recognition domain. The basic structural unit of collectins are trimers which are composed of three similar or identical polypeptides. These trimers then multimerize resulting in differently shaped multimeric forms.

SP-A is the most abundant protein in surfactant. Each monomer with a molecular mass of about 30–36 kDa contains four structural domains with a short N-terminal segment containing interchain disulfide bonds, a collagenous region, a hydrophobic neck region and a carbohydrate recognition domain. Three monomers form a trimer by association of the collagenous and neck regions. Six trimers form the octadecameric molecule, which is stabilized by disulfide linkages in the N-terminal regions. This octadecameric molecule forms a bouquet-like structure with an apparent molecular mass of about 650 kDa. The protein is closely associated with the phospholipids in the presence of calcium ions and together with SP-B and phospholipids tubular myelin is formed.

SP-D is composed of monomeric subunits, each with a molecular mass of about 43 kDa. Each monomer possesses similar domains as that of SP-A. SP-D usually forms a cruciform dodecamer assembled from four trimers with a molecular mass of about 520 kDa. However, SP-D can assemble into even higher-order multimers when dodecamers assemble into "fuzzy-ball" structures. SP-D binds to phosphatidylinositol and a variety of glycolipids, which are minor components of surfactant. However, only a small part of SP-D co-isolate with surfactant lipids.

SP-A and SP-D are synthesized and secreted by alveolar type II cells and by Clara cells but SP-D especially is also expressed in other tissues such as gastric and intestinal mucosa. Both proteins interact with a variety of pathogens such as bacteria, viruses and fungi and protect the lungs from infection by aggregation of pathogens, stimulation of phagocytic activity and modulation of inflammatory response. SP-A does not seem to have any effect on spreading of surfactant phospholipids but the protein enhances the resistance to inactivation of surfactant by proteins, e.g., albumin. It has also been shown that SP-A deficient mice survive and breed normally but they lack tubular myelin and have increased susceptibility for infections.

60.4.2.2 Surfactant Proteins B and C

The hydrophobic surfactant proteins SP-B and SP-C are important for surfactant function. SP-B is expressed in alveolar type II cells and Clara cells while SP-C is expressed only in type II cells. The proteins are structurally different but they are both required for sustaining respiratory physiology by decreasing surface tension of the alveolar air-liquid interface and to prevent the alveoli from collapse at end-expiration. Mutations in the SP-B gene have been shown to lead to lethal respiratory failure at birth [11]. However, these mutations also interact with SP-C processing by inhibiting the formation of mature SP-C from its proform. Also abnormalities in surfactant phospholipids have been observed in SP-B deficient infants. The pathophysiology of lung disease associated with mutations in the SP-C gene is incompletely understood. These mutations are usually linked to lung disease in older children and adults. Also heterozygotes have a lack of mature SP-C leading to alveolar instability with atelectasis, inflammation and fibrosis.

SP-B has 79 amino acid residues with three intramolecular disulfide bridges and one intermolecular disulfide bridge, thus forming a dimer. This dimer may interact with the surface of lipid bilayers by means of four or five amphipatic α-helices in each monomer. SP-B belongs to the saposin family of proteins, in which all members interact with lipids [7]. However, in contrast to the other members of the saposin family, SP-B is permanently associated to the membranes, which is probably due to its high hydrophobicity. The three-dimensional structure of SP-B has not been determined, but SP-B differs from the other saposins by being a covalent dimer not soluble in water. The dimeric structure of SP-B may account for its ability to cross-link juxtaposed lipid membranes, thus catalyzing the transfer of phospholipids from surfactant membranes into the interfacial surface-active film. The protein has a net positive charge which may promote a selective interaction with anionic phospholipids, especially phosphatidylglycerol, but clear evidence about that is missing. SP-B is critical for formation of lamellar bodies and is required for formation of tubular myelin.

SP-C is a small very hydrophobic lipopeptide of 35 amino acid residues with two palmitoylated cysteines in the N-terminal part [7]. It consists of a very regular and rigid α-helix covering more than 70% of the molecule and an unstructured N-terminal part. The α-helical segment adopts a transmembrane localization orientated near parallel to the phospholipid acyl groups. The length of the helix is in very good agreement with the thickness of a fluid dipalmitoylphosphatidylcholine bilayer. The primary translation product of human SP-C is a proform of 197 amino acid residues. Mutations in the C-terminal part of the molecule, not involving the mature SP-C, are seen in patients with interstitial lung diseases. These mutations may result in a conversion of the proSP-C from the native structure to β-sheets found in amyloid-like fibrils [12]. These fibrils are thought to be cell toxic and may give rise to organ malfunction and disease.

60.5 Structure of Pulmonary Surfactant

The surfactant components are synthesized in alveolar type II cells and secreted as lamellar bodies into the alveolar subphase. The lamellar bodies are transformed into tubular

myelin whereupon the material adsorbs quickly to the alveolar air-liquid interface forming a surface-active film. The thin aqueous phase covering the alveolar surface contains multiple membrane structures, including lamellar bodies, tubular myelin and the surface-active film. The air-liquid interface is necessary for respiratory gas exchange and the alveoli must be able to open during inspiration without collapsing during end-expiration. These criteria may be fulfilled with a complex phospholipid mixture which can be packed to a very high density at the air-liquid interface and have a melting point below the physiological temperature of the human body. For spreading the phospholipids during breathing the hydrophobic proteins SP-B and SP-C are necessary. The interface should also be a defense against different pathogens and for this reason native surfactant contains the hydrophilic proteins SP-A and SP-D.

Surfactant Metabolism in Neonatal Lung Diseases

Virgilio P. Carnielli and Paola E. Cogo

61.1 Background

Pulmonary surfactant reduces surface tension in the lungs to impressive low values. When secreted by the type II cells into the thin liquid layer that lines the alveolar air spaces, vesicles of pulmonary surfactant absorb readily to the air water interface and form an interfacial film. The surfactant unique tensioactive properties were originally explained by its unique phospholipid composition, which is strikingly comparable across species [1]. Of the surfactant lipids, 80–90% are phospholipids, of which phosphatidylcholine (PC) is quantitatively the most important, accounting for 70–80% of the total. Other lipids include phosphatidylglycerol (PG), phosphatidylethanolamine, phosphatidylinositol, phosphatidylserine, sphingomyelin, cholesterol, triacylglycerols, and free fatty acids. Approximately 60% of the PC contains two saturated fatty acids (DSPC) of which dipalmitoyl (16:0/16:0; DPPC) is the most abundant. DPPC and PG are key phospholipids that permit normal breathing by reducing surface tension to near zero at the end of the respiratory cycle.

More recent studies have suggested that the hydrophobic proteins SP-B and SP-C contribute to the stabilization of the phospholipid film. Four surfactant proteins have so far been identified [2]. SP-A and SP-D are hydrophilic, and SP-B and SP-C are hydrophobic. They are either exclusively lung associated or predominately found in the lung. SP-A is the most abundant surfactant protein and is essential for the formation of tubular myelin. It functions as a regulator of phospholipid insertion into the monolayer, and modulates the uptake and secretion of phospholipids by type II cells. However, mice that lack SP-A indeed have no tubular myelin but have normal lung function and surfactant metabolism even during exercise [3]. Furthermore, together with SP-D, SP-A has an important role in lung defense [4]. SP-A and SP-D bind pathogens and facilitate their clearance [4]. The absence of SP-D results in increased surfactant lipid pools in the airspaces and emphysema in lungs of mice [5]. SP-B plays a role in formation of tubular myelin and together with SP-C it promotes rapid phospholipid insertion into the air-liquid interface. SP-B also influences the molecular ordering of the phospholipid layer. Infants with a genetic absence of SP-B develop lethal respiratory distress after birth, which can only be treated by lung transplantation [6]. Absence of SP-B causes a loss of lamellar bodies, tubular myelin, and an incompletely processed SP-C [7]. SP-C regulates the phospholipid ordering in the monolayer, enhances the reuptake of surfactant lipids *in vitro*, and may have a role in surfactant catabolism. Mice that lack SP-C have normal surfactant and lung function, and have no abnormalities in SP-B processing [8]. Interestingly the alveolar pool of surfactant in newborn infants with respiratory distress syndrome (RDS) does not differ much from the alveolar pool of adults without respiratory disease [9].

61.2 Surfactant Kinetics: Animal Studies

Surfactant PC is synthesized from phospholipid precursors (e.g., fatty acids, glycerol, choline, glucose) in the Golgi apparatus [10]. In the fetal type II cell, intracellular glycogen stores appear to be a major source of the glycerol backbone of PC, whereas in the adult lung glucose from the circulation is a major substrate. Choline is mainly derived from the diet. The fatty acids of surfactant phospholipids are synthesized de novo in the type II cell, or taken up from the blood, or are derived from recycling of alveolar surfactant phospholipids [10].

Alveolar surfactant can be cleared by different pathways. Surfactant components can be reutilized through uptake by the type II cell, incorporation into the lamellar bodies and then direct re-secretion [11]. Another way is recycling of degraded surfactant components to synthesize new surfactant lipids or proteins. Finally, surfactant can be removed from the

lung, either as intact molecules or as degraded products [12]. The efficiency of recycling is age dependent, and has been calculated to be 90% in young pigs [13], >90% in the newborn rabbit and 50% in adult rabbits [14].

The time required for de novo PC synthesis, secretion, and significant alveolar accumulation has been studied in animals using radioactively labeled substrates [15]. Compared to adult animals, the time to reach peak specific activity is longer in term newborns [16]. Preterm ventilated lambs show a slow movement of surfactant PC from the synthesis sites to the alveolus similar to term ventilated lambs [17].

61.3 Surfactant Kinetics: Human Studies

Recently, stable isotope techniques were used to study surfactant metabolism in human infants. Labeled precursors were infused intravenously and incorporation of label was measured by mass spectrometry in surfactant PC or DSPC isolated from tracheal aspirates.

In preterm infants with RDS who received a 24-hour intravenous infusion of the stable isotope [U-^{13}C]glucose, the palmitic acid of surfactant PC became labeled approximately about 17 h and was maximally labeled after ~75 h [18, 19]. By using other precursors such as [U-^{13}C]palmitic acid, [U-^{13}C]linoleic acid, and [1-^{13}C]acetate to study surfactant kinetics, the same results were estimated [20, 21].

In term ventilated neonates without significant lung disease using infusion of [U-^{13}C]glucose, [U-^{13}C]palmitic acid or [1-^{13}C]acetate as precursors, the first appearance of label in surfactant PC was after ~9 h from the start of the infusion, and the maximal enrichment at ~44 h [21–23]. As in animal studies, these results of human stable isotope studies show slower surfactant kinetics in preterm infants compared to term infants. The kind of precursor does not affect the results. The fractional synthesis rate (FSR) of surfactant after infusion of labeled glucose is a measure of the percentage of surfactant that is synthesized from glucose per day. In premature infants who received a 24-hour [U-^{13}C]glucose infusion, the FSR was calculated to be ~4%/day [18, 19]. Different values were found for different precursors: preterm infants who received labeled palmitic acid and linoleic acid had an FSR of ~12 and ~25%/day, respectively [24]. FSR in preterm and term infants after infusion of labeled acetate was ~2 and ~15%/day, respectively [19]. When term infants received labeled palmitic acid, the FSR was found to be ~17%/day [22]. After infusion with labeled glucose, term infants had a FSR of ~8%/day [23]. These data show a lower FSR in preterm infants compared to term infants.

The slow secretion and alveolar accumulation of surfactant are balanced in the term and preterm lungs by slow catabolism and clearance. For example, the half-life of radiolabel surfactant phospholipids given endotracheally to term lambs is about 6 days [24]. However, in premature baboons using the same method the half-life is about 30 h [25], which may be due to more recycling in premature animals, and to species difference. Half-lives calculated in animal studies differ depending on gestational age, postnatal age, the labeled substrate used, and the surfactant pool studied.

Half-life measurements of disappearance of labeled surfactant in human infants have been performed mainly in preterm infants with RDS. Half-lives were longer when disappearance of label in surfactant was measured after the intravenous use of labeled precursors: the half-life of ^{13}C-labeled PC-palmitate measured in tracheal aspirates of preterm infants with RDS after labeled glucose infusion was ~96 h [18, 19, 26]. In preterm infants the surfactant half-life after infusion of [U-^{13}C]palmitic acid, [U-^{13}C]linoleic acid or [1-^{13}C]acetate was ~98, ~47, and ~106 h, respectively [21, 27]. Using [U-^{13}C]palmitic acid, [U-^{13}C]glucose, or [1-^{13}C]acetate in term infants, the half-life was ~43, ~63, and ~28 h, respectively [21–23]. Thus, surfactant half-life is different between preterm and term infants, with a lower disappearance of label in the preterm infants reflecting slower surfactant kinetics, especially in RDS.

There are two studies in the literature in critically ill term infants who were studied using different metabolic precursors for surfactant metabolism [21, 27].

Cogo and colleagues showed marked patient differences in PC kinetics after infusing labeled fatty acids in a group of critically ill infants with various diagnoses [27].

Bohlin and colleagues reported that term infants with primary respiratory failure had a surfactant metabolism similar to that of preterm infants with RDS, suggesting either delayed maturity of the surfactant system or disruption from the underlying disease [21].

In summary, in human studies using stable isotopes the surfactant PC metabolism is even slower in preterm infants with RDS compared to term infants without lung disease. Moreover, term infants with respiratory failure have abnormal surfactant metabolism, which resembles that of preterm infants with RDS.

61.4 Surfactant Pool Size

In most species studied, PC, and DSPC in particular, increase in the last trimester of pregnancy [28]. In amniotic fluid, surfactant concentrations increase, reflecting accumulation of alveolar surfactant. This increase is also reflected in an increasing lecithin/sphingomyelin (L/S) ratio [29].

During and shortly after birth large amounts of surfactant are released into the alveolar space [30]. Since there is no depletion of the intracellular surfactant pool, this increase in alveolar pool shortly after birth is accompanied by an increase in de novo surfactant synthesis. However, incorporation studies, as mentioned above, showed slow surfactant metabolism, which means that it takes a long time before de novo synthesized surfactant is detectable in the alveolar

space. Increased lung tissue and alveolar surfactant pools can only be explained by the rapid mobilization of surfactant from other pools (lamellar bodies, small vesicles) within type II cells. The amount of lung tissue and alveolar surfactant changes with age. Surfactant pools are very high in the newborn period in all species studied to date and decrease subsequently with lung maturity. In humans total amounts of sat PC in alveolar washes at autopsy also decrease with age [9]. In preterm infants with RDS, surfactant pool sizes in the alveolus are low (2–10 mg/kg) [16]. Total lung DSPC in the human adult, at autopsy, was ~22 mg/kg, and ~2 mg/kg in alveolar wash [9]. In human infants surfactant pool size can be estimated *in vivo* by measuring the dilution of a labeled surfactant component [31].

Hallman and colleagues [32] and Griese and colleagues [33] showed an apparent phospholipid pool size of ~16 mg/kg in human preterm neonates with RDS, by using PG as label to measure surfactant pool size. Pool size measurements in preterm infants with RDS using endotracheally administered stable isotope (^{13}C-DPPC) in combination with a treatment dose of surfactant (100 mg/kg) showed an endogenous surfactant PC pool size (before treatment) ranging from 1 to 15 mg/kg [34], while term infants without RDS have three times or more that value [35]. As synthetic rates of surfactant in preterm infants are low, it is clear that pulmonary surfactant can only be rapidly increased by surfactant replacement therapy.

61.5 Effects of Surfactant Therapy on Surfactant Kinetics in Preterm Infants with RDS

Although the administration of exogenous surfactant has become the routine treatment of RDS in the preterm infant, there is very little information regarding effects of exogenous surfactant on endogenous surfactant metabolism.

In healthy adult rabbits *in vivo*, administration of surfactant to the left lung only, resulted in increased incorporation of palmitic acid from plasma into surfactant PC in the left lung but not in the right lung [36], suggesting stimulation of endogenous synthesis.

In preterm ventilated lambs, surfactant treatment stimulated [^{3}H]palmitic acid incorporation into surfactant PC after correction for the increased surfactant pool [37]. In 3-day-old rabbits, the administration of surfactant did not, however, influence the incorporation of labeled precursor in the total lung surfactant pool [38].

In preterm infants with RDS, the half-life of PG was independent of the dose of exogenous surfactant (60 versus 120 mg/kg) [32]. This indicates that the absolute turnover had doubled after two doses of surfactant compared to one dose.

Studies in infants with stable isotopes showed that the incorporation of ^{13}C from intravenous [U-^{13}C] glucose into alveolar surfactant PC palmitate increased after exogenous surfactant treatment [26].

More recently surfactant kinetics of different doses of porcine surfactant (200 versus 100 mg/kg) were compared in preterm infants with moderate to severe RDS. This study showed that the administration of 200 mg/kg of exogenous surfactant was associated with a longer DSPC half-life and that the need of re-dosing was reduced [39]. Moreover independent risk factors for surfactant re-dosing were evaluated by multiple regression analysis in 125 RDS infants who received 100 or 200 mg/kg of exogenous surfactant. The need for surfactant re-dosing was predicted by shorter DSPC half-life, lower birth weight, worst RDS radiological score, use of conventional ventilation (*vs* high frequency) and a lower surfactant dosing [40].

In summary, surfactant kinetics is variable in infants with RDS, depending on several clinical factors. When optimizing surfactant replacement therapy and its cost-benefit ratio these clinical variables should be taken into account.

61.6 Effects of Prenatal Corticosteroids on Surfactant Synthesis in Preterm Infants with RDS

In many *in vitro* studies corticosteroids increase the activity of the enzymes involved in surfactant PC synthesis [41–45] and increase surfactant protein synthesis [43]. *In vitro* experiments with lung slices and isolated type II cells showed corticosteroids increase the incorporation of radiolabel precursors into surfactant PC, reflecting increased PC synthesis [42, 45, 46].

Prenatal corticosteroid treatment in preterm lambs rapidly increases surfactant protein mRNAs and surfactant proteins in lung tissue [47]. In a study by Kessler and colleagues [48] in premature baboons, a 72 hour treatment with prenatal dexamethasone did not increase radioactive palmitate incorporation in lung lipids, but it increased total lung phospholipids and alveolar lavage DPPC in lung lavage fluid at birth. Bunt and colleagues [49] used stable isotope labeled glucose in preterm baboons to measure the synthesis rate of surfactant PC from plasma glucose. The synthesis was doubled after a 48 hour treatment with prenatal corticosteroids. In preterm infants it was also found that two doses of prenatal corticosteroids doubled the endogenous surfactant synthesis from plasma [U-^{13}C]glucose [50].

In summary, prenatal corticosteroids enhance surfactant PC synthesis *in vivo*, but de novo synthesis rates remain low, and alveolar pool sizes are not increased within 48 h. In preterm animals with RDS, prenatal corticosteroids improve pulmonary compliance within 15 h [51] accompanied by stimulated structural development [52–57]. Therefore, the pathophysiology of the improved lung function after prenatal corticosteroids remains controversial.

61.7 Surfactant Status of Preterm Infants Recovering from RDS

The common belief that after surfactant replacement the exogenous surfactant is fully retained by the lung of the preterm infants suffering from RDS, has been recently challenged by Verlato and colleagues [31]. They studied whether reduced amounts of pulmonary surfactant contribute to post-extubation respiratory failure in preterm infants who had RDS, needed mechanical ventilation and exogenous surfactant replacement for treatment of moderate/severe RDS and could not be extubated before day 3 of life. Verlato and colleagues studied 88 preterms by the "exogenous" tracing approach. They administered endotracheally ^{13}C-DPPC as tracer before extubation, for the estimation of surfactant DSPC pool size and half-life. Patients were retrospectively divided into 3 groups, that is, a) extubation failure if, after extubation, they needed reintubation or high setting CPAP (6 or more cm H_2O of continuous positive airway pressure and a fraction of inspired oxygen grater than 0.4), b) extubation success if they did not meet the failure criteria, and c) not extubated if they needed ongoing ventilation. Sixteen, 23, and 24 neonates were categorized in the extubation failure, extubation success, and not extubated groups, respectively. Mean DSPC pool size was smaller in the extubation failure group than in the extubation success group (25 versus 43 mg/kg) and it was 37 mg/kg in the not extubated group. Mean DSPC half-life was 19, 24 and 28 hours in the extubation failure, extubation success, and not extubated groups, respectively. The authors concluded that marginal surfactant deficiency may contribute to extubation failures or need for high continuous positive airway pressure settings after extubation and perhaps more importantly draw the attention on individual differences in exogenous surfactant handling or on individual differences in endogenous synthesis. Interestingly a recent report in abstract form, showed that the administration of exogenous surfactant (Infasurf 3 mL/kg) in infants below 28 wks of gestation and beyond 7 days of age resulted in an improvement in respiratory severity score [58].

61.8 Neonatal Pneumonia

Pneumonia in children and newborn infants may be associated with surfactant dysfunction and severe acute RDS [59–64]. There are studies involving a small number of neonates who have been treated with rescue surfactant replacement for sepsis and pneumonia that have demonstrated improved gas exchange compared to no surfactant treatment [59, 61, 62, 65–67]. Verlato and colleagues [68] used the "exogenous" tracing approach with an endotracheal administration of ^{13}C labeled DPPC to study surfactant kinetics in full-terms with pneumonia, and in preterms with RDS. In this small study the authors found that the amount of DSPC recovered from the tracheal aspirates was not different among the study groups whereas its half-life was significantly shorter in full-terms with pneumonia (19.3 ± 7.3 h) than in preterms with RDS (28.7 ± 15.9 h).

Conclusion: If it is apparent from one side that large randomized controlled studies are necessary to evaluate the effects of surfactant treatment on morbidity and mortality, it may well be that the dose and time intervals of exogenous surfactant therapy ought to be different in neonatal pneumonia from the schemes currently used for neonatal RDS.

61.9 Meconium Aspiration Syndrome (MAS)

Aspiration of meconium into the lungs directly inhibits surfactant function and induces an inflammatory response in the lung with possible detrimental effects on type II cell function, and thereby surfactant metabolism. Surfactant function is inhibited by meconium in a concentration-dependent way [69, 70]. Meconium increases the minimum and maximum surface tensions and lowers the surface-spreading rate of surfactant [69–71]. Studies of surfactant concentrations and composition in MAS are scarce.

Cleary and colleagues [72] found decreased SP-A and SP-B levels in the large aggregates of surfactant in a rat model of MAS. However, phospholipid and DPPC levels did not change significantly after meconium instillation in either lung tissue or bronchoalveolar lavage fluid (BAL). Analyses of BAL fluid from 8 ventilated infants with MAS revealed no difference in phospholipid and SP-A content compared to control subjects [73]. However, concentrations of non-surfactant protein and albumin were more than 3 times those found in normal lung. In MAS infants who required ECMO, surfactant phospholipids, PC, and SP-A in tracheal aspirates increased during the ECMO treatment [74, 75]. One study investigated the surfactant kinetics in the presence of meconium [76]. This *in vitro* study in type II cells of adult rats showed that meconium in low concentrations (1%) increases the PC secretion by type II cells, but had no effect on surfactant PC synthesis. Higher meconium concentrations were toxic to cultured type II cells, though the effect of these higher concentrations on surfactant synthesis is not known.

Janssen and colleagues studied surfactant metabolism in MAS infants on ECMO with the "endogenous approach" using [U-^{13}C]glucose as a precursor for surfactant PC palmitate [23]. The FSR in MAS infants was ~3.3 %/day (compared to controls 8%/day, p = 0.058) and peak enrichment was significantly lower than in controls p = 0.027), suggesting lower synthesis in MAS. PC concentration in ELF in MAS was ~4 mg/mL (significantly lower than controls: 12.8 mg/mL). The half-life of endogenous surfactant was 69 h (not different from controls). With endotracheally administered $^{2}H_3$-DPPC as label, surfactant pool PC size was measured to be ~50 mg/kg

in neonates with MAS requiring ECMO, which was not significantly different from controls or other ECMO infants with persistent pulmonary hypertension of the newborn [77]. Exogenous administration of surfactant in animal models of MAS improves lung function and morphology, especially when surfactant is given at a high dose (200 mg/kg) [78]. Several studies showed an improvement in oxygenation after surfactant therapy, although most infants required 2 or more doses of exogenous surfactant [79]. In a randomized trial 3 doses of bovine surfactant (150 mg/kg) were administered to 20 infants with MAS. Infants treated with surfactant had improved oxygenation, a reduction in severity of pulmonary morbidity, a decrease in ECMO requirement, and a decrease in hospitalization time compared to the control group (n = 20) [80].

Lotze and colleagues [81] performed a trial in term infants with severe respiratory distress who received 4 doses of bovine surfactant (100 mg/kg/dose) at ~30 h after birth. Half of these infants had MAS. They were unable to demonstrate a difference in oxygenation, pulmonary morbidity, or hospitalization, although the need for ECMO in the surfactant-treated group was decreased. From these studies it seems that surfactant therapy in MAS is most effective when given in the early phase of respiratory failure, and at a high dose. Lavage with surfactant could remove meconium, inflammatory cells, edema fluid, proteins, and other debris from the lungs, leaving behind a layer of functional exogenous surfactant [82]. Animal studies showed a beneficial effect from surfactant lavage on pulmonary function, radiographical and histological appearance. There are few reports of lavage therapy in human neonates with MAS [83]. However, the patient groups were small and no control group was included. Recently, a multicenter, randomized controlled trial comparing surfactant lavage with standard treatment of MAS has been reported [84]. A trend towards shorter duration of ventilation and improvement in oxygenation were noted, but the differences were not statistically significant.

In conclusion, surfactant inactivation seems to play a more important role in the pathophysiology of MAS than surfactant deficiency. In the sickest MAS infants on ECMO, surfactant synthesis is disturbed. Surfactant therapy seems to be effective in MAS, and should probably be given at a high dose and at an early stage in the development of the disease.

61.10 Congenital Diaphragmatic Hernia (CDH)

Although CDH lungs are immature and morphologically show some resemblance to lungs of preterm infants with RDS, it is still unclear whether a primary surfactant deficiency is present in human CDH. Several animal models have been developed to study the pathogenesis of CDH. In bronchoalveolar lavage (BAL) fluid of surgically created CDH lambs, the amounts of phospholipids, PC, SP-A and SP-B are decreased compared to controls [85, 86]. However, the amniotic L/S ratio is not different in CDH lambs compared to control lambs [86]. *In vitro* studies in isolated type II cells of CDH lambs show a decreased incorporation of choline into PC [85], suggesting decreased surfactant synthesis in CDH. Human studies show contradictory results; the L/S ratios in amniotic fluid have been reported to be either decreased or to be normal [87]. SP-A and DSPC concentrations in amniotic fluid were lower in fetuses with CDH who died or required extracorporeal membrane oxygenation (ECMO) [88]. Autopsy studies in CDH infants who died at birth or within the first few days of life showed decreased SP-A in lung tissue [89]. No difference in L/S ratio, PC, and PG concentrations in BAL fluid from CDH infants was found compared to age-matched controls [90].

Cogo and colleagues have recently conducted a series of studies using stable isotope technology to trace pulmonary surfactant in newborn infants with CDH who were treated with mechanical ventilation and did not require ECMO. In the first study using the "endogenous approach", surfactant DSPC synthesis and metabolism were compared between CDH patients and control subjects. Secretion time was 8.3 ± 5.5 and 8.5 ± 2.5 hours and peak time 51.9 ± 15.2 and 51 ± 13 hours in infants with CDH and in control subjects, respectively. FSR was not different for infants with CDH and control subjects ($p = 0.4$). It was concluded that surfactant DSPC synthesis and kinetics were not significantly deranged in infants with CDH compared with control subjects. They also speculated that factors other than surfactant deficiency, such as lower surface area or increased DSPC catabolism, may contribute to surfactant pool alteration in CDH [22]. In a second study, Cogo and colleagues [35] studied surfactant DSPC half-life, turnover and apparent pool size in CDH newborns with no ECMO by the "exogenous tracing approach". In 13 CDH infants DSPC half-life was shorter (24 versus 53 h), turnover faster (0.6 versus 1.5 d-1), apparent pool size smaller (34 and 57 mg/kg body weight) and DSPC amount from tracheal aspirates lower (2.4 and 4.6 mg/mL Epithelial Lining Fluid [ELF]) than in controls. The data from the "exogenous tracer" suggested that surfactant kinetics was grossly abnormal in mechanically ventilated CDH. This study could not ascertain whether alterations of DSPC kinetics in CDH infants were caused by a primary surfactant deficiency or were secondary to oxygen therapy and ventilator support. In the third study of this series Cogo and colleagues [91] developed a new approach to measure DSPC net synthesis and kinetics by using dual stable isotope tracer approach i.e., combining the "endogenous" and "exogenous" techniques in the same patient. All infants simultaneously received an intratracheal (carbon-13 DPPC) and an intravenous (deuterated palmitic acid) stable isotope tracer. DSPC net synthesis from plasma palmitate was nearly identical in infants with CDH and control subjects (8.6 and 8.1 mg kg^{-1} d^{-1}). DSPC apparent pool size was 36.7 ± 7.5 and 58.5 ± 9.1 mg/kg, $p = 0.07$ and half-life was 26 and 50, $p = 0.03$ in infants with CDH and control subjects, respectively. Both DSPC turnover and percentage

of catabolism/recycling significantly correlated with duration of mechanical ventilation. In summary, this study confirmed that synthesis was not reduced in ventilator dependant CDH patients, that DSPC turnover was faster, presumably reflecting an increased DSPC catabolism/recycling, and the authors speculate that increased catabolism may ultimately lead to a secondary surfactant deficiency.

When patients with CDH were studied on ECMO by the "exogenous" tracer [77] surfactant PC pool size was comparable in CDH infants and in term newborn with severe respiratory failure who were not on ECMO (73 versus 69 mg/kg respectively). In CDH infants on ECMO Janssen [23] measured FSR by using [U-^{13}C]glucose as a precursor and found it to be lower than in controls (2.4 versus 8%/day) with a similar half-life of endogenous surfactant of ~65 h. It is unclear at present if these discrepancies in pool sizes and synthesis were due to ECMO or the severity of the patients studied. There are only a few reports of surfactant treatment in human CDH infants [92–94]. Bos and colleagues [92] showed an improvement of oxygenation in 3 of 5 infants with CDH after surfactant administration. When surfactant was given prophylactically to high-risk neonates with CDH, all 3 infants survived [93]. Surfactant treatment in 9 infants with CDH who required ECMO had no beneficial effect on lung function, morbidity, or survival [94]. Recent studies on surfactant supplementation in CDH [95] show no benefit associated with surfactant therapy for term infants with a prenatal diagnosis of isolated CDH and a lower survival rate in preterm infants with CDH [96].

Even today it is still not clear if there is a primary surfactant deficiency in CDH. We suggest that there is inactivation of surfactant function due to the intensive ventilation [97], which is often necessary in CDH infants, although, a decreased surfactant synthesis due to severe hypoplasia of the lungs (especially in the more severe cases of CDH) cannot be excluded.

Respiratory Distress Syndrome: Predisposing Factors, Pathophysiology and Diagnosis

Mikko Hallman and Timo Saarela

62.1 Introduction

Respiratory distress syndrome of newborn infants (RDS), called infantile RDS or IRDS, previously idiopathic RDS or hyaline membrane disease (HMD), is the most common serious disease affecting the newborn. Since the first description of hyaline membranes by Hochheim in 1903, a number of speculations and theories flourished concerning the primary cause [1]. During the past 40 years the advances in neonatal intensive care have been based on the understanding of molecular, structural and functional lung development, the knowledge of the cardiorespiratory adaptation in premature infants, the pathophysiology of RDS, molecular biology, pharmacodynamics and technological applications. As a result of the successful marriage between clinical investigation, applied and basic sciences, the mortality of RDS has dropped from about 50% to close to 5%. The infants affected by RDS are considerably more immature since previously many immature infants died before they developed HMD.

In 1926 Van Neergard described the hysteresis, i.e., higher airway pressure requirement during inspiration of the collapsed lung than during expiration of the air filled lung that additionally retained some air when the pressure was removed altogether. The theoretical significance of this phenomenon was not appreciated until surfactant was described by Clements and Pattle in the 1950's [1]. In 1959, Avery and Mead discovered that the airways of infants dying of HMD had deficient surface activity [2]. This finding was confirmed and further tested several years later when surfactant, then assumed to be dipalmitoyl phosphatidylcholine, was nebulized to the airways of preterm infants with RDS. However, the results were disappointing [3]. It took another 20 years to further define the structure of surfactant and to show that surfactant deficiency at birth is due to lack of differentiation of the alveolar epithelium. In randomized therapeutic trials it was possible to show that natural surfactant given in established RDS or at birth decreased the severity of respiratory failure and increased survival and survival without bronchopulmonary dysplasia (BPD) [4].

In the post surfactant era the management of RDS has improved and the focus has shifted to further improvement on the long-term pulmonary and neurosensory outcome. Despite advances in the management of most immature infants shortly after birth, prolonged intensive care is often required, the outcome is often less than optimal and attempts to prevent preterm births have failed. However, antenatal glucocorticoid treatment in threatened preterm birth has decreased the risk and severity of RDS. The concerns of adverse effects of antenatal steroid have not materialized.

As a result of effective early management, infants with RDS have an early remission of respiratory failure, translating into minimum requirement of supplemental oxygen or ventilation ("new RDS"). Despite this, the risk of BPD persists among the population of extremely preterm (ELGA, <28 weeks) infants despite mild symptoms of respiratory distress after birth. The phenotype of RDS is influenced by genetic and constitutional factors, most notably by the length of gestation at birth.

62.2 Risk Factors

RDS is a disease caused by immaturity, i.e., inadequate functional differentiation of the alveolar epithelial cells at birth and acute lung injury. The clinical features are dependent on a number of constitutional and genetic features and on therapeutic practices. The risk factors have changed as a result of improved antenatal anticipation of preterm birth and pharmacologic acceleration of fetal lung maturity.

The incidence of RDS has remained rather stable. Previously the disease predominantly affected near-term and term infants. More recently the gestational age of the RDS

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

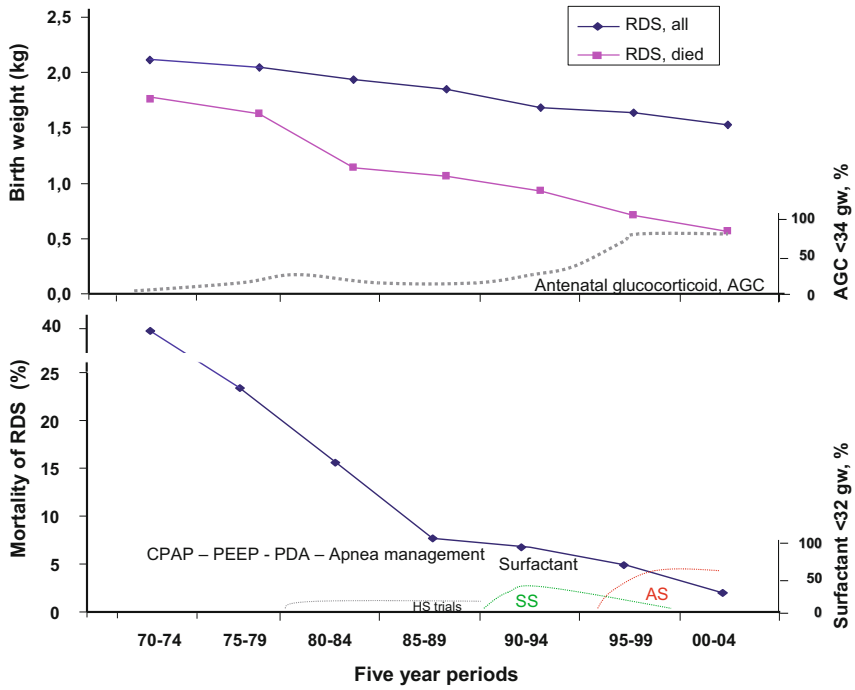

Fig. 62.1 Demographics of RDS during development of perinatal-neonatal treatment practices. Trends in mortality, and in birth weights of the infants with RDS during 1970–2004. The figures are from Finland with prematurity rate ranging from 5.2 to 6.0 percent during this period. The national incidence figures of RDS perinatal register have remained the range of 0.4–0.6% during the past 20 years, whereas the incidence figures from tertiary hospitals have ranged from 0.6 to 0.9%. Major developments in treatment practices are indicated. *HS* human surfactant; *SS* synthetic surfactant; *AS* animal surfactant. The figures are in part published, in part obtained from Hospital records and from Finnish National Institute for Health and Welfare (Dr. Mika Gissler acknowledged)

population has decreased. This has taken place because prevention of RDS in the near-term and preterm population has become partially successful, and because early treatment of newborn infants with very low gestation allows them to survive until the diagnosis of RDS is established. Fig. 62.1 shows the incidence of RDS (1970–2004) and mortality of RDS over 35 years in a homogeneous Caucasian population. The incidence of RDS among term born infants was 1 in 2000 [5]. The incidence increases by each week of decreasing the length of gestation. At 34–36 weeks it ranged from 2 to 8%, at 30–33 weeks from 10 to 35%, at 28–29 weeks from 30 to 50%, and in ELGA infants the risk exceeds 50%. High incidence in given gestation associates with the practice of elective deliveries without labor [6, 7], low use of antenatal glucocorticoid before preterm births [8] and Caucasian (*vs* African) ethnicity. Surfactant supplementation at preterm birth and continuous distending pressure ventilation from birth decreases the infant's risk of symptoms [9, 10]. Males have a higher risk than females, the difference corresponding to a mean of one week of gestation (Table 62.1). The length of gestation interacts with the risk factors. Multiple birth increases the risk of RDS in extremely preterm births and is a protective factor in near-term pregnancies (Fig. 62.1). The presenting twin has a lower risk of RDS (but higher risk of infection) than the non-presenting one [5]. Chorioamnionitis decreases the risk of RDS in ELGA births [11, 12]. Maternal diabetes and hydrops are recognized risk factors of RDS.

Table 62.1 Pregnancy-related states and complications associated with altered risk of RDS as compared to gestation controls

Accelerated maturation or control	Control or delayed maturation
Vaginal birth	Elective birth with labor
Elective birth with labour	Elective low risk birth w/o labour: late preterm or early term (37–38 wks)
Closeness to cervix in twin pregnancy (presenting)	Remote to cervix in twin pregnancy (non-presenting)
1st born premature twin ≥32 wks	Control premature singleton, ≥32 wks, twin pair
Singleton <28 wks	Twin <28 wks
Twin 32–36 wks	Singleton 32–36 wks
Preeclampsia 29–32 wks	Control 29–32 wks
Control <28 wks	Preeclampsia <28 wks
Chorioamnionitis 24–29 wks*	Control 24–29 wks
Gestation control	Maternal diabetes
Gestation control	RH immunization, hydrops
Circumvallatae placenta	Gestation control

* Mostly histologic chorioamnionitis. Clinical chorioamnionitis, when associated with foetal infection, is associated with respiratory distress mimicking RDS.

62.2.1 Genetic Factors Influencing Susceptibility to RDS

According to a twin study comparing the concordance of RDS between monozygotic and dizygotic same sex twins,

the genetic contribution to the susceptibility to RDS is only 0–40%. However, many genetic effects are due to gene-gene or gene-environment interactions. They undermine the estimates of the genetic effects on the basis of twin studies. For instance, the presenting twin has a lower risk of RDS compared to the non-presenting one and this difference is due to gene-environment interaction [13, 14].

Many surfactant lipids, surfactant proteins and proteins involved in intracellular processing of surfactant phospholipids are essential in respiratory function. Mutations that disrupt surfactant function include SP-B, ABCA3, and sometimes SP-C cause fatal lung disease that initially resembles RDS [15] (see Chapters 60 and 61). Several other proteins, including SP-A and SP-D have important, partly redundant functions that influence the susceptibility to infections and inflammatory insults. Genes with identified roles in lung function may have mutations or common allelic variants that influence surfactant function directly or indirectly. Studies thus far show that some genes expressed in type 2 cells influence the individual risk of RDS, including polymorphism of SP-A, SP-B, SP-C and ABCA3 [14]. RDS in near-term infants appears to have a different genetic background compared to RDS in very preterm infants. Many likely candidate genes remain to be studied. RDS is tightly linked to the degree of prematurity. The mediators influencing the risk of spontaneous premature birth and the risk of RDS are in part intertwined [16]. Typical multifunctional genes include collectins SP-A and SP-D that may influence cytokine responses mediating surfactant synthesis and the preterm labor process.

62.3 Symptoms and Clinical Findings

62.3.1 Lung Function

RDS is characterized by early rapid progression of respiratory distress that leads to respiratory failure in the absence of treatment within 1–48 hours. The healing phase starts within 1–6 days and is generally more gradual than the early phase. The clinical manifestation differs remarkably on the basis of the length of gestation as a result of constitutional differences in lung structure and host defense functions. The unifying features in RDS are the transient deficiency of surfactant in epithelial lining and the early lung injury. Very low functional residual capacity and low dynamic compliance are typical findings. Short inspiratory time constant have been reported early in the course of RDS, whereas during later in the course it may increase as a sign of airway obstruction [17]. Modest abnormalities in lung function may persist even weeks after the recovery from uncomplicated RDS in near-term infants.

The post-hospitalization course of RDS infants without developing BPD reveal a higher incidence of wheezing during infections and a higher hospitalization rates due to respiratory symptoms in infancy. These features persist during the infancy regardless of the gestation at birth, suggesting residual lung injury or aberrant immune activation during infection [18, 19].

62.3.2 Typical Course of RDS

Half of the infants with RDS are born between 29 and 33 weeks of gestation. First symptoms are observed very soon after birth. Tachypnea, nasal flaring, subcostal and intercostal retractions, cyanosis and expiratory grunt are characteristic, although not very specific. In RDS, the symptoms continue longer than 24 hours, unless specific therapies are applied. Cyanosis due to right-to-left pulmonary shunting of the blood is evaluated by oxygen saturation monitoring and objectively documented by measuring the arterial blood gases and calculating the alveolar–arterial O_2 tension difference. In the early phase, the breath sounds are often diminished; later inspiratory stridor may be evident. Observing the chest movements and the symmetry of the breath sounds is indicated, as pneumothorax sometimes complicates the course even with current advanced treatment strategies.

The early progressive phase of RDS is abrogated from most infants receiving early surfactant treatment. As a result of mild symptoms the diagnosis remains uncertain, unless pretreatment surfactant diagnostics are available or the patient had a favorable response to exogenous surfactant. The surfactant-induced remission may be followed by either recovery or relapse that requires retreatment. The response to exogenous surfactant is less predictable and generally less striking if surfactant is given later (>6 hours after birth). These infants have mostly uncomplicated recovery. Some develop patent ductus arteriosus (PDA). Apnea, feeding intolerance and infection are other complications.

62.3.3 Extremely Preterm Infants

Infants born before 28 weeks of gestation have simplified saccular airways, no true alveoli and wide interstitial spaces. The highly compliant chest cage generates striking retractions despite apparently deficient transpleural pressures. The surfactant pool is generally low and surfactant is susceptible to inhibitors. Without treatment the infants often die before development of HMD. The aim of pulmonary treatment starting at birth is by using gentle ventilatory treatment to limit the emerging lung injury and provide continuous distending pressures. Prophylactic surfactant is often the treatment of choice. Surfactant frequently induces a sustained remission characterized by requirement of generally small quantities if any supplemental O_2. Relapse of respiratory failure is common, and therefore retreatment is given early. The course of RDS is characterized by a high incidence of cardiopulmonary complications. Hypoxic respiratory failure, respiratory distress

associated with asphyxia, low cardiac output and hypotension, early symptomatic PDA, air leak syndromes (pneumothorax, interstitial emphysema) and pulmonary hemorrhage complicate the course. Severe RDS, particularly its life-threatening hemodynamic complications and associated infections are strong risk factors of extrapulmonary diseases (intraventicular hemorrhage; IVH, necrotizing enterocolitis; NEC, retinopathy of prematurity) and of BPD.

Despite antenatal steroids, early surfactant, noninvasive ventilatory treatment practices and other adjunct treatments, such as late cord clamping, dopamine, dobutamine, caffeine, and inhaled nitric oxide or corticosteroid to special high risk groups, even very mild or absent RDS, a significant risk of BPD remains [20]. The degree of prematurity in ELGA infants is a strong risk factor for BPD.

62.3.4 Near-Term or Term infants

Near-term or term infants with RDS are often born with elective cesarean section without active labor. Other risk factors include acute asphyxia, maternal diabetes, rapid progress of labor and delivery, and genetic risk [21]. Infection or severe asphyxia may cause a syndrome mimicking RDS but actually representing acute RDS due to primary alveolar injury (ARDS). Constitutional features alter the manifestation of RDS. The breathing is rapid but apparently effortless as the solid chest cage does not clearly reveal retractions. Undermining the early symptoms escalates the later respiratory course. Sometimes persistence of pulmonary hypertension, hyperexpansion of the lung fields or unexpected pneumothorax are dominant features. Studies reveal surfactant insufficiency despite atypical presentation and most patients respond to high distending pressures and to a high surfactant dose.

In near-term RDS, the structural development of the respiratory system explains the phenotype. The small size of newly developed true alveoli predisposes to therapy resistant atelectasis. The stable chest cage and strong respiratory drive generates very high transpulmonary pressures during inspiration, improving the clearance of edema fluid and contributing to the risk of pneumothorax. The pulmonary vasculature has a prominent smooth muscular layer that extends distally, and contracts in hypoxia and acidosis.

The clinical recovery from severe RDS often takes place within a short period. Continuing severe respiratory symptoms beyond the early neonatal period raises the possibility of underlying disease, such as hereditary interstitial lung disease (congenital alveolar proteinosis).

62.4 Diagnostics

The diagnosis is based on a combination of characteristic symptoms, clinical findings and the chest X-ray. Typical chest X-ray features reveal a diffuse reticulogranular pattern with superimposed air bronchograms (Fig. 62.2), indicating atelectasis and edema of respiratory units, distal to respiratory bronchioles. The prominent air bronchograms representing aerated bronchi and larger bronchioles become distinct when they are superimposed on a background of atelectatic lung parenchyma. Normal newborns occasionally have air bronchogram overlying left cardiac silhouette. The severity of RDS on the basis of the chest X-ray has been graded [22, 23]. Pulmonary whiteout (grade 4) is generally a sign of a severe disease; it is also observed in mild disease very soon after birth (<1h) or soon after extubation. Pulmonary edema is a prominent chest X-ray finding in RDS complicated by PDA. In near-term RDS population, reticulogranularity tends to be less distinct and the lung fields reveal a ground glass appearance. Some infants with rather advanced gestation have hyperexpanded lung fields and pulmonary hypertension. This entity has been called type 2 RDS [24]. Distinct chest X-ray may be explained on the basis of relatively large diameter alveolar ducts that dilate during high transpulmonary pressures generated during inspiration in near-term infants. The anatomical disproportion between small newly developed true alveoli and large alveolar ducts may explain the discrepancy between the chest X-ray and abnormal gas exchange.

Surfactant analyses performed on gastric or airway aspirates at birth differentiate RDS with specificity of and sensitivity of 50–75% and 78–97%, respectively, depending on the method of surfactant analysis and site of specimen [25, 26]. The false positive prediction may be due to blood contamination, and an occasional false negative prediction due to surfactant inhibition as a precipitating cause of RDS.

62.4.1 Differential Diagnosis

Transient tachypnea (wet lung) becomes distinguishable from RDS within several hours after birth. With new treatments these two diseases may be difficult to distinguish. Bacterial pneumonia, most notably due to Group B *Streptococcus* may even coincide with RDS; pleural exudate is common and focal infiltrates uncommon in infection. Congenital chylothorax is distinguished by typical appearance of pleural exudate. Severe lung edema due to secondary causes mimics RDS. Rare cases of small preterm infants with minimal respiratory symptoms develop cystic interstitial emphysema soon after birth (Wilson-Mikity syndrome) [27], a distinct form of obstructive inflammatory lung disease.

Congenital cardiac diseases associated with severe respiratory distress, most notably anomalous pulmonary venous return with abnormal infra diaphragmatic pulmonary vein return (Scimitar syndrome) are to be distinguished promptly from RDS as early diagnosis is required for proper treatment. Early respiratory distress due to diaphragmatic hernia, other causes of lung hypoplasia, esophagus atresia, isolated fistula,

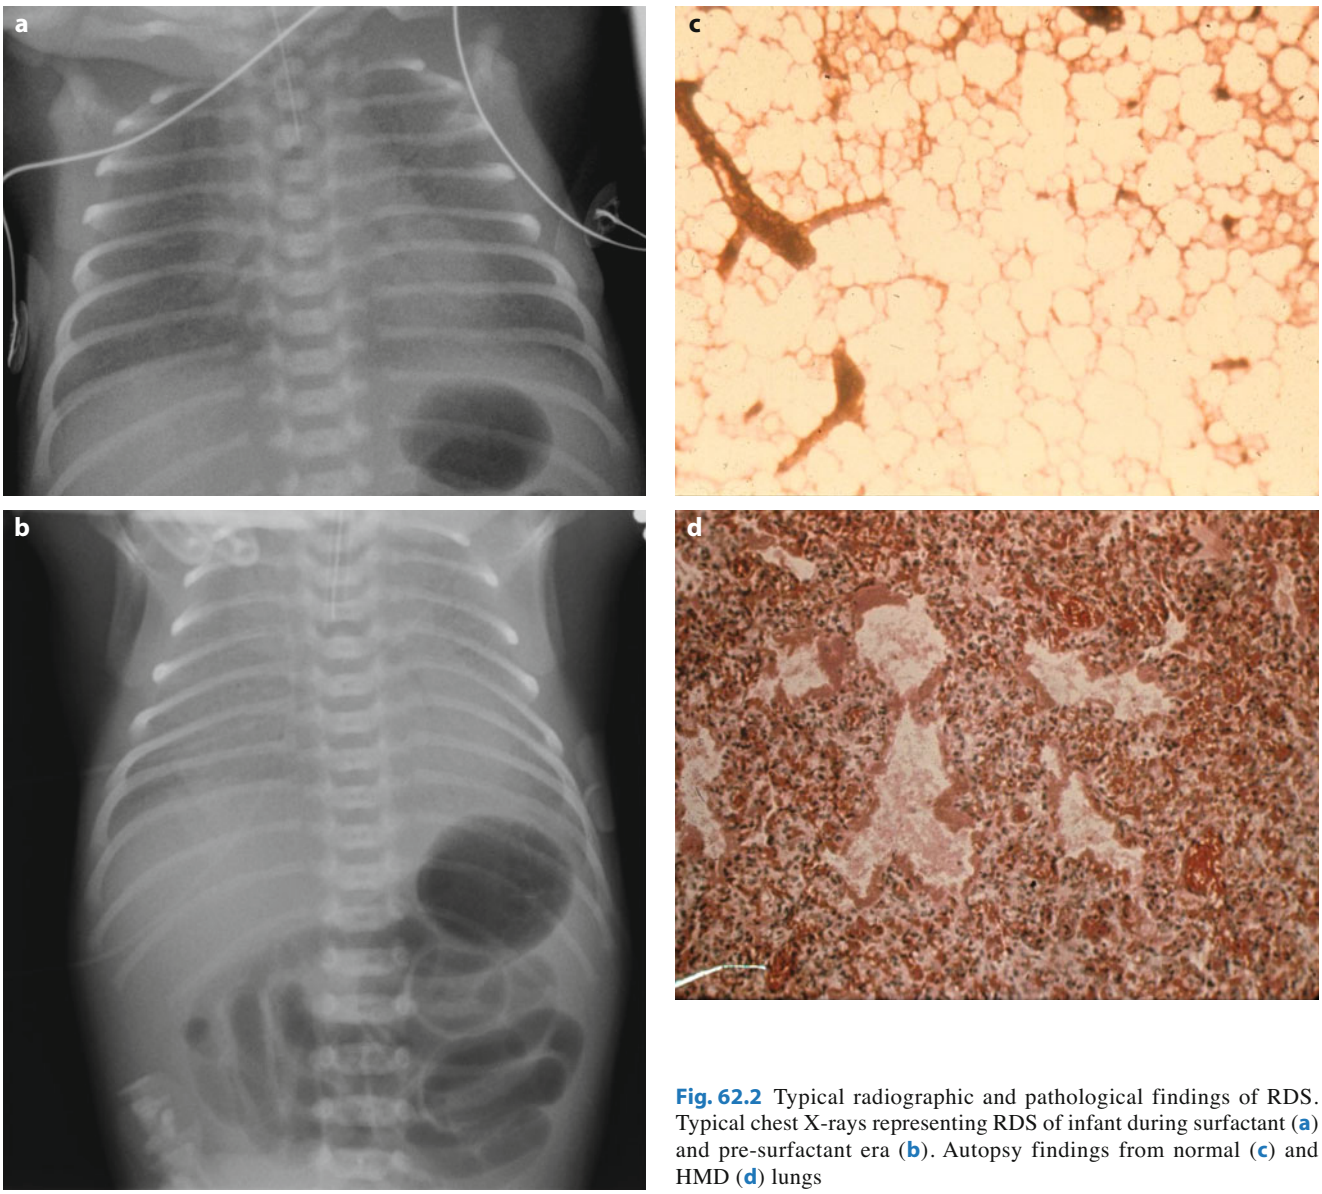

Fig. 62.2 Typical radiographic and pathological findings of RDS. Typical chest X-rays representing RDS of infant during surfactant (**a**) and pre-surfactant era (**b**). Autopsy findings from normal (**c**) and HMD (**d**) lungs

cystic adenomatous malformation, sequestration and tumors require early diagnosis.

A slow recovery from RDS may be a genetically determined constitutional feature, frequently due to PDA. Lack of recovery is a feature of PAP that often has positive family history [15]. Persistence of pulmonary hypertension (PPHN) mostly develops as a consequence of primary lung disease, often RDS. Alveolar capillary dysplasia is suspected on the basis of persistence of severe, persistent PPHN; pathologic descriptive diagnosis reveals severe growth disturbance of the lung and dysmorphic alveolar-capillary tissue [28]. In very severe lung disease, it is prudent to recover DNA, an airway specimen, and if possible to process lung for pathologic exam.

ARDS may sometimes develop in severe infection. These patients mostly respond acutely to a high dose of exogenous surfactant. However, the therapy has not significantly improved the outcome of this severe, heterogeneous syndrome.

62.5 Predisposing Factors

RDS is characterized by lung immaturity that results in poor cardiorespiratory adaptation and to respiratory failure without treatment. Surfactant deficiency is the primary cause of the tendency to generalized atelectasis. The peripheral lining of air spaces at 22 weeks of gestation contains some epithelial cells that morphologically resemble type 2 cells. Later in gestation the number of morphologically differentiated type 2 cells increase until the term, when the alveolar epithelium is

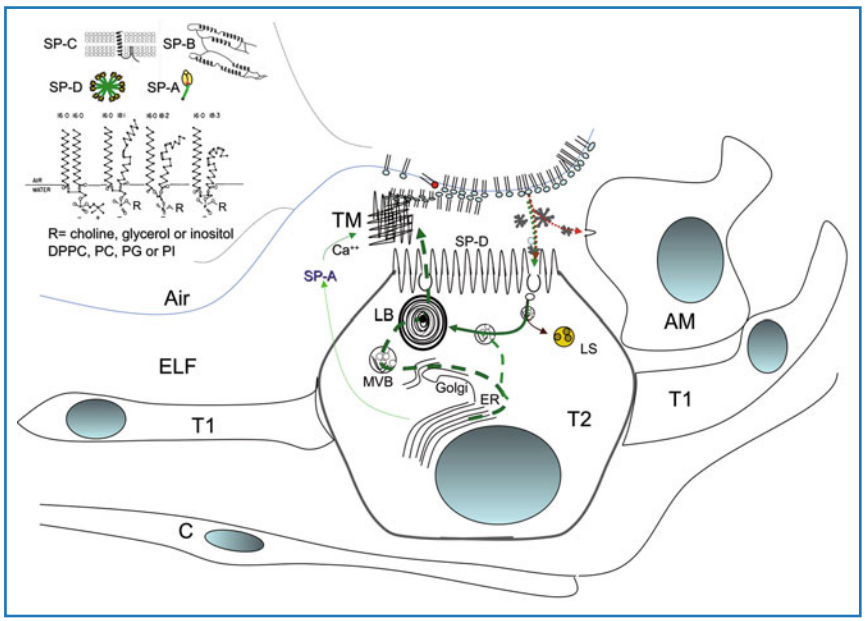

Fig. 62.3 Surfactant metabolism in alveolar epithelial cells and in epithelial lining fluid (ELF). Surfactant components are synthesized endoplasmic reticulum (ER) of type 2 cells (T2). Most surfactant components (phosphatidylcholine, phosphatidylglycerol, phosphatidylinositol, SP-B and SP-C) are processed [via Golgi apparatus and multivesicular bodies (MVB)] into lamellar bodies (LB). After secretion into alveoli, surfactant incorporates Ca^{++}-SP-A/SP-D, and transforms to tubular myelin (TM) that has rapid surface adsorption. During tidal breathing movements, some surfactant shuttles between surface and ELF. Eventually it is inactivated and taken up by alveolar macrophages (AM) and T2 cells for catabolism in lysosomes (LS) or for reprocessing into LB (recycling). In RDS there are multiple surfactant defects that are augmented by airway- and alveolar injury

loaded with type 2 cells. The rate of differentiation of the surfactant system and other pulmonary host defense systems each undergo a distinct antenatal development.

The major surfactant component, dipalmitoyl phosphatidylcholine (DPPC) concentrates at the air liquid interphase as a tightly packed lipid film (Fig. 62.3). However, it adsorbs very slowly from subphase to surface. Other surfactant components provide the extraordinary rapid surface adsorption of DPPC. These compounds are mostly unsaturated phospholipids containing anionic charge (phosphatidylglycerol, phosphatidylinositol) and hydorophobic surfactant proteins (SP-B and SP-C), containing stretches of entirely hydrophobic amino acids interrupted by individual amino acids with cationic charge. Besides deficient quantity and quality of surfactant in the epithelial lining of alveoli, the surfactant system after birth is a target of insults that deteriorate its function (inhibition, inactivation, degradation, de-aggregation, displacement) as part of the manifestation of lung injury. Despite characteristic lung injury, RDS is a self-healing disease, as the activation of the inflammation and anti-inflammatory endocrine axis promotes spontaneous maturation of the surfactant system and other host defense systems of the lung. This presentation focuses on alveolar epithelial cells.

62.5.1 Surfactant System

The lung has developed relatively late in evolution (~250 million years) and human evolution is extremely recent (~5 million years). The control of gene expression generates much of the diversity in human genome. Surfactant in healthy postnatal lung serves as a multifunctional, dynamic lipid protein complex. The lipophilic components, phospholipids, pro-SP-B and pro-SP-C, are synthesized in the endoplasmic reticulum, followed by serial cleavage of proproteins and transport via the Golgi apparatus to multivesicular bodies that transform to intracellular lamellar bodies. Shortly after secretion from lamellar bodies into the alveolar lining, surfactant binds Ca^{++} and SP-A and transforms to tubular myelin surfactant that has a very rapid surface adsorption. At the air-liquid interphase surfactant serves as a highly dynamic lipid layer that greatly reduces surface tension. Surfactant additionally serves as a lubricant that reduces barotrauma and, perhaps most important, serves as an immunomodulator that influences a range of pulmonary functions involved in defense against microbes and other insults regardless of etiology.

In the alveolar lining a minor fraction is removed by airway cilia. Most of it dissociates into smaller, protein-poor aggregates that are taken up by both type 2 alveolar cells and alveolar macrophages. In type 2 cells this surfactant may be reutilized and reincorporated into lamellar bodies (Fig. 62.3). Some genes are preferentially, but not exclusively, encoded in the lung, including SP-A, SP-B, SP-C and SP-D, and ABCA-3 is involved in intracellular processing of surfactant complex. The expression of these and many other proteins, including a number of signaling and transcription factors, hormones, growth factors and their receptors control the structural lung development and lung surfactant homeostasis. In human species the prematurity rate is exceptionally common. The high-risk fetuses are exposed to various stresses that induce abnormal fetal lung maturity.

Deletion of genes encoding SP-B, ABCA-3, a mutation in transcription factors TTF-1, C/EBPα, FOXA2, a glucocorticoid receptor GRα and some other genes selectively delay lung development causing fatal murine respiratory distress at birth. Some other genes are less selective and lack of them

may disrupt the development very early in gestation or delay the differentiation [29]. Biochemical maturation of the surfactant system involves increase in the activity of the enzymes required for synthesis of surfactant phospholipids. Surfactant proteins SP-A and SP-B show a distinct increase in the expression during near-term development, whereas the antenatal differentiation of SP-C and SP-D is somewhat different. The increase in intracellular synthesis of surfactant leads to intracellular processing and secretion of the complex that eventually accumulates into amniotic fluid [30]. Glucocorticoid is the main hormone regulating spontaneous functional differentiation of the lung [31]. The effects of glucocorticoid on the surfactant system are mediated by several pathways, one being fibroblast-derived growth factor that influences the differentiation of type 2 alveolar epithelial cells involved in surfactant synthesis and secretion. Glucocorticoid typically promotes differentiation of other functions in lung and in other organs, and structural maturation of the lung. High glucocorticoid activity decreases the growth. Absence of glucocorticoid also leads to lung hypoplasia and respiratory failure at birth. Other hormones contributing to biochemical lung maturity include adrenergic agents, thyroid hormone and prolactin, whereas testosterone delays lung maturity. Several growth factors and cytokines also influence the differentiation and growth of alveolar tissue.

Besides the transcription factors and signaling involved in normal differentiation of the alveolar epithelial cells, salvage pathways, influencing the lung beyond the timetable of normal differentiation operate in intrauterine stresses. Proinflammatory cytokines signal both the acceleration of lung maturation and spontaneous preterm labor in chorioamnionitis. IL-1 has been identified as a primary agonist upregulating the surfactant system in intrauterine inflammation [32]. In experimental settings an acute intra-amniotic infection rapidly induces surfactant maturity within 1–2 days. Endotoxin or proinflammatory cytokines introduced to the amniotic fluid have apparently little acute effect on fetal well-being as they accelerate differentiation of the surfactant and induce lung inflammation that may extend systemically. In contrast, severe systemic infections and inflammatory response syndrome have adverse fetal consequences [33, 34].

In hypoxia, expression of hypoxia inducible factors (HIF-1α, HIF-2α) is activated. HIFs are oxygen-regulated transcription factors that control the expression angiogenic genes, including VEGF. HIF-1α and other genes are involved in the development and growth of the capillary network around the airspaces. HIF-1α is required for differentiation of fetal type 2 alveolar cells. Increase in VEGF stimulates surfactant synthesis [35]. Extremely severe hypoxemia and restriction of placental supply of nutrients deteriorates fetal well-being and retards lung growth. These very preterm infants are prone to postnatal infections and chronic lung disease.

Deficient synthesis, intracellular processing and secretion of surfactant cause high surface tension in immature lung. Each of these steps may be rate limiting in RDS. In infants developing RDS, generally low although variable quantities of surfactant is present in the airways at birth. As a result of premature birth, a number of mediators that advance the epithelial differentiation, including glucocorticoid, secretion of adrenergic agent and of proinflammatory cytokines, promotes surfactant synthesis and secretion is activated. Surfactant sufficiency is established within 2–7 days in most cases [36–38].

62.5.2 Secretion of Fetal Lung Liquid

During the second trimester, the rapidly growing fetal lung already secretes Cl^- (150 mEq/L) [39]. During the second trimester this results in osmosis-driven liquid secretion of 0.3–0.8 liter per 24 hours of protein-poor liquid. At the same time, 7–10% of the cardiac output perfuses the alveolar tissue. A normal fetus makes periodic breathing movements with a small tidal volume (0.2–3 mL), resulting in transfer of liquid in and out from the airways. The fetus swallows some of the lung liquid, although remarkable quantities enter the amniotic fluid, contributing 5–15% to its volume. During the second trimester most of the amniotic fluid is formed by fetal urination and cleared by fetal swallowing, with a turnover time of ~48 hours.

The secretion of the lung liquid, tidal respiratory movements and airway contractility dilate the future peripheral airways. The tidal movements of the chest wall deliver some of the amniotic fluid content to the airways [40]. In chorioamnionitis, the content of amniotic fluid in the airways activates the host defense system [32, 34]. Experimental ligation of the fetal airways results in expansion of airways and hypercellularity of lung parenchyma. Lack of fetal breathing movements leads to poor lung growth that is particularly severe when the chest (lack of amniotic fluid) or lungs (diaphragmatic hernia, intrathoracic tumor, small chest cage) are compressed. Severe oligohydramnios from midpregnancy results in lung hypoplasia and deformations, originally described as a result of fetal anuria (Potter syndrome), but also caused by prolonged rupture of fetal membranes.

Chloride ion exits the epithelial cells of the airways and alveoli through apical anion-selective channels, including the cystic fibrosis transmembrane regulator protein. The driving force of the pump is linked to the Na,K-ATPases in the basolateral membrane, involved in active transport of Na^+ into the cells, generating the electrical potential difference allowing basolateral entry of Cl^- [41, 42] (Fig. 62.4).

62.5.3 Ion Channels and Pumps Responsible for the Absorptive State of Lung

Towards term the secretion of lung liquid decreases dramatically as the lung switches from a liquid secreting to a liquid

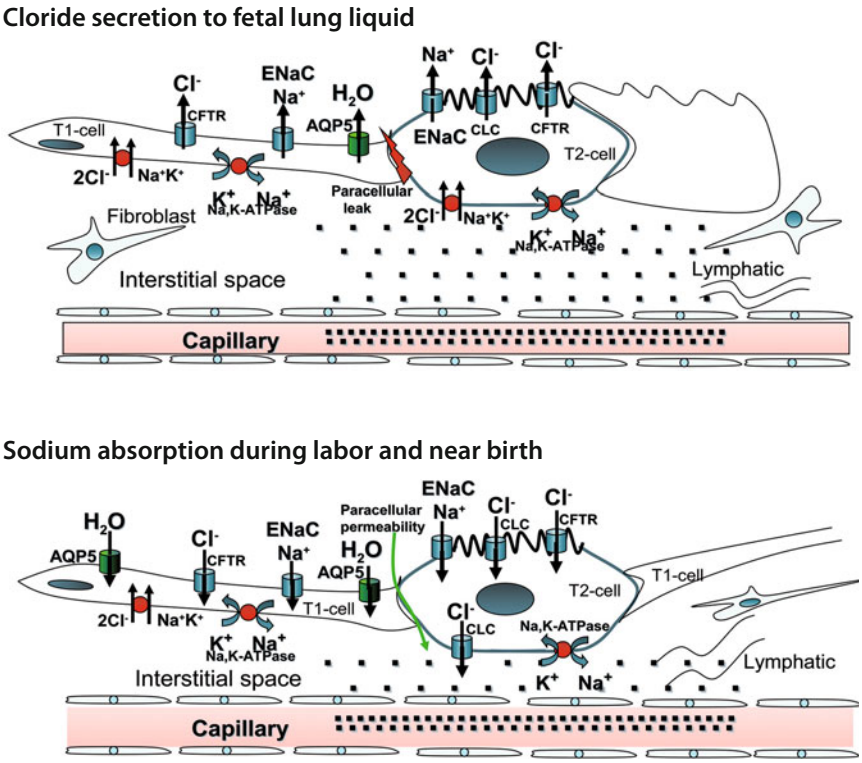

Fig. 62.4 Lung liquid secretion in fetal lung (*above*) and liquid absorption during labor and near birth (*below*) [43]. Liquid secretion is a risk factor of RDS and liquid absorption is a protective factor. Both are energy dependent processes driven by Na^+,K^+-transporters in the basolateral membrane of type 1 (T1) and T2 alveolar cells. The induction of the absorptive state involves glucocorticoid and adrenergic agents. The rate limiting activities for absorption include sodium channels (ENaC), aquaporins (AQP5 in T1-cells) and Na^+,K^+-ATPase. The fetal state of liquid secretion is driven by Na^+,K^+-$2Cl^-$ co-transporter. To maintain electroneutrality, Cl^- ion exits the apical membrane through cystic fibrosis transmembrane conductance regulator (CFTR) and through volume- and voltage- gated chloride channels (CLC). Sodium and water follow through specific channels. The resulting lung liquid promotes fetal lung growth but also increases the risk of lung damage and large paracellular leak during first breaths after birth

absorbing organ. The lung liquid during active term labor decreases by 40–50% as a result of active absorption of lung water. Lung extracellular water further decreases by another 40% during the first 6 hours of life at term.

Both Type 2 and Type 1 epithelial cells contain amiloride-inhibited ENaC protein complex (α, β, γ), attached in the apical plasma membrane. Besides the luminal transporters, basolateral Na,K ATPase and voltage gated Cl^- channels transport Na^+ and Cl^- ions to lung interstitium. Aquaporins facilitate the movement of water across cell membranes.

Adrenaline via cyclic AMP acutely induces the absorptive state of the fetal lung. Additive with adrenaline, corticosteroid decreases lung liquid formation. Adrenaline activates ENaC and corticosteroid increases the synthesis of ENaC protein, particularly the rate-limiting ENaC α. Flucocorticoid increases as a result of activation of the pituitary-adrenal axis towards normal pregnancy. In addition, adrenalin increases during labor, and a further increase takes place shortly after birth [43].

In infants developing RDS the ion channels responsible for clearance of the lung liquid are not active. This immaturity of the alveolar epithelium is likely to aggravate the symptoms of respiratory distress and activation of ion channels involved in liquid adsorption associated with the recovery. According to the favored hypothesis, wet lung syndrome is due to insufficient clearance of lung liquid and critical deficiency of the active clearance mechanism [44, 45].

62.5.4 Structural Lung Development

There are gestation-dependent changes in lung structure, including differences in microanatomy and in the amount and composition of the extracellular matrix. These factors influence the phenotype of RDS.

During the canalicular stage between 16th and 25th weeks of gestation the lung transforms from previable to a potentially viable organ, capable of gas exchange. This is accomplished by the growth and differentiation of the distal ends of the preacinar terminal bronchioles that grow and branch to two to four respiratory bronchioles. The potential gas exchange surface enlarges as a result of simultaneous vascular sprouting and acinar growth. In addition future airways and capillaries approach each other, decreasing the potential diffusion pathway of gas exchange. The epithelium undergoes thinning from columnar to cuboidal form as type 2 cells differentiate.

During the saccular stage between 23 and 34 weeks, clusters of thin-walled saccules form the acinus that simultaneously expands and grows in length as the respiratory bronchioles divide into 6–7 generations by branching. The capillaries still form a double capillary network between individual saccules. Elastic fibers are deposited along the airways and capillaries.

Towards the end of gestation and particularly after birth the elongated type 1 alveolar cells expand and increasingly cover the alveolar lining, whereas surfactant-secreting type 2

cells arrange around the alveolar corners. The alveolar stage involves microvascular maturation that starts already near term and continues during the first years. True alveoli grow from the walls of terminal saccules as spherical structures. They grow in size and the cellular intersaccular structure containing a double capillary network transforms into a single capillary network in close apposition to alveoli [46, 47].

62.6 Pathogenesis

Since the primary importance that lack of surfactant function as a triggering factor has been recognized and early surfactant therapy has been adopted, the severity of RDS has decreased considerably. Although the effect of surfactant is often dramatic in reducing or even abolishing the symptoms of respiratory distress, in some cases its effect is either transient or in rare cases missing altogether. This emphasizes the dynamic and interactive nature of additional factors influencing the alveolar stability, pulmonary circulation and structural integrity, essential to the gas exchange function of the lung. The interactive factors include the conducting airways that are intimately involved in lung injury, characteristics of the airways and cardiac function that is influenced by ductus arteriosus that tends to remain open despite improvement in alveolar gas exchange. Regardless of length of gestation and pregnancy complications, diffuse atelectasis, lung edema and hyaline membranes are a consequence of functional immaturity of alveolar epithelium. Infections and severe asphyxia and other adverse events complicate RDS and sometimes these acquired factors contribute to primary cause. Fig. 62.5. illustrates factors involved in pathogenesis that are additionally explained below.

62.6.1 Biotrauma

In addition to the pathogenic factors listed below, the innate immune system is of principal importance. The inflammatory reaction as a result of biotrauma induces both healing and tissue destruction (oxidants, lytic proteins). The balance between these numerous activities depends on management practices, constitution and hereditary factors.

62.6.2 Surfactant

High surface tension retracts the air spaces with very small principal radii (R_1 and R_2) according to the law of Laplace:

$$P \text{ (collapsing pressure)} = $$

$$= \text{surface tension constant } (\gamma) \times \left(\frac{1}{R_1} + \frac{1}{R_2} \right)$$

In true alveoli or at the tip of respiratory ducts of immature lung, the principal radii are equal ($R_1 = R_2$; $P = 2 \times \gamma/R$), whereas in tubular surfaces, the second radius is indefinite ($1/R_2 \sim 0$; $P = \gamma/R$). Surface tension is measured *in vitro* using modified Wilhelmy balance, pulsating bubble surfactometer or captive bubble surfactometer. In situ measurements during mechanical ventilation are based on microscopic observation of the alveolar surface containing droplets of specific fluorocarbons that have a constant, generally low surface tension.

Normal alveolar surface liquid lining after birth is virtually free from surface forces (γ close to 0 mN/m) *in vivo*. The rapid shallow breathing movements and the pressure waves induced by the cardiac cycle barely reshape the peripheral air spaces sufficiently to alter the low surface tension. During

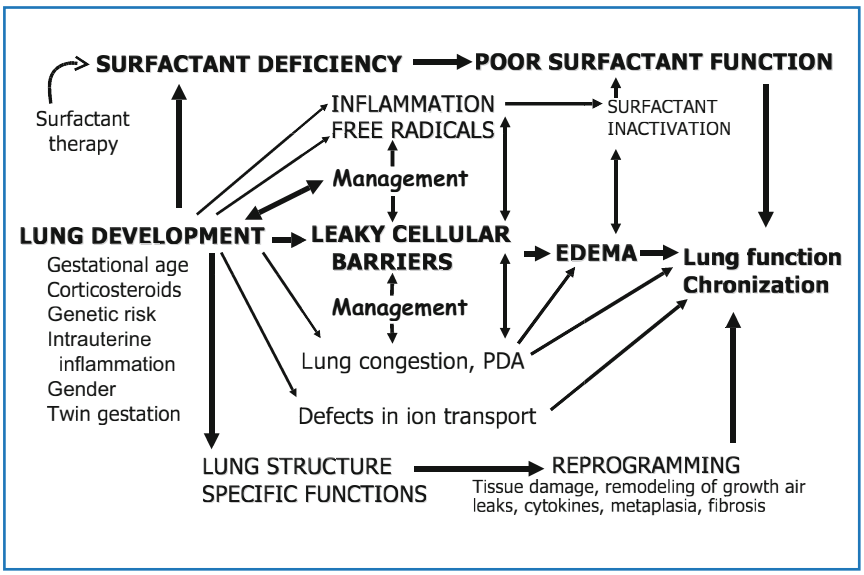

Fig. 62.5 Factors involved in pathogenesis of RDS. The primary factor is surfactant deficiency that is augmented by other defects of differentiation (e.g. lack of absorptive ion transport) and acquired factors (e.g. asphyxia, volutrauma). The resulting lung injury and inflammation promotes high permeability lung edema. Chronization of lung injury is opposed by the process of lung healing, plasticity and differentiation (e.g. induction/increase in surfactant), induced by the stress of perinatal transition

deep inspiration some increase in surface tension takes place as the surface area is significantly expanding followed by a drop in expiration (i.e., hysteresis). Due to exceptionally fast surface adsorption, the surface tension is low even during deep inspiration (10–20 mN/m) [48].

During the first breaths, lung liquid surfactant rapidly adsorbs and concentrates on the emerging air liquid interface. Lowering the surface tension from near 72 mN/m (isotonic saline in water) towards 0 mN/m, has a large impact on the forces required for liquid clearance from narrow tubular structures and alveolar saccules. Despite low surface tension, a large force is consumed against viscous resistance as the water moves out from the airways and alveoli. Transient negative interstitial pressures generated during the first forceful inspiration (as high as 50–70 cmH_2O) and positive pressures during the first cry (30–50 cmH_2O) may be exceptionally high. These pressures may cause some injury, particularly in structurally immature lung. Both large and smaller airways are exposed. Low surface tension facilitates clearance of lung liquid and protects the lung from injury. It reduces the very high pressures required to advance the meniscus towards smaller airways and alveolar saccules.

In RDS the minimum surface tension of the proteinous airway lining has minimum surface tension in the range of 20–50 mN/m. Distending pressures that maintain patency of alveoli with a radius of 50 μm and surface tension of 20–50 mN/m (similar surface tensions are evident in airway specimens recovered in RDS) is 8–20cm H_2O. As a result of slow surface adsorption surface tension increases during inspiration. High surface tension increases atelectasis (atelectotrauma) and alveolar edema and also airway resistance as it decreases the clearance of lung fluid and particularly the maintenance of alveolar patency during expiration. Surfactant deficiency additionally contributes to barotrauma (lack of lubricant property of surfactant) and volutrauma (overstretching of few remaining patent air spaces), manifesting as bronchial/bronchiolar permeability increase, perivascular edema, bronchiolar obstruction, and biotrauma.

At term birth total pool size of surfactant per kg BW is higher than in the adult (50–120 mg/kg versus 0–40 mg/kg). During the course of RDS, the surfactant system spontaneously expands and the pool size reaches the levels measured in the preterm controls by the age of 2–7 days [36]. In addition, the differentiating surfactant system is exposed to multiple injuries, delaying the recovery [38]. Besides the surface tension-reducing capacity, the individual components of the complex form an integral part of the immune defense of the lung. The coincidence of pneumonia and RDS reflects the immaturity of the innate immune system.

Besides the pool size of surfactant that critically influences the concentration of surfactant in the epithelial lining fluid, multiple factors perturb the capacity of surfactant to lower the surface tension after birth. The leakage of proteinous liquid across the epithelial lining not only dilutes surfactant but additionally reduces its ability to decrease the surface tension [36–38]. A number of proteins, cationic amino acids, carbohydrates and lipids inhibit surfactant function *in vitro*. Fibrin monomer is one of the most potent surfactant inhibitors described. Other mechanisms of surfactant inactivation include excess of proteolytic and phospholipase activities. Finally, oxidant injury by hydroxyl radicals and peroxynitrite deteriorate surfactant function [39]. Most of these noxious agents originate from inflammatory cells as a consequence of lung injury by barotrauma, hyperoxia and endotoxins.

In severe lung damage, as in some forms of interstitial lung disease, the surfactant complex may be displaced to the interstitial space. Another potential mechanism of apparently fast clearance of surfactant from air spaces is trapping within the airways that remain atelectatic or obstructed. As a result of recruitment of peripheral airways and alveoli, the trapped surfactant may reappear in airway specimens.

62.6.3 Lung Edema

Prenatal events influence the lung liquid adsorption and the amount of lung liquid at birth [40]. Spontaneous labor, advanced gestation and vaginal birth additively decrease the liquid in the airways at birth. Besides the electrochemical transport of lung liquid, water and ions move through interepithelial pores as the hydraulic conductivity and small solute permeability of the lung epithelium increases [41]. In healthy human infants the clearance of most airway liquid to lung interstitium takes place within seconds to minutes after the first breaths. Active, energy-requiring and passive mechanisms are likely involved. Both mechanisms are stretch-activated, with prominence of the energy requiring cation transport. The clearance of liquid from lung interstitium to lung circulation is more gradual, taking place during the first day as the solute directly enters the circulation or is cleared via lymphatics. The bulk of the liquid removed from the airways accumulates in distensible perivascular spaces of large lung vessels and airways, away from the gas exchange path.

Lung immaturity adversely affects the lung liquid clearance as the compliant chest cage complicates generation of high interstitial pressures and the activity of ion transport across the epithelium towards lung interstitium is low. Low ENaC expression in luminal cell membranes retards the active transport of Na^+ and oncotic transport of water to interstitial space. Term-born human infants with ENaC deficiency apparently do not develop respiratory distress as the lung liquid in term infants may have other clearance routes. During the third trimester, particularly during labor ENaC increases as a result of increased glucocrticoid and adrenergic activity. The increased risk of acute respiratory distress in near-term and even term cesarean sections without labor may be in part due to the high volume of lung liquid as a result of intranatal and early neonatal failure of activation of ion transport, including ENaC and active Na^+K^+ transport [42–44].

The adsorptive state of fetal lung liquid leads to retention and accumulation of surfactant in the airways and in air saccules, providing the critical pool of surfactant for reducing the surface tension at birth. At the same time surfactant secretion is modestly increased and continues shortly after birth. However, no rapid burst of surfactant secretion is associated with birth as originally described [46].

62.6.4 High-Permeability Lung Edema, Acute Lung Injury

The injury of alveolar and airways epithelial cells as well as capillary endothelium is a characteristic feature in RDS. The inducing events include oxygen toxicity, volutrauma/barotraumas, atelectotrauma and biotrauma (endotoxins, cytokines, infection). Regardless of etiology, the central feature is an increase in permeability to macromolecules. In RDS a profound increase in permeability exceeds the capacity of pulmonary lymphatics, resulting in interstitial edema. Airways and bronchioles are susceptible to volutrauma- or barotrauma-induced high permeability and edema-induced obstruction of the bronchioles. This enhances uneven aeration of alveolar ducts and saccules as some of them become overdistended while many are atelectatic as a result of compression by overdistended airways and of surfactant deficiency. "Effective" ventilation may not be helpful as it may increase volutrauma.

Increased epithelial permeability and high surface tension leads to alveolar edema and accumulation of surfactant inhibitors. Accumulation of fibrinogen into alveolar spaces precedes the formation of hyaline membranes. Epithelial debris, along with residue of inactivated surfactant components, is incorporated into the matrix of fibrin-rich hyaline membranes. Hyaline membranes stain with alveolar-epithelial cell-derived tissue factor that may initiate intra-alveolar coagulation [49] and they are eventually cleared by phagocytosis and fibrinolytic activity.

62.6.5 Pulmonary Hemorrhage

Pulmonary hemorrhage is a rare complication of RDS mostly in extremely preterm infants. In may be seen as an extreme form of high permeability lung edema that is associated with PDA, decrease in pulmonary vascular resistance and rapidly developing left cardiac failure and may be associated with coagulation disorder. Hemorrhage may be precipitated by surfactant therapy and inadequate PEEP (positive end-expiratory pressure) levels, allowing flux of blood from patent ductus arteriosus and rapid development of hydrostatic congestion, rupture of capillaries and airway epithelium. Treatment includes exogenous surfactant, high distending pressures and coagulation factors (pulmonary tamponade).

62.6.6 Abnormalities in Lung Perfusion

Both the epithelial differentiation and the vascular sprouting around the distal epithelium are essential for successful gas exchange. Acetylcholine, nitric oxide (NO) and other vasoactive agents dilate pulmonary vessels at birth. During the early hours, the failure of alveolar capillary gas exchange may in part be due to poor perfusion of alveoli, whereas mainly in later stages of RDS, symptoms of pulmonary vascular congestion prevail. Pulmonary hypoperfusion or congestion must be always considered as factors influencing the respiratory course.

In extremely immature lung (<26 wk) the active proliferation of alveolar capillary beds continues [46]. It is not constitutionally expanded and will barely provide a reservoir against hypo-hypervolemia and excessive distending pressures. The growth of both pulmonary vascular beds and the airways are seriously disturbed in lung hypoplasia. Predisposition to PPHN may be the result of acute biotrauma, caused by microbes and inflammatory agents. Increase in pulmonary vascular resistance in generalized acute lung disease is well recognized. This applies to RDS regardless of the gestation at birth.

In extremely premature infants the capacity of pulmonary vessels is low increasing the risk of pulmonary hypoperfusion during continuous distending pressures. These iatrogenic events increase the ventilation-perfusion mismatch, decreasing the gas exchange. Towards term, the muscularity of pulmonary arteries increases. The treatment of RDS in near-term infants is often delayed, allowing progression of respiratory distress and development of PPHN.

62.6.7 Patent Ductus Arteriosus (PDA)

In the fetus, the ductus arteriosus exceeds the diameter of aorta until early in the third trimester. Thereafter the ductus decreases in size in relation to major vessels. Prominent prostaglandin inhibitor-induced contraction of the fetal ductus arteriosus is evident beginning in the third trimester and increasing towards term. After birth, the cascade of events leading to permanent constriction followed by anatomical closure of the ductus takes place in virtually all term born infants, whereas the degree of prematurity progressively increases the risk of PDA.

PDA in VLGA and particularly ELGA continues to be a treatment challenge and an important factor influencing pathogenesis of prolonged respiratory distress. A left-to-right shunt through PDA causes pulmonary congestion at the expense of poor perfusion of other organs. This may happen rather soon after birth in RDS, as the surfactant-induced remission of RDS decreases pulmonary vascular resistance. Several co-morbidities may associate with hemodynamically significant PDA: severe RDS, intracranial hemorrhage, pulmonary edema/hemorrhage, necrotizing enterocolitis, retinopathy of prematurity and particularly BPD. Inhibitors

of prostaglandin synthesis and surgery are traditional therapies, and antenatal glucocorticoid, early neonatal caffeine or hydrocortisone decrease the risk of PDA. Value of several management practices in preventing/decreasing severity of BPD and adverse respiratory consequences (maintaining adequate blood volume while avoiding overhydration, continuous distending airway pressures) have been proposed.

62.7 Prevention of RDS

Elimination of prematurity would be most effective in prevention. There are remarkable variations in the risk of prematurity on the basis of ethnicity, socioeconomic status and the health care system (see Chapter 4). Supplementation of progesterone acetate from mid term pregnancies with previous spontaneous preterm birth has reduced the prematurity rate. However, the long-term risks have not been studied, and administration of progesterone in other indications has been barely successful. *In vitro* fertilization practices increase the risk of premature birth. This is mostly due to iatrogenic multiple births. Obstetric management and even early neonatal management of preterm infants influence the risk and severity of RDS. The practice of antenatal glucocorticoid and rate of elective near-term and term deliveries significantly influence the risk.

Currently, effective therapies of RDS are available and as a result the prognosis is remarkably improved. However, the mean cost of treatment is high and significant mortality continues to be evident even among near-term infants [50]. In very preterm infants RDS is a common disease that influences the risk of both acute (pneumothorax, lung hemorrhage, PDA, IVH, bowel perforation) and chronic morbidity (BPD, neurocognitive problems).

62.7.1 Pharmacological Acceleration of Fetal Maturity

In 1972 Liggins and Howie demonstrated that antenatal glucocorticoid (AGC) given in threatened preterm birth decreased the incidence of RDS and neonatal mortality [51]. This study based on similar evidence in pregnant ewes, was repeated a number of times, but first became fully accepted in the mid-nineties [8]. The concerns of adverse long-term effects have not materialized.

AGC influences the development of the fetal lung, gastrointestinal tract, cardiovascular system, liver, kidney and central nervous system. It accelerates the differentiation of the surfactant system, promotes the absorptive state of fetal lung, enhances the closure of PDA after birth, increases the generally low blood pressure of preterm infants shortly after birth, improves the performance of the immature left ventricle and has multiple potentially beneficial effects on the immune system. Other drugs and combinations of glucocorticoid and thyroid hormone have been studied in clinical trials. However, glucocorticoid is the drug of choice for this indication.

AGC given before 34 weeks of pregnancy in threatened preterm birth, decreases the incidence of RDS when started 1–7 days before the birth. The effect is observed in several high-risk groups. Antenatal glucocorticoid decreases the risks of RDS in preterm infants exposed to chorioamnionitis. This is not unexpected as glucocorticoid and cytokines or endotoxin have an additive effect in stimulating the maturation of the surfactant system.

Most of the studies were performed before introduction of exogenous surfactant. However, AGC and exogenous surfactant supplement each other. ACG increases the efficacy of surfactant in decreasing the respiratory failure and decreases the incidence of IVH in the era of surfactant therapy. The preferred drug is betamethasone (BM: 12 mg i.m. × 2, 24 h after 1st dose); an alternative drug is dexamethasone (6 mg × 4 i.m. q 12 h). According to meta-analysis, glucocorticoid decreased neonatal mortality (RR 0.69, 95% CI 0.58–0.81), IVH (RR 0.54, 95% RI 0.43–0.69), NEC (RR 0.46, 95% CI 0.29–0.74), and tended to decrease neonatal infections (RR 0.83 95% CI 0.66–1.04). No adverse effect on fetal, neonatal or postnatal growth has been observed. The cognitive and neurological problems observed in rodents following AGC have been of concern. However, according to follow-up trials, there is a trend towards improved outcome, if any. Exposure to AGC is associated with insulin resistance in young adults [52]. The follow-up continues.

Repeating the AGC when the premature fetus remains undelivered for longer than one week, has been evaluated. Weekly and bi-weekly repeat treatments or just one repeat dose of betamethasone in threatened preterm birth decreased the risk of RDS. Other beneficial outcomes observed after the single dose were not evident [53]. Repeating the drug weekly decreased the birth weight, including the head circumference. Altogether 20–25% of the fetuses exposed to multiple repeat doses were delivered at term. A single rescue dose of betamethasone before imminent preterm birth caused no growth retardation at birth. Although in follow-up studies no adverse influence on neurologic or cognitive function at the age of two years was evident. Longer follow-up studies are necessary [54] for defining AGC.

62.7.2 Amniotic Fluid Analysis for Fetal Lung Maturity

Lung surfactant secreted into liquid-filled air spaces is carried by the lung liquid, which is partly swallowed and partly accumulated into the amniotic fluid. This amniotic surfactant pool starts emerging with imminent functional maturity of fetal lung. Surfactant increases in concentration and quality

in a characteristic fashion as the pregnancy proceeds. Surfactant indices, measured in the amniotic fluid (lecithin/sphingomyelin ratio, phosphatidylglycerol, so-called lamellar bodies, lung profile) have been used to evaluate the risk of RDS of an unborn fetus, particularly in the era when antenatal glucocorticoid or exogenous surfactant were not used [30]. Assessment of fetal lung maturity in preterm and near-term pregnancies is still indicated when there is a need to balance the risk of continuing a risk pregnancy against the risk of iatrogenic RDS after elective near-term birth. The reported specificity and sensitivity of the surfactant indices in amniotic fluid have ranged from 92–100% and 30–70%, respectively. The accuracy suffers because surfactant in amniotic fluid is not only dependent on lung maturity but also on complex regulation of the volumes of fetal lung liquid and the amniotic fluid that serve as surfactant carriers.

62.7.3 Prevention of RDS in Near-Term and Term Pregnancy

Avoidance of birth asphyxia is a cornerstone of the fetal management. Asphyxia in term or near-term infants is currently a rare cause of RDS or ARDS. However, a significant fraction of near-term infants would develop RDS if delivered before the onset of active labor. This estimate is based on the analysis of surfactant profile from the amniotic fluid specimen and actually confirmed by clinical observations [30]. RDS among patients born at 39 weeks of pregnancy or later is very rare regardless of the mode of delivery whereas the risk of meconium aspiration syndrome continues to increase.

In elective near-term births without onset of labor, the fetus is exposed to increased risk of transient tachypnea, spontaneous pneumothorax, RDS, and persistence of fetal circulation. The induction of the adsorptive state of lung liquid secretion prevents the disappearance of secreted alveolar surfactant from the lung and results in accumulation of surfactant in lung liquid, particularly in alveoli. The levels of serum cortisol and adrenalin that induce the adsorptive state increase towards term, particularly during labor. Since the hormones additionally increase the secretion of surfactant, the labor decreases two major risk factors. According to available trials antenatal glucocorticoid in near-term pregnancies decreases the risk of respiratory distress. However, before this treatment is accepted as a therapy, further trials evaluating the efficacy and safety are required. It is imperative to avoid iatrogenic prematurity when it is safe to fetus and mother.

In pregnancies complicated by maternal diabetes, severe metabolic disease, acute bleeding (total placenta previa) or bleeding disorders, placental diseases causing IUGR or hemodynamic compromise of the fetus, in serious isoimmunization and some other rare diseases, elective near-term delivery is indicated, as the risk of continuing the pregnancy balance against early delivery.

Since RDS and the other forms of respiratory distress are relatively rare diseases in near-term infants, expanding routine indications of AGC beyond the 34th week of pregnancy remains to be critically evaluated. Balancing the benefits and potential risks (behavioral problems, increased risk of metabolic syndrome in later life among the exposed infants) contradicts against the use of AGC on a large scale, unless the long-term data on safety is available. In some near-term births ACG is indicated when the risk of respiratory distress is considerable. These cases include maternal diabetes, severe Rh immunization, diaphragmatic hernia, previous near-term RDS in the family and documentation of fetal lung immaturity.

Pulmonary Hemorrhage, Transient Tachypnea and Neonatal Pneumonia

Richard J. Martin and Amitai Kohn

63.1 Pulmonary Hemorrhage

In newborn infants, pulmonary hemorrhage, often a manifestation of pulmonary edema can range in severity from blood-tinged secretions in the endotracheal tube to life threatening blood loss with hypovolemic shock. It usually presents in the second to fourth day of life and may be associated with lung tissue damage (RDS, infection, and mechanical ventilation with high-inspired oxygen), hypoxia, hypervolemia, hypoproteinemia, congestive heart failure, and coagulation abnormalities. Klukow confirmed an association between pulmonary hemorrhage and a large patent ductus arteriosus with high pulmonary blood flow [1].

Pulmonary hemorrhage occurs when a build up of filtrate containing plasma and whole blood produces hemorrhagic edema fluid and results in an increased capillary pressure [2] When the pressure cannot be contained, the resultant injury leads to an acute hemorrhagic picture. Erosion or ulceration following an injury to the upper airway is another mechanism by which bleeding into the lung can occur.

Pulmonary hemorrhage was present in the lungs of up to 68% of infants who died in the first week of life and associated with the need for cardiopulmonary resuscitation in the neonatal intensive care unit [3]. In 9% of neonatal autopsies, pulmonary hemorrhage was the principal cause of death and a major risk of mortality associated with meconium aspiration syndrome. Of the total population of VLBW infants, 5.7% had pulmonary hemorrhage with a high associated mortality, possibly related to gasping during labor [4].

The clinical picture of pulmonary hemorrhage is quite distinct. The infant may present with signs of hypovolemic shock, cyanosis, and apnea. Red or pink tinged secretions are suctioned from the orophrynx or endotracheal tube and, at any time, secretions may turn into massive bleeding. The radiographic picture constitutes patchy infiltrates as seen in Fig. 63.1.

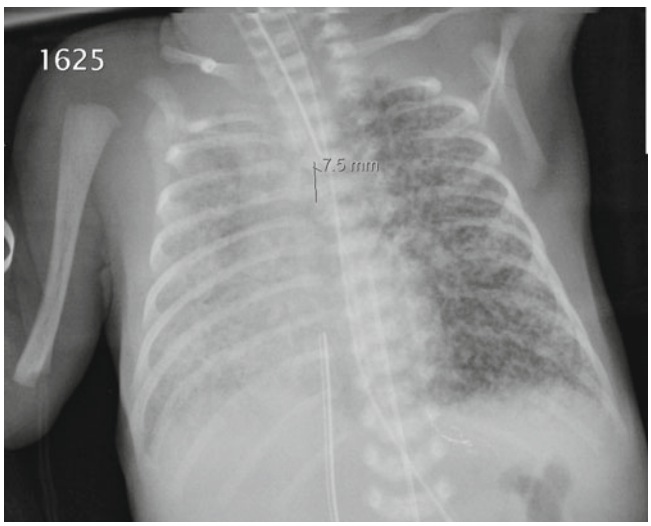

Fig. 63.1 Diffuse, patchy infiltrates and right-sided atlectasis caused by pulmonary hemorrhage

The management of pulmonary hemorrhage comprises maintaining cardiac output, transfusion of blood products as necessary and correction of acidosis. The initiation of mechanical ventilation with increase in PEEP or PIP may potentially tamponade small pulmonary vessels. In some instances, high frequency ventilation may also be helpful, possibly by maintaining a high mean airway pressure. Furthermore, several studies have suggested that closure of the patent ductus arteriosus with early medical intervention may reduce the risk of pulmonary hemorrhage. It is widely believed that pulmonary hemorrhage in the preterm infant is secondary to a patent ductus arteriosus and resultant pulmonary edema in the majority of cases.

While surfactant therapy has been implicated as one of the possible etiologies for pulmonary hemorrhage, it also has

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

a therapeutic role in the management of the same phenomenon [5–10]. This is due to the possible inactivation of surfactant production by the hemorrhagic fluid.

In a recent small study, the introduction of hemocoagulase via the endotracheal tube every 4–6 hours in addition to mechanical ventilation increased survival, decreased the length of pulmonary hemorrhage and decreased the need for prolonged mechanical ventilation due to the pulmonary hemorrhage [11]. The outcome of pulmonary hemorrhage depends on the underlying etiology and the severity of the infant's underlying cardiorespiratory status.

63.2 Transient Tachypnea of the Newborn

Transient tachypnea of the newborn (TTN) was originally described by Avery et al in 1966 as the clinical manifestation of delayed clearance of fetal lung fluid [12]. In her work, Avery characterized early onset of respiratory distress in eight late premature infants with radiographic findings of lung hyperinflation, increased pulmonary vascular markings and cardiomegaly. Symptoms were mild and transient with infants improving in a 2–5 day period. Until recently, it was believed that once TTN resolves, there is no added respiratory morbidity or long-term effect on the infant [12–14]. However, a recent large retrospective study of term infants suggested that TTN might be significantly associated with childhood asthma with increased propensity in males. This study also suggested TTN as a marker of diminished pulmonary function, which may reflect an inherited susceptibility to asthma [15].

The incidence of TTN is approximately 1% of live births. The risk for developing TTN seems to increase with prolonged labor with failure to progress, cesarean section, prematurity, birth of a male infant, and macrosomia [16, 17]. Prolonged maternal administration of hypotonic fluid such as during prolonged labor, decreased resorption of lung fluid in the neonate, and maternal asthma have all been suggested as a cause for TTN [13, 18, 19].

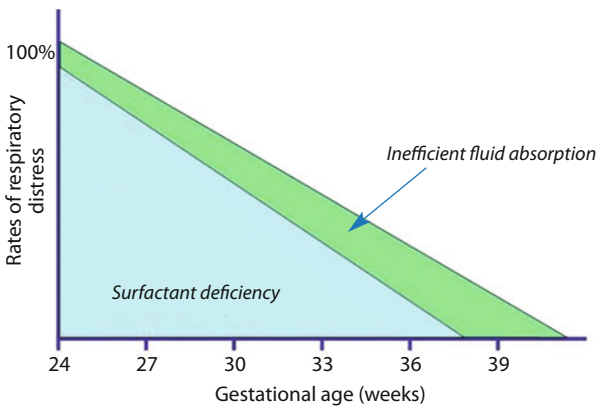

Fig. 63.2 Relative contribution of surfactant deficiency and insufficient fluid absorption [TTN] to neonatal respiratory distress. Adapted from [28]

Most of the published work related to the pathophysiology of TTN has sided with Avery's conclusions that TTN is the result of delayed fetal lung fluid clearance [20, 21]. The lung's functional residual capacity comprises a potential air space of 20–30 mL/kg body weight. This space is filled in utero with fetal lung fluid containing high potassium and chloride, and low bicarbonate and protein. Shifts between the body compartments are controlled by a chloride active pump [15, 22–25]. Two to three days prior to delivery, the fetus begins its lung fluid clearance in anticipation of transition to extrauterine life. This process begins with a decreased rate of fetal lung fluid secretion. The major clearance takes place with the onset of labor. At this time, the lung epithelium becomes a sodium absorbing membrane and lung fluid flow is directed from the air space to the intersititum. In addition, low protein containing lung fluid exhibits low oncotic pressure, which is another driving force for lung fluid to enter the vascular system.

Mechanical compression via vaginal delivery may also play a role in lung fluid clearance. Milner et al [26] showed that when infants were not delivered through the vaginal canal and were not exposed to vaginal compression they had higher interstitial and alveolar fluid volume. Furthermore, these infants also had a decrease in their lung gas volume. This hypothesis is not supported by later animal and human studies that showed no increase of functional residual capacity (FRC) in vaginally delivered infants [20, 27]. Results by Birnkrant and a retrospective study by Liem [15, 21], that found an association between TTN and the development of wheezing syndromes, support the pathophysiologic hypothesis of fetal lung fluid clearance at the cell pump level and not the mechanical compression theory.

The common clinical picture is of a term or a late premature infant with possible mild birth depression, who shortly after birth presents with respiratory distress including tachypnea, grunting, nasal flaring, subcostal retractions, and possibly cyanosis. The maternal history is often positive for maternal anesthesia, maternal diabetes, or cesarean section. Arterial blood gas is likely to show mild respiratory acidosis with potential hypoxemia. Chest radiographs typically demonstrates perihilar streaking which may be due to periarterial lymphatic engorgement. TTN may also present in premature infants. In this group of infants, TTN and pulmonary edema may further complicate surfactant deficiency and increase the likelihood of requiring exogenous surfactant and ventilator support. With advancing gestation and in the late preterm infant, TTN increasingly contributes to the pathophysiology of respiratory distress when compared to surfactant deficiency [28].

TTN is transient in nature and the resolution of symptoms is usually within 8–12 hours but may take up to 5 days. Infants may require oxygen support but, rarely over 40% inspired oxygen. In the case of respiratory acidosis, CPAP will support ventilation. Due to difficulty in distinguishing TTN from pneumonia, infants may receive a course of antibiotics. The radiographic findings of TTN should spontaneously resolve by 48 hours [13]. In the past, furosemide was thought

to help in the fluid clearance, however in a randomized control trial of oral furosemide there was no significant difference between treated and control TTN groups.

63.3 Neonatal Pneumonia

Lungs are a major site of origin and location for sepsis in the newborn. Pneumonia may be acquired pre- or postnatally and be of bacterial, viral, fungal or protozoan origin. Morbidity is high which should lead to high alertness when facing an infant with signs of respiratory distress. An immature immune system and poor mechanical defense mechanisms may increase susceptibility to invasion of pathogens into the lungs. Furthermore, when an infant has added morbidity such as respiratory distress syndrome (RDS), meconium aspiration syndrome or chronic lung disease (CLD), both vulnerability to and consequences of pneumonia may be enhanced.

The incidence of neonatal pneumonia is clearly much higher for preterm infants then term infants. Barnett and Klein [29] reported intrauterine and early onset pneumonia in 10–38% of stillbirths and in 20–63% of autopsies from live births that died in the first 28 days of life. The difficulty of reporting incidence is in the inconsistency of defining pneumonia in infants less than 1 month of age. The majority of late onset pneumonias are diagnosed in premature infants and most were on ventilatory support at the time of diagnosis. A small single center study by Apisarnthanarak [30] showed 28% of ventilated infants developed ventilator associated pneumonia (VAP) and in 1986, Halliday [31] reported a 35% incidence of pneumonia in intubated patients with RDS. Despite efforts by the Center for Disease Control (CDC) and National Nosocomial Infection Surveillance System (NNIS) there is still not a gold standard for diagnosing VAP [32, 33]. This adds to the major discrepancies between studies that report rates between 10–35% [34–36].

The etiology of neonatal pneumonia can be divided into 3 categories: congenital, early onset and late onset. Congenital or intrauterine pneumonia is usually caused by ascending infecting organisms from the maternal urogenital tract before or during pregnancy, or via the transplacental route. Prolonged rupture of membrane increases the risk of bacterial acquisition by the newborn however; this is also seen with intact membranes. Microorganisms such as viruses (cytomegalovirus, rubella, herpes simplex virus, adenovirus, varicella zoster virus, entroviruses and influenza A), bacteria (*Listeria monocytogenes*, *Mycobacterium tuberculosis*, *Treponema pallidum*), and protozoa (*Toxoplasma gondii*) are known causes of intrauterine pneumonia. However, these microorganisms cause multi-organ inflammation of which pneumonia represents a variable component.

Early onset pneumonia is usually due to introduction of bacteria from the mother's vaginal tract during the delivery process especially in a situation of prolonged membrane rupture [37, 38]. Gasping due to asphyxia and/or meconium aspiration may introduce organisms into the respiratory system or be a consequence of infection in the fetus. Other factors such as prematurity and maternal urinary tract infection have a major role in increasing the risk of neonatal pneumonia. Group B streptococcus [GBS] is one the major causes of pneumonia in the neonate [34]. Overt GBS sepsis is seen in 1% of colonized infants or 1–4/1000 live births if no intrapartum prophylaxis with antibiotics is given. Premature infants comprise one third of all infants with GBS bacteremia [39]. In 1993, committees of the American Academy of Pediatrics published guidelines for intrapartum chemoprophylaxis of group B streptococcal positive mothers [40]. These guidelines were revised in 1997 and have proven successful to date with a significant decrease in GBS sepsis to 0.6 per 1000 births in 1998 [41]. In 2002 [42], the Centers for Disease Control and Prevention (CDC) in the USA revised the prevention of perinatal Group B streptococcal disease guidelines concentrating on prenatal screening, updated prophylaxis regimens, prenatal specimen collection, culture methods and susceptibility testing. In addition, the CDC argued against routine intrapartum antibiotic prophylaxis for GBS colonized women delivering by planned cesarean section prior to the onset of labor or rupture of membranes. They suggested algorithms for management of patients at risk for preterm delivery as well as infants exposed to prophylaxis treatment. Unfortunately, other microorganisms known to cause early onset pneumonia have increased in importance since the implementation of the GBS guidelines. The common pathogens that may influence the infant in the immediate postpartum period are *Escherichia coli*, *Kelbsiella* spp, *Proteus mirabilis*, *H. influenzae*, Group D streptococci, *Listeria monocytogenes* and pneumococci. In addition, non-bacterial pneumonia may be seen in the early postnatal period such as caused by *Candida* [43, 44], viruses [45–47], and *Chlamydia* [48].

Late onset pneumonia is diagnosed when symptoms arise at or after 48 hours of life. The pathogens are commonly acquired from the environment and are nosocomial. Late onset pneumonia is more common in premature infants or infants on prolonged ventilatory support [30, 34, 49]. Gram-negative bacteria (*E. coli*, *Serratia marcescens*, *Proteus* spp, *Klebsiella* spp, *Pseudomonas* spp), coagulase-negative staphylococci [50, 51] and *Staphylococcus aureus* along with GBS are among the most common bacterial organisms isolated in late onset pneumonia. Viral organisms such as CMV [45, 52] VZV, RSV, parainfluenza, influenza A and B [53], rhinovirus [54], enterovirus [55], and coronavirus are also seen in this type of pneumonia. In addition, fungal etiologies have been implicated. Infections are acquired mainly through skin colonization and breakdown, gastrointestinal translocation of organisms, and from the respiratory tract of family and care providers. The colonization of an infant in the intensive care unit with common or unusual flora can be due to a weak immune system, health care provider exposure, and interventions (endotracheal tube, mechanical ventilation, and multiple courses of antibiotics) [56–59].

Ventilator associated pneumonia (VAP) is a nosocomial bacterial pneumonia that has developed in patients who are receiving mechanical ventilation. VAP can occur at any time and is defined as early or late, based on the timing as mentioned earlier [60]. While similar to neonatal VAP in many aspects, most diagnostic criteria and work up guidelines are based on adult studies. In the neonatal population the clinical and laboratory signs of VAP are nonspecific [61].

It is difficult to diagnose pneumonia with great certainty. Isolation of bacteria or viruses from the trachea or the oropharynx does not necessarily correlate with invasive infection and may just reflect colonization. Radiographic studies may suggest a focal pneumonia, but this presentation is not common and atelectasis may be difficult to differentiate from infiltrate secondary to pneumonia. The work up for suspected neonatal pneumonia whether congenital, early or late is similar. Blood, and airway cultures (nasophayngeal or tracheal if intubated) should be obtained and may be positive for the same microorganism in the case of respiratory infection [58]. Sherman [62], showed that tracheal secretions with a positive Gram stain in relation to neonatal bacteremia had a 74% sensitivity and 47% positive predictive value and concluded that gram stain of tracheal secretions may be of practical value in the diagnosis of congenital bacteremia. Positive airway culture alone may be more suggestive of early than late onset pneumonia, however in neither case is it sensitive [63, 64]. In the case of late, ventilator associated pneumonia (VAP), Mayhall [65] reviewed the diagnostic procedures for VAP based on the CDC (1997) Guidelines [66], although, these guidelines were intended for adult patients and are not specific for the neonatal population. Isolated positive tracheal culture did not distinguish between bacterial colonization and respiratory infection [61]. Radiographic studies are frequently non-specific, and it is more common to find pleural effusions in bacterial and fungal infections. Other non-specific laboratory values such as C- reactive protein (CRP) and WBC counts, especially immature to mature neutrophils ratio (I/T) may aid in the diagnosis of pneumonia.

The difficulty in diagnosing pneumonia especially when it coincides with RDS, presents the clinician with a therapeutic dilemma. Low absolute neutrophil count (ANC), high I/T ratio (>0.2) and CRP (>1) have shown to have positive predictive value of bacterial sepsis [66, 67]. Leslie et al [68] showed high I/T, low total neutrophil counts and positive gram stain to be more consistent with early onset bacterial pneumonia than RDS. However, diagnostic difficulty remains and if the index of suspicion for sepsis is high, the accepted treatment route is antibiotics for 48 hours while awaiting culture results and following the above markers trends. It is also accepted to treat every infant who deteriorates from a respiratory standpoint especially if the infant was asymptomatic for the first 6 hours of life.

The recommended empiric choice for early onset pneumonia is ampicillin in conjunction with an aminoglycoside (gentamicin). For late onset pneumonia, empiric therapy may constitute nafcillin and an aminoglycoside. Vancomycin is used empirically in extremely sick infants or infants deteriorating in spite of antibiotic treatment. When cultures are definitive and sensitivities are known appropriate antibiotics should be used. The prognosis of neonatal pneumonia depends on the underlying etiology and overall condition of the infant.

Pulmonary Air Leakage

Paola Papoff and Corrado Moretti

64.1 Pulmonary Air Leaks

Pulmonary air leaks include a number of clinical conditions characterized by overdistension and rupture of the alveolar wall with air leaking from the intra-alveolar space into the surrounding tissue. Air leaks are more common and more severe among neonates with pulmonary diseases that are characterized by poor lung compliance (e.g., respiratory distress syndrome) or by airway obstruction (e.g., meconium aspiration syndrome).

In neonates, the most common air leaks are pulmonary interstitial emphysema, pneumomediastinum and pneumothorax, while pneumopericardium, pneumoperitoneum and venous pulmonary embolism are less frequent. Affected neonates may be asymptomatic or have various degrees of respiratory distress. Diagnosis is suspected clinically because of respiratory distress and increased oxygen requirement and confirmed by X-ray. Treatment varies by type and severity of air leak.

64.2 Structure of the Lung

Macroscopically the lung is divided into three lobes on the right and two on the left, each of which have autonomous ventilation and blood supply. Each lobe comprises segments, which are pyramidal in shape with the apex towards the hilum and the base towards the surface of the lung. The segments are supplied by a bronchus and by a segmentary artery and are drained by a perisegmentary venous network. Each segment comprises pulmonary lobules, each of which is supplied by a lobular bronchiole, and a branch of the pulmonary artery.

P. Papoff (✉)
Pediatric Emergency Medicine Unit, Department of Pediatrics
'Sapienza' University of Rome, Rome, Italy

The lobular bronchiole continues branching until it reaches the level of terminal bronchioles, which ventilate the alveolar sacs that comprise clusters of alveoli. There are 10–15 alveoli in each alveolar sac. These are the functional units of the lung where gas exchange occurs.

The bronchial tree and associated vessels are wrapped in a sheath of collagen and elastic tissue. The pressure on the pleural surface is transmitted through the alveolar walls to the alveoli. Each alveolar unit is interdependent with the adjacent one so that the expansion of one alveolus determines the increase in wall tension of neighboring alveoli and ensures uniform pulmonary expansion.

Most of the development of the pulmonary elastic structure occurs during the fetal saccular period, which begins towards the 25th week of gestation.

The terminal bronchiole gives rise to two or more respiratory or alveolar bronchioles, which develop hemispheric evaginations called alveoli. Alveoli are more numerous in the distal portion of the respiratory bronchiolus, which ends by branching into alveolar ducts and finally the alveolar sacs, which form the terminal portion of the respiratory airways.

Each lung is enveloped by a serous membrane, the pleura.

64.3 Pulmonary Interstitial Emphysema

Pulmonary interstitial emphysema (PIE) may be defined as a collection of gas outside the airway and inside the interstitial space. It is caused by alveolar and bronchiolar rupture. The extent of PIE can vary. PIE may occur throughout the lungs or may be unilateral or lobar. In the former case, it may be difficult to differentiate PIE from early bronchopulmonary dysplasia (BPD).

The incidence of PIE has decreased because of treatments such as surfactant and the concept of "gentle ventilation", as well as the availability of high-frequency oscillatory ventilation (HFOV) for infants who are difficult to maintain with conventional ventilation [1].

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

Risk factors for PIE are:

- Mechanical ventilation with high pressures (the most important factor)
- Low gestational age (PIE usually develops in infants younger than 32 weeks' gestation, who weigh less than 1200 g) [2]
- Pulmonary hypoplasia
- Pulmonary diseases, e.g., severe respiratory distress syndrome (RDS), meconium aspiration syndrome (MAS), infectious or aspiration pneumonia [3]
- Chorioamnionitis and funisitis [4]
- Malpositioned endotracheal tube [5].

64.3.1 Etiology and Pathogenesis

The mechanisms involved in spontaneous, interstitial, mediastinal and subcutaneous emphysema have been described by Macklin and Macklin [6]. Their experimental work with various animal models led to the hypothesis that overdistended alveoli rupture into the pulmonary vascular sheaths and create PIE. Predisposing factors for PIE are positive pressure ventilation (PPV) with high mean airway pressures (MAP) and reduced lung compliance.

The basic requirement for rupture is the existence of a pressure gradient between the alveolus and its surrounding structure. However, in extremely premature infants, PIE can occur at low mean airway pressures and probably reflects increased sensitivity to stretch by the immature lung. The pressure within adjacent alveoli is generally assumed to be similar and the interalveolar wall remains intact. As illustrated schematically in Fig. 64.1, if a pressure difference develops between the alveoli, the risk of alveolar rupture is increased, causing interstitial emphysema. Since the mean pressure within the mediastinum is always rather lower than in peripheral lung parenchyma, air dissects proximally along the bronchovascular sheaths to the lung hilum and mediastinal soft tissue. Having reached the mediastinum, accumulated air may decompress into cervical and subcutaneous tissue or to the retroperitoneum, dissecting along the fascial planes. If mediastinal pressure rises abruptly or decompression via these routes is not sufficient to relieve the tension, the mediastinal parietal pleura may rupture, resulting in pneumothorax. This mechanism, rather than rupture of subpleural blebs, is thought to be responsible for spontaneous pneumothorax in a majority of cases [8].

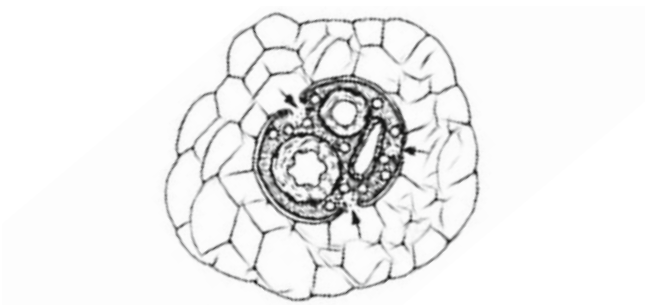

Fig. 64.1 Distal bronchovascular sheath surrounded by alveoli after expiratory airflow obstruction. Pressure gradient between airspace and perivascular interstitium leads to alveolar rupture (*arrows*) and direct introduction of air into bronchovascular sheath. Modified from [7]

The presence of air in the interstitial tissue causes reduced compliance, an increase in residual volume and dead space, and an increased ventilation perfusion (V/Q) mismatch. It also impedes pulmonary blood flow and obstructs the lymphatic drainage. These changes account for worsening oxygenation.

At an early stage of RDS, there is increased interstitial and perivascular fluid that rapidly decreases over the next few days. This fluid may obstruct the movement of gas from ruptured alveoli to the mediastinum through the bronchovascular sheaths, causing an increase of PIE. Another possible mechanism for entrapment of air in the interstitium is the increased amount of connective tissue in the immature lung. Entrapment of air in the interstitium may result in a vicious cycle that causes compression of the adjacent alveoli and a further increase in ventilation pressure with more air escaping from the overdistended alveoli into the interstitial tissues.

64.3.2 Clinical Aspects, Differential Diagnosis and Prognosis

PIE may occur during the first 72 hours of life or as a complication of prolonged positive pressure ventilation in older premature infants.

The clinical presentation of PIE varies with size and location of gas accumulation. PIE may cause compression of small airways with wheezing or diminished breath sounds because of decreased lung compliance. There may be changes in ventilator requirements, increased respiratory rate, and variations in heart rate and blood pressure. Trapped gas reduces pulmonary perfusion by compressing blood vessels, causing hypoxemia, hypercapnia and respiratory acidosis.

The air collection along the bronchovasal sheaths is visible radiologically as small rounded, nonconfluent, microradiolucencies throughout the lungs (Fig. 64.2). PIE may be unilateral (Fig. 64.3). If there is mechanical ventilation and because of rupture of interlobular septa, PIE tends to form hypertransparent bubbles that may be quite large and look like pseudocysts. Small areas of PIE alternating with pneumatoceles have the effect of making the pulmonary parenchyma look like a honeycomb.

Possible complications of PIE include other air leaks, such as pneumomediastinum, pneumothorax, pneumopericardium, pneumoperitoneum, subcutaneous emphysema, and pulmonary venous embolism, intraventricular hemorrhage, and possible epithelialization of the interstitial air pockets.

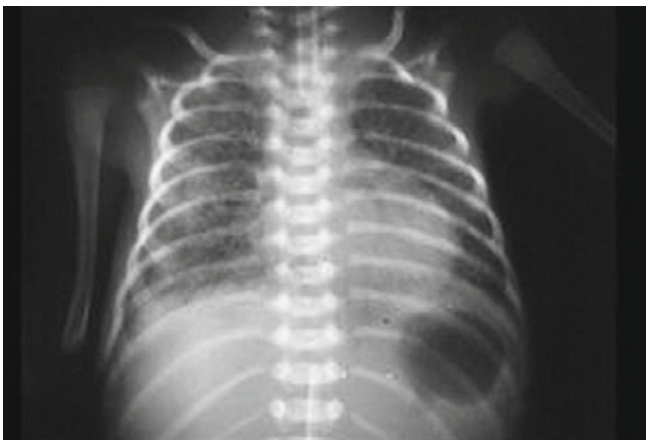

Fig. 64.2 Diffuse pulmonary interstitial emphysema

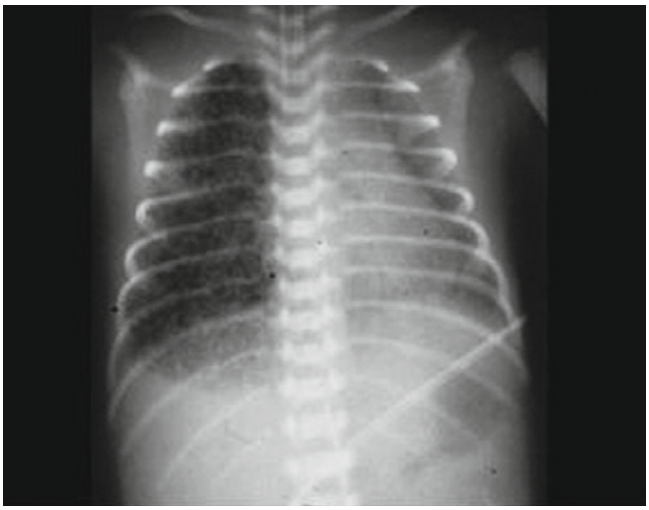

Fig. 64.3 Pulmonary interstitial emphysema, especially marked in the right lung

PIE may be confused with severe RDS, early BPD, cystic adenomatoid malformation, lymphangiectasia, bronchogenic cysts, congenital lobar emphysema, and pulmonary infection. PIE may take several weeks to resolve. The condition can therefore increase the length of time of mechanical ventilation and the incidence of BPD [2]. Some infants may develop chronic lobar emphysema and may require surgical lobectomies.

64.3.3 Therapy and Treatments

In mechanically ventilated infants, initial treatment of PIE should be aimed at obtaining maximum patient-ventilator synchrony, securing the endotracheal tube in the appropriate position, and reducing peak inspiratory pressure (PIP) and positive end expiratory pressure (PEEP) as much as possible, consistent with blood gas values. A short inspiratory time (Ti) and a triangular pressure wave morphology should be set to avoid inflating the parenchymal cysts that have a long time constant [9]. HFOV has been found to be effective in the treatment of PIE [1].

Treatment of the localized form includes positioning the infant with the affected side down or selectively intubating the main bronchus of the unaffected side [10, 11]. Severely ill premature neonates may not tolerate the latter treatment because it is difficult for them to compensate for distress with one functioning lung. Physiotherapy may be useful as the presence of mucus may contribute to the formation of cysts and bubbles through a valve mechanism [12]. A short course of dexamethasone has been shown to be as an effective treatment in infants with PIE, possibly by reducing airway edema and inflammation and airway obstruction [13].

64.4 Pneumomediastinum

Pneumomediastinum is defined as a collection of gas in the mediastinal space. Free air may not be confined solely to the mediastinum but may penetrate through tissue planes, causing pneumopericardium, pneumothorax, subcutaneous emphysema, or pneumoperitoneum. Pneumomediastinum occurs in approximately 2.5 per 1000 live births.

Risk factors for pneumomediastinum are:

- Gas trapping associated either with several lung diseases, including RDS, pneumonia, MAS or with mechanical ventilation
- Birth asphyxia requiring resuscitation
- Chest trauma
- Mechanical obstruction as seen with a foreign body or a tumor.

64.4.1 Etiology and Pathogenesis

Pneumomediastinum is in most cases a complication of a pre-existing pulmonary disease and may be preceded by PIE. The air that leaks out of the alveoli makes its way along the bronchovasal sheaths toward the hilum and into the mediastinum. Pneumomediastinum may appear spontaneously at birth or may occur later, secondary to the formation of a valve-like mechanism and consequent rupture of the alveoli. The air moving from the mediastinum towards the neck causes the dissection of the cervical aponeurosis and the supraclavicular tissue planes, forming subcutaneous emphysema. The air in the mediastinum may also spread to the sub-pleural space and simulate a basal pneumothorax. Air may also leak into the peritoneal cavity through areas of lower resistance, such as the sternocostal trigone, and cause subdiaphragmatic air collections (pneumoperitoneum).

64.4.2 Clinical Aspects and Differential Diagnosis

Pneumomediastinum rarely leads to clinically significant complications. However, compression of mediastinal structures may occur when there is extensive subcutaneous and mediastinal gas. The infant with pneumomediastinum is usually asymptomatic or has mild respiratory distress. In the absence of other pulmonary disorders it tends to regress spontaneously.

A large accumulation of trapped air may cause severe respiratory distress and reduced cardiac output. The first sign may be subcutaneous emphysema in the neck, face, or chest. The infant with a large pneumomediastinum may exhibit bulging in the midthoracic area, distended neck veins, and low blood pressure.

The pneumomediastinum is characterized radiologically by the presence of cardiac margins that are clearly delimited by a thin black streak. The edges of the right atrium and the left ventricle are generally well distinguished from the pulmonary parenchyma. In cases of pneumomediastinum with small quantities of air, the only sign is a radiolucent band (hyperlucency) in the retrosternal area on the lateral view (Fig. 64.4) [6, 14]. The main diagnostic element of pneumomediastinum is prominence of lobes of the thymus that may be more or less marked depending on the amount of air in the mediastinum (the image resembles the wings of a sea-gull or a spinnaker sail, Fig. 64.5) [15, 16]. When there is a pneumomediastinum, the lobes of the thymus are surrounded by air and in the lateral view this peculiar radiographic aspect is sufficient to diagnose an antero-medial pneumothorax. The air in the mediastinum may push both thymus lobes toward the pulmonary apices, thus simulating upper lobar collapse or pneumonia. The presence of other signs suggesting pneumomediastinum allows this condition to be differentiated from pulmonary consolidation.

Air may collect in some mediastinum recesses, such like the triangular ligament. In such cases, the chest X-ray shows a hyperlucent paravertebral area extending from the diaphragm up to the pulmonary hilum (Fig. 64.6) [17].

Pneumomediastinum should be differentiated from bronchogenic cysts [18], esophageal perforation and pneumothorax.

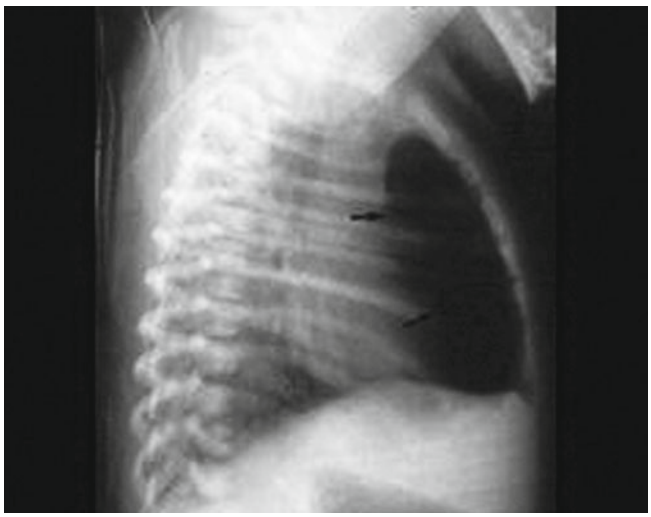

Fig. 64.4 Pneumomediastinum, lateral view

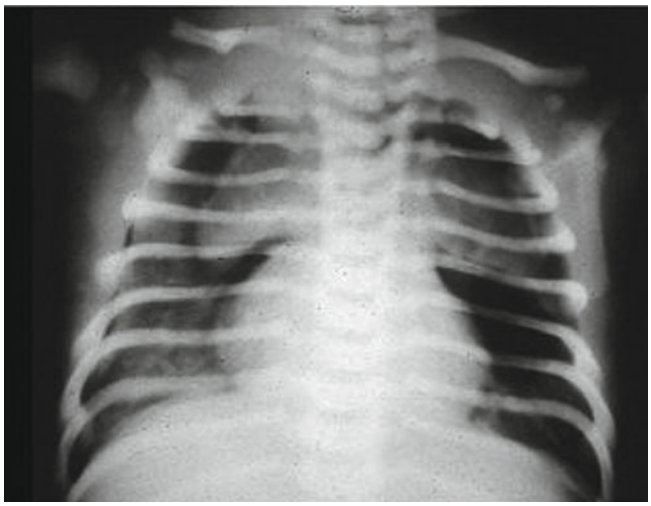

Fig. 64.5 Pneumomediastinum with the raised thymus lobes (spinnaker sail)

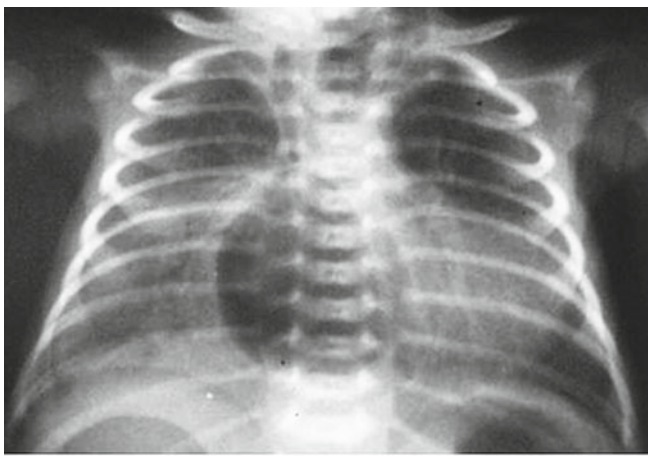

Fig. 64.6 Pneumomediastinum with the air collected in the triangular ligament

64.4.3 Therapy and Treatments

A conservative approach is usually adopted. Treatment with 100% oxygen may accelerate air reabsorption. High inspired O_2 concentrations facilitate nitrogen washout from the bloodstream (PN_2 drops from 573 mmHg at room air to 0 mmHg under 100% oxygen) creating a concentration gradient between pleural gas and pleural venous circulation. This gradient favors the reabsorption of nitrogen within the pleural pockets. This technique should not be applied to very low gestation infants because of the risk of oxygen toxicity.

64.5 Pneumothorax

Pneumothorax is defined as an accumulation of air in the pleural space. Pneumothoraces have been termed small, moderate or large if they occupy 15% or less, 15%–60%, or more than 60% of the pleural space.

Spontaneous pneumothoraces develop in up to 1% of normal term infants around the time of birth (only about 10% of these are symptomatic) [19]. A likely cause is because of high transpulmonary pressure during the first breaths. In the presence of lung disease, especially if mechanical ventilation is required, the incidence of pneumothorax increases dramatically (~10%). Fifteen–20% of pneumothoraces are bilateral. Two thirds of unilateral pneumothoraces affect the right side. There is no correlation between the incidence of pneumothorax and gestational age [5]. Reports of familial spontaneous pneumothoraces in neonates are rare [20].

Risk factors for pneumothorax are:

- Lung diseases, such as wet lung (following cesarean section) [21], MAS, congenital bullae, and pulmonary hypoplasia, which result in uneven lung compliance and alveolar overdistension
- Pulmonary interstitial emphysema (PIE)
- Ventilatory support. Predisposing factors during mechanical ventilation are:
  - lack of synchronization between the mechanical cycle of the ventilator and the spontaneous respiratory activity of the infant. Asynchrony is usually secondary to trigger delay, long inspiratory times (Ti) and an inspiratory/expiratory ratio (I/E) ≥ 1:1 [22]
  - high ventilation pressures
  - high PEEP [23]
  - high ventilation tidal volumes (more important than increase in pressure) [24]
  - intubation of the right main bronchus
- Nasal CPAP (the risk is lower than during mechanical ventilation)
- Low temperature of inhaled gases (<36.5°C). In infants weighing ≤1500 g at birth the incidence of pneumothorax increases if the temperature of inhaled gases is below 36.5°C. It is likely that lower temperatures cause a reduced content of water in the ventilation gas, which alters the muco-ciliary clearance [25] precipitating airway obstruction
- Direct injury (suction catheter and central venous catheter positioning).

64.5.1 Etiology and Pathogenesis

In an overdistended lung, air passes from a ruptured alveolus up the bronchovascular sheath into the mediastinum and from there into the pleural cavity causing pneumothorax. The pathogenesis of pneumothorax is comparable to that of the pneumomediastinum. Rarely pneumothorax is the result of the rupture of sub-pleural blebs.

In the neonate, the susceptibility to pulmonary rupture is further enhanced by a reduced number of alveolar connecting channels (pores of Kohn) that allow air to redistribute between ventilated and nonventilated units.

64.5.1.1 Classification

Pneumothoraces are commonly classified into three types: simple, communicating, and tension. Simple or noncommunicating pneumothorax occurs when there is no direct communication with the atmosphere. There is no mediastinal shift resulting from the accumulated air. A simple pneumothorax may occur spontaneously or as a consequence of barotrauma or volutrauma during positive pressure mechanical ventilation.

Communicating or open pneumothorax occurs when there is an association with an open defect in the chest wall, most commonly occurring as a complication of surgery, e.g., PDA surgery. As intrathoracic pressure is less than atmospheric pressure during spontaneous breathing, air rapidly accumulates in the pleural space. Loss of negative intrathoracic pressure results in varying degrees of lung collapse and further respiratory compromise.

Tension pneumothorax is caused by progressive accumulation of air in the pleural space. This collection of air shifts the mediastinum to the contralateral hemithorax and compresses the contralateral lung and great vessels, compromising both cardiovascular and respiratory function. Whether air enters the pleural space through a defect in the chest wall, a lacerated bronchus, or alveolus, a one-way valve effect is created so that air enters during inspiration but cannot escape during expiration. Accumulation of air continues until the intrathoracic pressure of the affected hemithorax equilibrates with atmospheric pressure. At this point, the accumulation of pressure within the thorax leads to collapse of the ipsilateral lung and displacement of the mediastinum (and associated great vessels) towards the contralateral hemithorax. While the superior vena cava is able to move to some extent, the inferior vena cava is relatively fixed within the diaphragm and will be distorted. As two-thirds of the venous return in children comes from below the diaphragm, compression of the inferior vena cava leads to a dramatic reduction in venous return to the heart and cardiovascular collapse.

64.5.2 Clinical Aspects

Diagnosis of pneumothorax is based on clinical signs, physical examination, arterial blood gases, transillumination, and imaging. Pneumothorax presents with signs of respiratory distress; chest asymmetry, episodes of apnea and bradycardia, tachycardia, and hypotension may also occur. During mechanical

ventilation, pneumothorax is frequently tension accompanied by compression of the mediastinal structures, which may cause impaired venous return and cardiocirculatory collapse [26]. On auscultation of the chest, breath sounds are decreased or absent in the affected side and it may be difficult to identify the heart sounds. A pneumothorax should be suspected when there is sudden worsening of the clinical condition. However, its exact location by auscultation is not always as straightforward, especially in very low weight infants. Arterial blood gases may show a respiratory or mixed acidosis and hypoxemia.

Transillumination is an effective method for demonstrating increased transmission of light on the affected side [27]. However, chest X-ray remains the gold standard for the diagnosis of pneumothorax. Large pneumothoraces are generally easy to identify radiologically. The affected hemithorax is larger than the contra-lateral hemithorax, with larger intercostal spaces and the diaphragmatic dome is lowered. The profile of the collapsed lung is sharply outlined (Fig. 64.7).

Fig. 64.7 Right tension pneumothorax

Fig. 64.8 Right antero-medial pneumothorax with a slight contra-lateral shift of the mediastinum

In tension penumothoraces, the contra-lateral shift of the mediastinum is generally considerable. In the most severe cases, the diaphragm is flattened or even concave [15]. Anterior or anteromedial collections of air inside the pleural cavity may easily be missed. The appearances are those of a lung with decreased markings and slight contra-lateral shift of the mediastinum (Fig. 64.8). In patients in whom an antero-medial pneumothorax is suspected, a lateral supine chest X-ray is useful. The thymus gland on the side of the pneumothorax may appear closely adherent to the mediastinum. A large thymus, may give a false impression of a space-occupying mass in the upper mediastinum. Ultrasonography has been shown to be accurate and efficient for the early detection of clinically important pneumothoraces [28].

64.5.3 Differential Diagnosis

- Lobar emphysema.
- Cystic adenomatoid malformation of the lung.
- Congenital diaphragmatic hernia.
- Bronchogenic cyst.
- Esophageal-pleural fistula (Boerhaave syndrome).

The most common complications of pneumothorax in the neonate are: respiratory or cardiac arrest, intraventricular hemorrhage, bronchopleural fistula, hemopneumothorax, and infection.

64.5.4 Therapy and Treatments

64.5.4.1 Asymptomatic Pneumothorax

The asymptomatic pneumothorax does not require any specific treatment other than close observation and may be managed conservatively. In term infants, reabsorption of the free air may be increased by increasing the inspired oxygen concentration (the infant is usually placed in a 100% oxygen hood for 12–24 hours). This treatment should not be used for preterm infants or infants with tension pneumothorax. When mechanical ventilation is used, the pneumothorax should be drained, even if apparently asymptomatic. There may be clinical doubt about whether to drain very small pneumothoraces when the clinical condition of the ventilated patients remains stable, but the risk of an acute tension pneumothorax suggests that intervention is to be preferred.

64.5.4.2 Needle Aspiration

Needle aspiration can be used to treat a symptomatic pneumothorax. It is frequently curative in infants who are not mechanically ventilated and may be a temporizing treatment in infants who are mechanically ventilated.

64.5.4.3 Thoracotomy

Chest tube drainage (thoracotomy) is usually needed for continuous drainage of pneumothoraces that develop in infants receiving positive pressure ventilation because the air leak may persist. In these cases, continuous aspiration with negative pressures of 5–10 cmH_2O may be useful.

Technique of pleural drainage:

a. Select a chest tube of appropriate size. For small infants, 8 Fr chest tubes are adequate. For larger infants, 10 Fr chest tubes are better
b. Locate the fifth intercostal space in the anterior axillary line on the affected side [29]
c. Prepare the site with antibacterial solution
d. Administer analgesic to the infant. Be ready for resuscitation
e. Inject the area with a small amount of 1% lidocaine (1–2 mg/kg)
f. Make a small incision (approximately the size of the tube) along the intercostal space directly over the sixth rib
g. Remove the trochar and insert the tube by blunt dissection
h. Advance the chest tube a few centimetres and check the position radiographically
i. Suture the tube in place. The drain should be left in place for 24–48 hours from the moment the pneumothorax has stopped draining, i.e., when the intermittent air leakage stops. In the case of residual air, attach the tube to a drainage system under low continuous suction (–10 to –20 cmH_20).

Complications of pleural drainage include:

- Infection
- Hemorrhage (laceration of intercostal vessels)
- Lung puncture
- Bronchopleural fistula, which is evidenced by persisting pneumothorax
- Chylothorax (secondary to lesions of the thoracic duct)
- Paralysis of the diaphragm (due to lesions of the phrenic nerve).

64.5.4.4 Intubation

Selective intubation of the contralateral main bronchus should be reserved for cases where there is a bronchopleural fistula.

64.5.5 Prevention

Pneumothorax may be prevented by using ventilation techniques that allow for synchronization between spontaneous and mechanical breaths so as to reduce transpulmonary pressure fluctuations. HFOV may reduce the incidence of pneumothorax in infants with severe pulmonary disease.

64.6 Pneumopericardium

Pneumopericardium is a collection of air in the pericardial space. It frequently occurs in association with pneumomediastinum. It is likely that gas enters the pericardium through a defect in the pericardial sac, probably at the pericardial reflection near the ostia of the pulmonary veins. The incidence has been estimated around 1.3% of term and preterm infants [30]. Pneumopericardium rarely occurs spontaneously [31].

Risk factors for pneumopericardium are:

- Prematurity
- Birth asphyxia requiring resuscitation
- Mechanical ventilation (PIP >32 cmH_2O, MAP >17 cmH_2O)
- Lung disease
- Anatomic predisposition (maldevelopment of the left pleuropericardial membrane).

64.6.1 Etiology and Pathogenesis

Pneumopericardium is frequently associated with a pneumomediastinum and/or pneumothorax since the pathogenic mechanism is the same, i.e., diffusion of air from the pulmonary interstices through the bronchovascular sheaths to the planes of pleural reflection at the level of the large vessels, where air under tension flows directly into the pericardium sac. Mediastinal air collection may spread around the heart because of congenital defects of the pericardium.

64.6.2 Clinical Aspects

Because of the speed at which it occurs, pneumopericardium is usually a dramatic event, causing cardiac tamponade. Symptoms appear when the pressure in the pericardium exceeds the ventricular filling pressure and cardiac output is reduced [31, 32]. Sometimes the presenting signs of pneumopericardium may be confused with those of a tension pneumothorax. The heart sounds are muffled, but a friction rub is occasionally audible. There are low voltages on electrocardiography. The radiological appearances of pneumopericardium are of a hypertransparent image, which outlines the heart entirely, except for where the great vessels emerge (Fig. 64.9).

64.6.3 Therapy and Treatments and Prognosis

Treatment is conservative if asymptomatic. Oxygen administration will help the reabsorption of air in cases with mild respiratory distress [33]. If cardiac tamponade occurs,

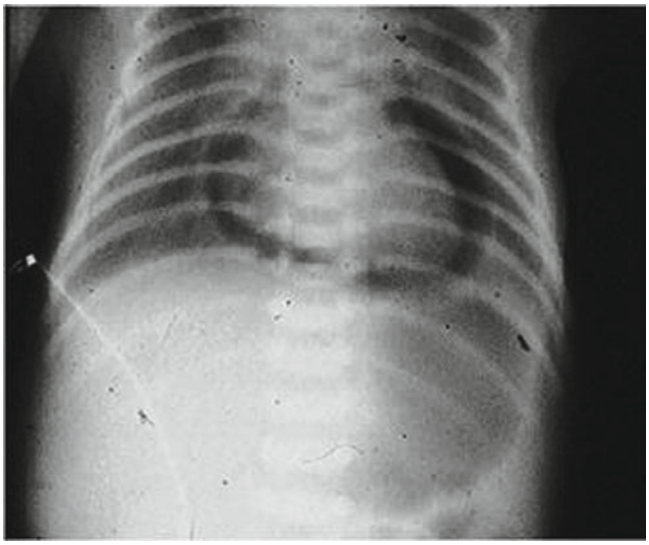

Fig. 64.9 Pneumopericardium: a hypertransparent image that entirely delimits the heart except for the emergence of the great vessels

drainage with a cannula needle will be performed via the subxiphoid route. Relapses are frequent and require the positioning of an in-dwelling drainage tube [34]. Mortality is high, between 70 and 90%.

64.7 Pneumoperitoneum

Pneumoperitoneum is defined as the presence of air within the peritoneal cavity.

64.7.1 Etiology and Pathogenesis

Pneumoperitoneum usually results from perforation of the gut, although in some instances it can be caused by air under pressure dissecting from the chest (pneumomediastinum, bronchopleural fistula) through the diaphragmatic apertures into the peritoneal space [35, 36].

64.7.2 Clinical Aspects, Therapy and Treatments

Pneumoperitoneum may be an incidental finding or may present with abdominal distension or in most severe cases with cardiovascular collapse.

On the posteroanterior radiograph, pneumoperitoneum may be difficult to see if free intaperitoneal gas accumulates between intestinal loops. If gas is present on both sides of the bowel it may outline the bowel wall, rendering it visible as a thin, linear stripe (double wall sign or Rigler's sign). If there is doubt about the diagnosis of pneumoperitoneum, consider a lateral shoot-through abdominal X-ray (with the baby lying on his back and the X-ray film at right angles to the mattress), or a lateral decubitus abdominal X-ray, both of which will demonstrate the liver clearly separate from the abdominal wall. Free abdominal air requires a surgical opinion. Either peritoneal drainage or laparotomy may be required.

64.8 Pulmonary Gas Embolism

The presence of intravascular gas is a rare complication of positive pressure ventilation [37]. This condition is usually fatal and results from direct communication between airway lumen, interstitium and small vascular channels, as demonstrated by barium studies at autopsy [38]. It can be a consequence of air leaks syndromes or lung trauma.

64.8.1 Clinical Aspects, Therapy and Treatments

Affected infants are usually premature and have severe respiratory failure necessitating very high ventilatory pressures. Pulmonary gas embolism causes a catastrophic deterioration of the patient's condition with cardiocirculatory collapse.

The radiographs of thorax and abdomen show pulmonary interstitial emphysema and pulmonary venous air embolism (i.e., air within the heart and many vessels).

Treatment is directed to sustain cardiopulmonary function.

Bronchopulmonary Dysplasia/Chronic Lung Disease

Vineet Bhandari

65.1 Introduction

Bronchopulmonary dysplasia (BPD) is the most common cause of chronic lung disease in infancy [1]. The consensus definition of BPD has been summarized in Table 65.1. The "classic" BPD described by Northway in 1967 has now been replaced by less severe forms of "new" BPD, which are infrequently found in patients >30 weeks of gestation and with birth weights (BW) >1200 grams. Presently, infants who weigh <1250 grams account for 97% of all BPD patients [2]. The incidence of BPD, defined as oxygen need at 36 weeks post-menstrual age (PMA), was 52% (BW 501–750 g), 34% (BW 751–1000 g), 15% (BW 1001–1200g), and 7% (BW 1201–1500 g). Using a physiologic definition based on an oxygen reduction challenge at 36 weeks PMA led to a 10% decrease in the incidence of BPD.

65.2 Pathology

The pathology of "old" BPD (pre-surfactant era) was remarkable for the presence of severe airway injury, inflammation and parenchymal fibrosis. There was marked heterogeneity in lung pathology with severe alveolar septal fibrosis in some areas and presence of normally inflated and/or hyperinflated lung in the adjacent sub-lobule or lobe. Post-surfactant use, the "new" BPD lung revealed a more uniform inflation and less marked fibrosis and absence of small and large airway epithelial metaplasia, smooth muscle hypertrophy and fibrosis. Arrest of acinar development resulting in a decrease in alveolar number and arterial counts with a normal alveolar/arterial ratio was reported in the lungs of BPD patients regardless of surfactant treatment. Abnormalities of distal microvasculature have been linked to arrest/impairment of vascular development. There is controversy about the pulmonary microvasculature being decreased or increased; however, it is undoubtedly dysregulated in BPD [1, 3].

The observed vascular changes include marked angiogenesis proportionate to the growth of the air-exchanging lung parenchyma, abnormal distribution of alveolar capillaries, prominent corner vessels with variable capillary density in adjacent alveoli, or vessels that are more distant from the air surface.

65.3 Etiology and Pathogenesis

Genetic predisposition, baro- and volutrauma from mechanical ventilation in surfactant-deficient premature lungs, pulmonary edema, pre- and postnatal infections, and reactive oxygen species from prolonged oxygen use and high oxygen concentrations, have been associated with the development of BPD (Fig. 65.1).

65.3.1 Genetics

Genetic factors contribute 53–82% susceptibility [4, 5], making BPD a disease occurring secondary to "gene-environmental" factors. In the first study, it was observed that in premature twins (63 monozygotic and 189 dizygotic twin pairs), <32 weeks gestational age (GA), BPD occurred at a rate of 29% in one or more of a twin pair. After controlling for other covariates, 53% ($p = 0.004$) of BPD was explained by genetic factors alone [4]. These results were independently confirmed [5]. Multiple genetic variants have been assessed in the evaluation of carrier states that predispose to the development of BPD [6, 7].

65.3.2 Prenatal Infections

Chorioamnionitis may be a risk factor for the development of BPD. Though the pathogenesis is incompletely understood, studies have evaluated cytokines in the amniotic fluid of infants born prematurely. Increased levels of cytokines, predominantly interleukins (IL), IL-1β, IL-6, IL-8, have been noted in many who go on to develop BPD.

Though there is difficulty in correlating clinical and histologic chorioamnionitis, infants born at <28 weeks GA who have evidence of histologic chorioamnionitis have worse pulmonary outcomes than those born at later GA. These infants also had elevated levels of inflammatory cytokines in their blood. Investigators, exploring the relationship between chorioamnionitis and BPD, have indicated that in utero exposure to low level inflammation may induce a pulmonary maturation (as evidenced by decreased rates of respiratory distress syndrome [RDS]); however, there was no decrease in BPD. Other investigators have noted antenatal infection, coupled with postnatal sepsis, and mechanical ventilation increased the rates of BPD in preterm neonates [8].

65.3.3 Lung Immaturity

Intrinsic to the development of BPD is prematurity. Normal lung development occurs in phases that correspond to structural differences. The first phase, the embryonic phase (3–7 weeks PMA) is followed by the pseudoglandular phase (5–17 weeks). Many premature neonates are born during the late canalicular phase (16–26 weeks) of lung development. The saccular phase occurs at 24–38 weeks and accounts for the majority of infants who later develop BPD. The last phase, the alveolar phase, starts from ~32 weeks PMA till about 2 years after birth, with the majority of the alveolarization process occurring 5–6 months after birth. The process of alveolar development can extend longer, possibly up to 8 years. Alveolarization incorporates the processes of "elastogenesis and angiogenesis" with multiple cell-to-cell interactions between fibroblasts, epithelial (type I and II pneumocytes), interstitial, and endothelial cells. Premature birth, with its subsequent medical disorders and their management, alters the postnatal development of lungs, via changes in the molecular signal transduction pathways. Factors that disrupt normal angiogenesis, control of inflammation (i.e., imbalance between "pro"- and "anti-inflammatory" cytokines), and appropriate fibrin deposition or removal are at play in the pathogenesis of BPD.

65.3.4 Hyperoxia

Excessive oxygen induces oxidative stress with production of reactive oxygen species with increased production of inflammatory cytokines from epithelial, endothelial and inflammatory cells. Initial hyperoxic cellular damage induces alveolar or interstitial macrophages to express early cytokines such as IL-1 and tumor necrosis factor (TNF). Chemoattractants are

then induced from multiple cell types in the lung, in turn recruiting other inflammatory cells, such as neutrophils [9]. An immature lung that is exposed to ante- and postnatal environmental factors contributes to the release of a variety of pro- and anti-inflammatory cytokines. An imbalance in these mediators leads to activation of the cellular death pathways in the lung. Thus, direct (via reactive oxygen species) or indirect (via cytokines) damage to the respiratory endothelium and epithelium occurs by inducing necrotic and/or apoptotic cell death [9]. This is followed by healing (resolution of injury) or repair of the lung [10, 11]. The latter process is characterized by impaired alveolarization and dysregulated angiogenesis leading to fewer, larger simplified alveoli and a dysmorphic pulmonary vasculature (Fig. 65.1), the pathologic hallmarks of BPD [1].

65.3.5 Barotrauma and Volutrauma

Mechanical ventilation has long been associated with the development of BPD. Intubated neonates who ultimately develop BPD often have significantly increased levels of "pro-inflammatory" cytokines, possibly from microbial colonization and increased distention of alveolar tissue with subsequent baro- and volutrauma leading to increased inflammation [12]. The association of a patent ductus arteriosus (PDA) and BPD is likely due to the increase in pulmonary circulation and subsequent pulmonary edema. This usually instigates increased ventilatory support and oxygen administration, both being important contributory factors to the development of BPD.

65.3.6 Postnatal Infections

Systemic infections predispose to the development of BPD [8]. The inflammatory response occurring secondary to infection increases release of inflammatory and vasoactive cytokines on an already damaged pulmonary organ, increasing the need for mechanical ventilation. Airway colonization, with increased neutrophilic presence and pro-inflammatory cytokines may also predispose to the development of BPD [12].

65.3.7 Role of Cytokines

The common theme of inflammation noted above is underscored by the role played by cytokines. Cytokines are chemicals produced by virtually all cell types including fibroblasts, white blood cells, endothelial and epithelial cells. They mediate immune, inflammatory and hematopoietic functions in response to various stimuli. In preterm infants, inciting events cause an inflammatory response, either systemically or localized to the pulmonary organ. We have only a partial understanding of how inflammation in the setting of prematurity causes BPD. Soon after birth, upon initiation of oxygen exposure and/or mechanical ventilation, there is an influx of neutrophils and macrophages into pulmonary interstitium. Neutrophils adhere to the endothelium, with interaction between these two cell types occurring via adhesion molecules (eg., selectins and integrins). This allows for extravasation of neutrophils and macrophages towards the specific areas of injury. These inflammatory cells produce cytokines and other signaling molecules for augmentation of the inflammatory response in an attempt to mitigate the damage of the inciting insult. There is subsequent disruption of the alveolar capillary unit and pulmonary tissue integrity. The imperfect attempt at repair, differentiation and growth of these tissues act in concert with the inflammation to produce the biochemical profile, signs and symptoms we see in patients with, and those at risk, for BPD [12, 13].

Many studies have been conducted to evaluate the presence of cytokines in the amniotic fluid, cord blood, plasma and tracheal secretions of preterm neonates at risk or who have BPD in an effort to determine a biochemical profile of the condition. Many of the pulmonary biomarkers relate to the possible disruption in the mechanisms described above. A multitude of biomarkers detected in tracheal aspirates (TA), blood and urine have been proposed for early identification of infants who subsequently develop BPD.

65.4 Biomarkers in BPD

Though there are many clinical associations indicative of an increased risk for the eventual development of BPD, currently no one factor or marker exists that uniformly and accurately predicts its development. The inciting events that predispose to development of BPD likely occur fairly soon after birth, and we are limited by a lack of ability to distinguish very early on, those neonates who will likely go on to develop this chronic disorder. A majority of the biomarkers discussed below are likely abnormal due to damage that has already occurred. Some biomarkers are capable of being perceived as either pro- or anti-inflammatory depending on their concentration in relation to their physiologic role. Given the proximity to the lung, the primary focus of most investigators has been to access pulmonary secretions to evaluate putative biomarkers for BPD.

The initial TA studies focused on the cytology of the secretions. The exfoliation of dysplastic, metaplastic bronchial cells was found to be 95% specific and 71% sensitive for the subsequent development of BPD. Categories of pulmonary biomarkers that are deranged in BPD include IL and other chemoattractant molecules, markers indicative of abnormal angiogenesis, those signifying abnormal fibrin deposition or

Table 65.2 Use of tracheal aspirate analytes as biomarkers for BPD [14]

Analyte	Total no. of infants*	Association with BPD
Neutrophil counts	30; 20	Increased
Fibronectin	32	Increased
Elastase	20; 65	Increased
Lactoferrin	36	Decreased

degradation, markers of oxidative damage, and peptide growth factors. While a study has shown that TA specimens may be suitable substitutes for bronchoalveolar lavage samples in preterm infants, there has been some controversy about whether measurements of the markers in the TA are valid without normalization. While some have advocated use of total protein, secretory component of IgA, and serum urea, others have espoused that no normalization is required.

Table 65.2 summarizes the results of various TA analytes, focusing more on recent reports that would be more reflective of the "new" BPD, usually obtained in the first week of life, from babies at risk of developing BPD. More details are available from a recent review [14].

65.4.1 Interleukins (IL)

IL are chemicals made by one cell type that act on other inflammatory cells. They may induce growth, differentiation and proliferation of other leukocytes. They may also act as chemoattractants for recruitment of other cell types (immune and non-immune cells) to a site of injury, and may exert pro- or anti-inflammatory effects.

IL-1β, 6, 8, 16 IL-1β and 6 are particularly active in the acute phase response to injury, while IL-8 is a potent chemotactic agent for recruitment of neutrophils. These cytokines are typically viewed as pro-inflammatory, and have been shown to be elevated in the TA very early in the respiratory course of the preterm population that ultimately develops BPD. IL-16 acts as a chemoattractant for CD4+ T lymphocytes, monocytes and eosinophils. Levels of IL-16 correlated significantly with neutrophil counts in the TA and subsequent development of BPD.

IL-10, 4, 13 These cytokines usually act in an anti-inflammatory capacity, and are responsible for the production, differentiation and proliferation of B-cells and macrophages. It has been suggested that decreased levels of anti-inflammatory cytokines would predispose to the development of BPD given the role that inflammation likely has in this disorder. However, there are discrepant findings regarding the levels of anti-inflammatory cytokines in the TA of preterm infants at risk for BPD.

IL-10 IL-10 was found to be decreased in TA samples taken in the first seven days of life in those infants who developed BPD. Other investigators found detectable levels of IL-10 in TA of preterm ventilated infants, but could not correlate the levels with development of BPD. When lipopolysaccharide (LPS), a potent inducer of inflammation was used to induce production of IL-10 from lung inflammatory cells (obtained from premature infants) there was a decreased ability to induce IL-10 in those infants who went on to develop BPD. A majority of preterm infants (97%) unable to constitutively express the IL-10 gene developed BPD.

IL-4, 13 IL-4 is produced by T lymphocytes and alveolar macrophages. Levels of these potentially anti-inflammatory cytokines (IL-4, 13) could not be significantly correlated with the development of BPD.

65.4.2 Angiopoietin-2

Angiopoietin-2 is an angiogenic growth factor that destabilizes blood vessels, enhances vascular leak and induces epithelial cell necrosis in hyperoxic conditions. Angiopoietin-2 concentration was observed to be increased in infants with BPD and/or death in the first week of life, when compared to those infants with RDS who recovered [15, 16]. Furthermore, the levels decreased after exposure to dexamethasone [16].

65.4.3 Cathepsin K

Cathepsin K is a cysteine protease, which degrades existing extracelluar matrix and regulates the release of matrix proteins from fibroblasts. In one study, infants who developed BPD had declining cathepsin K levels by day 13, when compared to neonates who did not develop BPD.

65.4.4 Chemokines

There are 4 families of chemokines (chemotactic cytokines, CC); they play a role in regulating inflammation by recruiting inflammatory cells to the area of injury. The CC family consists of monocyte chemoattractant proteins (MCP) 1, 1α, 1β, 2 and 3. These chemokines were measured in a study to assess the role of CCs in acute lung injury in the preterm, ventilated infant over the first 21 days of life. MCP-1, 1α, 1β, 2 and 3 were all increased in those infants developing BPD. However, only MCP-1, 2 and 3 were statistically significant, with MCP-3 being the most significant [17].

65.4.5 Clara Cell Secretory Protein (CCSP)

CCSP is produced by Clara cells, which are non-ciliated epithelial cells lining the respiratory and terminal bronchioles. This protein may act to modulate acute pulmonary inflammatory processes. In preterm infants with TA samples taken up to 2 weeks after birth, CCSP increased with maturity, and in those neonates who had evidence of infection. In another study, the results indicated that lower levels of CCSP predisposed to development of BPD.

65.4.6 3-Chlorotyrosine

3-Chlorotyrosine is a biomarker of the neutrophil oxidant, hypochlorous acid, which is utilized in the inflammatory process. The only source is from neutrophils and monocytes which release myeloperoxidase to catalyze oxidation of chloride by hydrogen peroxide to give hypochlorous acid. In support of data that neutrophilic infiltration and subsequent oxidative injury is closely related to the development of BPD, investigators assessed levels of 3-chlorotyrosine, and found that an increase in their concentration correlated with development of BPD.

65.4.7 Fibronectin

An extracellular matrix component, fibronectin is important in maintaining the integrity of pulmonary tissues and microvasculature. Researchers have found a higher fibronectin level in those infants who developed BPD.

65.4.8 Lactoferrin and Lysozyme

Lactoferrin is said to be a marker of inflammation by regulating granulocyte and macrophage proliferation, and may also have some antioxidant properties. Lysozyme is a bactericidal protein that degrades the walls of susceptible bacteria. Both are hypothesized to be released from the serous cells of the submucous glands of the respiratory tract. Both lactoferrin and lysozyme when measured in the first 3 days of life were decreased in patients with BPD as compared to those without BPD, with the decrease in lysozyme being significant.

65.4.9 Macrophage Migration Inhibitory Factor (MIF)

MIF is an upstream regulator of the innate immune response. It has been implicated in the pathogenesis of a number of inflammatory disorders including sepsis, acute RDS (in adults), asthma, and inflammatory/autoimmune diseases. MIF was quantified in TA obtained during the first 2 days of life in a cohort of neonates with RDS. There was a reduction in the concentration of MIF in the lungs of those infants who went on to develop BPD [18].

65.4.10 Malondialdehyde

Malondialdehyde is marker of oxidative damage, possibly from oxygen radicals produced under hyperoxic conditions, or the respiratory burst from inflammatory cells present in the pulmonary organ. In one study of ventilated infants, the pulmonary concentrations were noted to be elevated, but weakly correlated with the development of BPD.

65.4.11 Matrix Metalloproteinases (MMPs)

MMPs are a family of endoproteinases that aid in the remodeling and degradation of extracellular matrix and basement membranes. They are secreted in inactive form, activated in extracellular spaces and cell surfaces by oxidants and serine proteinases. They also have the capacity to activate each other. The development of BPD is partially characterized by disordered pulmonary repair after inflammation. Patients who went on to develop BPD had increased levels of tracheal MMP-8, with decreased levels of its inhibitor, tissue inhibitor of metalloproteinases (TIMP) [19].

65.4.12 Nuclear Factor-kappa B (NF- κB)

NF-κB is a transcription factor activated by cellular stress, subsequently promoting expression of multiple genes including pro-inflammatory cytokines. TA levels of NF-κB were significantly elevated in the infants who developed BPD or died. However, this difference did not persist when GA was taken into account.

65.4.13 Parathyroid Hormone-Related Protein (PTHrP)

PTHrP is secreted by type II pneumocytes and plays a role in normal alveolar growth and development. Its signaling was shown to be down-regulated in alveolar over-distention and under hypoxic conditions. Infants developing BPD had significantly lower levels of PTHrP in the first week of life, when compared to those who did not [20].

65.4.14 Plasminogen Activator Inhibitor - (PAI-1)

PAI-1 is a regulator of fibrinolysis. It was hypothesized that inhibition of fibrinolysis may play a role in the development of BPD. Infants who developed BPD had significantly higher levels of PAI-1 than non-BPD patients.

65.4.15 Pulmonary Trypsin-2

Trypsin-2 is a serine protease expressed in a variety of human epithelial cell types, including in the lung. It can directly attack extracellular protein matrix, basement membrane proteins, and can activate MMPs and initiate protease cascades, causing tissue destruction. It was hypothesized that when trypsin is ineffectively inhibited by its natural inhibitor, tumor-associated trypsin inhibitor (TATI), it may play a role in the development of BPD. Results in TA samples from preterm infants indicated that there was significantly higher trypsin-2 to TATI ratio during first 2 weeks in those infants developing BPD.

65.4.16 Soluble Intercellular Adhesion Molecule-1 (ICAM-1)

ICAM-1 plays a role in early inflammation and is the ligand for lymphocyte function-associated antigen 1 (LFA-1). ICAM-1 is expressed by lymphocytes, eosinophils, mast, endothelial and bronchial epithelial cells. Infants who developed BPD had significantly higher levels of soluble ICAM-1 in TA at 6-14 days of age.

65.4.17 Transforming Growth Factor–β1 (TGF-β1)

TGF–ß1 is produced mostly by alveolar macrophages, and acts on fibroblasts to increase the transcription of fibronectin and procollagen. It also inhibits synthesis of proteases and increases the synthesis of anti-proteases, thus resulting in a net increase in fibrosis. Infants who developed BPD had significantly increased levels of TGF-β1 in TA.

65.4.18 Tumor Necrosis Factor–α (TNF-α)

TNF-α is a pro-inflammatory cytokine that induces cell death, and enhances expression of other cytokines. In a study of premature infants, TNF-α was noted to be increased early in the patients who developed BPD.

65.4.19 Peptide Growth Factors

Peptide growth factors are important for normal lung development, maturation and repair. This group includes endothelin-1 (ET-1), fibroblast growth factor-2 (FGF-2), keratinocyte growth factor (KGF), hepatocyte growth factor (HGF), and vascular endothelial growth factor (VEGF).

ET-1 ET-1 is a potent endothelium-derived vaso- and broncho-constricting factor, produced in virtually all tissues, though its largest concentration is in the lung. Under the influence of cytokines (IL-1β, IL-6, IL-8), production of ET can be induced in macrophages and monocytes. ET-1 has also been hypothesized to increase the production of oxygen radicals from alveolar macrophages. In preterm infants with RDS, TA concentrations of ET-1 in the first week of life were significantly elevated in infants developing BPD [21]. However, this was not confirmed by others [22].

FGF-2 FGF plays a role in angiogenesis, by stimulating endothelial cell proliferation, degrading extracellular matrix and appears to interact with VEGF. There was a significant elevation in the levels of FGF-2 in the TA in the BPD/death population on day 1 of life [22].

KGF A member of the FGF family, KGF regulates proliferation of alveolar epithelial cells, and enhances synthesis of surfactant and accelerates wound closure in airway epithelium. It was noted that in premature infants who developed BPD, KGF was lower than in those who did not develop it.

Pulmonary HGF HGF in fetal rat lungs stimulates branching of both alveolar and bronchial epithelia, and contributes to growth, maturation and maintenance of tissue homeostasis.

It has been suggested that HGF also mediates repair of type II pneumocytes after acute lung injury. Infants who developed BPD had significantly lower levels of HGF in the first 2 weeks of life, when compared to non-BPD counterparts.

VEGF VEGF promotes endothelial cell growth and remodeling. In the pulmonary system it appears to be essential for the appropriate development of alveolar tissue; in rats its antagonism has been shown to result in dramatically impaired alveolarization [23]. In heavily vascularized tissues, such as the lung, VEGF exists in high concentrations. During hyperoxic episodes when damage to the microvasculature occurs, VEGF plays a role in the remodeling process, and its levels are increased, sometimes disproportionately. In preterm infants with RDS, infants developing BPD had significantly lower levels of TA VEGF closer to one week of life [14]. Conversely, no difference in TA VEGF levels were noted between BPD and no BPD infants in another study [22]. In a recent study, a phasic pattern of VEGF concentrations was noted in infants who go on to develop BPD. These infants had an initial spike over the first 12 hours of postnatal life, followed by a decrease over the next few days and then a subsequent significant increase [24].

65.4.20 Other Biomarkers

Given the complexity of the pathogenesis of BPD, investigators have also attempted to use the relative concentration of TA markers to predict BPD. Infants who developed BPD had higher IL-1β concentrations and IL-1β/IL-6 ratios. Premature infants who developed BPD had higher levels of IL-1 receptor antagonist (IL-1RA) in their airways on the first day of life. IL-1β also increased significantly for BPD patients early, both compared to non-BPD patients, and also within the BPD group. While the early (day 1) IL-1 antagonist/agonist molar balance offered protection, by days 5 and 7, a threshold for IL-1RA in the presence of increasing IL-1β expression favored pro-inflammation in the BPD group. Others have demonstrated a sustained increase of TGFβ1 levels in TA from preterm infants who developed BPD, combined with an absent or irregular secretion of IL-4, IL-10 and IL-12. Babies who developed BPD or died had lower IL-6/VEGF ratios in the TA, than those who did not have such an adverse outcome [14]. In other studies, BPD infants had significantly lower TIMP-1 levels with a higher MMP-9/TIMP-1 ratio during the first 2 weeks of life and low TIMP-2 and MMP-2 levels during the first 3 days of life compared with no BPD infants [25].

Cord blood (and TA) soluble E-selectin has been noted to be increased in infants who developed BPD. Increased serum levels of soluble E-selectin were associated with the development of BPD. In another study, low levels of soluble L-selectin and increasing levels of soluble E-selectin were reported to be potential risk factors for BPD. The cord blood placental growth factor concentrations were noted to be increased in infants developing BPD. Serum C-IV (an antigen marker of type IV collagen, a component of basement membranes) levels were elevated in the first week of life in infants subsequently diagnosed with BPD. In another study of serial measurements of the C-terminal fragment of type I procollagen, levels at week 4 were significantly lower in infants who subsequently developed BPD. Patients with both the old and new categories of BPD had elevated serum levels of TGF- β1, though these were not statistically significant [26]. Other blood markers include measures of eosinophilic activation (eosinophilic cationic protein and the cellular surface antigen CD9), which were increased in BPD. The plasma KL-6 (a circulating high molecular weight mucinous glycoprotein, which is the extracellular soluble region of MUC-1 mucin, possessing an undefined sialylated carbohydrate chain that is recognized by KL-6 antibody) was noted to be increased in patients with moderate/severe BPD. The plasma levels of 8-iso-prostaglandin F2alpha (a stable metabolite of F2- isoprostanes, a marker for oxidant injury) have been noted to be increased in infants who developed BPD/died. In another study, however, urinary levels of the same metabolite were not correlated with BPD.

Older infants with established BPD had higher levels of urinary leukotriene E 4 when compared to healthy infants of the same age; however, it was not found to be an early marker of BPD. Elevated urinary elevated bombesin-like peptide levels in infants at 1–4 days after birth were associated with a 10-fold increased risk of developing BPD [27]. Given the importance of vascular development in the pathogenesis of BPD, investigators have postulated evaluating the vascularity of the lower gingival and vestibular oral mucosa as a marker for BPD. Infants with BPD showed a significantly lower blood vessel area as well as a higher vascular network complexity than control subjects.

A majority of these studies comprise of a small number of babies. Appropriately so, most attempts to identify biomarkers have been to access the pulmonary compartment by collecting TA. However, TA have been collected at a variable number of time points, measurements usually done of single markers, with or without normalization and with variable definitions of BPD (oxygen requirement for 28 days or at 36 weeks PMA, with or without radiographic criteria). Few have been replicated in different cohorts. Those with consistent results include: elastase, IL-1β, IL-6, MCP-1, ET-1 and angiopoietin 2 (Table 65.2). VEGF has been replicated but showed variable results (Table 65.2). Most of the above comments are also true of the blood and urinary markers. Not surprisingly, none of the aforementioned markers for BPD are in general clinical use.

The majority of the above biomarkers show only an association with BPD. In order to prove a causal relationship, they need to be studied in developmentally-appropriate animal models and human lungs with BPD. Some progress in this direction has been made with the following: elastin [28], cathepsin-S [29], HGF [30], KGF [31], IL-1β [32], IL-6 [33], MCP-1 [34], TGF-β1 [35], VEGF [36], bombesin-like peptide [37] and angiopoietin-2 [15] but additional work is needed.

65.5 Clinical Aspects

65.5.1 Clinical Diagnosis

The classical presentation is a history of a premature infant with RDS who has been intubated and mechanically ventilated and exposed to supplemental oxygen for the first week of life or longer. Usually these infants experience bouts of postnatal sepsis and have inadequate nutritional intake. Over time, these infants fulfill the diagnostic criteria for BPD, as defined earlier.

In the early phase of BPD (up to the first postnatal week of life), the clinical presentation may be indistinguishable from an infant with RDS. Such infants may require intubation and surfactant administration. Occasionally, premature infants may require minimal respiratory support with nasal continuous positive airway pressure (NCPAP) or nasal intermittent positive pressure ventilation (NIPPV), with a supplemental oxygen requirement of <40%. In the evolving phase of BPD (after 1 week of life to 36 weeks PMA), such infants have not been able to be successfully extubated or have been re-intubated. These infants usually require escalation of ventilatory support and higher concentrations of supplemental oxygen. Signs and symptoms of established BPD (after 36 weeks PMA) include tachypnea, dyspnea, and chronic or intermittent crackles and wheezing. In children with subglottic stenosis secondary to prolonged intubation, there may be presence of a stridor on exam. Noisy breathing exacerbated with high airflow activities such as feeding and agitation may be heard in infants with tracheomalacia and bronchomalacia. BPD spells are episodes of tracheal obstruction associated with episodes of cyanosis and oxygen desaturations and bradycardia, usually occurring secondary to agitation, and are thought to be related to tracheomalacia and bronchomalacia. Cardiac complications of severe BPD include pulmonary hypertension and cor pulmonale. Poor growth may be related to undiagnosed hypoxia, cardiac disease, gastroesophageal reflux and swallow dysfunction or recurrent aspiration.

65.5.2 Radiological Findings

In the early phase of BPD, the chest X-ray shows RDS or in some case, minimal respiratory disease. In the evolving phase, the lung fields become more hazy and dense suggesting pulmonary edema, atelectasis or infiltrates. Recently there has been a change in the radiographic findings associated with established BPD. This change has likely been brought about by the younger GA of surviving infants, widespread use of surfactant, and less aggressive respiratory management strategies. Traditionally, in the pre-surfactant era, BPD was represented on radiographic imaging by emphysematous areas with other portions of the lung displaying volume loss. This correlated with the pathology of a pulmonary specimen that would also exhibit signs of increased inflammation, fibrosis and small airway disease. Over the clinical course of evolving "new" BPD, the radiological signs are fairly nonspecific and the lung fields appear hazy and dense secondary to pulmonary edema and atelectasis (Fig. 65.2). Once the "new" BPD is well-established, the appearance of the lungs progresses to hyperinflation and cystic areas, but without the large cysts typical of the older form of BPD [12, 38].

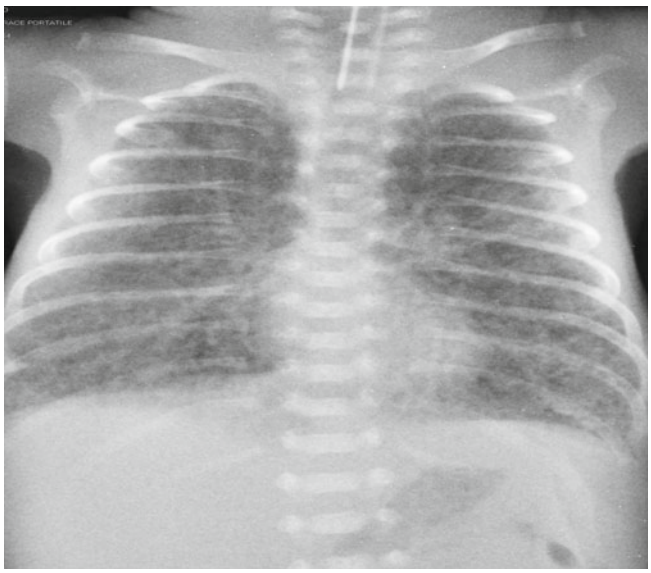

Fig. 65.2 Chest X-ray of an infant with established BPD

65.6 Differential Diagnoses

65.6.1 Aspiration Pneumonia

In the early phase of BPD, respiratory distress can be secondary to aspiration of amniotic fluid or maternal blood during delivery. The radiological picture may show localized lobar infiltrates or an interstitial pattern. With supportive care that usually includes supplemental oxygen with or without mechanical ventilation, intravenous fluids and antibiotics, such infants show significant clinical improvement within the first week of life.

65.6.2 Congenital Heart Disease

Infants with cyanotic congenital heart disease will show evidence of hypoxemia, not responsive to supplemental oxygen. In addition, there may be signs suggestive of a cardiovascular etiology (hypotension, heart murmurs, heart rhythm disturbances). Chest X-rays may be helpful in terms of the size and shape of the cardiac silhouette. Cardiac echocardiography will be diagnostic.

Table 65.3 Differential diagnoses of BPD

- Aspiration pneumonia
- Congenital heart disease
- Infectious pneumonia
- Interstitial lung disease
- Pulmonary lymphangiectasia
- Wilson-Mikity syndrome

65.6.3 Infectious Pneumonia

These are mostly viral or bacterial in the immediate newborn period. There may be maternal history (for example, chorioamnionitis) that may predispose an infant to an infectious pneumonia. Chest X-rays show lobar or perihilar infiltrates. Neonates usually improve with supportive care (as mentioned above) within the first week of life.

65.6.4 Interstitial Lung Disease

In the neonatal period, genetic and developmental disorders leading to interstitial lung disease are most likely to be considered in the differential diagnoses of BPD. These include specific conditions that affect surfactant function i.e., mutations in surfactant proteins –B, -C and ABCA3. Confirmation of diagnoses may require lung biopsy and genetic testing.

65.6.5 Pulmonary Lymphangiectasia

Pumonary lymphangiesctasia is a rare developmental disorder that results in dilated and obstructed lymphatics. Confirmation of the diagnosis requires a lung biopsy. There is an association with Noonan and Turner syndromes.

65.6.6 Wilson-Mikity Syndrome

There is significant overlap between Wilson-Mikity syndrome and the premature infants with BPD who do not have significant respiratory disease at birth (*vide supra*). Infants with Wilson-Mikity syndrome do not develop RDS. The exact etiology is unknown. Proposed predisposing factors include air trapping, fluid overload secondary to chronic PDA, recurrent aspiration, infection, rickets, and surfactant deficiency. Clinical features are characterized by features of respiratory distress. This syndrome is commonly seen between 1 and 2 months of age, and most cases slowly resolve. Chest radiographic findings are normal in the first week, but later they are similar to those of BPD, with hyperinflation, streaky infiltrates, and cystic changes. Radiographic changes persist for a few months to years after clinical findings resolve. It is perhaps a genetic variant of the "new" BPD.

65.7 Prognosis

This is primarily dependent on pulmonary and neurodevelopmental outcomes.

65.7.1 Pulmonary Outcomes

65.7.1.1 Morbidity

There is significant pulmonary morbidity associated with BPD. Compared to non-BPD, infants with BPD have higher rates of rehospitalizations (up to 50%) in the first year, and 36% in the second year of life. Reasons for rehospitalization included reactive airway disease, pneumonia, respiratory syncytial virus (RSV) infection and worsening BPD [39]. Although recurrent respiratory symptoms needing hospitalization decrease over time, this increase in respiratory symptoms persists beyond the first 2 years of life into preschool years, adolescence and early adulthood [39]. It is unclear whether it is the severity of BPD or prematurity per se that influences the persistence and severity of symptoms.

65.7.1.2 Radiological Findings

In children with a history of BPD, abnormal chest X-rays with subtle radiological abnormalities have been noted later in adolescence and adulthood [39]. The chest radiograph is relatively insensitive to the structural changes present in the BPD lung. In contrast, high resolution computed tomography (CT) is much more sensitive for visualizing radiological abnormalities in patients with BPD. Investigators have reported that there is little difference in the radiological appearance of "old" versus "new" BPD, with the absence of bronchial involvement being the only striking difference. A positive correlation between abnormal radiographic findings and pulmonary function has been reported, with severity of the clinical course being associated with extensive CT scan abnormalities [39]. A new chest CT scan scoring system for clinical assessment of patients with BPD has been proposed which correlated well with clinical scores at 36 weeks PMA and duration of oxygen dependence.

65.7.1.3 Pulmonary Function

Despite many advances in neonatal care, patients with BPD continue to have significant impairment in lung function and their lung function may continue to deteriorate into late adolescence [40]. Fortunately, this impaired lung function typically does not interfere with the patient's ability to participate in daily activities, including exercise. Persistent airway dysfunction likely reflects severity of neonatal disease. Although there is a plethora of literature describing abnormal lung function in

patients with BPD at all ages from infancy to early adulthood, there are only a few studies correlating the extent of pulmonary function impairment with various therapies used. An inverse relationship has been reported between FEV1 at school age and duration of supplemental oxygen. V′max25, a measure of flow through small airways, was reduced at school age in inverse proportion to an oxygen score that quantified neonatal supplemental oxygen exposure. Conversely, others have reported poor correlation between duration of mechanical ventilation and oxygen supplementation and forced expiratory flow (FEF) in infants with BPD [39]. BPD infants had low FEF measurements at 6 and 12 months who were treated initially with either high frequency oscillatory ventilation (HFOV) or conventional mechanical ventilation (CMV) compared with published reference values [41]. Infants treated initially with HFOV had significantly better lung function at 12 months than those treated with CMV [41], suggesting that early HFOV in combination with surfactant treatment could lessen the neonatal lung injury that leads to BPD [41]. It is not known if this difference persists into adulthood. Others have found no significant difference in the degree of mild obstructive lung disease as a function of mode of ventilation at 8-9 years of age. This suggests that other factors influence long-term pulmonary outcome [39]. Other studies have noted a correlation in the V′max FRC (forced residual capacity), FEV1 and FEF 25-75% measured at 2 years and school age [39].

Large airways can also be affected in BPD. Prolonged endotracheal intubation and mechanical ventilation result in tracheomalacia and bronchomalacia, which are associated with increased airway compliance. Other problems commonly encountered are subglottic stenosis, airway granulomas and pseudopolyps that may require surgical intervention [39].

Most studies show no reduction in exercise capacity in children with BPD when compared to children that were healthy term infants or preterm babies without lung disease [39]. Decreased gas transfer and oxyhemoglobin saturations during exercise in school aged children (6–9 years) has been reported in those with a history of BPD when compared with full-term and preterm children without BPD. Others have shown a decrease in maximal exercise in capacity in BPD survivors aged 6–12 years when compared to healthy controls. Exercise tolerance continues be relatively unchanged in young adulthood. Higher airway obstruction and CO diffusing capacity and decreased exercise capacity but normal mean lung function in former premature babies at young adulthood (mean age 19 years), when compared to controls, has been reported. This suggests that the impaired exercise tolerance in these young adults was not related to pulmonary function but perhaps poor physical fitness [39].

Many changes occur in pulmonary function with growth and development. While lung mechanics and some volumes may normalize over time, small airway dysfunction persists. Whether the pulmonary dysfunction in these patients will predispose them to obstructive lung disease as older adults remains to be seen.

65.7.2 Neurodevelopmental Outcomes

BPD children have a greater fine and gross motor skill impairment as well as cognitive function and language delay compared to infants without BPD. Children with severe BPD had worse outcomes and required more interventions at age 8 years than did children with mild or moderate BPD [42].

Most studies of BPD have been cross-sectional in nature and the independent effect of BPD is difficult to assess, given the high likelihood of the presence of additional medical complications in these infants. While preterm infants have an increased risk of neurodevelopmental impairment, BPD is an additional risk factor [43]. BPD does not appear to be associated with a specific neuropsychological, but rather a global impairment [43]. Importantly, the spectrum of neurodevelopmental impairment appears to correlate well with the BPD disease severity [44, 45]. As with pulmonary outcomes, ongoing data will be needed to assess the neurodevelopmental outcomes in infants with “new” BPD.

65.8 Therapy

The current status of the various therapeutic approaches in the 3 (early, evolving and established) phases of BPD is shown in Tables 65.4A-C. The robustness of the evidence has been classified based on the type of clinical studies using the system developed by the U.S. Preventive Services Task Force:

- Level I: Evidence obtained from at least one properly designed randomized controlled trial.
- Level II-1: Evidence obtained from well-designed controlled trials without randomization.
- Level II-2: Evidence obtained from well-designed cohort or case-control analytic studies, preferably from more than one center or research group.
- Level II-3: Evidence obtained from multiple time series with or without the intervention. Dramatic results in uncontrolled trials might also be regarded as this type of evidence.
- Level III: Opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert committees.

The recommendation for use in the clinical setting is also based on the guidelines developed by the U.S. Preventive Services Task Force:

- Level A: Good scientific evidence suggests that the benefits substantially outweigh the potential risks.
- Level B: At least fair scientific evidence suggests that the benefits outweigh the potential risks.
- Level C: At least fair scientific evidence suggests that there are benefits provided, but the balance between benefits and risks are too close for making general recommendations.
- Level D: At least fair scientific evidence suggests that the risks outweigh potential benefits.

Table 65.4A Management of BPD: Early phase (up to 1 postnatal week)

Therapeutic intervention	Current status	Level of evidence	Level of recommendation
Oxygen supplementation	A wide variation in the acceptable oxygen saturation levels exists across centers, but generally <95% [57]; usually between 85–93%	I	A
Ventilatory strategy	Avoid intubation. If intubated, give "early" surfactant [58]	I	A
	Use short inspiratory times (0.24–0.4s) [59], rapid rates (40–60/min), low PIP (14–20 cmH_2O), moderate PEEP (4–6 cmH_2O), low tidal volume (3–6 mL/kg) [60]	I III III III III	A B B B B
	Extubate early to SNIPPV/NCPAP [61]	I	A
	Blood gas targets: pH 7.25–7.35 PaO_2 40–60 mmHg $PaCO_2$ 45–55 mmHg [62]	III III I	B B C
	High frequency ventilation for "rescue", if conventional ventilation fails [57]	I	A
Methylxanthines	Improves successful extubation rate [63]	I	A
	Decreases BPD [64]	I	A
Vitamin A	If considering use, dose is 5000 IU administered intramuscularly 3 times per week for 4 weeks. 1 additional infant survived without BPD for every 14 to 15 infants who received vitamin A [65, 66]	I	A
Fluids	Restrictive fluid intake may decrease BPD [67, 68]	II-2	B
Nutrition	Provide increased energy intake [69]	I	B

PIP peak inspiratory pressure, *PEEP* positive end expiratory pressure, *SNIPPV* synchronized nasal intermittent positive pressure ventilation, *NCPAP* nasal continuous positive airway pressure. From [56] with permission.

Table 65.4B Management of BPD: Evolving phase (>1 postnatal week to 36 weeks PMA)

Therapeutic intervention	Current status	Level of evidence	Level of recommendation
Oxygen supplementation	Same as in Table 65.4A	I	A
Ventilatory strategy	Avoid endotracheal tube ventilation. Maximize non-invasive ventilation (SNIPPV/NCPAP) for respiratory support [61]	I	A
	Blood gas targets: pH 7.25–7.35 PaO_2 50–70 mmHg $PaCO_2$ 50–60 mmHg [60]	III III III	B B B
Methylxanthines	Same as in Table 65.4A	I	A
Vitamin A	Same as in Table 65.4A. If using, continue for 4 postnatal weeks	I	A
Steroids	Dexamethasone effective in weaning off mechanical ventilation when used "moderately early" and "delayed" [70, 71]	I	A
	Increased incidence of neurological sequelae with early use (<96 hours) [72]	I	D
Diuretics	Furosemide: may use daily or every other day with transient improvement in lung function [73]	I	B
	Spironolactone and Thiazides: chronic therapy improves lung function, decreases oxygen requirements [73]	I	B
Nutrition	Same as in Table 65.4A	I	B

PMA post-menstrual age, *SNIPPV* synchronized nasal intermittent positive pressure ventilation, *NCPAP* nasal continuous positive airway pressure. From [56] with permission.

Table 65.4C Management of BPD: Established phase (>36 weeks PMA)

Therapeutic Intervention	Current Status	Level of Evidence	Level of Recommendation
Oxygen supplementation	For prevention of pulmonary hypertension and cor-pulmonale. A wide variation in the acceptable oxygen saturation levels exists across centers, but generally ~95% [57, 74]	III	C
Ventilatory strategy	Blood gas targets: pH 7.25-7.35 PaO_2 50-70 mmHg $PaCO_2$ 50-65 mmHg [60]	III	B
Steroids	Oral prednisolone may be helpful in weaning oxygen [75]	II-2	C
Diuretics	Chronic therapy as in Table 65.4B	I	B
Beta agonists	Transient relief: increased compliance and reduced pulmonary resistance [73]	I	C
	No significant effect on incidence or severity of BPD [76]	I	C
Anticholinergics	Used in combination with beta agonists in infants with bronchospasm. Increased compliance and decreased respiratory system resistance [77]	II-3	C
Nutrition	Same as in Table 65.4A	I	B
Immunization	Prophylaxis against RSV and influenza decreases incidence of rehospitalization and morbidity	I	A

PMA post-menstrual age. From [56] with permission.

- Level I: Scientific evidence is lacking, of poor quality, or conflicting, such that the risk versus benefit balance cannot be assessed.

65.8.1 Novel Approaches/Therapies

Allopurinol In a randomized controlled trial (RCT) of 400 preterm infants, allopurinol given for 1 week did not impact on the incidence of BPD (at 28 days).

Alpha-1 Proteinase Inhibitor (α1P1) Systemic treatment with α1P1 did not reveal any statistically significant differences in the rates of BPD between the treated and placebo groups of preterm infants.

Continuous Tracheal Gas Insufflation (CTGI) In a prospective RCT in 34 premature infants, CTGI was not found to decrease death or BPD, compared to controls.

Cromolyn Two trials did not show any decrease in the incidence of BPD with the use of cromolyn (a mast cell stabilizer), which was confirmed in a meta-analysis.

Hydrocortisone Low–dose hydrocortisone did not improve survival without BPD [46]. The RCT had to be terminated early due to the hydrocortisone-treated infants receiving indomethacin having more gastrointestinal perforations [46].

Inositol In a meta-analysis of RCT using inositol supplementation in premature infants, the outcome of death or BPD was reported in two trials, and was found to be significantly reduced [47].

Liquid Ventilation In an uncontrolled study of 13 premature neonates treated with partial liquid ventilation, among 8 infants who survived till 36 weeks PMA, 4 had BPD.

Macrolide Antibiotics Erythromycin has not been shown to decrease BPD in infants when treated prophylactically or after known Ureaplasma colonization. Azithromycin, in a pilot study, did not reduce the incidence of BPD.

N-Acetyl Cysteine (NAC) In a large RCT, use of a 6-day course of NAC did not prevent BPD or death in infants with BW <1000 grams.

Nasal Continuous Positive Airways Pressure (NCPAP) Early surfactant replacement therapy with extubation to NCPAP compared with later selective surfactant replacement and continued mechanical ventilation with extubation from low ventilator support was associated with less need for mechanical ventilation, lower incidence of BPD and fewer air leak syndromes [48]. Use of a cut-off value of FiO2 of 0.45 to decide on transient intubation and surfactant replacement appeared to decrease the incidence of air leaks and BPD [48]. The Cochrane review, however, did not include the results of the COIN Trial, which reported that in infants born at 25–28 weeks' gestation, early nasal CPAP did not significantly

reduce the rate of death or BPD, as compared with intubation and the CPAP group had a higher incidence of pneumothoraces [49]. The NICHD-sponsored Neonatal Research Network SUPPORT Study, which looked at the same issue, in addition to optimal oxygen saturation ranges, did not find a difference in death or BPD.

Nasal Intermittent Positive Pressure Ventilation (NIPPV) NIPPV, both in the synchronized (SNIPPV) [50] and non-synchronized [51] modes, has been found to decrease BPD in RCT. The on-going NIP Trial is a large multicenter international RCT attempting to confirm the findings of the above-mentioned initial studies.

Nitric Oxide Inhaled nitric oxide (iNO) may or may not be beneficial in preventing BPD [52]. It does appear to be safe in this population, though it does not appear to impact on surfactant composition or pulmonary function. Routine use of iNO to decrease BPD in the preterm population is not recommended, pending long-term outcome data.

Patient-Triggered Ventilation Studies done to date have not shown any reduction in the incidence of BPD.

Recombinant CC10 Use of an anti-inflammatory protein, recombinant human Clara cell 10 kDa protein (CC10) has shown some initial promise.

Recombinant SOD Although the antioxidant recombinant Cu-Zn superoxide dismutase (SOD), did not show any difference in outcome, infants <27 weeks of gestation that received SOD had decreased hospitalizations, emergency room visits and less frequent use of bronchodilator therapy at age 1 year, as compared to infants that did not receive it [53].

Synthetic Surfactant A new synthetic surfactant (lucinactant), which contains the novel peptide, sinapultide, a surfactant-associated protein B mimic, appears to be similar to animal-derived surfactant in 2 multicenter randomized clinical trials. A meta-analysis of the studies revealed no statistically different differences in the outcomes of death and BPD [54].

Surfactant Delivery An attractive alternative to intubation and delivery of intra-tracheal surfactant would be aerosol delivery. To date, no effective aerosolized surfactant preparation is available for routine use in the clinical setting.

Thyroxine In a RCT, postnatal supplementation of thyroxine in preterm newborns did not decrease the incidence of BPD.

Vitamin E In a RCT, oral vitamin E supplementation did not reduce BPD in infants with BW <1500 grams.

Volume-Targeted Ventilation In a meta-analysis comparing volume-targeted ventilation to pressure-limited ventilation, there was no difference in the incidence of BPD, between the 2 groups.

More research is needed with these approaches before definite recommendations can be made.

65.9 Prevention

Among the antenatal factors, prevention of premature birth is the single most effective preventive measure for BPD. Understanding the biology of, and targeting therapies to inhibit, preterm labor safely would be an important goal. The use of progesterone in prevention of premature labor has shown promise, although the prolongation of gestation with this approach has yet to improve infant outcomes.

Antenatal steroids still remains the single most effective intervention for lung maturation and is recommended for clinical use. The impact of antenatal steroids on BPD has been somewhat controversial with studies reporting no or some benefit; other factors may perhaps mask the benefit of antenatal steroids. Weekly courses of antenatal steroids are not recommended. Betamethasone is preferred over dexamethasone.

Considerable research has gone into understanding the role of antenatal and postnatal inflammation in the pathogenesis of BPD [12, 13]. Antenatal interventions to treat chorioamnionitis have not decreased BPD; postnatal interventions may be too late to be effective. In most circumstances, maintenance of target oxygen saturation ranges >85–<95% is prudent in preterm neonates to avoid oxygen toxicity in an attempt to prevent the development of BPD, though achieving intended targets may be difficult. Restrictive fluid intake to meet physiological needs without resulting in significant dehydration showed a trend towards a lower risk for BPD [55]. Use of non-invasive methods of ventilation appears to show early promise in the prevention of BPD.

Given the complex nature of BPD (Fig. 65.1), it is unlikely that a single magic bullet (with the possible exception of prevention of preterm birth) will make a highly significant impact on BPD. Incremental improvements are possible by targeting multiple aspects of this condition include early diagnosis and treatment of antenatal and postnatal sepsis, optimal maintenance of oxygenation and fluid/electrolyte status, aggressive early parenteral/enteral nutrition, along with appropriate ventilatory strategies.

65.10 Conclusions

Focusing on aspects of basic biology (lung development, identification of biomarkers, genetics, animal models), and pharmacotherapeutic approaches [2] has the maximum potential to make an impact on BPD. Significant improvements in the future will likely depend on our ability to identify the genetic components of BPD and to target specific therapies.

Rare Lung Diseases

Paolo Tagliabue and Clotilde Farina

66.1 Introduction

Rare lung diseases include a wide spectrum of conditions and are important causes of morbidity and mortality in newborn babies and infants. Despite the low incidence of these conditions, neonatologists are likely to encounter these disorders because they present with respiratory distress. For intensive care staff, radiologists, pathologists, and surgeons, the management and care of newborns affected by these diseases can require considerable time and resources within a tertiary care center. Embryological, pathological, surgical, antenatal and pediatric classifications for rare lung diseases have been reported [1–3]. The causes of rare respiratory diseases in neonates may be classified as: (a) Bronchial ultrastructural anomalies (e.g., primary ciliary dyskinesia [Kartagener's syndrome]), parenchymal molecular defects (e.g., congenital surfactant protein abnormalities), vascular malformations (e.g., congenital pulmonary lymphangiectasia and alveolar capillary dysplasia); (b) Developmental parenchymal abnormalities (e.g., pulmonary hypoplasia and cystic lung diseases [Table 66.1]).

The approach to rare lung diseases in neonates involves consideration of the prenatal history, clinical features and radiologic findings. A positive family history, ultrasonographic chest findings, polyhydramnios and associated congenital anomalies are suggestive. Clinical features may include: term gestation, unexpected respiratory distress, untreatable hypoxia without cyanotic heart defects, recurrent pulmonary infections or chronic lung disease of unknown origin. Relevant radiologic findings are chest asymmetry, dextrocardia, mediastinal shift, opacities or hyperlucencies, cystic pulmonary masses or fluid-filled lesions (Table 66.2).

Table 66.1 Rare pulmonary causes for respiratory distress in neonates

Parenchymal conditions
Primary ciliary dyskinesia (Kartagener's syndrome)
Congenital surfactant protein abnormalities
– Surfactant protein-B gene mutations
– Surfactant protein-C gene mutations
– ABCA3 transporter gene mutations
Congenital pulmonary lymphangiectasia
Alveolar capillary dysplasia
Developmental abnormalities
Lung agenesis
Pulmonary hypoplasia
Congenital diaphragmatic hernia
Cystic lung diseases
– Cystic adenomatoid malformation
– Bronchopulmonary sequestration
– Bronchogenic cyst
– Congenital lobar emphysema
Mechanical abnormalities
Rib cage anomalies
– Skeletal
– Muscular
– Central nervous
Chylothorax
Extrapleural and mediastinal masses

66.2 Parenchymal Diseases

66.2.1 Primary Ciliary Dyskinesia (PCD)

An autosomal recessive disease characterized by congenital impairment of mucociliary transport. This genetically, functionally, and ultrastructurally heterogeneous disease affects 1:20–30,000 individuals. Situs inversus is present in nearly 50% of cases. PCD rarely presents during the neonatal period and there is considerable variability in the severity of the clinical phenotype. Clinical manifestations include chronic respiratory infections beginning in early childhood. There is a

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

Table 66.2 Approach to rare lung diseases in neonates

Prenatal history
Positive familiar history
Prenatal ultrasonographic chest findings
Polyhydramnios
Associated congenital anomalies
Neonatal clinical features
Term newborn
Unexpected respiratory distress
Untreatable hypoxia without cyanotic heart defects
Recurrent pulmonary infections
Chronic lung disease of unknown origin
Radiologic findings
Asymmetric chest imaging
Dextrocardia
Mediastinal shift
Radiological opacities
Radiological hypertransparencies
Cystic pulmonary masses
Fluid-filled lesions

history of neonatal respiratory distress in 43% of patients, and 55% have had recurrent lower respiratory tract infections from birth onwards.

The single most effective test is light microscopy of transnasal brushings for the ciliary beat pattern. Normal ciliary function excludes the diagnosis of PCD. Abnormality of the ciliary ultrastructure may be a primary defect or secondary to infections.

The mainstays of treatment are chest physiotherapy and the prompt and prolonged treatment of intercurrent respiratory infections, monitoring of hearing and oto-rhino-laryngological procedures.

The prognosis for a child with PCD is good. It is not considered to be a life-limiting condition and the outcome is very different from that of cystic fibrosis (CF) [4].

66.2.2 Congenital Surfactant Protein Abnormalities

Recessive mutations affecting surfactant protein-B (SP-B) and the ATP-binding cassette family member A3 (ABCA3) genes present as lethal surfactant deficiencies in the newborn, whereas other recessive mutations of ABCA3 and dominant mutations of the surfactant protein-C (SP-C) gene result in interstitial lung disease in older infants. Deficiency of surfactant protein B (SP-B) is the most common (Fig. 66.1). Shortly after birth, term infants continue to suffer from severe respiratory distress despite mechanical ventilation and repeated surfactant replacement. The only effective therapy is lung transplantation, without which the infants die within few months [5].

66.2.3 Congenital Pulmonary Lymphangiectasia (CPL)

A congenital malformation, with presentation from the fetus to early adulthood. CPL results from a failure of the pulmonary interstitial connective tissue to regress, leading to dilatation of lymphatic capillaries. Radiological findings include diffuse thickening of the peribronchovascular interstitium and the interlobular septa with pleural effusions. Supportive therapy includes albumin infusions, diuretics, thoracocentesis, and paracentesis. Nutrition plays an important role in reducing lymph production. Enteral nutrition with medium-chain triglycerides and total parenteral nutrition has been used successfully. CPL is often associated with congenital and genetic diseases, including Noonan, Ullrich-Turner, Ehlers-Danlos, and Down syndromes. In rare localized disease, surgical resection is curative. If presentation is during the newborn period, the clinical course is likely to be fatal.

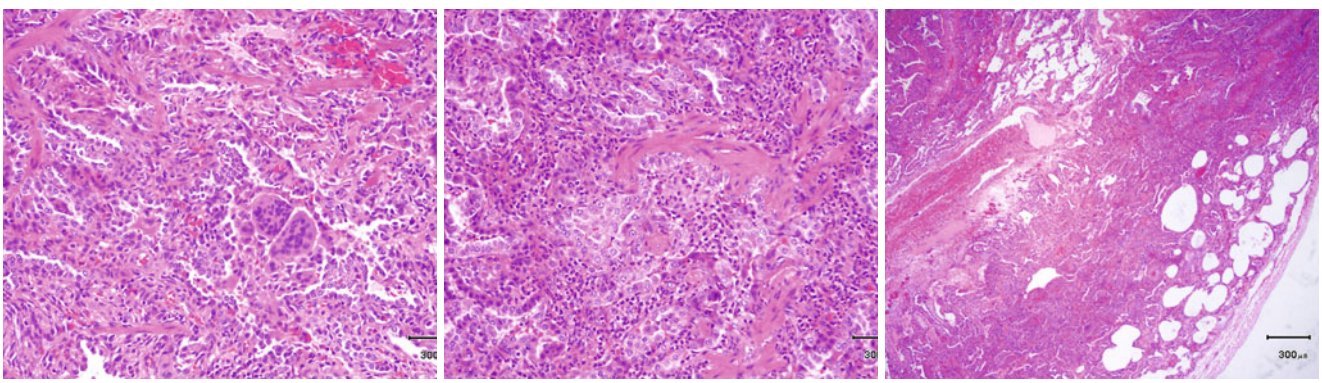

Fig. 66.1 Histopathology of a lung disorder caused by ABCA3 gene deletion. Alveolar proteinosis, admixed with alveolar macrophages, and thickened alveolar septa are seen in a biopsy from a neonate with fatal lung disease who was homozygous for a large ABCA3 gene deletion transmitted by consanguineous parents. (Personal case, by courtesy of Dr. V. Lucchini, pathologist)

For the majority of patients with neonatal presentations, gradual improvement and survival are possible, particularly if there are no significant co-existing abnormalities [5, 6].

66.2.4 Alveolar Capillary Dysplasia (ACD)

A disorder of pulmonary vascular development associated with persistent pulmonary hypertension in the newborn (PPHN) and unremitting hypoxemia that is unresponsive to pulmonary vasodilators and various modes of mechanical ventilation. Autosomal recessive inheritance is suspected. The diagnosis of ACD is confirmed at autopsy in 90% of cases, and in 10% by lung biopsy. Failure of development of alveolar capillaries leads to absence of a normal air-blood barrier. ACD is characterized by paucity of capillaries adjacent to the alveolar epithelium, anomalous distended veins, immature alveolar development and muscularization of the arterioles. Pathological features are diffuse in 85% and patchy in 15% of subjects. The symptoms and timing of presentation are related to the distribution of capillary dysplasia and the extent of alveolar underdevelopment. More than 95% are full-term with normal transition. Respiratory distress progressing to untreatable respiratory failure is the most common presentation. The onset of abnormal clinical signs is within the first hours of age in half the cases, while presentation at 2–6 weeks is reported in the 14% of cases. There is an association with other congenital malformations in 80% of cases, the commonest being gastrointestinal (30%), cardiac (30%), and renal anomalies (23%). If here is a high index of suspicion, diagnostic lung biopsy could be considered. ACD is generally fatal [7, 8].

66.2.5 Pulmonary Hypoplasia

In this condition, alveoli are reduced in number or size. Severe hypoplasia may be incompatible with extrauterine life. Lung growth before birth is dependent on blood supply, availability of space, respiratory movements, and fluid filling the airways in utero. Malformations of the rib cage, pleural effusions, thoracic masses or intestinal loops in congenital diaphragmatic hernia (CDH) compete with the developing lung for space. Adequate amniotic fluid is essential for normal lung development and conditions that produce oligohydramnios lead to diminished lung growth. Significant and prolonged oligohydramnios can result from chronic loss of liquor after preterm premature rupture of membranes, or from inadequate production or excretion of urine because of renal and urinary tract malformations: airway and arterial branching is inhibited, limiting the surface available for gas exchange. In the oligohydramnios sequence, the common phenotype is a flattened nose, contractures and growth impairment of extremities, known as Potter's syndrome.

Prolonged preterm premature rupture of membranes is not universally lethal but depends on the degree of pulmonary hypoplasia. The following conditions increase the risk of mortality:

- premature rupture of membranes at less than 25 weeks' gestation,
- severe oligohydramnios (amniotic fluid index <4) for more than 2 weeks,
- preterm delivery earlier than 28 weeks' gestation.

Serial amnioinfusions may be helpful if there is oligohydramnios. Abnormalities of the thoracic cage, with a small and bell shaped chest, are typical radiological findings. Lung hypoplasia is usually complicated by pulmonary hypertension and high-frequency ventilation and early use of inhaled nitric oxide therapy may be useful [1, 9].

66.3 Cystic Lung Diseases

Cystic lung lesions are the most common pulmonary lesions detected by routine antenatal ultrasound scanning. Different entities, such as congenital cystic adenomatoid malformation (CCAM), bronchopulmonary sequestrations (BPS), bronchogenic cyst (BC) and congenital lobar emphysema (CLE), may be difficult to differentiate, and antenatal MRI can provide more detail. A postnatal chest CT scan is useful in confirming the presence and extent of the lesions. Small lesions are usually asymptomatic both in utero and after birth. Large lesions may cause a mass effect resulting in esophageal compression and polyhydramnios, pulmonary hypoplasia, or vena caval obstruction with fetal hydrops. In these cases, fetal intervention may include thoraco-centesis or thoraco-amniotic shunting. The postnatal presentation is variable and depends on the size, location and type of lesion. Some infants may develop PPHN and respiratory failure. If there is associated pulmonary hypoplasia or ECMO is required, mortality is increased.

66.3.1 Congenital Cystic Adenomatoid Malformation (CCAM)

A congenital hamartomatous lesion of the lung, accounting for approximately 25% of congenital lung lesions. The incidence of CCAM is reported as between 1 in 11,000 and 1 in 35,000 live births. CCAM consists of a multicystic mass of dilated bronchiolar-like spaces that proliferate at the expense of alveoli. The cysts that enlarge following air and fluid trapping cause compression of the adjacent normal lung and mediastinum.

CCAM is categorized into four types. Type 1 is characterized by a few large cysts and is the most common (75%). In type 2, there are evenly spaced small cysts. Type 3 is very rare and appears solid on gross examination. Type 4

is characterized by acinar-type epithelium rather than the bronchiolar epithelium. Usually only one lobe is involved.

Enlarging lesions may cause progressive signs because of expansion of the cysts shortly after birth. Alternatively, abnormal signs may develop later if there are intercurrent infections. The neonatal presentation therefore ranges from respiratory failure (affecting approximately 50% of cases) to a healthy asymptomatic infant.

Large lesions may compromise the normal development of the fetal lung, resulting in pulmonary hypoplasia or neonatal death. CCAM is a cause of fetal hydrops and polyhydramnios. Infants with highly symptomatic CCAMs require surgery. Most commonly, this occurs in neonates presenting with respiratory failure of sufficient severity to require ventilatory support. When considering the timing of surgery for asymptomatic infants, some clinicians favor operating during the neonatal period but others prefer to wait until the child is between 6 months and 2 years of age. The prognosis depends on the size of the lesion, the degree of development of the adjacent lung, and the presence of other congenital anomalies [3, 5, 10, 11].

66.3.2 Bronchopulmonary Sequestration (BPS)

Composed of abnormal lung tissue without connection to the normal tracheo-bronchial tree. There are two types of BPS based on their relationship to the pleurae: extra- and intralobar. Both receive an anomalous arterial supply from the systemic circulation, usually a branch of the aorta.

With extralobar BPS, the mass of pulmonary parenchyma is outside the pleurae. The lesion is found between the left lower lobe and the diaphragm in 66% of the cases. More common in males (3:1), 50% of newborns have respiratory distress because of compression of the rest of the lung parenchyma. In more than 65%, there are associated anomalies, including CDH (30%), pericardial defects, and anomalous pulmonary venous return.

Intralobar BPS is characterized by a lesion within the lobe of the lung without separate pleurae. Intralobar BPS accounts for 75% of all BPS. Usually in the lower lobe (95%), on antenatal US, BPS appears as a solid mass. The presence of hydrops or polyhydramnios are poor prognostic factors. The majority of BPS (68%) undergo spontaneous regression before birth and survival is 95%. Early complications are usually related to the degree of associated pulmonary hypoplasia, but also result from other associated anomalies. Large BPS or BPS with high systemic blood flow are indications for resection. Lobectomy is the treatment of choice for intralobar BPS [2 ,3, 8].

66.3.3 Bronchogenic Cyst (BC)

Commonly mediastinal, it is a solitary cyst filled with fluid or mucus, attached and not communicating with the tracheobronchial tree. Lined with pseudostratified ciliated columnar epithelium with goblet cells and enlarged with mucous, these are considered to be infected peripheral lesions. Treatment is by lobectomy or excision of the cyst only [3].

66.3.4 Congenital Lobar Emphysema (CLE)

Caused by an intrinsic or extrinsic obstruction of a lobar bronchus with progressive air trapping and overinflation of the affected areas. Histologically, the lung parenchyma is normal with enlargement of the airspaces. Usually diagnosed postnatally by 6 months of age. The upper lobes are involved in 90% of cases and it is more common in males (2:1). In 40% of CLE, there are associated cardiovascular anomalies. If there is respiratory distress, the affected part of the lung should be removed. Spontaneous resolution has been reported and asymptomatic cases may be followed expectantly. The prognosis is generally good and depends on whether there are associated anomalies [3, 5].

Persistent Pulmonary Hypertension of the Newborn and Congenital Diaphragmatic Hernia

Steven H. Abman

67.1 Introduction

Persistent pulmonary hypertension of the newborn (PPHN) is a clinical syndrome that represents the failure to achieve or sustain the normal decrease in pulmonary vascular resistance (PVR) at birth, leading to severe respiratory distress and hypoxemia. PPHN is a major clinical problem, affecting nearly 10% of full-term infants admitted to neonatal intensive care units, and contributes significantly to high morbidity and mortality [1, 2]. Newborns with PPHN are at risk for severe asphyxia and its complications, including death, chronic lung disease, neurodevelopmental sequelae, and other problems. This chapter will review the pathophysiology and treatment of pulmonary hypertension in the setting of PPHN, including newborns with congenital diaphragmatic hernia (CDH).

67.2 Insights into PPHN from the Laboratory

Diverse animal models have been used in order to better understand the pathogenesis and pathophysiology of PPHN. Such models have included exposure to acute or chronic hypoxia after birth, chronic hypoxia in utero, placement of meconium into the airways of neonatal animals, sepsis and others. Each model demonstrates interesting physiologic changes that may be especially relevant to particular clinical settings, but most studies only examine brief changes in the pulmonary circulation, and mechanisms underlying altered lung vascular structure and function of PPHN remain poorly understood. Neonates with severe PPHN who die during the first days after birth already have pathologic signs of chronic pulmonary vascular disease, suggesting that intrauterine events may play an important role in this syndrome [3]. Adverse intrauterine stimuli during late gestation, such as abnormal hemodynamics, changes in substrate or hormone delivery to the lung, hypoxia, inflammation or others, may potentially alter lung vascular function and structure, contributing to abnormalities of postnatal adaptation. Several investigators have examined the effects of chronic intrauterine stresses, such as hypoxia or hypertension, in animal models in order to attempt to mimic the clinical problem of PPHN. Whether chronic hypoxia alone can cause PPHN is controversial. There has been a report that maternal hypoxia in rats increases pulmonary vascular smooth muscle thickening in newborns, but this observation has not been reproduced in more extensive studies of maternal rats or guinea pigs [4]. Acute hypoxia alone is insufficient to account for PPHN, which is further reflected in recent clinical observations that PPHN is rare in patients with severe asphyxia who were enrolled in hypothermia studies.

Pulmonary hypertension induced by early closure of the ductus arteriosus (DA) in fetal lambs alters lung vascular reactivity and structure, causing the failure of postnatal adaptation at delivery, and provides an experimental model of PPHN [5, 6]. Over days, pulmonary artery pressure and PVR progressively increase, but flow remains low and PaO_2 is unchanged [6]. Marked right ventricular hypertrophy and structural remodeling of small pulmonary arteries develops after 8 days of hypertension. After delivery, these lambs have persistent elevation of PVR despite mechanical ventilation with high oxygen concentrations. Studies with this model show that chronic hypertension without high flow can alter fetal lung vascular structure and function. This model is characterized by endothelial cell dysfunction and abnormal smooth muscle cell vasoreactivity and growth, including findings of impaired NO production and activity and down-regulation of lung endothelial NO synthase mRNA and protein expression [7–9]. Fetal pulmonary hypertension is also associated with decreased cGMP concentrations, associated with decreased soluble guanylate cyclase and upregulated cGMP specific phosphodiesterase (PDE5) activities, suggesting further impairments in downstream signaling [10, 11]. Thus, multiple

alterations in the NO-cGMP cascade appear to play an essential role in the pathogenesis and pathophysiology of experimental PPHN, contributing to altered structure and function of the developing lung circulation, and leading to failure of postnatal cardio-respiratory adaptation. Recent evidence indicates that excessive production of reactive oxygen species (ROS), such as superoxide in the pulmonary vasculature may further contribute to the disruption in NO-cGMP signaling in this model, and may contribute to poor responsiveness to inhaled NO therapy [9, 12, 13].

Upregulation of ET-1 may also contribute to the pathophysiology of PPHN. Circulating levels of ET-1, a potent vasoconstrictor and co-mitogen for vascular smooth muscle cell hyperplasia, are increased in human newborns with severe PPHN [14]. In the experimental model of PPHN due to compression of the DA in fetal sheep, lung ET-1 mRNA and protein content is markedly increased, and the balance of ET receptors are altered, favoring vasoconstriction [15, 16]. Chronic inhibition of the ET-A receptor attenuates the severity of pulmonary hypertension, decreases pulmonary artery wall thickening, and improves the fall in PVR at birth in this model [17]. Thus, experimental studies have shown the important role of the NO-cGMP cascade and the ET-1 system in the regulation of vascular tone and reactivity of the fetal and transitional pulmonary circulation.

Oxidant stress plays an important role in the pathogenesis of PPHN. Increased ROS such as superoxide (O_2^-) and hydrogen peroxide (H_2O_2) have been demonstrated in pulmonary arteries in the ovine ductal ligation model of persistent pulmonary hypertension [12, 18]. Mitochondrial dysfunction, increased expression and activity of NADPH oxidase, and uncoupled eNOS activity can each generate ROS [12, 19–21]. Increased ROS production promotes vasoconstriction directly and through multiple mechanisms that may include increased endothelin levels [22] and oxidization of free fatty acids to create vasoconstrictor metabolites, such as isoprostanes [23]. O_2^- rapidly combines and inactivates NO and forms peroxynitrite, a potent oxidant with the potential to produce vasoconstriction and cytotoxicity. Increased ROS in the pulmonary vasculature of the ductal ligation model promotes dysfunction of NO-cGMP signaling at multiple steps in the pathway, including blunted eNOS expression, uncoupled eNOS activity (thus further promoting ROS production), and increased activity and expression of cGMP-specific phosphodiesterases, and impaired sGC activity [9, 13, 24]. Superoxide dismutases (SOD) catalyze the conversion of superoxide anions to H_2O_2 and O_2. Due to the efficiency of the reaction between NO and superoxide, the local concentration of SOD is a key determinant of the biological half-life of endogenous NO [25]. Evidence for a critical pathologic role for ROS in PPHN includes the recent observation that administration of a single intratracheal dose of rhSOD in neonatal lambs with PPHN produced a sustained increase in oxygenation over a 24 hour period, reduced production of isoprostanes and peroxynitrite, and restored normal eNOS expression and function.

In addition to vasoactive mediators, alterations of growth factors, such as VEGF and platelet-derived growth factor (PDGF), likely play key roles in PPHN. VEGF is markedly decreased in experimental PPHN, and treatment with recombiant human VEGF restores endothelial function and lowers PVR in this model [26–28]. In addition, inhibition of PDGF-B attenuates smooth muscle hyperplasia in experimental pulmonary hypertension in fetal lambs, suggesting a potential role in the pathogenesis of PPHN [26]. Additional new data suggest that maternal exposure to selective serotonin reuptake inhibitors (SSRI) during late gestation is associated with a six-fold increase in the prevalence of PPHN [29], although it is not clear how many infants developed severe disease. Newborn rats exposed in utero to fluoxetine develop pulmonary vascular remodeling, abnormal oxygenation and higher mortality when compared with vehicle-treated controls [30]. However, these findings showed only mild changes in right ventricular hypertrophy and pulmonary vascular remodeling in the neonatal rat pups, with minimal changes in vasoreactivity after maternal SSRI exposure. Whether these effects were related to direct impact on the fetal lung circulation or secondary to altered maternal or umbilical-placental physiology remains unknown. As SSRIs have been reported to reduce pulmonary vascular remodeling in adult models of pulmonary hypertension, these findings also serve to highlight the unique vulnerability of fetal pulmonary vascular development.

67.3 Clinical PPHN

The first reports of PPHN described term newborns with profound hypoxemia who lacked radiographic evidence of parenchymal lung disease and echocardiographic evidence of structural cardiac disease. In these patients, hypoxemia was caused by marked elevations of PVR leading to right–to-left extrapulmonary shunting of blood across the patent ductus arteriosus (PDA) or foramen ovale (PFO) during the early postnatal period. Due to the persistence of high PVR and blood flow through these fetal shunts, the term "persistent fetal circulation" was originally used to describe this group of patients. Consequently, it was recognized that this physiologic pattern can complicate the clinical course of neonates with diverse causes of hypoxemic respiratory failure. As a result, the term PPHN has been considered as a syndrome, and is currently applied more broadly to include neonates that have a similar physiology in association with different cardiopulmonary disorders, such as meconium aspiration, sepsis, pneumonia, asphyxia, congenital diaphragmatic hernia, respiratory distress syndrome (RDS), and others (Table 67.1).

Striking differences exist between these conditions, and mechanisms that contribute to high PVR can vary between these diseases. However, these disorders are included in the syndrome of PPHN due to common pathophysiologic features,

Table 67.1 Disorders associated with neonatal pulmonary hypertension

1. *Pulmonary*
   - Meconium aspiration syndrome
   - Respiratory distress syndrome
   - Lung hypoplasia
   - Congenital diaphragmatic hernia
   - Pneumonia/Sepsis
   - Idiopathic
   - Transient tachypnea of the newborn
   - Alveolar-capillary dysplasia
   - Associated abnormalities in lung development
   - – congenital lobar emphysema (rare association)
   - – cystic adenomatoid malformation (rare association)
   - – idiopathic, with impaired distal alveolarization
   - – pulmonary interstitial glycogenosis
   - – surfactant protein B and C deficiency
   - – ABCA 3 deficiency
   - – others
2. *Cardiovascular*
   - Myocardial dysfunction (asphyxia; infection; stress)
   - Anatomic cardiac diseases
   - Hepatic and cerebral arteriovenous malformations (AVMs)
   - Total anomalous pulmonary venous return
   - Pulmonary vein stenosis (isolated)
   - Pulmonary atresia
3. *Associations with Other Diseases*
   - Neuromuscular disease
   - Metabolic disease
   - Maternal drugs or smoking
   - – cyclooxygenase inhibitors
   - – selective serotonin reuptake inhibitors

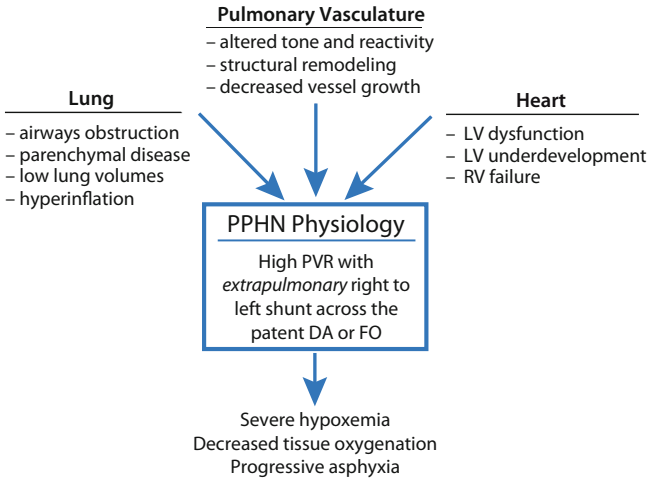

Fig. 67.1 Heart, lung and pulmonary vascular interactions in PPHN

including sustained elevation of PVR leading to hypoxemia due to right-to-left extrapulmonary shunting of blood flow across the ductus arteriosus (PDA) or foramen ovale (PFO). In many clinical settings, hypoxemic respiratory failure in term newborns is often presumed to be associated with PPHN-type physiology; however, hypoxemic term newborns can lack echocardiographic findings of extrapulmonary shunting across the PDA or PFO. Thus, PPHN should be reserved to describe neonates in whom extrapulmonary shunting contributes to hypoxemia and impaired cardiopulmonary function. Recent estimates suggest an incidence for PPHN of 1.9/1000 live births, or an estimated 7400 cases/year [31] (Fig. 67.1).

Diseases associated with PPHN are often classified into one of 3 categories: i) maladaptation: vessels are presumably of normal structural but have abnormal vasoreactivity; ii) excessive muscularization: increased smooth muscle cell thickness and increased distal extension of muscle to vessels which are usually non-muscular; and iii) underdevelopment: lung hypoplasia associated with decreased pulmonary artery number. This designation is imprecise, however, and high PVR in most patients likely involves overlapping changes among these categories. For example, neonates with congenital diaphragmatic hernia (CDH) are primarily classified as having vascular underdevelopment due to lung hypoplasia, yet lung histology of fatal cases typically shows marked muscularization of pulmonary arteries, and clinically, these patients can respond to vasodilator therapy. Similarly, neonates with meconium aspiration often have clinical evidence of altered vasoreactivity, but excessive muscularization is often found at autopsy.

As described above, autopsy studies of fatal PPHN demonstrate severe hypertensive structural remodeling even in newborns who die shortly after birth, suggesting that many cases of severe disease are associated with chronic intrauterine stress. However, the exact intrauterine events that alter pulmonary vascular reactivity and structure are poorly understood. Epidemiologic studies have demonstrated strong associations between PPHN and maternal smoking and ingestion of cold remedies that include aspirin or other non-steroidal anti-inflammatory products [32, 33]. Since these agents can induce partial constriction of the ductus arteriosus, it is possible that pulmonary hypertension due to antenatal ductal narrowing contributes to PPHN. Other perinatal stresses, including placenta previa and abruption, and asymmetric growth restriction, are associated with PPHN; however, most neonates who are exposed to these prenatal stresses do not develop PPHN. Circulating levels of L-arginine, the substrate for NO, are decreased in some newborns with PPHN, suggesting that impaired NO production may contribute to the pathophysiology of PPHN. It is possible that genetic factors increase susceptibility for pulmonary hypertension. A recent study reported strong links between PPHN and polymorphisms of the carbamoyl phosphate synthase gene [34]. However, the importance of this finding is uncertain and further work is needed in this area. Studies of adults with idiopathic primary pulmonary hypertension have identified abnormalities of bone morphogenetic protein (BMP) receptor genes; whether polymorphisms of genes for the BMP or TGF-β receptors, other critical growth factors, vasoactive substances

or other products increase the risk for some newborns to develop PPHN is unknown.

67.4 Clinical Physiology and Evaluation

Clinically, PPHN is most often recognized in term or near-term neonates, but clearly can occur in premature neonates as well. PPHN typically presents as respiratory distress and cyanosis within 6–12 hours of birth. While PPHN is often associated with perinatal distress, such as asphyxia, low APGAR scores, meconium staining, and other factors, idiopathic PPHN can present without signs of acute perinatal distress. Radiographic findings are variable, depending upon the primary disease associated with PPHN. Classically, the chest X-ray in idiopathic PPHN is oligemic, normally or slightly hyperinflated, and lacks parenchymal infiltrates. In general, the degree of hypoxemia is disproportionate to the severity of radiographic evidence of lung disease.

Not all term newborns with hypoxemic respiratory failure have PPHN physiology [35]. Hypoxemia in the newborn can be due to extrapulmonary shunt, as described above, in which high pulmonary artery pressure at systemic levels leads to right-to-left shunting of blood flow across the PDA or PFO. However in many infants intrapulmonary shunt or ventilation-perfusion mismatch, is the predominant abnormality, in which hypoxemia results from the lack of mixing of blood with aerated lung regions due to parenchymal lung disease, without the shunting of blood flow across the PDA and PFO. In the latter setting, hypoxemia is related to the amount of pulmonary arterial blood that perfuses non-aerated lung regions. Although PVR is often elevated in hypoxemic newborns without PPHN, high PVR does not contribute significantly to hypoxemia in these cases.

Several factors can contribute to high pulmonary artery pressure in neonates with PPHN-type physiology. Pulmonary hypertension can be due to vasoconstriction or structural vascular lesions that directly increase PVR. Changes in lung volume in neonates with parenchymal lung disease can also be an important determinant of PVR. PVR increases at low lung volumes due to dense parenchymal infiltrate and poor lung recruitment, or with high lung volumes due to hyperinflation associated with overdistension or gas–trapping. Cardiac disease is also associated with PPHN. High pulmonary venous pressure due to left ventricular dysfunction (e.g., asphyxia or sepsis) can also elevate PAP, causing right-to-left shunting, with little vasoconstriction. In this setting, enhancing cardiac performance and systemic hemodynamics may lower PAP more effectively than promoting pulmonary vasodilation. Thus, understanding the cardiopulmonary interactions is key to improving outcome in PPHN.

PPHN is characterized by hypoxemia that is poorly responsive to supplemental oxygen. In the presence of right-to-left shunting across the PDA, "differential cyanosis" is often present, which is difficult to detect by physical exam, and is defined by a difference in PaO_2 between right radial artery versus descending aorta values >10 torr, or an O_2 saturation gradient >5%. However, post-ductal desaturation can be found in ductus-dependent cardiac diseases, including hypoplastic left heart syndrome, coarctation of the aorta or interrupted aortic arch. The response to supplemental oxygen can help to distinguish PPHN from primary lung or cardiac disease. Although supplemental oxygen traditionally increases PaO_2 more readily in lung disease than cyanotic heart disease or PPHN, this may not be obvious with more advanced parenchymal lung disease. Marked improvement in SaO_2 (increase to 100%) with supplemental oxygen suggests the presence of V/Q mismatch due to lung disease or highly reactive PPHN. Most patients with PPHN have at least a transient improvement in oxygenation in response to interventions such as high levels of inspired oxygen and/or mechanical ventilation. Acute respiratory alkalosis induced by hyperventilation to achieve $PaCO_2$ <30 torr and a pH >7.50 may increase PaO_2 >50 torr in PPHN, but rarely in cyanotic heart disease.

The echocardiogram plays an important diagnostic role and is a useful tool for managing newborns with PPHN. The initial echocardiographic evaluation rules out structural heart disease causing hypoxemia or ductal shunting (e.g., coarctation of the aorta and total anomalous pulmonary venous return). Further, as stated above, not all term newborns with hypoxemia have PPHN physiology. Although high pulmonary artery pressure is commonly found in association with neonatal lung disease, the diagnosis of PPHN is uncertain without evidence of bidirectional or predominantly right-to-left shunting across the PFO or PDA. Echocardiographic signs suggestive of pulmonary hypertension (e.g., increased right ventricular systolic time intervals and septal flattening) are less helpful. In addition to demonstrating the presence of PPHN physiology, the echocardiogram is critical for the evaluation of left ventricular function and diagnosis of anatomic heart disease, including such PPHN mimics as coarctation of the aorta; total anomalous pulmonary venous return; hypoplastic left heart syndrome; and others. Studies should carefully assess the predominant direction of shunting at the PFO as well as the PDA. Although right-to-left shunting at the PDA and PFO is typical for PPHN, predominant right-to-left shunting at the PDA but left-to-right shunt at the PFO may help to identify the important role of left ventricular dysfunction to the underlying pathophysiology. In the presence of severe left ventricular dysfunction with pulmonary hypertension, pulmonary vasodilation alone may be ineffective in improving oxygenation. In this setting, efforts to reduce PVR should be accompanied by targeted therapies to increase cardiac performance and decrease left ventricular afterload. In the setting of impaired LV performance, cardiotonic therapies that increase systemic vascular resistance may further worsen LV function and increase pulmonary artery pressure. Thus, careful echocardiographic assessment provides invaluable information about the underlying pathophysiology and will help guide the course of treatment.

67.5 Treatment of PPHN

In general, therapy includes optimization of systemic hemodynamics with volume and cardiotonic therapy (dobutamine, dopamine, and milrinone), in order to enhance cardiac output and systemic O_2 transport. Failure to respond to medical management, as evidenced by the failure to sustain improvement in oxygenation with good hemodynamic function, often leads to treatment with extracorporeal membrane oxygenation (ECMO) [36]. Although ECMO can be a life-saving therapy, it is costly, labor intensive, and can have severe side effects, such as intracranial hemorrhage. Since arterio-venous ECMO usually involves ligation of the carotid artery, the potential for acute and long-term CNS injuries continues to be a major concern.

The goal of mechanical ventilation is to improve oxygenation, achieve optimal lung volume to minimize the adverse effects of high or low lung volumes on PVR, and to minimize the risk for lung injury (volutrauma). Mechanical ventilation using inappropriate settings can produce acute lung injury (ventilator-induced lung injury; VILI), causing pulmonary edema, decreased lung compliance and promotes lung inflammation due to increased cytokine production and lung neutrophil accumulation. The development of VILI is an important determinant of clinical course and eventual outcome of newborns with hypoxemic respiratory failure, and postnatal lung injury worsens the degree of pulmonary hypertension [37]. On the other hand, failure to achieve adequate lung volumes (functional residual capacity) contributes to hypoxemia and high PVR in newborns with PPHN. Some newborns with parenchymal lung disease with PPHN physiology improve oxygenation and decrease right-to-left extrapulmonary shunting with aggressive lung recruitment during high frequency oscillatory ventilation [38] or with an open lung approach of higher positive end-expiratory pressure with low tidal volumes, as more commonly utilized in older patients with ARDS [39].

Past studies have shown that acute hyperventilation can improve PaO_2 in neonates with PPHN, providing a diagnostic test and potential therapeutic strategy. However, there are many issues with the use of hypocarbic alkalosis for prolonged therapy. Depending upon the ventilator strategy and underlying lung disease, hyperventilation is likely to increase VILI, and the ability to sustain decreased PVR during prolonged hyperventilation is unproven. Experimental studies suggest that the response to alkalosis is transient, and that alkalosis may paradoxically worsen pulmonary vascular tone, reactivity and permeability edema [40, 41]. In addition, prolonged hyperventilation reduces cerebral blood flow and oxygen delivery to the brain, potentially worsening neurodevelopmental outcome. Overall, hyperventilation is currently not recommended for prolonged treatment of PPHN.

Additional therapies, including infusions of sodium bicarbonate, surfactant therapy and the use of intravenous vasodilators, are also highly variable between centers. Although surfactant improved oxygenation and reduced ECMO in some lung diseases, such as meconium aspiration and RDS, a multicenter trial showed benefit in infants with relatively mild disease, and failed to show a reduction in ECMO utilization in the subset of newborns with idiopathic PPHN [42]. The use of intravenous vasodilator drug therapy, with agents such as tolazoline, magnesium sulfate, prostacyclin and sodium nitroprusside, is also controversial due to the non-selective effects of these agents on the systemic circulation. Systemic hypotension may worsen right-to-left shunting, impair oxygen delivery and worsen gas exchange in patients with parenchymal lung disease. In addition, the initial response to agents such as tolazoline is often transient, and severe adverse effects such as gastrointestinal hemorrhage have been reported. Endotracheal administration of vasodilators, including tolazoline, sodium nitroprusside, and prostacyclin may cause selective pulmonary vasodilation and minimize systemic hypotension. However, these data are largely limited to animal studies, and evidence is needed to confirm the safety and efficacy of this approach in humans.

Inhaled nitric oxide (iNO) therapy at low doses (5–20 ppm) improves oxygenation and decreases the need for ECMO therapy in patients with diverse causes of PPHN (Fig. 67.2) [43–48]. Multicenter clinical trials support the use of iNO in near-term (>34 weeks gestation) and term newborns, although the use of iNO in infants less than 34 weeks gestation remains largely investigational. Studies support the use of iNO in infants who have hypoxemic respiratory failure with evidence of PPHN, who require mechanical ventilation and high inspired oxygen concentrations. The most common criterion employed has been the oxygenation index (OI; mean airway pressure times FiO_2 times 100 divided by PaO_2). Although clinical trials commonly allowed for enrollment with OI levels >25, the mean OI at study entry for these studies approximated 40. Whether treatment at lower OI levels reduces ECMO use is uncertain [49] (see Chapter 71).

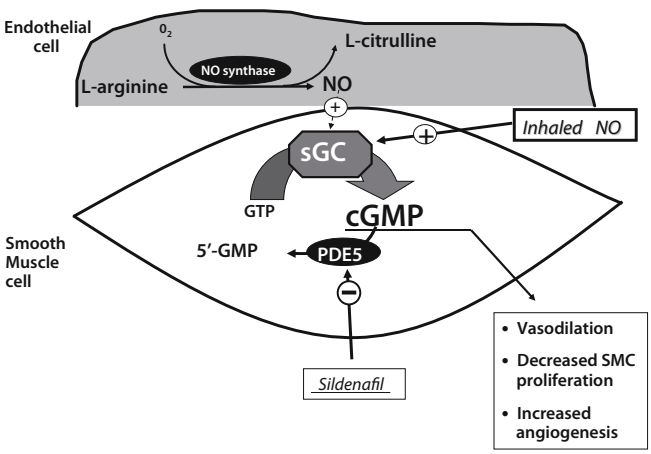

Fig. 67.2 Mechanisms of NO-cGMP Therapy in PPHN

In newborns with severe lung disease, HFOV is frequently used to optimize lung inflation and minimize lung injury. The combination of HFOV with iNO often enhances the improvement in oxygenation in newborns with severe PPHN complicated by diffuse parencyhmal lung disease and under inflation (e.g., RDS, pneumonia). A randomized, multicenter trial of infants with severe PPHN demonstrated that treatment with iNO in combination with HFOV was successful in many patients who failed to respond to HFOV or iNO alone [46]. For patients with PPHN complicated by severe lung disease, response rates for HFOV+iNO were better than HFOV alone or iNO with conventional ventilation. In contrast, for patients without significant parenchymal lung disease, both iNO and HFOV+iNO were more effective than HFOV alone. This response to combined treatment with HFOV+iNO likely reflects both improvement in intrapulmonary shunting in patients with severe lung disease and PPHN (using a strategy designed to recruit and sustain lung volume, rather than to hyperventilate) and augmented NO delivery to its site of action. Although iNO may be an effective treatment for PPHN, it should be considered only as part of an overall clinical strategy that simultaneously addresses the role of parenchymal lung disease, cardiac performance, and systemic hemodynamics.

Although clinical improvement during inhaled NO therapy occurs with many disorders associated with PPHN, not all neonates with acute hypoxemic respiratory failure and pulmonary hypertension respond to iNO. Several mechanisms may explain the clinical variability in responsiveness to iNO therapy. As noted above, an inability to deliver NO to the pulmonary circulation due to poor lung inflation is a major cause of poor responsiveness. In addition, poor NO responsiveness may be related to myocardial dysfunction or systemic hypotension, severe pulmonary vascular structural disease, and unsuspected or missed anatomic cardiovascular lesions (such as total anomalous pulmonary venous return, coarctation of the aorta, alveolar capillary dysplasia, pulmonary interstitial glycogenosis, surfactant protein deficiency, and others). Since iNO is usually delivered with high concentrations of oxygen, there is also the potential for enhanced production of reactive oxygen and reactive nitrogen metabolites, both of which may contribute to vasoconstriction and/or inadequate responses to iNO.

While hyperoxic ventilation is standard therapy for PPHN, high FiO_2 may be toxic to the developing lung through formation of ROS [47]. As noted above, iNO responsiveness may be blunted after even brief (30 minutes) periods of ventilation with 100% O_2, and that oxidant stress alters NO responsiveness in part through increasing expression and activity of cGMP-specific phosphodiesterases [24, 50].

The pulmonary vasodilator response to iNO is mediated primarily by the generation of cGMP after activation of soluble guanylate cyclase (sGC). This effect is limited by high PDE5 activity, which rapidly metabolizes cGMP, and decreases the ability of iNO or other agonists to sustain vasodilation [51]. Recently approved by the FDA for the treatment of adult chronic pulmonary hypertension, sildenafil is a potent and highly specific PDE5 inhibitor that has been used in several preclinical studies in animal models. For instance, in lambs with experimental pulmonary hypertension, both enteric and aerosolized sildenafil dilate the pulmonary vasculature and augment the pulmonary vascular response to iNO [52, 53]. Intravenous sildenafil was found to be a selective pulmonary vasodilator with efficacy equivalent to inhaled nitric oxide in a piglet model of meconium aspiration, although hypotension and worsening oxygenation resulted when sildenafil was used in combination with iNO [54, 55]. Data have only recently begun to emerge on the use of sildenafil alone or in combination with iNO in clinical populations, and investigations in newborn infants have been limited because sildenafil is currently available only in enteric form. A recent report demonstrated that enteric sildenafil improved oxygenation and survival in human infants with PPHN compared to placebo [56]. Preliminary findings from a pilot study of intravenous sildenafil in newborns with pulmonary hypertension indicate that the infusion was generally well tolerated, with improvements in oxygenation noted in the cohorts that received higher infusion doses [57].

Prostacyclin is a potent vasodilator that causes pulmonary vasodilation through stimulation of adenylate cyclase to increase intracellular cAMP levels. Although iv prostacyclin may worsen gas exchange in PPHN patients with lung disease and systemic vasodilation, inhaled PGI_2 may enhance oxygenation in infants that are poorly responsive to iNO [58]. Another potential approach taking advantage of cAMP signaling is inhibition of phosphodiesterase type 3 (PDE3) that metabolizes cAMP. Milrinone, a PDE3 inhibitor, has been shown to decrease pulmonary artery pressure and resistance, and to act additively with iNO in animal studies. A recent report indicates that the addition of intravenous milrinone to neonates with severe PPHN and poor iNO responsiveness was associated with improvements in oxygenation without compromising hemodynamic status [59]. Milrinone is of additional benefit by lowering systemic afterload in the setting of PPHN newborns with poor LV function.

67.6 Pulmonary Vascular Disease in Congenital Diaphragmatic Hernia

Advances in our understanding of PPHN physiology and its treatment has led to marked reductions in morbidities and the need for ECMO therapy. However, ECMO remains an effective and potentially life-saving rescue modality for severe PPHN. Of multiple diseases associated with PPHN, neonates with congenital diaphragmatic hernia (CDH) are often refractory to therapy and continue to have high ECMO use and mortality. CDH occurs in roughly 1:3,000 births and is a complex disease of varying degrees of severity, which includes elements of lung hypoplasia with reduced alveolarization and

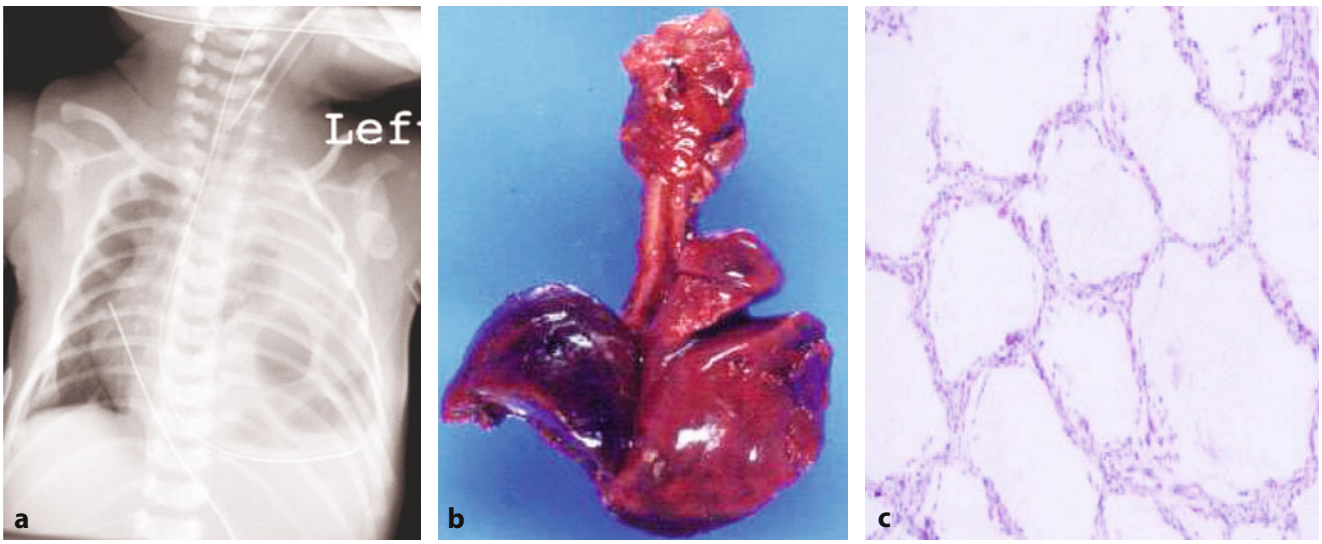

Fig. 67.3 Congenital diaphragmatic hernia (CDH): radiographic (**a**), anatomic (**b**) and histologic (**c**) aspects

lung size; pulmonary vascular disease; and cardiac dysfunction (Fig. 67.3) (reviewed in [60]).

Pulmonary vascular disease in CDH is more severe than most forms of PPHN due to the combinations of high tone and abnormal vasoreactivity, structural remodeling of the vessel wall and marked reduction in vascular density associated with lung hypoplasia [61]. Data from experimental models and clinical studies have clearly shown that abnormalities of lung vascular growth during late fetal life play a significant role in the pathophysiology of CDH and long-term outcomes. For example, fetal echocardiography and MRI studies have shown that decreased left pulmonary artery blood flow and impaired vasodilation with brief maternal hyperoxia in utero is strongly associated with the severity of lung hypoplasia and mortality [62]. In addition, lung histology of infants who die early with CDH and pulmonary hypertension shows substantial vascular remodeling (Fig. 67.4). Severe pulmonary hypertension in CDH is not due to reduced vascular growth alone, and intrauterine stimuli lead to marked hypertensive structural changes as well.

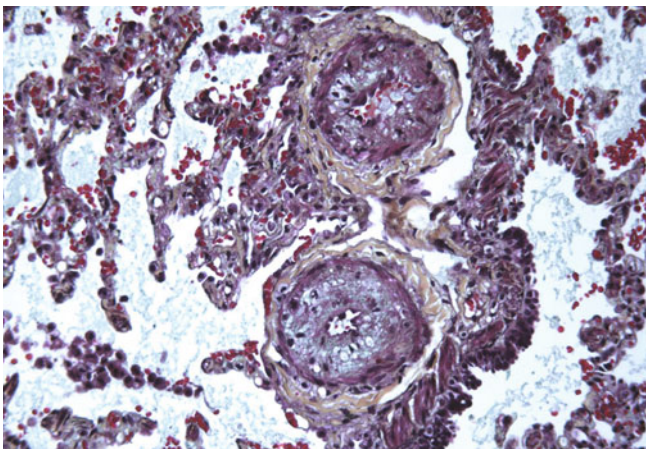

Fig. 67.4 Lung hystology of infant with CDH and PPHN

Early descriptions of inhaled NO in CDH infants showed that some infants have marked and sustained increases in PaO_2 with reduction of PVR, suggesting that high tone contributed to pulmonary hypertension in these cases. However, clinical trials suggest poor responsiveness in CDH overall [63]. Differences in outcomes regarding inhaled NO therapy between babies and centers suggest variability in disease severity, reflects different components of cardiac, pulmonary and vascular components to their disease (as discussed above; Fig. 67.1), differences in management between centers and other factors. Perhaps a major factor is the relative contribution of more severe structural lung vascular disease in non-responders. Such structural features, including smooth muscle cell hyperplasia, adventitial thickening and intimal occlusion (in severe cases), along with reduced lung alveolar-vascular surface area, contribute to the failure of neonates with severe CDH to respond to conventional therapies as well as patients with other causes of PPHN [43]. In addition to difficulties with pulmonary hypertension during the early neonatal period, infants with CDH are also at risk for prolonged and late pulmonary hypertension (Table 67.2) [61].

Sustained pulmonary hypertension in CDH, despite aggressive therapies, is strongly linked with high mortality [64]. Recent approaches to improve outcomes with severe CDH include earlier use of HFOV, delayed repair until evidence of hemodynamic stability and improved pulmonary hypertension is achieved, the use of prostaglandin E1 to maintain ductal patency with severe disease, augmentation of LV function with milrinone, and the use of additional pulmonary hypertension therapies beyond inhaled NO alone. These latter

Table 67.2 Stages of pulmonary hypertension in congenital diaphragmatic hernia

– Early (hours to weeks) - severe PPHN, but with variable contributions of lung disease and LV abnormalities (size, function)
– Late (weeks to months) - PH remains high, often near systemic levels, which can persist despite weaning from mechanical ventilation
– Chronic (months to years) - significant PH despite stable respiratory course

agents include sildenafil and bosentan, which are being used more readily in severe or late pulmonary hypertension in CDH infants [65]. More studies are needed to improve pulmonary hypertension therapies to enhance short and long-term outcomes of infants with CDH.

67.7 Summary

PPHN is a clinical syndrome that is associated with diverse cardiopulmonary diseases, with pathophysiologic mechanisms including pulmonary vascular, cardiac and lung disease. Experimental work on basic mechanisms of vascular regulation of the developing lung circulation and models of perinatal pulmonary hypertension has improved our therapeutic approaches to neonates with PPHN. Inhaled NO has been shown to be an effective pulmonary vasodilator for infants with PPHN, but successful clinical strategies require meticulous care of associated lung and cardiac disease. More work is needed to expand our therapeutic repertoire in order to further improve the outcome of the sick newborn with severe hypoxemia, especially in patients with CDH and advanced structural vascular disease.

Treatment of Respiratory Failure: Mechanical Ventilation

Colin J. Morley

68.1 Introduction

Respiratory diseases, with different etiologies, are one of the major problems in neonatal medicine and one of the main reasons for an infant receiving intensive care support. Without respiratory support many ill newly born infants would die.

Respiratory support can be given with several different techniques. From the least intensive to the most intensive they are: additional oxygen, continuous positive airways pressure (CPAP), bi-level CPAP or nasal ventilation, untriggered mechanical ventilation, triggered mechanical ventilation and high frequency oscillatory ventilation. This chapter will only present information about mechanical ventilation.

In any discussion of mechanical ventilation it is important to define the terminology of spontaneous inspiration and mechanical ventilation because this can be confusing.

It is important to realize that only people have breaths and ventilators deliver inflations.

- A *breath* is a spontaneous inspiration by an infant.
- An *inspiration* is a breath taken by the baby.
- An *inflation* is a pressure applied to the airways by a ventilator with the intention of inflating the lungs.
- *Spontaneous expiration* is gas leaving the lung after a breath.
- *Ventilator expiration* is gas leaving the lung after an inflation.
- *Inspiratory time* is the time during which a baby inspires.
- *Inflation time* is the duration of a mechanical inflation.
- *Ventilator expiration time* is the expiration time set on the ventilator.
- *Expiration time* is the time gas leaves the lungs after an inspiration or expiration until a new inflation or inspiration occurs.

68.2 Problems with Mechanical Ventilation of Infants

Mechanical ventilation is associated with a number of problems so it is most important not to ventilate an infant unless it is absolutely necessary.

The problems with ventilation are:

- Gas is pushed into the lungs rather than sucked in. This is unphysiological. It is much more effective for lung aeration and blood circulation through the lungs to have a negative pressure with each inspiration.
- The endotracheal tube (ETT) by passes the larynx. This may lower the residual lung volume because the larynx is very important for maintaining lung volume during lung disease. During expiration it may narrow or close to reduce the expiratory flow and maintain lung volume [1].
- An ETT increases resistance to gas flow and breathing.
- Inflations can injure the airways and alveoli [2]. This is by several mechanisms. 1) Volutrauma where the tidal volume is too high and the over-distension injures the lungs [3]. 2) Repeated expansion and collapse of atelectatic areas of the lung – called atelectrauma [4]. 3) Barotrauma where repeated high ventilator pressures damage the lungs. 4) Injury from the ETT in the airway.
- Ventilation increases infection.
- Mechanical ventilation may interfere with the baby's control of breathing and blood gases.
- We still do not have good rules about when to start ventilation, how to prevent lung damage, the optimal way to wean the ventilation and extubate the infant, or when to stop ventilation.

68.3 Indications for Mechanical Ventilation

The major reason for ventilating an infant is apnea. However, the difficult decision comes with deciding when to ventilate an infant who is very premature, or breathing with retraction

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

of the lower chest wall, or requiring oxygen treatment, or having numerous apneic episodes.

Intubation and ventilation of very premature babies with respiratory difficulty soon after birth used to be considered mandatory. However, it is now realized that even very premature babies can often be supported with CPAP alone particularly if treated early with caffeine [5].

68.3.1 Apnea

Apnea unresponsive to stimulation, nasal CPAP, caffeine and hand ventilation for a short time, is an absolute indication for mechanical ventilation.

There are few other absolute guidelines about when to ventilate a baby. It is often a matter of clinical judgment and local policy, considering the infant's gestational age, and other factors.

68.3.2 Respiratory Failure

The first question is does the infant have respiratory failure? An arterial $PaCO_2$ that has risen above 60 mmHg (~8 kPa) is a good sign of respiratory failure. However, this judgment should not be made on the first blood gas measurement, unless the baby is obviously very ill, because many babies improve over the first hour or two with careful and gentle management and after the baby has been appropriately positioned and nasal CPAP has been used.

A capillary CO_2 is not accurate enough for making the decision to ventilate an infant because it might be spuriously high in an infant with poor peripheral circulation.

A severe uncompensated metabolic acidosis may be an indication for ventilation.

68.3.3 Oxygenation

A high and rising FiO_2, despite treatment with nasal CPAP, is a strong pointer to the need for ventilation. There is little consensus about the FiO_2 that should be used to determine when a baby should be ventilated. To a certain extent the FiO_2 does not matter if the PaO_2 is maintained. However, a high FiO_2 is a sign that there is a low lung volume. Oxygen is toxic to the lungs and the higher it is the more likely lung injury occurs. Pragmatically, an FiO_2 of 0.60 or higher is an indication for ventilation in a very premature infant treated with CPAP [6].

The criteria for ventilation may vary depending on the size of the baby. Babies born at <26 weeks gestation may need earlier ventilator support because of their extreme immaturity. More mature babies, are stronger and ventilation should not be used unless absolutely necessary.

68.4 Investigations

68.4.1 Arterial Blood Gas Measurements

Understanding and assessing arterial blood gases is one of the most important aspects of the care of a baby with respiratory failure. Unless the baby has mild RDS, as indicated by a low FiO_2 and minimal dyspnoea, an arterial line should be inserted to enable easy and repeated measurement of arterial blood gases. A ventilated baby will require several accurate blood gases in the first days and so an arterial line is optimal for the baby and carers. Capillary blood gases can be misleading and venous blood gases should not be used to assess the respiratory function.

68.4.2 Chest X-ray

An anterior/posterior chest X-ray should be done as early as possible to confirm the respiratory diagnosis and exclude diagnoses that may need different treatment. If umbilical arterial and/or venous lines have been used the X-ray should include the abdomen to show their position.

68.4.3 Investigate Infection

Infection must always be suspected in babies presenting with respiratory failure soon after birth because it cannot be excluded, even in babies born by cesarean section. Infection at this age usually causes septicemia and can be quickly life threatening if antibiotics are not given quickly. Blood cultures, gastric aspirate microscopy and culture, and blood tests for indicators of infection should be taken and then intravenous antibiotics given. Penicillin and gentamycin are safe and effective.

68.5 The Basic Principles of Mechanical Ventilation

Several aspects of ventilation need to be adjusted to optimize the blood gases, lung volume, tidal volume and minute volume, and minimize lung injury.

68.5.1 Improving Oxygenation

Oxygenation can be improved by increasing the FiO_2. However, the higher the FiO_2 the greater the chance of lung injury because high levels are toxic to the epithelium. Therefore

other techniques should be used to improve oxygenation and reduce the need for a high FiO_2.

Oxygenation is not dependant on the movement of gas in and out of the lungs. It only requires oxygen to enter the lungs and an appropriate surface area for diffusion.

Adequate oxygenation depends on ensuring the lungs are expanded with a good surface area for gas exchange [7]. Oxygenation is closely related to the PEEP or mean airway pressure used because this is the key factor to maintain lung volume in an intubated infant with lung disease. The level of PEEP should be between 5 and 10 cmH_2O. There is no easy guide to the exact level to use in any baby at any time. PEEP can be increased when a high FiO_2 is used or when the chest X-ray shows low lung volume.

Controlling the PEEP depends on clinical assessment, chest X-ray appearance and FiO_2. PEEP can be increased to open the lungs if the FiO_2 is high and the chest X-ray also shows the lungs to be under inflated. The levels of PEEP to use in different situations have not been determined.

Altering peak pressure or inflation and expiration times will alter the mean airway pressure, and have some effect on oxygenation, but adjusting these is not as effective at altering oxygenation as changing PEEP.

In a normal lung high PEEP may cause oxygenation to deteriorate by compressing the alveolar capillaries. However, there is no evidence this is a problem in babies ventilated for respiratory failure unless increased to a very high level.

Oxygenation is dependant on the lungs being appropriately perfused. Inadequate oxygenation may be due to low blood pressure or pulmonary hypertension. Therefore to ensure optimal pulmonary perfusion and oxygenation the blood pressure must be maintained.

Primary pulmonary hypertension, with right to left shunting of venous blood past the lungs, can be recognized when a baby has a high FiO_2 to obtain a satisfactory PaO_2 yet the $PaCO_2$ is easily controlled. The chest X-ray shows lungs with a normal volume and reduced vascular markings. Echocardiography is used to confirm the diagnosis.

One problem to be aware of is when the peak inflating pressure (PIP) is progressively increased to try and improve oxygenation but the oxygenation deteriorates. This may be because the pressure is causing over-distension and interfering with pulmonary blood flow. A pointer to this is that oxygenation improves when the baby is transiently disconnected from the ventilator.

68.5.2 Controlling the Blood Level of Carbon Dioxide

CO_2 control is related to moving gas in and out of the lung. Inadequate spontaneous breathing is the primary reason for ventilation. Altering the tidal volume and ventilator rate controls the $PaCO_2$. Careful control of the $PaCO_2$ is very important. Over ventilation causing hypocarbia ($PaCO_2$ <30 mmHg) is strongly associated with chronic lung disease and adverse neurodevelopmental outcomes [8]. Hypercarbia ($PaCO_2$ >60 mmHg) may also be damaging because it causes acidosis and increased cerebral perfusion. The normal $PaCO_2$ range for a ventilated baby is about 35–60 mmHg.

During ventilation the tidal volume is determined by the applied pressure i.e., PIP – PEEP and the baby's breathing. Neonatologists think of neonatal ventilation in terms of applied pressures and the effect they have on the $PaCO_2$, however the pressure is a proxy for the tidal volume. The higher the PIP the greater the tidal volume delivered. Most modern neonatal ventilators measure and display tidal volume so this can now be targeted. Large tidal volumes can damage the lungs very quickly – called volutrauma. The appropriate tidal volume for ventilated spontaneously breathing babies is around 3.5–6 mL/kg depending on the ventilator rate. If the $PaCO_2$ is too high or too low the tidal volume (or peak inflating pressure) is altered a little (0.5 mL/kg or 2 cmH_2O) and the $PaCO_2$ rechecked in about 30 minutes.

The ventilator rate should be adequate to ensure the $PaCO_2$ is in the normal range. Most babies are ventilated while breathing. They breathe between 50 and 90/min. Modern ventilators enable inflations to be triggered and synchronized with each breath to assist the baby's respiratory efforts. This is called assist control mode of ventilation. This means that the baby triggers inflations and controls the ventilator rate and to some extent the minute volume. With triggered ventilation the back-up rate should be set at about 30/min, well below the baby's spontaneous rate. The product of ventilator rate and tidal volume is the minute volume. The minute volume should be ~ 200–300 mL/kg/min.

The $PaCO_2$ is related to the minute volume and so it can be increased or decreased by altering ventilator rate. However, because ventilated babies are spontaneously breathing and triggering the ventilator, altering the set rate may have little effect on the delivered minute volume.

68.5.3 Heating and Humidification of Ventilation Gases

Inspired gases are heated and humidified by the nose, pharynx and upper respiratory mucosa. They are delivered to the lungs at 37°C and with a saturation of 100%.

Medical gases are 100% dry and cold. An ETT by-passes the upper airway and so all heating and humidification of the gases must be from a heater humidifier in the circuit. Even slightly cold gases or dry gases quickly thicken the mucus and damage the mucosa. It is important to ensure that all gas reaches the lungs at no less than 37°C and carries 44 mg% H_2O (100% relative humidity) [9]. Any condensation of water vapor from the inspired gas is a loss of humidity and must be avoided by using a heated inspiratory ventilator circuit.

68.5.4 Measuring Blood Gases

During mechanical ventilation, adjusting the ventilator settings in response to frequently measured blood gases is necessary for control of $PaCO_2$ and pH. The frequency depends on the stability of ventilation. In the acute phase, when the lung function is changing, blood gases should be measured no more than 30 minutes after a change in ventilator settings. Transcutaneous measurements of CO_2 can be useful, give quick feed back about changes in CO_2 and reduce the number of blood gases measured but are prone to drift.

68.5.5 Monitoring Ventilator Parameters

Most modern ventilators have numerical and graphical displays of ventilator parameters. It is important these are understood and interpreted correctly. The most useful graphical display is pressure, flow and tidal volume against time with a horizontal axis showing about ten seconds worth of waveforms. See Figs. 68.1–68.6 for recordings during different ventilator modes and their interpretation [10].

68.5.5.1 Pressure Wave

This shows the ventilator pressure wave changing with inflations. It shows the level of PEEP and how this changes with spontaneous inspirations, the onset of inflation, the rate of rise of the pressure, whether the set PIP is achieved and whether there is any pressure plateau.

68.5.5.2 Flow Wave

This shows the gas flow changing as the baby breathes and the ventilator inflates. Flow above the zero line is down the ETT, flow below the zero line is flow out of the ETT. It displays: a small inspiratory flow immediately before inflation that triggers inflation; any flow from spontaneous breaths not associated with inflations; the gas flow during inflations; enables comparison of inflation and expiratory flow curves and whether there is any gas leak during inflation; any interaction between the spontaneous breaths and inflations; whether the inflation time is adequate; whether the expiratory time is appropriate for full expiration; whether there is gas trapping; diaphragmatic braking; or any obstruction or splinting against the inflations.

68.5.5.3 Tidal Volume Wave

This shows the volume of gas passing down the ETT as an up stroke, the volume of gas leaving the lung as a downward curve and any gas leak around the ETT as a vertical line at the end of each inflation.

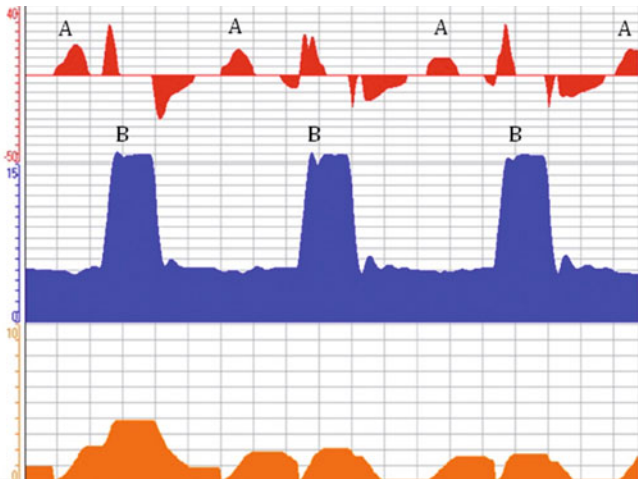

Fig. 68.1 This shows about 3.8 seconds of a recording of CMV with the flow wave at the top with gas going down the ETT above the zero line and gas coming out of the ETT below the zero line. The pressure wave is in the middle showing 5 cmH_2O PEEP pressure and 16 cmH_2O peak pressure. The bottom line shows the tidal volume wave. At "A" the baby is inspiring, the PEEP falls slightly and there is an inspiratory tidal volume. At "B" the ventilator pressure rises to a plateau for the inflation time of about 0.3 sec. This results is an inflationary tidal volume about the same size as the baby's inspiratory volume. It can be seen that ventilator inflations and baby's inspirations and expirations are completely out of synchrony.

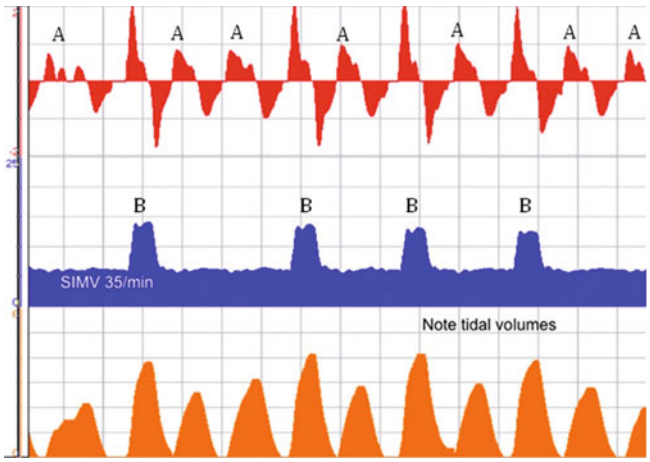

Fig. 68.2 This shows about 9 seconds of a recording of SIMV at a rate of 35/minute with the flow wave at the top with gas going down the ETT above the zero line and gas coming out of the ETT below the zero line. The pressure wave is in the middle showing about 6 cmH_2O PEEP pressure and 14 cmH_2O peak pressure. The bottom line shows the tidal volume wave. At "A" the baby is inspiring without ventilator inflations. There is an inspiratory and expiratory tidal volume of about 2–3 mL. At "B" the ventilator pressure rises to a plateau for the inflation time of about 0.3 sec. This results in an inflationary tidal volume about 20% larger than the baby's tidal volume. What cannot be seen is that these inflations were triggered by the baby's inspiratory flow and so the tidal volumes are a combination of the baby's breathing and synchronous inflation. The baby is breathing at about 75 breaths per minute. It can be seen that baby makes about seven inspirations without ventilator support and four with ventilator support. Out of a combined tidal volume during this time of about 34 mL the ventilator has contributed only 4 mL. It would appear that this baby probably does not need to be ventilated.

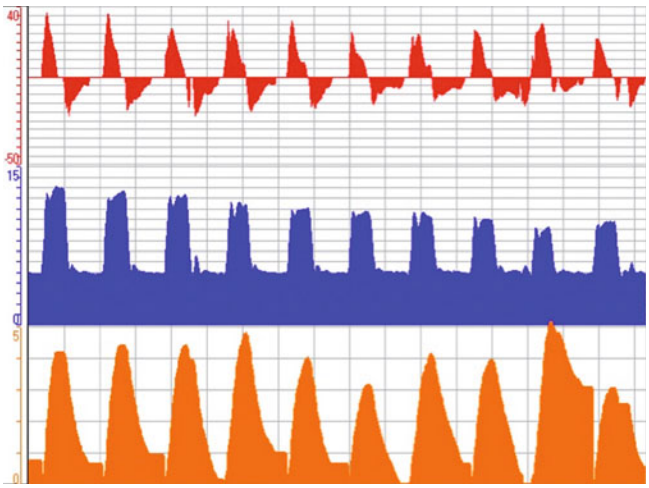

Fig. 68.3 This shows about 9 seconds of a recording of A/C (SIPPV) and volume guarantee mode at a set rate of 50 /min with the flow wave at the top with gas going down the ETT above the zero line and gas coming out of the ETT below the zero line. The pressure wave is in the middle showing about 6 cmH_2O PEEP pressure and the PIP changing from 13 down to 11 cmH_2O. The bottom line shows the tidal volume wave. Each of the baby's inspirations triggered an inflation and drove the ventilator at about 65/min. There is an inspiratory and expiratory tidal volume varying slightly between 4 mL and 6 mL with variable a leak. This shows how well A/C ventilation supports each of the baby's breaths and how volume guarantee changes the pressure to try and maintain the tidal volume as the baby changes its breathing.

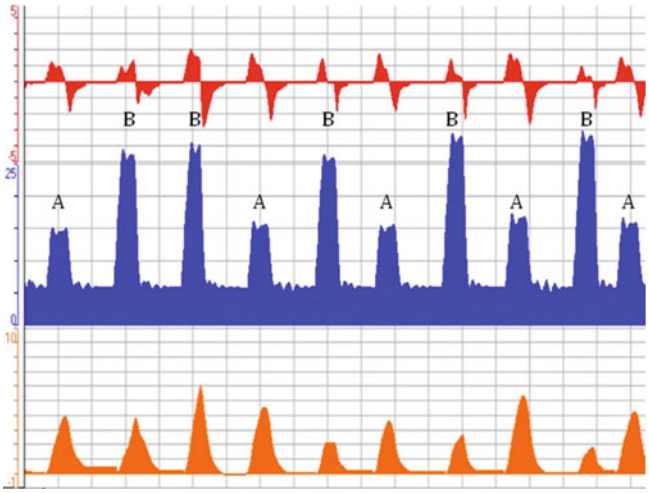

Fig. 68.4 This shows about 9 seconds of a recording of A/C (SIPPV) and volume guarantee mode at a set rate of 50/min with the flow wave at the top with gas going down the ETT above the zero line and gas coming out of the ETT below the zero line. The pressure wave is in the middle showing about 6 cmH_2O PEEP pressure. The PIP changes from about 15 cmH_2O to about 30 cmH_2O. The bottom line shows the tidal volume wave. The waves marked A are triggered inflations with a lower PIP and the waves marked B are untriggered inflations with a much higher PIP. This is happening because the volume guarantee program targets triggered and untriggered PIP separately. The pressures are changing slightly to try and produce the set tidal volume of 4.5 mL. Note even though there is a large difference in the driving pressure the tidal volume for triggered and untriggered inflations are similar and sometimes the untriggered inflations with the higher PIP have the smaller tidal volumes. There is an inspiratory and expiratory tidal volume varying slightly between 4 mL and 6 mL with variable a leak. This shows the problem of having the back up rate very close to the baby's spontaneous rate. The ventilator frequently changes from triggered to untriggered inflations.

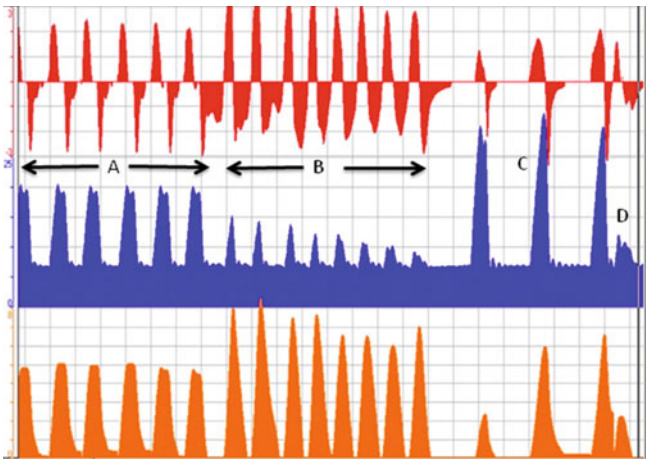

Fig. 68.5 This shows about 13 seconds of a recording of A/C (SIPPV) and volume guarantee mode at a set rate of about 50/min with the flow wave at the top with gas going down the ETT above the zero line and gas coming out of the ETT below the zero line. The pressure wave is in the middle showing about 7 cmH_2O PEEP pressure. The PIP changes to try and maintain the set tidal volume 5 mL. The bottom line shows the tidal volume wave. The group of waves marked A are all triggered inflations with a stable tidal volume. The group of waves marked B are all triggered inflations but here the tidal volume has suddenly increased because the baby started breathing hard with inflation tidal volume of more than 130% of the set tidal volume. The volume guarantee program reacts by stopping the inflations. Note their inflation times are shorter. The PIP is lower and reducing each inflation to try and bring the tidal volumes back to the set level. At C there are 3 large inflations at a slower rate. These are untriggered inflations at the back-up rate and have PIPs that correspond to the PIP of previous untriggered inflations. At D the baby inspires and a much smaller triggered PIP is delivered. This all shows the dynamic nature of the volume guarantee program responding to large changes in the infants breathing pattern.

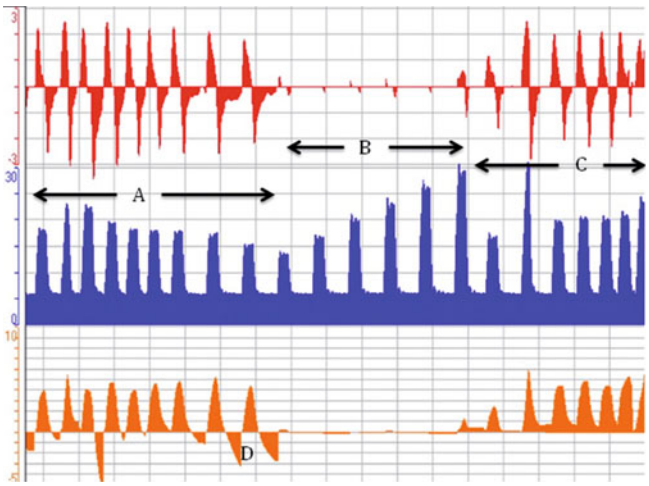

Fig. 68.6 This figure shows A/C volume guarantee ventilation. At A the inflations are all triggered and the PIP changes a little to maintain the tidal volume. At B the infant splints against the ventilator inflations and stops the flow and tidal volumes even though an inflation is being delivered. As the tidal volume is lower than set the volume guarantee program uses untriggered, back-up, inflations and increases the PIP by 3 cmH_2O every inflation until the baby starts breathing again at C, except for one untriggered inflation. Note at D there are expiratory tidal volumes larger than the inspiratory ones. This often happens just as the baby starts splinting and blowing down the lung volume.

68.6 Techniques of Mechanical Ventilation

This section will be illustrated from my experience and studies with using the Drager Babylog 8000+ ventilator and the Sensormedics 3100A high frequency oscillating ventilator for many years [11–26]. Other neonatal ventilators may have slightly different modes but the general principles of use are the same.

68.6.1 Conventional Mandatory Ventilation (CMV) or Intermittent Mandatory Ventilation (IMV)

CMV and IMV are exactly the same mode and use pressure limited, time cycled ventilation. The ventilator is adjusted to deliver a set PIP and a set PEEP with every inflation. There is no single PIP or PEEP that can be used for all babies under all circumstances. The starting PIP is chosen by experience e.g., 20 cmH_2O and the infant's chest wall movement assessed by observation. If this is considered to be too much the PIP is reduced. If there is none, or too little chest wall movement the PIP is increased. When changing PIP by observing chest movement remember in normal babies the movement with each breath is barely discernable. Subsequently, the PIP is adjusted according to the $PaCO_2$. There is no easy way to determine the appropriate PEEP for a baby and this usually starts at 5 cmH_2O.

The inflation time is usually set to 0.3 sec, as this is the mean inspiratory time of a ventilated preterm infant. If it is set longer the infant may breathe out during the ventilator inflation. The expiratory time is set to provide the desired respiratory rate, ~ 60 per minute.

See Fig. 68.1 for a recording of ventilator, flow and tidal volume waves during CMV showing the asynchrony between inflations and inspirations.

This is the only ventilator mode available on transport ventilators.

There are many problems with this mode of ventilation.

- It is unresponsive to the infant's respiratory efforts because it is not triggered or synchronized with the infant's breathing. It may inflate when the infant is breathing out or it may inflate on top of a large inspiration resulting in a very large tidal volume.
- The set PIP may be too high or too low for the infant resulting in over or under ventilation. Over ventilation can cause high tidal volumes, acute lung injury and the resulting hypocarbia is associated with periventricular leukomalacia.
- It provides little or no monitoring of the actual ventilation the baby receives.
- The ventilator rate cannot match the infant's respiratory rate, particularly as it changes.

68.6.2 Triggered Ventilation

The purpose of triggered ventilation is for the ventilator to inflate the infant in synchrony with the infant's inspiration and augment the inspiratory gas flow and tidal volume. With the Drager Babylog 8000 + ventilator triggering is from a hot wire flow sensor which is placed between the Wye piece of the ventilator circuit and the ETT. Two fine tungsten wires heated to 400°C detect the gas flow by the cooling effect of the gas. It detects inspiratory gas flow and when this has reached about 0.2 L/min, ~ 30 ms after the beginning of inspiratory flow an inflation is started. The delay time depends on the set trigger sensitivity on a scale of 1 to 10 with 1 being the most sensitive. This sensitivity should always be set to 1 so that the inflation occurs as close as possible to the onset of the baby's inspiration. A higher number will mean a longer delay between the onset of inspiration and the start of inflation resulting in a non-synchronous inflation.

A potential problem with flow triggering is that the sensor detects gas flow from condensed water bubbling in the ventilator circuit and this triggers an inflation even though the baby may not be inspiring at this time – so called auto-triggering. Some people reduce the sensitivity to prevent this, however, this causes an unacceptable delay between the onset of inspiration and the inflation. Ensuring the ventilator circuit is free of condensed water can prevent this.

Two other trigger mechanisms have been used.

1. Uses a capsule stuck on the abdomen to detect abdominal movement. This is unreliable. The effectiveness and accuracy depends on where it is placed on the abdomen. It may not detect the start of an inspiration. On many occasions it triggers on expiration.
2. Using a change in the pressure in the ventilator circuit depends on the baby making a sufficiently large inspiration to change the circuit pressure (~0.5 cmH_2O). It is inaccurate if the baby is very small or has a low inspiratory effort.

Some people worry that adding a flow sensor increases the dead space and thereby increases the infant's $PaCO_2$. This is rarely a problem because as an uncuffed ETT is sued there is almost always a leak around the ETT. Even with no leak the effect on $PaCO_2$ is small and not of clinical significance compared with the gains from using the sensor.

68.6.3 Synchronised Intermittent Ventilation (SIMV)

In this mode the ventilator is a pressure limited, time cycled ventilator but inflations are triggered by the baby's inspiratory gas flow in synchrony with a set number of inspirations. This means that not all the baby's inspirations are supported by a ventilator inflation e.g., if the baby is breathing at 80/min and the ventilator is set to deliver 30/min only 30 of the breaths will coincide with an inflation. For all other breaths the inspiration is through the ETT with only PEEP for support. It the baby is apneic the set ventilator rate is delivered.

The ventilator divides each minute by the set number of inflations, called the ventilator interval, e.g., if set to 60/min because the inflation time is 0.3 s and the expiratory time 0.7 s then the ventilator interval is 1 sec. If the rate is set to 30/min, inflation time 0.3 s and expiratory time 1.7 s the ventilator interval is 2 sec. The ventilator will deliver each inflation, triggered or untriggered, within each set ventilator interval.

See Fig. 68.2 for a recording of the pressure, flow and tidal volume waves during SIMV.

The problems with SIMV ventilation are:

- Not all inspirations are supported by an inflation.
- The unsupported breaths through the ETT increase the work of breathing and can lead to exhaustion.
- The tidal volume delivered may vary considerably from the triggered inflations to the spontaneous breaths and also due to the set PIP being delivered on top of the baby's tidal volumes.

When should SIMV be used? Because of the problems with spontaneous breaths not being supported by the ventilator it is inappropriate to use SIMV when the baby is initially ventilated or in respiratory failure. It may have a place when weaning ventilation but this can be a problem if the ventilator rate is set so low that the majority of the baby's breaths are unsupported. It has not been shown to be superior to A/C (SIPPV).

68.6.4 Assist Control (A/C) also Called Synchronised Intermittent Positive Pressure Ventilation (SIPPV)

In this mode inflations are triggered by all the baby's inspirations. So it inflates the baby in synchrony with each spontaneous inspiration. This is the most appropriate mode to use when the baby requires full ventilatory support [27–29].

It is pressure limited, time cycled ventilation and the PIP, PEEP, inflation time and expiratory time are set. However if the rate is less than the baby's rate the baby's inspiration controls the rate.

It is important to realize the purpose of A/C is to support all inspirations. If the ventilator rate (the back-up), is set too high the baby does not have enough time to make a breath before the mandatory inflation starts, the spontaneous breaths are overridden by the ventilator and the ability to trigger inflations and assist the infant is lost, e.g., if the back-up rate is 60/min then the infant will only trigger inflations if it breathes faster than 60/min. At this back-up rate only about half the baby's breaths will trigger an inflation [22]. It is "confusing" for the baby to be trying to breathe and suddenly have an inflation asynchronous with its inspirations. The main purpose of the A/C ventilation is lost. Therefore it is important to set the back-up rate slower, about 30/min, so all the baby's breaths can trigger an inflation. If the baby stops breathing the ventilator rate will be 30/min. Spontaneously breathing ventilated babies rarely become completely apneic for very long but obviously a rate of 30/min for several minutes after a spontaneous triggered rate of about 70/min would need careful monitoring.

See Fig. 68.3 for a recording of the pressure, flow and tidal volume waves during A/C ventilation.

People have told to me they worry that with A/C mode babies are more likely to become over ventilated if they trigger the ventilator all the time. In my experience this is no more of a problem than with other modes if the PIP is set to ensure reasonable average tidal and minute volumes. The clinicians need to carefully monitor the tidal volume and minute volume.

In A/C mode the baby mainly controls the ventilator rate and so if the $PaCO_2$ is low it is inappropriate to reduce the rate to reduce minute volume because the baby is controlling the rate. To control $PaCO_2$ PIP is the parameter to change.

68.6.5 Volume Guarantee Ventilation

One of the major complications from ventilating infants is acute lung injury leading to bronchopulmonary dysplasia. Volutrauma is one of the main causes of this. Tidal volumes of more than 8 mL/kg can cause volutrauma and so it is important to measure and control the tidal volume. This mode reduces volutrauma.

Traditionally, during neonatal ventilation altering the PIP has been used to change the $PaCO_2$. It is often forgotten, or not realized, that the PIP is a proxy for tidal volume and altering the PIP changes the tidal volume. The delivered PIP can now be changed to target a specified tidal volume. This should be in the range of 3.5–6.0 mL/kg depending on the baby's breathing rate and the ventilator back-up rate.

The volume guarantee mode specifically targets the delivery of an expiratory tidal volume set by the clinicians [30]. It works in all triggered modes: SIMV, A/C and PSV. The ventilator monitors expired tidal volume and determines whether it is higher, lower or identical to the set expired tidal volume. If it is higher the PIP is reduced for the next inflation and if the tidal volume is lower the PIP is increased to try and ensure the set tidal volume is achieved.

The volume guarantee mode controls the expired tidal volume very closely to the set tidal volume [30]. Analyses from 6693 inflations: mean (SD) for triggered expired tidal volume = 102% (29%) of set, range 0–378%; for untriggered = 97% (31%), range 0–322% [22]. It can be seen that there can be large variations in the tidal volume. This is due to the infant's breathing. If the infant takes breaths larger than the set tidal volume the ventilator cannot, and should not, prevent this. The ventilator response is to lower the PIP for subsequent inflations. If the inspired tidal volume is more than 130% then the inflation is stopped. Sometimes ventilated infants "splint" or contract their abdominal muscles very hard and completely stop an inflation. The response of the ventilator will be to increase the PIP in a stepwise fashion to try and restore the tidal volume. This overcomes the splinting, and consequent hypoxia, quicker than ventilation continuing with a set PIP.

See Figs. 68.3, 68.4, 68.5 and 68.6 for recordings of assist control with volume guarantee.

Some pressure limited ventilators have two inflating pressures called pressure support ventilation. In this mode the PIPs are set and not related to the delivered tidal volume for many inflations. However, in volume guarantee mode the PIP changes all the time to try and maintain the tidal volume in response to the infant's breathing.

There are several safety features with volume guarantee that ensure the tidal volume is safe and as accurate as possible.

- If the inflating tidal volume is more than 130% of the set expired tidal volume the current inflation is stopped.
- The PIP does not change, up or down, by more than 3 cm H_2O from one inflation to the next. This works independently for triggered and untriggered inflations [22].
- There is a separate control of PIP for triggered and untriggered inflations. This is because the baby is contributing to the delivered tidal volume and the PIP required with triggered inflations will be lower than with untriggered inflations where the tidal volume has to be achieved totally by the PIP.
- Sudden large changes in PIP can occur from one inflation to the next if the back-up rate is set too close to the infant's spontaneous rate because the ventilator changes from triggered to untriggered inflations with the untriggered inflations having a larger PIP than triggered ones. However, importantly it does not result in sudden large changes in tidal volume because these are being controlled. This over rides the algorithm for the PIP not changing from one inflation to the next by more than 3 cmH_2O.
- The PIP can be limited to a level the clinicians are comfortable with. However, this frequently causes the alarm "low tidal volume" when the ventilated needs to deliver a higher PIP to deliver the set tidal volume. It is important the ventilator is able to choose an appropriate PIP. A peak PIP of 35 cmH_2O is the lowest that should be set.

The expired tidal volume is used as the set tidal volume rather than inspired tidal volume because part of the inflation tidal volume is lost through leak around the ETT.

The volume guarantee automatically weans the PIP as the lungs heal, compliance and resistance improve and the baby breathes more effectively. If a baby generates a tidal volume larger that the set tidal volume the PIP may reach the PEEP level.

When ventilating with volume guarantee I always use the A/C mode so that every spontaneous breath triggers an inflation. With this combination of A/C and volume guarantee the baby's spontaneous rate controls the ventilator rate and the volume guarantee controls the PIP. Therefore to control the $PaCO_2$ the important control is the set tidal volume. This can be increased to reduce the $PaCO_2$ or lowered to increase the $PaCO_2$.

68.6.6 Pressure Support Ventilation

With the Drager 8000+ ventilator there is another triggered mode called pressure support ventilation (PSV). This is a confusing term because all the other modes are pressure supported. It is a mode that triggers expiration and therefore automatically controls the inflation time. The ventilator tracks the inflation flow curve as it rises and falls. As the flow decreases from the peak flow to 15% of the peak flow this triggers the ventilator to stop inflation. It automatically takes account of any leak flow. It is therefore important the expiratory time is set much longer than normal ventilation to allow the ventilator to increase the expiratory time if needed. An expiratory time of 0.6 sec would be appropriate even though the program will usually be choosing expiratory times nearer 0.3 sec.

The shape and timing of the inflation flow curve is dependant on the gas flow in the circuit. A high gas flow will result is a shorter inflation time and a low gas flow a longer inflation time. When ventilating a baby with a low gas flow e.g., 4 L/min then the pressure support mode is very valuable to pick the appropriate expiratory time. The advantage of this mode is that the infant cannot exhale against inflation.

68.6.7 High Frequency Ventilation

This mode of ventilation is used when "conventional" ventilation is unable to ensure satisfactory CO_2 exchange without using a high PIP (e.g., 30 cmH_2O or more) to deliver the tidal volume.

High frequency ventilation (HFOV) is done in different ways by different ventilators and so I will concentrate on the principles.

- The lung volume is produced and maintained by a continuous high mean airway pressure ~10–20 cmH_2O, not just an end expiratory pressure of ~5 cmH_2O.
- The tidal volume delivered is approximately equal to the infants dead space volume ~2 mL/kg.
- The ventilator rate is much higher than conventional ventilation at between 5 and 15 Hz (300–900 /min).

Adjusting three main parameters controls the ventilation:

1. The mean airway pressure (MAP). As this controls the lung volume and oxygenation is approximately proportional to lung volume the MAP is increased until the FiO_2 required to produce an appropriate PaO_2, is at the lowest that can be achieved. If the MAP is increased too much the oxygenation will deteriorate. It is best to start with a MAP slightly higher than that used on conventional ventilation and increase it until FiO_2 is optimized. Frequent chest X-rays will provide some information about the lung inflation, particularly whether the lungs are under inflated, one lung is collapsed, the lungs are seriously over inflated or there is air leak. Changing MAP has the same effect on all HFOV ventilators.
2. The amplitude of the ventilating pressure swing (ΔP). This is the change in the pressure that is driving the change in tidal volume. This is one controller of CO_2. The higher the ΔP the more CO_2 is removed. The best way to judge whether the ΔP is correct is to start low and increase it until the chest is seen to be just wriggling with the ventilator. It is very easy to quickly over-ventilate babies with HFOV and drive the $PaCO_2$ down to dangerous levels in a few minutes. To monitor, use a transcutaneous CO_2 sensor before HFOV is started. As the $PaCO_2$ falls ΔP is reduced accordingly. The ΔP is not very powerful with the Drager 8000+ and increasing it above 60% has little added benefit.
3. The high frequency rate also affects the $PaCO_2$. It is important to realize this is the opposite of conventional ventilation: as the rate is reduced the $PaCO_2$ is likely to fall and as the rate is increased the $PaCO_2$ rises. This is because at a lower rate the ΔP has more time and therefore is likely to increase removing more CO_2, as the rate increases the ΔP is reduced. It is best to start at ~ 8–10 Hz, adjust the MAP and ΔP to optimize the blood gases and only adjust the frequency if the $PaCO_2$ cannot be controlled at the frequency chosen. With the Drager Babylog 8000+ changing the rate has more effect on $PaCO_2$ than changing ΔP.

The advantages of HFOV are:

- Improvement in oxygenation by using a higher mean airway pressure than can be used in conventional ventilation modes.
- Better CO_2 removal in infants with very stiff lungs where a high PIP would be required to produce an appropriate tidal volume.

The disadvantages of HFOV are:

- It does not work with the baby's spontaneous intense breathing.
- The Sensormedics ventilator provides no feed-back to the clinicians.
- The Sensormedics ventilator has few alarms about the adequacy of ventilation. In fact the ETT can be clamped and no gas delivered to the baby and yet there is no alarm.
- It is very easy to over ventilate and produce hypocarbia with HFOV.
- It is not clear how well the infant is breathing or when the infant is ready for weaning.

68.7 Weaning the Infant from Ventilation

The longer the baby is intubated and ventilated the more likely infection will occur and neonatal chronic lung disease develop. It is therefore important to wean babies from the ventilator and extubate them as soon as possible.

The FiO_2 is reduced to maintain appropriate PaO_2 and SpO_2. The PIP (tidal volume) is reduced to maintain the $PaCO_2$ in the normal range.

When the FiO_2 and PIP have been reduced to ~ <0.40 and <16 cmH_2O respectively the lungs are improving and if the baby breathes adequately extubation may be possible.

Some people advocate reducing the ventilator rate in SIMV mode so that the baby has more spontaneous and less supported breaths. One problem is the unsupported breaths are made through the ETT and are ETT CPAP. This increases the work of breathing. This becomes significant if the ventilator rate is reduced below about 30/min. Lower rates are unnecessary because to maintain a normal $PaCO_2$ the baby will be breathing well.

Many babies can be extubated from A/C ventilation when the FiO_2 and PIP are low without the need for SIMV. Similarly, babies can be extubated from SIMV at 30/min.

To help decide whether a baby will breathe adequately after extubation the ventilator can be switched to ETT CPAP for ~ three minutes, and see how well the heart rate, SpO_2 and respiratory pattern are maintained [19]. A baby who can maintain the SpO_2 and heart rate on a few minutes ETT CPAP has a high chance of successful extubation. A baby who becomes bradycardic or hypoxic during this time is unlikely to breathe well after extubation.

Preterm babies should be treated with caffeine [31, 32] or theophylline before extubation. This increases the chance of

successful extubation. They should be extubated to nasal CPAP rather than straight to unsupported breathing. This has been shown to reduce the incidence of reintubation [33].

68.8 Managing Complications of Ventilation

68.8.1 Endotracheal Tube not in the Trachea

In order for a baby to be ventilated an ETT has to be passed into the trachea. This is not a simple procedure and it has been shown that this takes two or more attempts [34, 35]. It has also been shown that the person intubating the baby often thinks (hopes) that the ETT is in the trachea and it may take several minutes before they realize that the baby's failure to respond to the ventilation is because the ETT is not in the trachea. Some infants have been seriously compromised because the clinicians failed to appreciate they had intubated the esophagus. It is so important to ensure the ETT is in the trachea that after every intubation a CO_2 detector [36] or a gas flow detector are connected to the ETT so that expired CO_2 or the inspiratory and expiratory gas flow can be detected to ensure the ETT is properly placed.

68.8.2 Endotracheal Tube Inserted too far down into the Right Main Bronchus

If the ETT is either inserted too far, or it slips down after insertion, it will enter the right main bronchus. The left lung and right upper lobe will then not be ventilated. The diagnosis is made from a chest X-ray. The treatment is to withdraw the ETT to the appropriate level.

68.8.3 Accidental Extubation

Accidental extubation of a ventilated baby is a serious problem because the baby's condition may deteriorate quickly. Securing the ETT so it does not come loose can prevent it. Accidental extubation can be difficult to differentiate from other causes of a rapid deterioration. There are several ways to make the diagnosis. The quickest, most accurate technique is to watch the display of the ETT flow wave. If the ETT becomes dislodged the flow pattern immediately changes so there is flow down the ETT but not back up. Placing a carbon dioxide detector on the distal end of the ETT will also rapidly show whether CO_2 containing gas is coming out of the ETT [37]. This is rapid and sensitive. Other techniques, such as auscultation of both lungs and misting of the ETT are not so accurate. Inspection of the larynx with a laryngoscope is invasive but the only way to determine the position of the ETT if other methods are unavailable.

68.8.4 Pneumothorax

A tension pneumothorax is one of the commonest causes of acute deterioration in a ventilated baby. This is manifest by an increased FiO_2 and/or a rising $PaCO_2$ and increased ventilatory pressures when in volume guarantee mode. Occasionally it presents with apnea.

The diagnosis is made by seeing a pneumothorax on an urgent chest X-ray. Occasionally, the pneumothorax is not very obvious because the gas is anterior and with the baby lying supine the lung appears to fill the chest. One of the best radiological signs is an obvious clear demarcation around the heart, diaphragm or mediastinum. These are normally blurred in a baby with RDS. Transillumination of the chest with a bright light in darkened surroundings usually shows the hemithorax glowing. Although this is useful in an emergency it is not completely reliable and so a chest X-ray should always be obtained to confirm the diagnosis if possible.

The treatment is an intercostal drain, placed under strict sterile conditions, with the distal tubing underwater in a sealed bottle with suction applied to the outlet. The insertion site should be the 4th or 5th intercostal place in the anterior axillary line but away from the breast bud. The baby should be placed on his back with the affected side elevated so the body is at approximately 45° to the mattress. The drain is then inserted from the posterior lateral aspect. This ensures the drain passes anteriorly rather than posteriorly and therefore drains the air at the front of the chest. Under local anesthetic a small hole is made in the chest wall, just above a rib, and then enlarged appropriately with small artery forceps. These are used to introduce the catheter. A trocar should not be used because this increases the chance of perforating the lung.

68.8.5 Pulmonary Interstitial Emphysema

This mostly occurs in ventilated very premature babies. It can be a serious problem and may cause death if not treated promptly and effectively. In this condition gas tracks into the interstitial tissues and compresses the airways. It commonly occurs throughout one or both lungs and probably comes from a tear in the hilum where the gas is forced into the tissues. It causes a serious deterioration in the respiratory and clinical status of the baby. The diagnosis is made from the chest X-ray.

There are two important aspects to the treatment of PIE [38]. 1) Reduce the ventilator pressure, even if the $PaCO_2$ or FiO_2 rise as a consequence. However, do not compromise the baby's clinical and physiological stability to an extent where the baby may deteriorate. 2) Lay the baby with the affected side down and with the back at right angles to the mattress. The affected lung is dependant and slowly looses the PIE.

This is one of the best ways of treating PIE. If both lungs are effected, lay the baby so the worst lung is dependent. This treatment may lead to complete collapse of the dependent lung. This is a transient problem and with repositioning the lung usually reinflates without PIE.

68.9 Drug Treatments During Ventilation

68.9.1 Muscle Relaxing Drugs

In the past muscle relaxing drugs were commonly used for ventilated babies. This has now become uncommon, as neonatologists have realized that it is better to support the spontaneous breathing of the baby rather than take over ventilation completely. There is no evidence that the use of muscle relaxing drugs improves the outcome for babies with RDS [39]. In fact their use reduces venous return, causes edema, increases the ventilator pressure required and prolongs ventilation. They should only be used when babies are very difficult to ventilate and opposing inflation.

68.9.2 Caffeine

Caffeine when given to ventilated very premature babies has been shown to reduce the incidence of apnea, reduce the duration of ventilation, duration of oxygen treatment, the incidence of BPD and may reduce the incidence of neurodevelopmental problems [31]. It appears to have few serious side effects [32]. The beneficial effects strongly suggest that it should be given early to all ventilated very preterm infants.

68.9.3 Sedation

Many people sedate ventilated infants to make them feel less stressed and more comfortable. Several different sedatives have been used. The appropriate sedative and dose has not been elucidated. There is no good evidence that they improve the outcomes for the babies and they may adversely affect the baby's respiratory drive so that it takes longer for the baby to breathe sufficiently to be extubated [40, 41]. The best way to keep the baby comfortable is with good nursing care and appropriate positioning.

Continuous Positive Airways Pressure and other Non-Invasive Ventilation Techniques

Fabrizio Sandri and Gina Ancora

69.1 Background

Continuous positive airways pressure (CPAP) is a method of assisted respiration that consists of the application of continuous positive pressure to a spontaneously breathing patient's airways throughout the entire respiratory cycle. The first use of a CPAP was in the 1930s [1–3], but its first notable application in the neonatal field was in 1971 when CPAP was used in the treatment of RDS (respiratory distress syndrome) in spontaneously-breathing newborns undergoing tracheal intubation [4].

There is a distinction between CPAP and PEEP (positive end expiratory pressure). CPAP maintains a constant pressure of a level above ambient air pressure, thus providing a continuous transpulmonary pressure gradient during the various phases of the respiratory cycle. Another term for CPAP is continuous distending pressure [5]. Administered nasally, (a technique first proposed in journals by Italian authors in the early 70s [6, 7]) CPAP became a cornerstone of respiratory support in the 1990s. When PEEP is used, positive pressure is applied to the airways of a patient undergoing mechanical ventilation in the phases between artificial breaths.

69.2 Physiopathology

69.2.1 Respiratory System

The main purpose of CPAP in the newborn is to reduce the work of breathing (WOB). Work is expressed as the function of force × distance and specifically, in the case of respiratory work, as pressure × volume ($P \times V$). It is necessary to create a pressure gradient between the atmosphere and the alveoli so that a volume of air comes into contact with the alveolar-capillary membrane during each inspiration. The pressure generated must be capable of overcoming the elastic properties and resistance of the respiratory system, thus

$$P_{tot} = P_{el} + P_{res} = V/C + FR$$

where P_{tot} is the total pressure, P_{el} is the pressure necessary to overcome the elastic forces, P_{res} is the pressure required to overcome the resistance, C is compliance, R is resistance, V is volume and F is flow (equation of motion of the respiratory system).

The amount of work expended in order to expand the ribcage depends principally on:

- the elasticity of the lungs (the work is inversely proportional to the compliance of the lungs);
- the resistance to airflow imposed by the airways;
- the elastic and resistive properties of the ribcage.

We will examine below the physiopathological characteristics of the neonatal respiratory system, with particular attention to aspects relating to premature infants and will analyze the effects of CPAP application with respect to neonatal respiratory physiology.

The neonate, particularly if premature, has a double disadvantage in performing respiratory work:

- there is increased pulmonary elastic resistance;
- the airways provide considerable resistance;
- the compliance of the ribcage is increased.

69.2.1.1 Increased Pulmonary Elastic Resistance

The lungs are elastic in nature – elasticity describes the tendency of a structure to return to its initial state after the application of a force causes it to depart from its initial conditions. Compliance (the change in volume created by change in pressure: $\Delta V/\Delta P$) is the inverse of elasticity and measures the distensibility of a structure.

F. Sandri (✉)
Neonatology and Neonatal Intensive Care Unit, Ospedale Maggiore Bologna, Italy

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

Premature newborns present with reduced compliance for various reasons:

- low surfactant production with consequent increase in pulmonary surface tension and reduction in pulmonary volume at the end of expiration (functional residual capacity, FRC);
- excessive quantity of pulmonary fluid: the clearance of the pulmonary fluid is slower in the premature newborn, particularly when delivered by elective cesarean section. Furthermore, the left to right shunt that occurs when there is a patent ductus arteriosus, especially during the recovery phase of RDS, can contribute to an increase in pulmonary fluid.

69.2.1.2 Greater Resistance of the Airways

The premature newborn presents increased resistance above all due to the proximal airways for various reasons:

- absence of the superficial layer of adipose tissue in the neck that helps to stabilize the airways, thus keeping them patent [8, 9];
- reduced mobility of the genioglossus muscle that normally stabilizes the pharynx [10];
- reduced diameter of the airways;
- increased compliance of the airways, which creates a tendency for them to collapse during inspiration; this increased compliance also increases the ventilation of the dead space.

The premature newborn also presents increased resistance at the level of the peripheral airways. The reasons for this are:

- the structural composition of the lungs is insufficient to keep the smaller airways open;
- the reduction of FRC causes a reduction in diameter of the smaller airways.

69.2.1.3 Increased Compliance of the Ribcage

Compliance of the ribcage is inversely proportional to gestational age. The compliance of the ribcage is around 5 times greater than that of the lungs in premature newborns (for normal values of pulmonary compliance) and around 3 times greater in full-term newborns. In adults the ratio is 1:1 [11]. As such, the newborn's ribcage is much weaker and more flexible, and is therefore incapable of maintaining adequate transpulmonary pressure at the end of expiration. This brings a reduction in FRC, ventilation at near-closing volumes, alveolar collapse, imbalance in the ratio of ventilation to perfusion and hypoxemia (see Chapter 57).

The combined effect of reduced pulmonary compliance and increased compliance of the ribcage results in a reduced FRC (Fig. 69.1) with a tendency towards atelectasis and a reduction in gaseous exchange.

A mechanism enacted by the newborn to maintain an adequate FRC is the partial closure of the epiglottis during expiration (grunting): the premature newborn often cannot maintain adequate laryngeal tone and so may undergo a loss of pulmonary volume. It has been shown that the suppression of grunt caused by endotracheal intubation creates a reduction in paO_2 [12].

Aside from the cry, the newborn has two further mechanisms to increase FRC: 1) Maintaining the contraction of the inspiratory muscles during the first phase of expiration; 2) commencing the inspiration before expiration has finished. This strategy, which has the effect of increasing the FRC (dynamic increase of FRC), can facilitate gaseous exchange but is disadvantageous from the point of view of the amount of energy expended [13]. Fatigue or the presence of apnea in the newborn with respiratory distress syndrome can defeat the above-mentioned mechanism and can encourage the development of atelectasis with consequent respiratory insufficiency [5].

The reduction in FRC means that the newborn is working in the lower part of the compliance curve (Fig. 69.2, part A) and so is constrained to develop high pressures in order to gain small increases in volume. A low volume at the end of inspiration also induces closure of the small airways, followed by collapse of the alveoli. This necessitates greater pressures during inspiration in order to reopen the collapsed alveoli (critical opening pressure). Pulmonary collapse also causes epithelial damage with consequent protein exudates and surfactant consumption (see Chapter 70). This reduction in pulmonary volume also brings a change in the ratio of

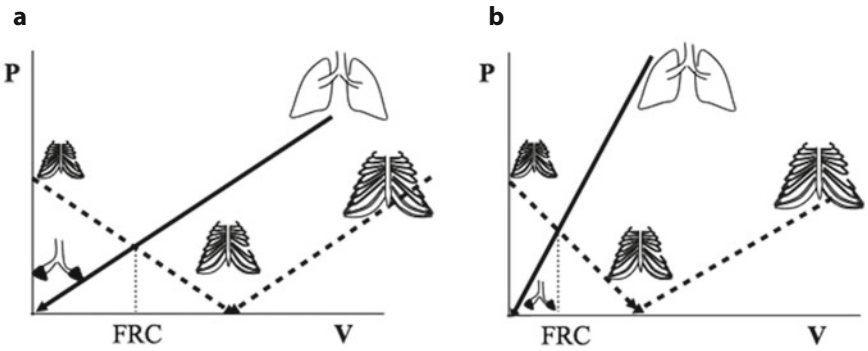

Fig. 69.1 Schematic representation of lung elastic (*continuous line*) and of chest wall (*discontinuous line*) forces in static conditions: lung tends to a volume equal to zero whereas the chest wall tends to a volume different from zero: the functional residual capacity (FRC) is achieved when the retraction force of the lung is equal to the expanding force of the chest wall. FRC is lower in the preterm (**b**) compared to the term newborn (**a**) due to both an higher force of lung retraction (lower lung compliance) and to a lower force of chest wall expansion. *P* pressure, *V* volume

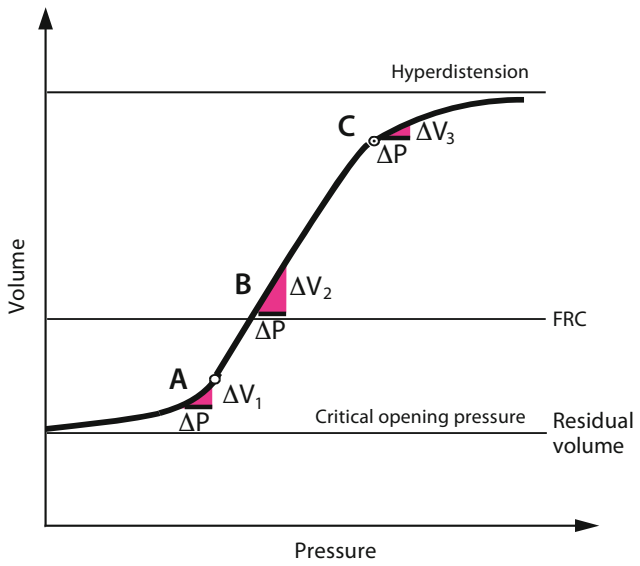

Fig. 69.2 Pressure/volume curve of the lung (compliance curve). ΔV = change in volume; ΔP = change in pressure; FRC = functional residual capacity. Normal compliance in B; low compliance in A and C

ventilation to perfusion with a consequent increase in the alveolar-arterial gradient and CO_2 concentration.

69.2.1.4 Respiratory Effects of CPAP

The application of continuous positive pressure to the airways amplifies the effect of the strategies by the spontaneously-breathing newborn that are aimed at maintaining an adequate volume at the end of expiration, minimizing the energy expended to stabilize the respiratory system, and carrying out the mechanical work of respiration. This prevents collapse of the airways and improves many critical situations that bring about an increase in the respiratory workload required of the newborn. In summary, CPAP acts on the respiratory system by the following mechanisms.

1. Increasing FRC (Fig. 69.2, Part B), eliminating dynamic elevation of FRC reducing resistance in the airways. The reduction in airways resistance is obtained by:
   - increasing the transverse section of the pharynx (the oropharynx can account for 66% of supraglottidal resistance [14])
   - dilating the airways and making them more rigid, stabilizing them and preventing their collapse. In particular an increase from 12.5% to 47% of the ratio of width to length of the larynx at the moment of maximum abduction of the vocal cords has been shown following CPAP application [15]
   - increasing the FRC thus can favor caudal traction across the supraglottidal airways reducing their resistance [16].
2. Reducing the R-L shunt thanks to the improved oxygenation and the consequent vasodilation of the pulmonary circulation.
3. Stabilizing the thoracic wall, reducing its distortion and curbing paradoxical movement.
4. Regularizing and slowing respiratory frequency [17].
5. Improving the capacity to generate a valid inspiratory force and thus to reopen collapsed alveoli following an obstructive event, probably through the elimination of the Hering-Breuer deflation reflex which is activated by a distortion in the inferior portion of the ribcage [18]. In this way it also reduces the incidence of obstructive apnea.
6. Increasing the average pressure in the airways (mean airways pressure–MAP) increasing the ventilation-perfusion ratio.
7. Preserving the surfactant on the surface of the alveoli
8. Reducing alveolar edema.

Normalizing pulmonary volume, ventilations/minute and the ventilation-perfusion ratio, CPAP improves oxygenation, increases the elimination of CO_2 and reduces the WOB [1].

69.2.2 Cardio-Circulatory System

CPAP results in a reduced preload in the right ventricle and consequently systolic output. The extent of these effects depends on how much pressure is applied by the lungs to the vascular spaces: the lower the compliance, the lower the applied pressure [19]. In the premature newborn, in the presence of a highly-compliant ribcage and often low pulmonary compliance, the pressure applied by the airways to the pleural spaces is only 5–10%, with little effect on cardiac output. In full-term newborns with normal lungs, 25% of the pressure in the airways (Paw) can be transferred to the pleural spaces and therefore the use of high pressure in these babies can have a significant effect on cardiac output. The increased thoracic compliance of the premature newborn therefore protects the intrathoracic vascular structure from a large increase in intrapleural pressure and from a consequent reduction in central venous return [11]. On the other hand, CPAP reduces pulmonary resistance in babies with RDS because of the vasodilatation of the pulmonary circulation resulting from improved oxygenation; this is the most important effect in newborns with respiratory pathologies treated with CPAP.

69.2.3 Renal Function

Renal function depends largely on the hemodynamic situation of the patient [20]. In cases of low pulmonary compliance, the application of CPAP brings an improvement in oxygenation and renal function can only be positively affected. In the presence of restricted water intake for the treatment or prevention of a patent ductus arteriosus – a common situation in cases which require the application of CPAP – the administration of dopamine at renal doses may be useful (approx. 3 μ/kg/min).

69.2.4 Intracranial Pressure

A reduction in cerebral perfusion has been reported in the course of the application of PEEP. This is related to the level of the PEEP.

An increase in intracranial pressure was found during the application of CPAP by a box around the head, due to compression of the veins in the neck. It does not appear that CPAP applied by endotracheal or nasal tube results in an increase of intracranial pressure [20].

69.3 Technical Aspect

CPAP can be delivered by a variety of devices and interfaces. There are two main types of CPAP devices, categorized on the basis of the flow characteristics: continuous and variable flow systems.

An important prerequisite for success in the use of CPAP is a circuit that allows the pressure to remain at the desired level throughout the respiratory cycle. Excessive inspiratory or expiratory fluctuations directly increase WOB and offset any benefits in pulmonary mechanics produced by CPAP [21].

Substantial differences were found in the fluctuations of Paw in different respiratory circuits hooked up to a mechanical lung model [22].

69.3.1 Continuous Flow Systems

These systems use a resistance to flow at the end of the respiratory circuit to produce pressure above that of atmospheric pressure. These CPAP systems include bubble CPAP. This device uses a fixed gas flow, and the column of water in the expiratory limb generates CPAP equal to the length of the tube that is immersed under water, which creates chest vibrations through bubbling. All these devices are also fitted with systems to humidify and heat the air. Continuous-flow mechanical ventilators can also be used to produce CPAP by the means of the PEEP valve to maintain continuous positive pressure throughout the entire respiratory cycle.

69.3.2 Variable Flow Systems

69.3.2.1 Benveniste System

The positive pressure is generated by a jet of gas directed toward an opening into a small chamber from which the mixture for the newborn comes out. Flow rates of 4–20 L/min serve to generate pressures in the chamber from 0–13 cmH_2O. These pressures are comparable to those measured at the oropharynx in the course of CPAP administered via 1 or 2 nasal prongs (this is indifferent, as long as the mouth is kept closed by use of a pacifier) [23].

69.3.2.2 Infant Flow System (Fig. 69.3)

A generator is connected to a circuit composed of a 3-channel tube (Fig. 69.4): one channel (inspiratory limb) provides gas flow and is connected to the nasal cavity via nasal prongs or mask, one (expiratory limb) is open to ambient pressure and one is used to measure the level of pressure created at the generator level. The flow provided by the Infant Flow driver is accelerated in the twin injector nozzles of the nCPAP generator. When the patient makes a spontaneous inspiratory breathing effort, the generator provides assistance by converting the kinetic energy of the flow to pressure energy. When the infant makes a spontaneous expiratory effort a pressure is applied at the nasal attachment of the NCPAP generator. This causes the flow to flip round and leave the generator via the expiratory limb. CPAP is maintained at the nasal connection throughout. When the expiratory breathing effort stops, the flow instantly flips back to the inspiratory position. The operating principle is that the high-pressure jet flows in different directions in response to the pressure generated at the level of the nasal cavities and the respiratory effort of the patient. During inspiration the drop in pressure in the nasal cavities creates a pressure gradient that directs the flow toward the nasal cavities, thus assisting inspiration. During expiration there is an inversion of the direction of the jet that helps the expiration (Coanda effect). The kinetic energy of this high-velocity flow is transformed into pressure in the area of the nasal cavities thus generating CPAP. Flow rates between 5 and 11 L/min generate pressures between 2 and 10 cmH_20. As such, the system does not require an expiratory valve. Tests on mechanical lung models have demonstrated that a CPAP circuit achieves greater stability in Paw and a reduction in WOB of around one quarter compared to traditional circuits [24–26]. Available clinical studies have, on the other hand, reported conflicting

Fig. 69.3 Infant flow generator

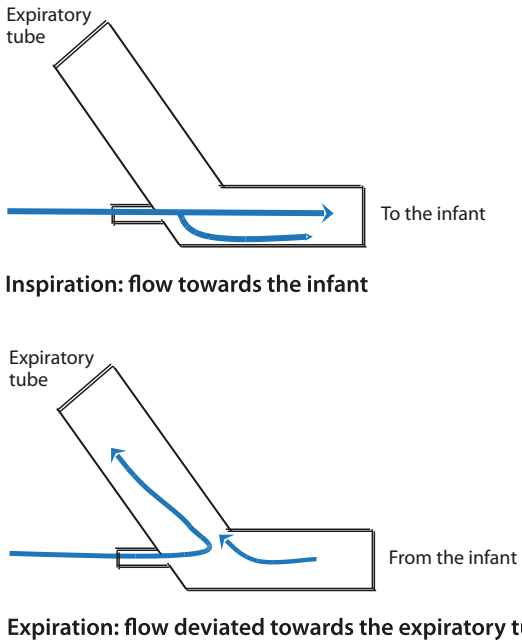

Fig. 69.4 Functioning of the infant flow generator

results. Two studies did not show any difference between this system and traditional ones in terms of improving pulmonary compliance, reducing oxygen requirements and improving respiratory frequency [27, 28].

A recent study comparing 3 circuits (Infant Flow system, double nasal prongs and single nasal prong fed by mechanical ventilators) for the application of NCPAP in newborns weighing less than 1800 g with light respiratory distress or apnea demonstrated better pulmonary recruitment using the Infant Flow circuit [29].

69.4 Methods of Administering CPAP

- *Endotracheal Tube* This method entails a notable resistance (directly proportional to its length and inversely proportional to its radius) and as such involves a significant increase in WOB. At this time it is no longer recommended as a system for the administration of CPAP. Furthermore, by bypassing the nasal and pharyngeal mucosa, it creates an alteration in the humidification and heating of the inhaled gases. Also the trauma applied to the respiratory mucosa makes its use inadvisable for newborns who do not need mechanical ventilation.
- *Head-Box (Helmet CPAP)* This system is of low efficacy below 1500 g bodyweight, extremely noisy and cumbersome and does not allow access to the newborn's head. Furthermore, it has been associated with an increased incidence of cerebral hemorrhage due to compression of the neck [30]. Aspiration pneumonia has also been reported during feeding.
- *Face Mask* This system too is rarely used, particularly for premature infants. The mask should cover the nose and mouth and should always be used with an orogastric feeding tube to avoid excessive abdominal distension. In the premature newborn, apart from the problem of keeping the mask in place and the consequent difficulty of generating a sufficient level of CPAP with adequate flow, there are also problems of excessive dead space that can be 2 or 3 times greater than in a full-term newborn. Cases of cerebral hemorrhaging have been reported in very low birth weight newborns undergoing this therapy due to the forces applied to the back of the head by the mask's attachments [31].
- *Facial Chamber* The entire face protrudes into a chamber held in place by a latex ring filled with styrene particles. This system too is now not used as it does not permit access to the newborn's face for alimentation or aspiration.
- *Nasopharyngeal Tube (Mono-Nasal CPAP)* The same type of tube used for tracheal intubation is inserted through the nostril as far as the pharynx. This is a simple technique, which is widely used for mild forms of respiratory distress or apnea in the premature. The disadvantages lie in the fact that this tube provides elevated resistance, particularly if it is of small diameter, and that the tube also totally bypasses the humidifying-heating action provided by the nasopharyngeal mucous.
- *Nasal Prongs (Bi-Nasal CPAP)* Currently this is the most used and effective system for the administration of CPAP in the newborn. The baby has to breathe through the nose; the nasal prongs also allow the air to be humidified and heated by most of the nasopharyngeal mucous. The mouth in this case acts as a pop-off pressure valve. The nasal prongs are easily applied and less invasive than the endotracheal tube; first examples of nasal prongs were put into use in the early 1970s [6, 7, 32]. Particular attention has been paid to the work required of the newborn in order to overcome the resistance due to the small diameter of the nasal prongs (the so-called superimposed work of breathing). A study reported an increase of 100% in WOB during CPAP administered with nasal prongs compared to CPAP with a face mask [33]. A closer evaluation of the study, however, revealed that this increase could, in part, be put down to the increased resistance caused by the catheter placed inside the prongs to relieve pressure. Recently these prongs have been redesigned with a precise angle and structure in order to minimize resistance to the airflow [26]. Another problem with these prongs is related to the loss of flow (and hence of pressure) around the prongs themselves if they are not secured properly. Nowadays the prongs are made from a soft silicon material that expands slightly in contact with the warmth and humidity of the nostrils, adapting to their dimensions and so favoring a good fit.
- *Nasal Masks* These devices, which consist of silicone masks that completely cover the nose, are sometimes a useful alternative to nasal prongs, in particular in extremely low birth weight infants.

69.5 Clinical Applications

69.5.1 Respiratory Distress Syndrome-RDS

The main physiopathological aspects of RDS, whose principal cause is a deficit of surfactant [34], are: reduction in pulmonary compliance; reduction in FRC and alteration in the ratio of ventilation to perfusion. The rigidity of the ribcage is also reduced with a paradoxical distortion during inspiration which is greater the larger the reduction in pulmonary compliance, with a consequent reduction in tidal volume [5, 35]. These alterations lead to a profound alteration in gas exchange and increase the respiratory workload, the consequences of which are the presence of hypoxemia, hypercapnia and acidosis.

69.5.1.1 Clinical Evidence

The first clinical experience of neonatal CPAP application came in 1971 with a case report of 20 patients affected by RDS [5]. This was followed by others [36–38].

The rationale behind the use of early NCAP in the VLBW newborn lies in the facilitation of the acquisition and maintenance of an adequate pulmonary volume (FRC). As well as improved gas exchange, a normal air-liquid interface is maintained at the level of the terminal alveoli. This promotes the liberation of reserves of pulmonary surfactant, which in turn further stabilize the air spaces preventing the formation of hyaline membranes and the following atelectasis that is typical of surfactant deficiency. This should lead to a decrease in the requirement for mechanical ventilation with a reduction in its complications, in particular bronco-pulmonary dysplasia.

The main reason for the interest in adopting NCPAP, especially in very low birth weight newborns (VLBW, that is <1500 g), came from the publication of two multi-centre retrospective studies. They showed that the incidence of chronic lung disease, assessed as the percentage of VLBW survivors who were oxygen dependent at 28 days from birth, was significantly lower in centers that had been early adopters of NCPAP, despite having amongst the highest survival rates. The early adoption of NCPAP at these centers was part of a low-invasiveness strategy consisting of the tolerance of relatively high pCO_2 values, up to 60 mmHg (permissive hypercapnia), before proceeding to intubation and mechanical ventilation, and the non-use of paralyzing drugs [39, 40].

Early NCPAP was largely used in VLBW infants with recourse to intubation and mechanical ventilation only when it was held to be essential, based on well established criteria [41–44]. The common denominators of these clinical experiences are:

- intubation in the delivery room only if considered essential for cardio-pulmonary resuscitation;
- early NCPAP, i.e. application of NCPAP to all newborns within the first 30 minutes of life or at the appearance of the first signs of respiratory distress;
- intubation and, if necessary, mechanical ventilation only if one or more of the following criteria are met (criteria for failure of NCPAP): untreatable apnea, respiratory acidosis (pCO_2 >65-70 mmHg and pH <7.20) and requirement of exogenous surfactant.

In general, the success of NCPAP in treating VLBWI avoiding mechanical ventilation, is proportional to the gestational age (76% of newborns ≤26 weeks GA require ventilation compared to 43% of newborns >26 weeks) regardless the use of pre-natal prophylaxis with steroids [41].

There is a general tendency to tolerate higher pCO_2 values than in the past [39, 42, 43], and this has reduced the need for intubation. Even when mechanical ventilation is undertaken, it does not require the use of aggressive ventilation strategies in search of blood gas values that are obtained at the cost of high baro-volutrauma [41].

A study carried out on 67 newborns of <1000 g birthweight (Extremely Low Birth Weight-ELBW) who underwent early NCPAP if they were not intubated in the delivery room for primary resuscitation, demonstrated that it was not necessary to intubate and start mechanical ventilation in 73% of the newborns >28 weeks and in 32% of the newborns ≤28 weeks [45]. In another study, Finer et al [46] found that all infants of 23 weeks' gestation required intubation in the delivery room whereas only 3 of 21 (14%) infants of 27 weeks' required such intubation.

The reduction in the percentage of mechanically-ventilated newborns did not cause an increase in mortality or negative side effects such as cerebral hemorrhage [41, 43, 45, 47–49].

However, despite uncontrolled and cohort studies suggesting the efficacy of NCPAP in avoiding MV and ventilatory-induced lung injury, there are few randomized clinical trials confirming the benefit of NCPAP as the primary type of respiratory support in preterm newborns. Morley et al published the COIN trial in 2008 [50]. In this trial NCPAP was compared with intubation and ventilation on the hypothesis that the use of NCPAP shortly after birth would reduce the rates of death and bronchopulmonary dysplasia. The main eligibility criteria were a gestational age at delivery between 25 and 28 weeks and an ability to breathe at 5 minutes after birth but needing respiratory support. Infants were ineligible if they had been intubated before randomization or if they required no respiratory support or oxygen. At 5 minutes after birth, the allocated treatment was started. In infants who were assigned to receive NCPAP, this was started at a pressure of 8 cm of water with nasal prongs. They were intubated and underwent ventilation only if they had any of the following clinical signs: apnea unresponsive to stimulation and methlyxanthine treatment, an arterial pH of less than 7.25 with a partial pressure of arterial carbon dioxide ($PaCO_2$) of more than 60 mmHg (8.0 kPa), a metabolic acidosis not responsive to treatment, or treatment with more

than a 60% concentration of oxygen. Infants receiving NCPAP were treated with surfactant only after intubation. Surfactant treatment, ventilation settings, and extubation and reintubation criteria were not mandated in either group and followed local protocols. Half the infants in the NCPAP group were subsequently intubated. Infants in the NCPAP group had a better outcome at 28 days than those in the intubation group. The two groups had similar outcomes at 36 weeks' gestational age, but there was an increased incidence of pneumothorax in the NCPAP group.

There are studies of great interest that have demonstrated the efficacy of an approach that prescribes the use of early NCPAP together with the administration of surfactant in the treatment of RDS. This approach, known as the INSURE approach (INtubation-SURfactant-Extubation) is based upon the adoption of the following procedure. In a newborn undergoing NCPAP, whenever administration of surfactant is indicated, the patient is intubated, surfactant is administered in the usual doses and the patient is then placed again in NCPAP after extubation (assuming that the patient is breathing spontaneously). Mechanical ventilation is only applied when indicated by well-defined criteria of failure [51].

A multi-centre study carried out in Sweden compared the incidence of mechanical ventilation in two groups of newborns affected by moderate-to-severe RDS to whom early CPAP was applied (e.g., application at the first clinical signs of respiratory distress). The treatment group received the INSURE approach if their oxygen requirement exceeded 60%. The control group received treatment only with NCPAP and surfactant was reserved for cases where mechanical ventilation was required. The criteria for application of mechanical ventilation (apnea and or oxygen requirement >80%) was the same for both groups. Recourse to mechanical ventilation was reduced from 85% in the control group to 43% in the treatment group [52].

The same authors later carried out a multi-centre study on newborns with RDS below 30 weeks gestational age and who were undergoing early NCPAP. They demonstrated that when the INSURE approach was adopted early on in RDS, i.e. at an oxygen requirement between 40% and 60%, there was a reduction in the need for mechanical ventilation and of death in the first seven days post partum from 63% to 21% compared to a later approach (oxygen requirement >60%) [53].

This last work, aside from demonstrating the efficacy of the INSURE approach, permitted the establishment of a limit to the oxygen requirement in patients with RDS undergoing NCPAP (FiO_2 about 40%) above which the administration of surfactant is indicated.

A study conducted in Italy on 155 newborns of gestational age ≥28 and <32 weeks treated by the INSURE approach at oxygen requirements >40%, showed no difference in requirements for surfactant and mechanical ventilation comparing two groups to which NCPAP had been applied: in the first group NCPAP was applied within 30' of birth, regardless of the clinical picture; in the second group NCPAP was applied only in the presence of respiratory distress with oxygen requirements >40% [54].

A recent systematic review of the INSURE approach, reported a reduced need for MV in the first week of life, when used early in respiratory distress syndrome [55].

Either prophylactic surfactant or delivery room NCPAP to maintain functional residual volume were identified as potentially beneficial practices which, if adopted in extremely preterm infants, could reduce lung injury [56].

Recently, the CURPAP study compared the administration of prophylactic surfactant followed by NCPAP (prophylactic INSURE) with early NCPAP followed by early selective surfactant given through a brief course of endotracheal intubation (early rescue INSURE) to preterm newborns of GA 25-28 weeks not intubated at birth [57]. In both groups, MV was started after surfactant in the absence of good respiratory drive. Infants who were extubated to NCPAP after surfactant were eligible for MV if the following NCPAP failure criteria occurred: FiO_2 >0.40 on NCPAP to maintain oxygen saturation of 85–92% for at least 30 minutes unless rapid clinical deterioration occurred, intractable apnea, respiratory acidosis defined as PCO_2 >65 mmHg (8.5 kPa) and pH <7.20. This study showed that, in spontaneously breathing preterm newborns treated with NCPAP, prophylactic surfactant given within 30 minutes from birth is not superior to early selective surfactant in terms of requirement of MV in the first 5 days of life.

The main implication for clinical practice of the CURPAP study is that NCPAP should be started soon after birth in spontaneously breathing infants of 25–28 weeks' gestation and early selective surfactant should be given once signs of respiratory distress have developed. Extubation after surfactant administration should be attempted as soon as possible. With this strategy, more than 50% of infants will need only NCPAP, 49% intubation and surfactant, and nearly one third also mechanical ventilation in the first 5 days of life. Overall, the respiratory approach used in this study resulted in a very good respiratory outcome: 78–79% of infants, in both arms, survived without any supplementary oxygen or respiratory support at 36 weeks' postmenstrual age. The incidences of moderate/severe broncho-pulmonary dysplasia were 14.3 and 11.7%, respectively in the prophylactic surfactant and NCPAP groups, which is lower than the 30% incidence reported in other studies [58, 59].

In the past, doubts have been cast on the possibility of generalizing low-invasiveness treatment strategies in VLBW infants [60]. Currently, similar doubts may be raised for ELBW infants, in whom the application of results from studies [46, 50, 57] should take into account the rate of prenatal steroid use and the type of antenatal health care program.

In conclusion, the available published data suggests that:

- VLBW infants, not intubated at birth for cardiopulmonary resuscitation, can be treated conservatively using NCPAP, with the administration of surfactant and mechanical ventilation only being used if precise clinical, laboratory test and instrumental criteria are met;

- prenatal steroids, higher GA and female sex are associated with higher chances of being treated non-invasively;
- a precise limit of gestational age or birth weight below which NCPAP cannot be used with success has not yet been established;
- using NCPAP together with early selective surfactant to avoid more invasive strategies does not entail an increase in mortality rates or negative side effects.

69.5.2 Neonatal Apnea

Apnea is traditionally classified into three categories based on the presence or absence of obstruction of the upper airways: central, obstructive and mixed (see Chapter 74) [61, 62].

Because most apneic episodes have an obstructive component, CPAP appears to be one of the most effective strategies. It splints the upper airway with positive pressure and decreases the risk of pharyngeal or laryngeal obstruction. CPAP probably also improves apnea by increasing functional residual capacity (FRC) and so improving oxygenation status [61, 62]. The positive effect of CPAP is also due to the stabilization of the ribcage, [14, 16, 61], that contributes to the airways opening and to the reduction of the Hering-Breuer reflex [18].

Given that NCPAP does not have a direct effect on apnea of central origin, its use in association with stimulants of the respiratory centers such as methylxantine below 32 weeks gestational age is generally accepted [63–65].

69.5.3 Weaning the Patient from Mechanical Ventilation (Post-Extubation Phase)

It is well known that after a period (long or short) of intubation and mechanical ventilation, extubation can fail, leading to the re-intubation of the newborn [66]. The reasons for this failure are substantially as follows:

- apnea;
- an increase in oxygen requirements (this can be correlated to a loss of volume from a malfunction of the glottis after intubation, or to atelectasis);
- respiratory acidosis.

Various contributors have demonstrated the efficacy of NCPAP application in the post-extubation phase following mechanical ventilation. NCPAP compared to direct extubation reduces the need of re-intubation, both in newborns weighing < 1500 g (16% failure rate versus 52%) [67] and in those weighing <1000 g (24% failure rate versus 79%) [68]. The factors that necessitate re-intubation, principally apnea but also an increase in oxygen requirement due to loss of pulmonary volume and respiratory acidosis, are counteracted by NCPAP. A recent meta-analysis confirmed the efficacy of NCPAP in weaning of patients from mechanical ventilation and thus recommended its adoption as an elective method for use after extubation, if necessary in combination with a methylxantine [69]. To achieve successful extubation to NCPAP, it is also important to choose the most appropriate moment in terms of parameters of mechanical ventilation. This should be at a point where the respiratory problem can be considered overcome by ventilation (FiO_2 <0.35, mean airways pressure [MAP] <7 cmH_2O, ventilatory frequency ≤20/min) [67–69]. A recent study comparing a continuous flow with a variable flow CPAP device (Bubble CPAP versus Infant Flow system) concluded that both devices were effective in the post-extubation management of infants with RDS. However in infants ventilated for ≤14 days, bubble CPAP is associated with a significantly higher rate of successful extubation and with a significantly reduced duration of CPAP support [70].

69.5.4 Other Clinical Applications

- *Transient Tachypnea of the Newborn (TTN)* Some doubts have been raised regarding the safety of NCPAP in TTN (see Chapter 63) due to the theoretical risk of air trapping and pneumothorax. There are, however, no relevant published data [71]. Authoritative guidelines include TTN in indications for NCPAP application [63, 72], and our personal experience is that the early application of NCPAP for TTN brings about a reduction in the clinical signs of respiratory distress without a significant increase in the incidence of pneumothorax.
- *Meconium Aspiration Syndrome (MAS)* The application of a continuous distending pressure could be beneficial, resolving the areas of atelectasis and re-opening and stabilising the airways [20, 73]. However it should be reserved for the less severe forms of MAS (Chapter 59). More serious cases will require intubation, broncho-alveolar lavage with surfactant and mechanical ventilation [74, 75].
- *Congenital Cardiopathies with Hyperafflux* Pulmonary hyperafflux can lead to a reduction in pulmonary compliance and to a change in the ventilation-perfusion ratio, with consequent hypoxemia, which is potentially correctable with CPAP [20].
- *Tracheobronchomalacia* CPAP resolves the collapse of the airways present in this condition, considerably relieving the respiratory distress correlated with it [63, 76].
- *Atelectasis* The onset of atelectasis can be due to different factors but its resolution will require the removal of the root cause in each case. However, in many situations, e.g. post-extubation atelectasia, CPAP may be used electively [63].
- *Bronchiolitis* Early CPAP (predominantly nasal) can rapidly aid respiratory muscles, improve respiratory distress symptoms (retractions, tachypnea, agitation) and blood-gas measurements (pO_2, pH, pCO_2). These effects have

been attributed to widening of the bronchioli by positive pressure, followed by emptying of the lung and restoration of a normal FRC. This leads to a reduction in the use of mechanical ventilation [77, 78]. NCPAP has also demonstrated its efficacy in the treatment of apnea associated with RSV infection [79].

- *Paralysis of the Phrenic Nerve* Cases have been published in which paralysis of the phrenic nerve was successfully treated with NCPAP application, which corrects the deficit in transmural pressure caused by paralysis of the diaphragm [80].
- *Nebulization of Pharmaceuticals* NCPAP has recently been used for the respiratory administration of pharmaceuticals (beta blockers, steroids, acetylcysteine and adrenaline), although this does not currently seem to be of great clinical interest [81].

69.6 Side Effects

- *System Malfunctions* The obstruction of the nasal prongs or the tube by mucous (like the obstruction of the nasal passages) is common during nasal CPAP, with potentially serious consequences (sudden decrease in oxygenation) due to the lack of airflow delivered to the patient [63].
- *Pulmonary Over-Distention* Pulmonary hyperdistension is the most serious complication that can occur during NCPAP. This condition can occur whenever the positive pressure applied is excessive with respect to the patient's pulmonary compliance.
  The presence of a hyperdistended lung brings an increased risk of pneumothorax, a worsening of the ventilation-perfusion ratio and an increase in CO_2 retention and WOB. It is also known that the higher the pulmonary compliance, the greater the transmission of positive pressure to the posterior mediastinum, followed by an increase in central venous pressure with a decrease in venous return and cardiac output. Fig. 69.5 shows the effects of rising CPAP values on central venous pressure, on paO_2 and on $paCO_2$, the onset of which correlates directly with hemodynamic and respiratory interferences (Fig. 69.2, part C) [82].
  These hemodynamic effects can have serious consequences on gastro-intestinal, renal and cerebral perfusion and can cause an increase in intracranial pressure due to the decrease in venous drainage [20, 63].
- *Gastric Distension* It can cause reduced ventilatory excursion due to compression of the diaphragm or even gastric perforation (CPAP belly syndrome) [20, 63, 83]. It can be prevented by properly affixing the nasal prongs, by positioning a permanent orogastric tube and by periodically checking the degree of abdominal distension.
- *Nasal Lesions* Nasal-cutaneous lesions have been described during NCPAP with possible permanent deformities [84, 85]. These lesions can be prevented by choosing silicone nasal prongs (which permit good contact without being harmful), nasal prongs of the correct dimensions with relation to the newborn's nostrils and ensuring their correct positioning.

69.7 Suggestions for NCPAP Use in the Clinical Practice

69.7.1 Pressure Level

There have been few data published to evaluate a method that would allow the establishment of an optimum pressure for CPAP, and its clinical applicability in practice is very limited [86, 87].

It is advisable to:

- start with a level of CPAP between 5 and 7 cmH_2O;
- individualize the CPAP level on the basis of respiratory dynamics, respiratory frequency, grunting and thoracic retraction. The level of CPAP can be increased up to 8–10 cmH_2O;
- choose higher values if there is reduced pulmonary volume;
- once an improvement in the respiratory dynamic has been reached, adjust the FiO_2 so as to maintain PaO_2 between 60 and 80 mmHg or tcO_2 saturation (measured by pulse oximetry) at between 85% and 93% in preterm infants;
- reduce the level of CPAP as long as lung compliance, lung volume and oxygenation improve in order to avoid hyperdistension and transmission of positive pressure to the mediastinum.

69.7.2 Monitoring

The use of NCPAP therapy requires accurate monitoring to both evaluate the evolution of the illness and to identify negative side effects.

- Blood gas analysis from arterial or an arterialized capillary blood, represents the gold standard for blood gases measurement. It should be carried out within 15–30 minutes of starting therapy and whenever clinically indicated [20].
- Pulse oximetry. This is the method of choice for the continuous monitoring of the level of oxygenation, particularly when the situation has stabilized, despite its universally known limitations. It is advisable to target O_2 saturation values between 85% and 93% [88].
- Transcutaneous PO_2 and PCO_2. This type of monitoring, though potentially very useful, has in reality many limitations that require great caution in interpreting the values it obtains, which should be verified and checked frequently against the blood gas values.
- ECG and systemic arterial pressure. The potential side effects of CPAP on circulation require continuous monitoring of heart rate and periodic measurement of systemic blood pressure.
- Chest X-ray provides valuable information in evaluating the effect of CPAP on the evolution of the disease, such as improvement of the radiological picture or the development of complications such as hyperdistension or pneumothorax.

69.7.3 Failure of Nasal CPAP

This subject is addressed in detail in the paragraph on clinical applications, in particular in the part dedicated to RDS.

69.7.4 Weaning from Nasal CPAP

Once clinical improvement has been obtained as previously described, the improved situation is shown by the ability to progressively reduce FiO_2 (in 2–5% steps down to 21%) and the level of positive pressure (1 cmH_2O at a time down to 2–3 cmH_2O). Once minimal values have been reached for both parameters, the NCPAP therapy can be stopped more or less gradually, having regard to the weight and gestational age of the baby and depending on the presence or lack of other indications for therapy, e.g., apnea of prematurity.

69.8 Nursing of the Neonate in NCPAP

The importance of nursing is particularly important when CPAP is administered via nasal prongs. The following require particular attention:

- correct attachment (headset and nasal prongs);
- correct positioning (circuit and infant);
- correct temperature setting on the humidifier;
- correct aspiration of the airways and feeding.

69.8.1 Attachment (Headset and Nasal Prongs)

The attachments for the nasal prongs always include a bonnet, which the prongs themselves are fixed to. The bonnet must be large enough to reach the level of the eyebrows and to cover the ears completely. If it is too small it will tend to ride up, forcing the circuit toward the neonate's nose. The prongs generally come in three sizes (small, medium and large): the size that is most compatible with the patient's nostrils must be chosen. It is wrong to assume that the smallest prongs are for the most delicate neonate. If the prongs are too small they do not give an adequate hold, which is necessary to maintain a constant level of CPAP and to avoid an increase in airways resistance. This does not allow for a reduction in WOB and may cause it to increase.

The silicone nasal prongs warm up when inserted into the nostrils, and in doing so they become softer and expand slightly, improving their hold. The use of creams or plasters around the nose is not recommended. Once the circuit has been positioned care must be taken that the edge of the prongs does not adhere to the nasal septum: the base of the prongs must always be visible (Fig. 69.6) (see also § 69.8.2).

The prongs can increase the production of nasal secretions and for this reason the system for humidifying and heating the administered gas is very important (see § 69.8.4). When the infant cries there may be a loss of pressure: therefore correct nursing is extremely important during the administration of CPAP (see also § 69.8.3).

Silicone masks are available as an alternative to nasal prongs for very small or large infants (Fig. 69.7).

Fig. 69.6 Correct positioning of the nasal prongs

Fig. 69.7 Nasal mask for the application of nasal CPAP

69.8.2 Positioning of the Circuit

The tubes should be positioned so as not to pull on the flow generator or put pressure on the neonate's nose (Fig. 69.8)

The flow generator is connected to the nasal mask by ribbons, which must not be too tight. Once the ribbons have been fixed they should be directed downwards, that is towards the base of the ears and away from the eyes in order to avoid swelling at this level. Plasters or knots between the ribbons and the nasal mask should be avoided to facilitate the rapid adjustment of the prongs. Only the gas arrival tube should be attached to the bonnet while the others should be left free.

In the case of the Infant Flow generator it is important that the outlet tube be positioned outside the incubator in order to minimize noise: if necessary use the extension tube.

69.8.3 Positioning the Infant

The infant can be placed in a prone, supine (with support) or lateral position; the neck however must always be slightly extended. The prone position has been shown to be better for the premature neonate with respiratory distress [89].

Kangaroo-care is possible during NCPAP. It is important to keep the infant's mouth closed. This confers at least three benefits:

- it avoids loss of pressure and consequent instability of CPAP therefore reducing WOB;
- it avoids drying of the mucous and the formation of dense, whitish secretions because it favors the deglutition of saliva;
- it keeps the jaw in the forward position, thus avoiding the tongue falling backwards and guaranteeing the patency of the airways.

The infant can be helped to keep their mouth closed. Initially it can be of use to place a support (e.g., roll of gauze) under the neonate's chin. The use of a pacifier favors deglutition and reduces the formation of saliva in the infant's mouth. It also helps keep the jaw in the forward position.

69.8.4 Humidification and Heating

Adequate humidification is important in order to avoid drying of the mucous and the accumulation of dense secretions, which can block the airways. The recommended gas temperature is 37°C: this is obtained by setting the resistance temperature of the circuit at 39°C and that of the gas at 2°C less. It is always important to ensure that the temperature sensor is placed outside the incubator. If the neonate is positioned under an infant warmer, the sensor should be thermally isolated.

69.8.5 Airways Suction

It is not necessary to regularly suction the infant in NCPAP and this maneuver should be performed only when necessary. To reduce the formation of oral and nasal secretions, the following measures can be used:

- set the humidifier to a suitable temperature (see previous paragraph): if the temperature is too low it can favor the formation of dry secretions;
- keep the infant's mouth closed (see § 69.8.3).

69.8.6 Feeding

The use of NCPAP does not prevent feeding. Food intake should be encouraged (via orogastric feeding tube or bottle). Additionally, fed newborns will avoid swallowing air thus reducing abdominal distension. An orogastric tube is not always necessary.

Lung Diseases: Surfactant Replacement Therapy

Henry L. Halliday

70.1 Introduction

In the past 3 decades introduction of prenatal steroid treatment, postnatal surfactant therapy and assisted ventilation have lead directly to improved neonatal outcomes [1]. Improved survival is directly related to more effective prevention or treatment of respiratory distress syndrome (RDS), which prior to the 1990s had a high mortality. Following unsuccessful clinical trials with nebulized synthetic surfactants, comprised of phospholipids without surfactant proteins, in the 1960s [2] a number of randomized controlled trials in the 1980s demonstrated benefits of surfactants instilled directly into the lungs of preterm infants [3–5]. These surfactants were of 2 main types: natural (derived from animal lungs or human amniotic fluid) [3] containing surfactant proteins-B and C (SP-B and SP-C) and synthetic [4, 5] (containing phospholipids and other agents to facilitate spreading and adsorption). Both types of surfactant given, either prophylactically (in the delivery room within 15 minutes of birth) [3, 4] or for treatment of RDS [5], increased neonatal survival and reduced pulmonary air leaks such as pneumothoraces and pulmonary interstitial emphysema.

More recently, further randomized clinical trials helped determine the best surfactant, the optimal timing for initial treatment, need for redosing and dose of phospholipids needed for best outcomes [1, 2]. Results from these trials have provided guidelines for best practice and these are now available in Europe [6], USA [7], Canada [8] and UK [9]. The aim of this chapter is to summarize the recommendations for surfactant treatment based on evidence from clinical trials and systematic reviews and to point out areas where controversy still exists.

70.2 Respiratory Distress Syndrome and Rationale for Surfactant Therapy

Respiratory distress syndrome (RDS) is caused by surfactant insufficiency [10] which leads to progressive hypoxia, respiratory failure and mixed respiratory and metabolic acidosis as a result of alveolar collapse and increased work of breathing [11]. Surfactant deficiency is strongly associated with prematurity and progressive acidosis further reduces surfactant production. The normal surfactant phospholipid pool size at birth is about 100 mg/kg but in preterm infants this is often reduced to below 25 mg/kg and, if severe RDS is present, less than 5 mg/kg [11]. Surfactant may also be inactivated by leaking of inhibitory proteins from the plasma into the alveoli. Prior to the introduction of surfactant therapy, infants with RDS who survived began to produce their own endogenous surfactant after 2–3 days and this heralded their recovery [11]. Those infants who did not survive either developed progressive respiratory failure with irreversible hypoxic injury to the cardiovascular and central nervous systems or acute deterioration associated with pulmonary air leaks or intraventricular hemorrhage.

Surfactant therapy prevents or overcomes alveolar collapse, especially at end expiration, increases lung volumes and pulmonary compliance, and reverses respiratory failure [11]. The result is improved survival and significant reduction in pulmonary air leaks following surfactant treatment [3–5]. There is evidence from both animal studies and clinical trials that natural surfactants, containing SP-B and SP-C act more rapidly than synthetic preparations containing mainly phospholipids leading to improved outcomes with regard to survival and pulmonary leaks [12]. Timing of surfactant therapy may also be important in determining outcome with evidence pointing to earlier or prophylactic therapy being superior to later treatment [13]. It is important to note that incidence of RDS varies from about 80% at 28 weeks' gestation or below to about 50% at 30 weeks, 30% at 32 weeks and 10% at 34 weeks [11].

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

70.3 Results from Randomized Trials and Systematic Reviews

These are discussed under the following sub-headings: efficacy, timing of first dose, size of first dose, method of administration, need for redosing, type of surfactant, concomitant interventions and other indications for surfactant therapy.

70.3.1 Efficacy

Randomized clinical trials of synthetic (protein-free) and natural (containing SP-B and SP-C) surfactants, given both prophylactically (within 10 to 15 minutes of birth in the delivery room) or as treatment for established RDS in the neonatal unit, reduce neonatal mortality and pulmonary air leaks such as pneumothoraces [1, 3-5]. Although these trials took place mainly in the 1980s and 1990s, at a time when prenatal corticosteroid treatment was much less than today, there is no reason to believe that surfactant treatment does not continue to have a positive impact on the outcome of preterm infants [1, 2]. Indeed prenatal corticosteroids and postnatal surfactant have synergistic effects [14] and both should be considered when preterm birth is likely. The sizes of the effects of prophylactic surfactant administration on neonatal mortality, pneumothorax and other selected outcomes are shown in Table 70.1.

70.3.2 Timing of First Dose

It is clear that the earlier surfactant is given in the course of RDS the better the outcomes [15]. For infants of less than 31 weeks' gestation prophylactic surfactant reduces neonatal mortality (RR 0.61, 95%CI 0.48–0.77; NNT 22, 95%CI 15–42) and pneumothorax (RR 0.62, 95%CI 0.42–0.89; NNT 48, 95%CI 27–200) compared to later treatment of established RDS [13]. This systematic review did not find a significant reduction in bronchopulmonary dysplasia (BPD) (RR 0.96, 95%CI 0.82–1.12) [13] but an earlier report using data from 3 randomized trials of poractant alfa found a reduction in chronic lung disease (CLD) in survivors at 28 days (adjusted OR 0.54, 95%CI 0.34–0.86) after adjustment for the following confounders: gender, birth weight, gestational age and prenatal administration of corticosteroids [16]. A subsequent analysis of these 3 trials of poractant alfa showed that prophylaxis significantly reduced severe intraventricular hemorrhage (IVH) compared to later treatment (OR 0.56, 95%CI 0.35–0.89) and this was especially apparent in preterm infants born outside tertiary perinatal centers (OR 0.11, 95%CI 0.02–0.49) [17]. All these trials of prophylaxis versus later treatment were conducted in the 1990s and could be criticized because of low rates of prenatal steroid use (about 20%) and relatively late treatment (1.5–6 hours after birth) in the comparison groups [1]. In a randomized trial of 651 infants of less than 28 weeks' gestation immediate (before the first breath) administration of calfactant was not superior to a post-ventilatory instillation of surfactant after initial resuscitation and stabilization at 10 minutes after birth [18].

Administration of surfactant generally requires endotracheal intubation and routine prophylaxis of infants less than 31 weeks' gestation might lead to unnecessary treatment in up to 50% of cases [1]. This will increase costs of care and could cause unwanted lung injury leading to BPD. On the other hand infants of 29–32 weeks' gestation treated with prophylactic calfactant showed clinical benefits compared to those treated at a median of only 1.5 hours later [19]. Nevertheless, currently because of increased use of prenatal steroids and early CPAP it is still not clear if prophylaxis is superior to early rescue treatment as soon as clinical signs of RDS develop [1].

70.3.3 Size of First Dose

Clinical trials used surfactant doses ranging from 25 to 200 mg phospholipids/kg [20]. These doses are all much larger by at

Table 70.1 Meta-analyses of prophylactic surfactant treatment of preterm infants

	Natural surfactant				Synthetic surfactant

Table 70.2 Surfactant preparations in clinical use

Generic name	Trade name	Source	Phospholipids (mg/mL)	Dose (mg/kg)	Volume (mL/kg)	Manufacturer (country)
Beractant	Survanta	Bovine mince	25 (50% DPPC)	100	4	Abbott (USA)
BLES	bLES	Bovine lavage	27	135	5	BLES Biochemicals (Canada)
Bovactant	Alveofact	Bovine lavage	42	50	1.2	Thomae and Boehringer Ingelheim (Germany)
Calfactant	Infasurf	Bovine lavage	35 (74% DPPC)	105	3	ONY and Forest Labs (USA)
Poractant alfa	Curosurf	Porcine mince	80 (70% DPPC)	100 to 200	1.25 to 2.5	Chiesi Farmaceutici (Italy)
Surfactant TA	Surfacten	Bovine mince	30 (48% DPPC)	120	4	Tokyo Tanabe and Mitsubishi Pharma (Japan)

All preparations contain SP-B and SP-C in varying amounts. *BLES* bovine lipid extract surfactant.

least tenfold than the amount of lipids needed to form a monolayer on the alveolar surface of the lungs [11, 21]. For licensed surfactant preparations the recommended doses vary from 50–200 mg/kg with dose volumes of 1.2–5 mL/kg (Table 70.2) [1]. Larger doses of surfactant are superior to smaller ones [22, 23]. Surfactant TA in a dose of 120 mg/kg (100 mg phospholipids/kg) improved oxygenation and reduced BPD compared to 60 mg/kg [22]. When 100 mg/kg of bovactant was compared with 50 mg/kg the larger dose was associated with better improvement in oxygenation [23]. For poractant alfa 200 mg/kg gives a better acute response than 100 mg/kg [24, 25] and probably an improved survival [24]. The dose of surfactant required for optimal effects is not known but is probably at least 100 mg phospholipids/kg which is close to the 100-250 mg/kg estimated to form the total pulmonary surfactant pool in a full-term neonate [26]. It is possible that 100 mg/kg is sufficient for prophylactic treatment [2] but 200 mg/kg may give better outcomes for rescue therapy [25].

70.3.4 Method of Administration

Surfactants usually need to be administered directly into the lungs during at least a brief period of endotracheal intubation [1]. Preterm infants at high risk of developing RDS should be born in centers where personnel and equipment are readily available to allow appropriate care to begin from birth [6]. In some of the earlier clinical trials surfactant was administered as a bolus into each main bronchus or as a single bolus into the lower trachea whereas in other trials it was given as divided doses directed into each lung lobe by positioning the baby [21]. After instillation the baby is either manually ventilated for a short time or reconnected to the ventilator to distribute the surfactant. A sterile feeding tube is often used to deliver the surfactant through the endotracheal tube. Bolus administration has been compared with infusion over 30 minutes in an animal model with the former giving more uniform distribution [27]. However, a small clinical trial with beractant found no differences in outcome when 3 dosing procedures were compared [28] and this was supported by a study with poractant alfa, which compared a bolus dose with a 1 minute infusion through a dual lumen tube [29]. It is important to minimize duration of mechanical ventilation after surfactant administration as this is an independent risk factor for development of BPD [30]. The INSURE (INtubate SURfactant Extubate to CPAP) technique minimizes duration of ventilation and is useful for babies initially treated with CPAP who may avoid mechanical ventilation altogether [31]. Although more surfactant is used with INSURE the benefits of reduced air leak (RR 0.52, 95%CI 0.28–0.96) and BPD (RR 0.51, 95%CI 0.26–0.99) mean that this technique is recommended [32]. The benefits appear to be even greater when infants are treated at a lower threshold oxygen requirement of less than 45%.

Other methods to forgo need for endotracheal intubation include nebulization [33], direct tracheal instillation at laryngoscopy using a fine feeding catheter [34], intrapartum pharyngeal deposition [35] and use of a laryngeal mask [36] although none is presently in widespread use and all need to be further evaluated in large clinical trials [1].

70.3.5 Need for Redosing

At least 2 studies demonstrated that multiple doses (up to three) are superior to a single dose [37, 38] and this is confirmed in a systematic review [39]. Multiple dose treatment with poractant alfa reduced both neonatal mortality and pneumothorax in preterm infants with severe RDS [37]. This study used retreatment criteria based on continued need for mechanical ventilation and oxygen supplementation at 12 and 24 hours after the first dose and about two-thirds of babies needed retreatment. Currently babies with RDS are being treated with surfactant earlier or prophylactically and need for retreatment is much less than before. Poractant alfa in an initial dose of 200 mg/kg compared to 100 mg/kg lead to much less need for second and third doses [24, 25]. Although criteria for redosing in the past were fixed it is best to adopt a more flexible approach [1, 7]. Redosing of infants needing more than 30% oxygen has been compared with more than 40% in a randomized trial using calfactant [40]. Babies with uncomplicated RDS did equally well with the higher threshold retreatment criterion but about one-quarter of those enrolled

had complicated RDS (associated with birth asphyxia or sepsis) and they had a lower mortality when retreated earlier [40].

Specific recommendations by surfactant manufacturers differ slightly: for beractant retreatment may be given at intervals of at least 6 hours for up to 4 doses; for poractant alfa treatment may be repeated 12 hourly for 2 further doses if still intubated, and after prophylaxis may be repeated 6–12 hours later and after a further 12 hours [1]. However, the Canadian Paediatric Society recommends retreatment of infants needing more than 30% oxygen as early as 2 hours after the first dose [8] and the European Association of Perinatal Medicine recommends retreatment if there is ongoing RDS indicated by need for mechanical ventilation and supplemental oxygen [6]. The latter also recommends that babies extubated to CPAP should be retreated when they need more than 50% oxygen or if they are likely to need mechanical ventilation [6].

70.3.6 Type of Surfactant

Surfactant preparations studied in the 1990s were either synthetic (containing phospholipids without surfactant proteins) or natural (derived from animal lungs and containing both phospholipids and SP-B and SP-C) [1]. Of these the most well known synthetic surfactants were colfosceril palmitate and pumactant but they are no longer available for clinical use. The most well known natural surfactants are: beractant, calfactant, surfactant TA and bovactant (all of bovine origin) and poractant alfa (of porcine origin) (Table 70.2). Recently other surfactants have been produced in Cuba (Surfacen), Korea (Newfacten), Brazil and India but there is little information about them [1, 41]. Also, more recently studied are the so called "new generation synthetic surfactant preparations" [7] which contain phospholipids and surfactant peptide analogues such as lucinactant [42, 43] and recombinant SP-C surfactant [44] although the latter has not been studied in neonates.

As noted earlier studies comparing synthetic and natural surfactants provide evidence that the latter act more rapidly to improve pulmonary status and in the longer term they show improved survival with fewer pulmonary air leaks [12]. As a result the older synthetic surfactants, colfosceril palmitate and pumactant are no longer available as commercial products. There have been at least 10 trials comparing various natural surfactant preparations [1, 41] and the largest of these compared beractant with calfactant for both prevention and treatment of RDS [45]. Unfortunately, the planned sample size was not reached, although more than 2000 infants had been recruited to the 2 arms of the study, due to slow recruitment, but in those studied there was no trend to suggest different outcomes including survival without BPD [45]. Studies comparing beractant and poractant alfa are smaller but show that the latter produces a more rapid onset of action in preterm infants with RDS [25, 46]. A US trial of 293 preterm infants with moderately severe RDS compared 2 doses of poractant alfa (200 mg/kg and 100 mg/kg) with a 100 mg/kg dose of beractant and found that there was a reduced need for redosing with the higher dose of poractant alfa [25]. Furthermore, there was improved survival for infants of less than 32 weeks' gestation treated with the 200 mg/kg dose of poractant alfa compared with those treated with beractant. A meta-analysis of 5 randomized trials comparing poractant alfa with beractant confirmed the reduction in mortality with the former (RR 0.57, 95%CI 0.34–0.96; NNT 20, 95%CI 11–1000), although the benefit seemed to be limited to those infants treated with the higher dose of poractant alfa (RR 0.29, 95%CI 0.10–0.79; NNT 14, 95%CI 8–50) [46]. Despite the numbers of infants studied in these comparisons being small and the American Academy of Pediatrics stating that it is still "unclear whether significant differences in clinical outcomes exist among the available (animal-derived surfactant) products" [7], poractant alfa is now the most widely used surfactant preparation worldwide.

Two studies reported comparisons between lucinactant (a new synthetic surfactant) and colfosceril palmitate (with beractant as a reference group) [42] and poractant alfa [43] respectively. Lucinactant was more effective than colfosceril palmitate in reducing incidence of RDS at 24 hours and BPD at 36 weeks' postmenstrual age but was similarly effective as beractant [42]. Lucinactant was claimed to be similar in terms of efficacy and safety to poractant alfa [43] but this study was really too small to justify this [47] and there are concerns about early trial closure and limited statistical power [7]. A Cochrane review of these 2 lucinactant trials calls for further well designed studies of adequate size and power [48] and in the future this surfactant may be approved for use in neonates [1, 49]. Natural surfactants (beractant, calfactant and poractant alfa) remain the drugs of choice for prevention and treatment of RDS [1] and there is some evidence to support the superiority of poractant alfa [50].

70.3.7 Concomitant Interventions

Prenatal steroids, methods of respiratory support including CPAP and caffeine treatment will be considered in this section. There have been at least 21 randomized trials of prenatal steroids involving over 4000 infants at risk of RDS [51]. Treatment with prenatal steroids is associated with an overall reduction in neonatal mortality (RR 0.69, 95%CI 0.58–0.81), RDS (RR 0.66, 95%CI 0.59–0.73), intraventricular hemorrhage (RR 0.54, 95%CI 0.43–0.69), necrotizing enterocolitis (RR 0.46, 95%CI 0.29–0.74), respiratory support and intensive care admissions (RR 0.80, 95%CI 0.65–0.99) and systemic infections in the first 48 hours of life (RR 0.96, 95%CI 0.38–0.85) [51]. As prenatal steroids are also effective in women with premature rupture of membranes and pregnancy related hypertension they should be given in most cases where preterm birth is anticipated before 35 weeks' gestation. Furthermore, there is evidence of synergistic effects of prenatal steroids and postnatal surfactant [52] and therefore both are indicated in cases with high risk of RDS.

The combination of early surfactant treatment and CPAP was assessed in many studies [7, 32, 53–55] and one study compared nasal CPAP with intubation at birth in very preterm infants [56]. It is clear that the combination of CPAP and early surfactant administration reduces the need for mechanical ventilation particularly in infants of greater than 27 weeks' gestation [32, 53, 55] although the reduction in BPD is rather modest [32]. CPAP started in the delivery room without prophylactic surfactant in infants of 25–28 weeks' gestation does not significantly reduce the rate of death or BPD compared to intubation and is associated with a threefold increased risk of pneumothorax [56]. Until more information from trials [54] becomes available prophylactic surfactant followed by early CPAP if tolerated is recommended best practice for preterm infants of less than 27 weeks' gestation [2, 6]. To facilitate extubation after early surfactant administration by the INSURE technique administration of respiratory stimulants such as caffeine has been recommended [31].

There are other reasons for recommending caffeine administration for treatment of apnea of prematurity as this has been shown to reduce risks of BPD, persistent ductus arteriosus and need for ductus ligation [57]. The reduced incidence of BPD in infants less than 1250 grams may be due to shortening the duration of mechanical ventilation by about 1 week and at 18–20 months the surviving caffeine treated infants had better neurodevelopmental outcomes with less cerebral palsy [58]. There are clear benefits from treatment of very preterm infants with caffeine for apnea of prematurity and to facilitate extubation following surfactant therapy although further longer term follow-up studies are needed to confirm this. There is no clear evidence that early inhaled nitric oxide will prevent BPD in these very immature babies.

Management of persistent ductus arteriosus (PDA) in surfactant treated infants is discussed below with treatment of pulmonary hemorrhage. It is good practice to monitor surfactant treated infants for PDA and to use prostaglandin synthetase inhibitors (indomethacin or ibuprofen) early to prevent relapse of respiratory status and/or pulmonary hemorrhage.

70.3.8 Other Indications for Surfactant Therapy

Secondary surfactant dysfunction may occur in neonatal respiratory disorders other than RDS where the deficiency is primary [10]. Surfactant inactivation and secondary dysfunction probably occur in meconium aspiration syndrome, congenital pneumonia, pulmonary hemorrhage, acute lung injury or acute respiratory distress syndrome (ARDS) and early stages of BPD [7, 49]. There are varying degrees of evidence of effectiveness of surfactant replacement therapy in these conditions and the evidence base is much weaker than for RDS [1]. Four randomized trials of surfactant treatment in meconium aspiration syndrome are included in a systematic review that found improved oxygenation and a reduced need for extracorporeal membrane oxygenation (ECMO) in treated infants (RR 0.64, 95%CI 0.46–0.91; NNT 6) [1, 59]. However, there were no differences in risk of pneumothorax, CLD or mortality. These studies used a 6-hourly dosing regimen with up to 150 mg/kg of bovine surfactant for up to four doses and in general the improvement in oxygenation is not seen until after the third dose of surfactant [1, 59]. More recently dilute surfactant lavage has been used to try to remove meconium particles from the lungs and future studies may compare this technique with standard bolus dosing [60].

Surfactant inactivation is also present in neonatal pneumonia and a subgroup of term infants with this condition showed improved oxygenation and reduced need for ECMO in a small, randomized trial of beractant [61]. A larger observational study of poractant alfa in infants with group B streptococcal pneumonia showed similar short-term improvements in oxygenation but these were less impressive than those in preterm infants with RDS [62]. Although the number of infants with pneumonia and respiratory failure treated with surfactant is relatively small the improved oxygenation warrants further study and continued use of surfactant for this indication.

Pulmonary hemorrhage is now relatively uncommon but may still occur in very preterm infants following surfactant therapy and it has been postulated that this is due to rapidly improving pulmonary vascular resistance and large left-to-right shunt through a PDA [63]. It is sensible to monitor preterm infants after surfactant therapy for PDA clinically, echographically and by blood pressure assessment and to use either indomethacin or ibuprofen at an early stage to prevent pulmonary hemorrhage. Surfactant has been used to treat massive pulmonary hemorrhage and the rationale is that blood inhibits surfactant function. There is evidence of modest improvement in oxygenation after surfactant treatment but this comes from observational studies rather than randomized trials, which clearly would be difficult to perform [64].

In acute lung injury or ARDS surfactant is inactivated by proteins and other substances leaking into the alveolar spaces. Pneumonia and sepsis are frequently underlying causes and surfactant is at least partially effective in reversing signs of respiratory failure in these term infants [49, 61, 62]. In some preterm infants born to mothers with severe pre-eclampsia there may be delayed onset of respiratory distress which could be due to surfactant inactivation, a form of ARDS, and in these infants surfactant may be only partly effective with multiple doses being needed. Acute lung injury may be a prelude to development of BPD and surfactant has been used to treat infants with early CLD in a small observational study, which showed transient improvement in oxygenation [65]. Recently a bovine surfactant has been used as a vehicle to deliver budesonide to the airways of preterm infants with severe RDS with a view to preventing BPD [66]. In this relatively small randomized trial there was an unexpectedly large reduction in the combined outcome of death and BPD in infants treated with beractant plus budesonide compared to those treated with beractant alone

(32% versus 61%; p = 0.003) [66]. Clearly further larger trials of this approach to preventing BPD are needed.

Congenital diaphragmatic hernia is also associated with surfactant insufficiency but surfactant treatment in a large series of infants did not improve outcomes [7]. On the contrary there were increased rates of CLD, mortality and need for ECMO in surfactant treated infants [67]. Until more evidence is forthcoming surfactant replacement cannot be recommended for infants with congenital diaphragmatic hernia.

70.4 Future Developments

Further research is needed to more precisely define which infants benefit most from prophylactic surfactant as opposed to early treatment. Efforts should continue to reduce the rates of BPD while maximizing survival and this will mean limiting the duration of mechanical ventilation with judicious use of CPAP and perhaps caffeine. Alternative means of administering surfactant without the need for endotracheal intubation will be pursued and tested in large randomized trials. New generation synthetic surfactants are likely to eventually replace natural surfactants especially if they can be produced more cheaply and in greater quantities [1, 7]. There will also be further studies to widen the indications for surfactant treatment beyond prevention and treatment of RDS [1, 67]. In particular it is likely that surfactants will be used in future to deliver other drugs, such as budesonide [66] or other anti-inflammatory agents directly to the airways to ameliorate acute lung injury and prevent BPD.

Nitric Oxide Therapy in Neonatology

John P. Kinsella

71.1 Background

After multiple approaches to the treatment of PPHN (see Chapter 67) since its first recognition as a disease marked by severe pulmonary hypertension, the discovery of the elusive "selective pulmonary vasodilator" markedly changed our understanding and clinical management of this syndrome. The most striking change in the management of PPHN in the last decade evolved from an improved understanding of the role of endogenous NO production and exogenous NO delivery on pulmonary vasoregulation.

Because the successful transition from fetal placental dependence to survival at birth requires that PVR rapidly declines and pulmonary blood flow increases, the role of NO in the transitional circulation has been intensively investigated to understand its relationship to the pathophysiology and treatment of PPHN.

NO was recognized as a potent vasodilator as early as 1979 [1], and in 1980, Furchgott and Zawadzki reported that acetylcholine-induced vasorelaxation was dependent on an intact endothelium through the elaboration of an endothelial-derived relaxing factor (EDRF) that diffused to the subjacent vascular smooth muscle [2].

In 1987 investigators from two separate laboratories reported that the biologic activity of EDRF was identical to NO or an NO-containing substance.

Palmer et al [3] induced the release of EDRF from porcine aortic endothelial cells in culture and compared the effects on superfused aortic strips with that of NO in solution. They found that the effects of EDRF were indistinguishable from those of NO. Ignarro et al [4] using a bioassay cascade superfusion technique with intrapulmonary arteries and veins, identified EDRF pharmacologically and chemically as NO, and found that EDRF and NO produced similar vasorelaxation and were inhibited by common antagonists.

Ignarro et al also recognized that NO was inactivated by combining with hemoproteins, and speculated that hemoglobin could trap endogenously produced NO that diffused into the vascular lumen, thus preventing any "downstream" vasorelaxation by this paracrine mediator.

The recognition that the endogenous production of this EDRF/NO mediator could be competitively blocked by modified L-arginine analogues prompted early experiments into the effects of NO in the fetal and transitional pulmonary circulation.

Abman et al performed the first experiments on the role of EDRF on the ovine fetal circulation, demonstrating that endogenous EDRF/NO production modulates basal pulmonary vascular tone in the late-gestation fetus, and that pharmacologic NO blockade inhibits endothelium-dependent pulmonary vasodilation [5]. These investigators also showed that pharmacologic NO blockade attenuates the rise in pulmonary blood flow at delivery, thus implicating endogenous NO formation in postnatal adaptation after birth and linking this laboratory observation to the life-threatening clinical condition of PPHN.

In addition, experiments using this ovine model showed that increased fetal oxygen tension augments endogenous NO release [6, 7], and the increase in pulmonary blood flow in response to rhythmic distention of the lung and high inspired oxygen concentrations are mediated in part by endogenous NO elaboration [8].

The observation that dilute NO gas could be therapeutically delivered by inhalation was first described by Higgenbottam et al who reported that brief (10 minute) inhalational NO treatment caused potent and selective pulmonary vasodilation in adults with severe pulmonary hypertension [9, 10]. Frostell et al demonstrated the selectivity of inhaled NO in an adult animal model of hypoxic pulmonary vasoconstriction [11], and the first description of the potent, sustained and selective vasodilator effect of inhaled NO in newborn lambs was reported by Kinsella et al in 1992 [12].

71.2 The Syndrome of Persistent Pulmonary Hypertension of the Newborn

The clinical syndrome of persistent pulmonary hypertension of the newborn (PPHN) occurs in association with various neonatal diseases, including meconium aspiration syndrome, group B streptococcal sepsis, and congenital diaphragmatic hernia, as well as from undetermined causes (idiopathic) (see Chapter 67). Although severe PPHN is commonly associated with near-term and term neonates, echocardiographic studies in premature infants with hyaline membrane disease (HMD) show that pulmonary hypertension may also complicate the course of severe HMD.

The treatment of PPHN commonly focuses only on pharmacologic therapy to reduce pulmonary vascular resistance. For the relatively small subset of neonatal patients with idiopathic PPHN who have pulmonary hypertension without concomitant lung disease, selective pulmonary vasodilation alone can cause marked improvements in oxygenation. However, PPHN often occurs with more common causes of neonatal respiratory distress, including disorders characterized by moderate to severe lung disease. Sepsis neonatorum and perinatal asphyxia can also severely compromise systemic vascular tone and cardiac performance, leading to systemic hypotension in addition to severe pulmonary hypertension. The pulmonary vasculature in many newborns with severe PPHN has marked structural changes, which include endothelial swelling, smooth muscle hypertrophy, and increased adventitial thickening. Moreover, functional abnormalities lead to altered responses to vasodilator and vasoconstrictor stimuli.

PPHN is a dynamic syndrome characterized by progressive changes in pulmonary vasoreactivity, cardiac performance, and parenchymal lung disease. The therapeutic approach to PPHN requires meticulous attention to all aspects of the cardiopulmonary perturbations (pulmonary hypertension, systemic vasodilation, decreased cardiac performance, and parenchymal lung disease) that characterize this syndrome and management is aided by serial hemodynamic, echocardiographic, and radiographic assessments (see Chapter 67).

71.3 Rationale for Inhaled NO Therapy

Early laboratory studies demonstrated that inhaled nitric oxide (NO) therapy caused marked and sustained reduction in pulmonary vascular resistance (PVR) in newborn animal models [12–14], and initial pilot studies showed marked improvement in oxygenation in term newborns with PPHN [15, 16]. Subsequent trials confirmed the safety and efficacy of inhaled NO in this population, and it is now an integral component of PPHN therapy [17–22].

As described above, the physiologic rationale for inhaled NO therapy in the treatment of PPHN is based on its ability to achieve potent and sustained pulmonary vasodilation without decreasing systemic vascular tone [23]. As a syndrome, PPHN is associated with diverse neonatal cardiac and pulmonary disorders that are characterized by high PVR causing extrapulmonary right-to-left shunting of blood across the arterial duct and/or oval foramen. The ability of inhaled NO therapy to selectively lower PVR and decrease extrapulmonary venoarterial admixture accounts for the acute improvement in oxygenation observed in newborns with PPHN [24]. However, oxygenation can also improve during inhaled NO therapy in critically ill patients who do not have extrapulmonary right-to-left shunting [25, 26]. Hypoxemia in these cases is primarily due to intrapulmonary shunting caused by continued perfusion of lung units that lack ventilation (e.g., atelectasis), with variable contributions form ventilation/perfusion (V/Q) inequality. Distinct from its ability to decrease extrapulmonary right-to-left shunting by reducing PVR, low dose inhaled NO therapy can also improve oxygenation by redirecting blood from poorly aerated or diseased lung regions to better aerated distal air spaces (microselective effect).

Finally, the diagnostic value of inhaled NO therapy is also important, in that failure to respond to inhaled NO raises important questions about the specific mechanism of hypoxemia. Poor responses to inhaled NO should lead to further diagnostic evaluation for unsuspected functional/structural cardiovascular or pulmonary disease.

71.4 Nitric Oxide Therapy in PPHN

Due to its selective pulmonary vasodilator effects, inhaled NO therapy is an important adjunct to available treatments for term newborns with hypoxemic respiratory failure. However, hypoxemic respiratory failure in the term newborn represents a heterogeneous group of disorders, and disease-specific responses have clearly been described. For example, patients with extapulmonary right-to–left shunting (PPHN) show acute improvement in oxygenation when PVR becomes subsystemic during NO therapy, and patients with predominantly intrapulmonary shunting (e.g., RDS) have less dramatic responses.

Several pathophysiologic disturbances contribute to hypoxemia in the newborn infant, including cardiac dysfunction, airway and pulmonary parenchymal abnormalities, and pulmonary vascular disorders. In some newborns with hypoxemic respiratory failure, a single mechanism predominates (e.g., extrapulmonary right-to-left shunting in idiopathic PPHN), but, more commonly, several of these mechanisms contribute to hypoxemia. For example, in a newborn with meconium aspiration syndrome, meconium may obstruct some airways decreasing V/Q ratios and increasing intrapulmonary shunting. Other lung segments may be over-ventilated relative to perfusion and cause increased physiologic dead space. Moreover, the same patient may have severe pulmonary hypertension with extrapulmonary right-to-left

shunting through the ductus arteriosus and foramen ovale. Not only does the overlap of these mechanisms complicate the clinical management, but the tendency for time-dependent changes in the relative contribution of each mechanism to hypoxemia requires continued vigilance as the disease progresses. Therefore, understanding the relative contribution of these different causes of hypoxemia becomes critically important as the inventory of therapeutic options expands.

Considering the important role of parenchymal lung disease in many cases of PPHN, pharmacologic pulmonary vasodilation alone may not be expected to cause sustained clinical improvement. The effects of inhaled NO may be suboptimal when lung volume is decreased in association with pulmonary parenchymal disease [27]. Atelectasis and air space disease (pneumonia, pulmonary edema) will decrease effective delivery of inhaled NO to its site of action in terminal lung units. In PPHN associated with heterogeneous (patchy) parenchymal lung disease, inhaled NO may be effective in optimizing ventilation-perfusion matching by preferentially causing vasodilation in lung units that are well ventilated. The effects of inhaled NO on ventilation-perfusion matching appear to be optimal at low doses (<20 ppm) [28, 29]. However, in cases complicated by homogeneous (diffuse) parenchymal lung disease and underinflation, pulmonary hypertension may be exacerbated because of the adverse mechanical effects of underinflation on pulmonary vascular resistance. In this setting, effective treatment of the underlying lung disease is essential (and sometimes sufficient) to cause resolution of the accompanying pulmonary hypertension.

Clinical trials of inhaled NO in the term newborn have incorporated ECMO treatment as an endpoint. Therefore, most patients have been enrolled in the first few days of life. Although one of the pivotal studies used to support the new drug application for inhaled NO therapy included as an entry criterion a postnatal age up to 14 days, the average age at enrollment in that study was 1.7 days [21]. Currently, clinical trials support the use of inhaled NO before treatment with ECMO, or usually within the first week of life. However, clinical experience suggests that inhaled NO may be of benefit as an adjuvant treatment after ECMO therapy in patients with sustained pulmonary hypertension (e.g., congenital diaphragmatic hernia). Thus, postnatal age alone should not define the duration of therapy in cases where prolonged treatment could be beneficial.

Studies support the use of inhaled NO in infants who have hypoxemic respiratory failure with evidence of PPHN, who require mechanical ventilation and high inspired oxygen concentrations. The most common criterion employed has been the oxygenation index. Although clinical trials commonly allowed for enrollment with OI levels > 25, the mean OI at study entry in multicenter trials approximated 40.

Thus it is unclear whether infants with less severe hypoxemia would benefit from inhaled NO therapy. However, Davidson et al reported a controlled clinical trial in which the average OI at study entry was 24±9 [30]. It is important to note that inhaled NO treatment did not reduce ECMO utilization in this study. Although entry criteria for this trial included echocardiographic evidence of pulmonary hypertension, only 9% of the patients had clinical evidence of right-to-left ductal shunting. Because of the mechanism of action of inhaled NO as a selective pulmonary vasodilator, it is likely that acute improvement in oxygenation caused by decreased pulmonary vascular resistance and reduced extrapulmonary right-to-left shunting would be most predictive of clinical improvement. Current multicenter studies suggest that treatment with inhaled NO may include an OI >25 with echocardiographic evidence of extrapulmonary right-to-left shunting.

The first studies of inhaled NO treatment in term newborns reported initial doses that ranged from 80 ppm to 6–20 ppm. Roberts et al reported that brief (30 minutes) inhalation of NO at 80 ppm improved oxygenation in patients with PPHN, but this response was sustained in only one patient after NO was discontinued [15]. In the second report, rapid improvement in oxygenation in neonates with severe PPHN was also demonstrated, but this was achieved at lower doses (20 ppm) for 4 hours [18]. This study also reported that decreasing the inhaled NO dose to 6 ppm for the duration of treatment provided sustained improvement in oxygenation. The relative effectiveness of low-dose inhaled NO in improving oxygenation in patients with severe PPHN was confirmed by a study by Finer et al [31]. Acute improvement in oxygenation during treatment was not different with doses of inhaled NO ranging from 5–80 ppm.

These laboratory and clinical studies established the boundaries of inhaled NO dosing protocols for subsequent randomized, clinical trials in newborns. Increasing the dose to 40 ppm does not generally improve oxygenation in patients who do not respond to the lower dose of 20 ppm. The initial dose in the NINOS trial was 20 ppm, but the dose was increased to 80 ppm if the improvement in PaO_2 was less than 20 torr [32]. In this study, only 3 of 53 infants (6%) who had little response to 20 ppm had an increase in PaO_2 >20 torr when treated with 80 ppm inhaled NO. Whether a progressive increase in PaO_2 would have occurred with continued exposure to 20 ppm could not be determined with this study design. Roberts et al initiated treatment with 80 ppm NO and subsequently weaned the inhaled NO concentration if oxygenation improved, thus the effects of lower initial inhaled NO doses could not be evaluated and the effects on ECMO utilization were not evaluated [18].

These studies did not systematically evaluate individual doses in an interpretable fashion. Davidson et al reported the results of a randomized, controlled, dose-response trial in term newborns with hypoxemic respiratory failure [30]. In this study, patients were randomized to treatment with either 0 (placebo), 5, 20 or 80 ppm NO. Each inhaled NO dose improved oxygenation compared to placebo, but there was no difference in responses between groups. However, at 80 ppm, methemoglobinemia (blood levels >7%) occurred in 13 of 37 patients (35%) and high inspired NO_2 concentrations (>3 ppm)

were reported in 7 of 37 patients (19%). Thus, 80 ppm inhaled NO was not more effective in improving oxygenation than 5 or 20 ppm, but was associated with adverse effects. Unfortunately, this trial was limited by early termination due to slow enrollment and the exclusion of lung recruitment approaches to optimize inhaled NO efficacy.

The available evidence, therefore, supports the use of doses of inhaled NO beginning at 20 ppm in term newborns with PPHN. Although brief exposures to higher doses (40–80 ppm) appear to be safe, sustained treatment with 80 ppm NO increases the risk of methemoglobinemia. The lowest effective starting dose for inhaled NO in term newborns with PPHN has not been determined. Cornfield et al reported that initiating treatment at 2 ppm does not acutely improve oxygenation and may diminish the subsequent response to 20 ppm [33]. However, this effect was not confirmed by Finer et al who found that initial exposure to low NO doses (1–2 ppm) did not compromise subsequent responses to higher doses (10–20 ppm), and dose increases were required in 80% of the low dose group [31]. Sustained improvement in oxygenation (after > 4 hours of treatment with 20 ppm) has been demonstrated for doses <10 ppm.

After improving oxygenation with inhaled NO therapy, strategies for weaning from NO become important. Numerous approaches have been employed, and few differences have been noted until final discontinuation of inhaled NO treatment. In one study, inhaled NO was reduced from 20 ppm–6 ppm after 4 hours of treatment without acute changes in oxygenation [30]. It is important to recognize that weaning inhaled NO is a different process than discontinuation of inhaled NO therapy.

In multicenter, clinical trials of inhaled NO therapy, the typical duration of inhaled NO treatment has been less than 5 days, which parallels the clinical resolution of PPHN. However, individual exceptions occur particularly in cases of pulmonary hypoplasia [34, 35]. If inhaled NO is required for longer than 5 days, investigations into other causes of pulmonary hypertension should be considered (e.g., alveolar capillary dysplasia), particularly if discontinuation of inhaled NO results in suprasytemic elevations of pulmonary artery pressure by echocardiography. In our practice, we discontinue inhaled NO if the FiO_2 is <0.60 and the PaO_2 is >60 mmHg without evidence of rebound pulmonary hypertension or an increase in FiO_2 > 15% after inhaled NO withdrawal.

Early clinical studies reported rapid and sometimes dramatic decreases in oxygenation and increases in PVR after abrupt withdrawal of inhaled NO during prolonged therapy. These responses are often mild and transient, and many patients with decreased oxygenation after inhaled NO withdrawal respond to brief elevations of FiO_2 and careful observation. In patients with a persistent need for treatment with higher inspired oxygen concentrations or with increased pulmonary hypertension after inhaled NO withdrawal, restarting inhaled NO treatment will generally cause rapid clinical improvement. In general, this so-called "rebound" response appears to decrease over time after more prolonged therapy. However, inhaled NO withdrawal can be associated with life-threatening elevations of pulmonary vascular resistance, profound desaturation, and systemic hypotension due to decreased cardiac output.

Mechanisms which contribute to these rebound effects are incompletely understood, but may be related to downregulation of endogenous NO production during exogenous NO therapy. Alternatively, the rise in pulmonary vascular resistance and drop in oxygenation after inhaled NO withdrawal may simply represent the presence of more severe underlying pulmonary vascular disease with loss of treatment effect of inhaled NO. The sudden increase in pulmonary artery pressure after rapid withdrawal of vasodilator therapy is not unique to inhaled NO, and has been observed in other clinical settings, such as prostacyclin withdrawal in adults with primary pulmonary hypertension and in postoperative cardiac patients.

Considering the important role of parenchymal lung disease in specific disorders included in the syndrome of PPHN, pharmacologic pulmonary vasodilation alone should be expected to cause sustained clinical improvement in many cases [36]. Moreover, patients not responding to inhaled NO can show marked improvement in oxygenation with adequate lung inflation alone. High success rates in early studies were achieved by withholding inhaled NO treatment until aggressive attempts were made to optimize ventilation and lung inflation with mechanical ventilation. These early studies demonstrated that the effects of inhaled NO may be suboptimal when lung volume is decreased in association with pulmonary parenchymal disease, for several reasons [37]. First, atelectasis and air space disease (pneumonia, pulmonary edema) may decrease the effective delivery of inhaled NO to its site of action in terminal lung units. Second, in cases complicated by severe lung disease and underinflation, pulmonary hypertension may be exacerbated because of the adverse mechanical effects of underinflation on pulmonary vascular resistance. Third, attention must be given to minimize overinflation to avoid inadvertent positive end expiratory pressure and gas trapping that may elevate pulmonary vascular resistance from vascular compression. This commonly complicates the management of infants with asymmetric lung disease or airways obstruction as observed in meconium aspiration syndrome.

In newborns with severe lung disease, HFOV is frequently used to optimize lung inflation and minimize lung injury [38]. In clinical pilot studies using inhaled NO, was found that the combination of HFOV and inhaled NO caused the greatest improvement in oxygenation in some newborns who had severe PPHN complicated by diffuse parencyhmal lung disease and underinflation (e.g., hyaline membrane disease, pneumonia) [39, 40]. Subsequently, a randomized, multicenter trial was conducted to determine the relative roles of inhaled NO and HFOV in newborns with severe PPHN [17]. In this study, treatment with HFOV+inhaled NO was more successful than HFOV or inhaled NO alone in severe PPHN, and differences in responses were related to the specific disease associated with the complex disorders of PPHN. For patients with PPHN

complicated by severe lung disease, response rates for HFOV+inhaled NO were better than HFOV alone or inhaled NO with conventional ventilation. In contrast, for patients without significant parenchymal lung disease, both inhaled NO and HFOV+inhaled NO were more effective than HFOV alone. This response to combined treatment with HFOV+inhaled NO likely reflects both improvement in intrapulmonary shunting in patients with severe lung disease and PPHN (using a strategy designed to recruit and sustain lung volume, rather than to hyperventilate) and augmented NO delivery to its site of action. In a single center randomized trial, Waffarn et al also reported improved responses to inhaled NO during HFOV when compared to conventional ventilation [41]. In this study, 13 of 14 infants randomized to HFOV and inhaled NO responded compared with 5 of 15 patients treated with conventional ventilation and inhaled NO. These findings underscore the importance of stratification of PPHN patients in NO trials, and the potential impact of adjuvant therapies on clinical responses to this potent and selective pulmonary vasodilator. Although inhaled NO may be an effective treatment for PPHN, it should be considered only as part of an overall clinical strategy that cautiously manages parenchymal lung disease, cardiac performance, and systemic hemodynamics.

71.5 Inhaled NO in the Premature Newborn

Early reports of iNO therapy in a premature newborn with pulmonary hypertension demonstrated marked improvement in oxygenation caused by effective treatment of severe pulmonary hypertension and resolution of extrapulmonary right-to-left shunting [42], as well as other preterm infants with severe respiratory failure [43, 44]. Subsequently, several randomized, controlled trials (RCTs) have confirmed the acute improvement in oxygenation caused by iNO treatment. However, in contrast to the direct pulmonary vasodilator effects of iNO, the focus of the most recently published studies has been on the potential beneficial effects of prolonged iNO administration on lung parenchymal and vascular development [45].

In a small, unmasked, randomized trial of iNO (20 ppm) and dexamethasone treatment, Subhedar et al reported no differences in survival, chronic lung disease, or intracranial hemorrhage between iNO treated infants and controls [46]. In a randomized, masked, multicenter clinical trial of low dose iNO therapy (5 ppm) in severely ill premature newborns with RDS who had marked hypoxemia despite surfactant therapy ($a/A\,O_2$ ratio < 0.10), iNO acutely improved PaO_2, but did not reduce the incidence of mortality or BPD [47]. Notably, there was no increase in the incidence or severity of ICH in this trial, and the incidence of the most severe ICH (grade 4) was 19% for the iNO group and 29% for the control group. The Franco-Belgian study group reported the results of an acute iNO response study (2 hour oxygenation endpoint); however, a brief duration of therapy and a high rate of crossover before the 2 hour trial endpoint compromised the interpretation of late outcome measures [48]. Hascoet et al reported the results of an unmasked, randomized trial of iNO in 145 premature newborns with hypoxemic respiratory failure [49]. They found no difference between the iNO and control groups in the primary outcome measure (intact survival at 28 days), and no differences in adverse events. As noted by Finer in an accompanying editorial, interpretation of the findings is limited by a relatively high rate of open-label iNO use and the lack of important outcomes such as death before discharge and BPD incidence at 36 weeks [50]. However, these investigators also studied the effect of low-dose iNO on serum markers of oxidative stress, and found that iNO treatment apparently reduced signs of oxidative stress in these patients [51]. Field et al described the findings of the UK INNOVO trial. In this unblinded study, 108 premature infants with severe hypoxemic respiratory failure were randomized to receive or not receive iNO [52]. There was no difference between the iNO and control group in the main outcome measures (death or severe disability at 1 year corrected age), and no difference in adverse events. Limitations of the study included an 8% crossover to iNO treatment, and treatment with other pulmonary vasodilators in 30% of the control group. Furthermore, Field et al described a lack of equipoise among investigators demonstrated by the observation that 75 infants eligible for enrollment were treated with iNO outside of the trial, leaving only infants with very severe lung disease enrolled in the study [53].

The largest trials of iNO therapy in premature newborns reported to date include the single center study of Schreiber et al [54], and the multicenter trials of Van Meurs et al [55], Ballard et al [56], and Kinsella et al [57]. All these studies were randomized, controlled and masked, but there were key differences in patient population, disease severity, dose and duration of therapy, and other factors.

Schreiber et al [54] randomized 207 infants to treatment with iNO or placebo. The main finding of the trial was a reduction in the incidence of BPD and death by 24% in the iNO group. These benefits appeared to accrue predominantly from a subset of newborns with relatively mild respiratory failure (OI<6.94). In addition to apparent pulmonary benefit caused by low-dose iNO, these authors also reported a 47% decrease in the incidence of severe ICH and periventricular leukomalacia (PVL). Furthermore, a subsequent report by the same group showed that the early decrease in ICH/PVL associated with iNO treatment manifested in improved neurodevelopmental outcome on follow-up examinations of this population [58]. In this follow-up study, 138 children (82% of survivors of the RCT) were evaluated for neurodevelopmental outcome at 2 years of age. In the group treated with iNO in the newborn period, 24% had abnormal outcomes (defined as cerebral palsy, blindness, hearing loss, or one score of less than 70 on the Bayley Scales of Infant Development II), in contrast to 46% in the control group.

Van Meurs et al [55] enrolled 420 newborns (401–1500 grams birthweight) in a multicenter RCT. Although the focus

of this study was on premature newborns and the major outcome measure was BPD, the design of the trial was similar to the previous NINOS trial in which term newborns were enrolled and acute changes in oxygenation determined continued treatment with study gas. That is, an acute dose-response study was performed and only patients who showed significant improvement in PaO_2 were continued on study gas. In contrast with other studies, the average duration of iNO treatment was only 76 hours. Overall, they found no difference in the incidence of death/BPD between the iNO and control groups. However, in post-hoc analyses, infants with birthweight >1000 grams showed a reduction in death/BPD following treatment with iNO (50% iNO versus 69% control). But a worrisome outcome was suggested in a post-hoc analysis of newborns weighing <1000 g. This analysis showed an increased risk of ICH/PVL (43% iNO versus 33% control). However, as noted in an editorial by Martin and Walsh [59], baseline ultrasound examinations were not performed, and it cannot be determined whether these very severely ill infants had ICH before iNO was initiated. Indeed, the severity of illness of infants in this trial of Van Meurs et al was also markedly different from the study of Schreiber et al. In the Van Meurs trial, the mean oxygenation index (OI) at enrollment for the iNO group was 23, compared to the median OI of 7.3 in the Schreiber study. This suggests that the degree of illness based upon the severity of respiratory failure may be related to iNO safety and efficacy in this population. However, an increased risk of ICH/PVL was not observed in a previous trial of iNO in premature newborns with severe hypoxemic respiratory failure (OI = 30) [47]. Other differences between these 2 trials may offer insights into the disparate outcomes, including the duration of iNO treatment (3 days versus 7 days), birthweight (839 g versus 992 g), and gestational age (26 weeks versus 27.4 weeks). Thus, Van Meurs et al enrolled smaller, more immature infants with severe respiratory failure who were treated relatively briefly with iNO, making direct comparisons between these 2 trials problematic.

The results of the two largest randomized, controlled and masked trials of iNO treatment in premature newborns were recently reported.

In the first trial, Ballard et al [56] randomized 582 premature newborns with birth weights of 500–1250 grams who required ventilatory support between 7 and 21 days of age. Infants were treated with study gas for a minimum of 24 days, and had an estimated OI of 7. They found that the incidence of survival without BPD was increased in the iNO treatment group (43.9%) compared to controls (36.8%, P = 0.042). A major finding of this trial was that the benefit of BPD reduction derived almost entirely from the subset of patients enrolled between 7–14 days, suggesting that early treatment is important to prevent BPD. There were no differences between the iNO and control groups in adverse events, including medical or surgical treatment of PDA. There were also no differences between the groups in ICH incidence, however infants were enrolled after the first week of life. Thus, this trial does not help inform the debate about iNO effects on brain injury in the premature newborn.

In the second trial [57], 793 premature newborns with birth weights of 500–1250 grams and requiring mechanical ventilation in the first 48 hours of life were randomized to treatment with 5 ppm iNO or placebo gas and treated for 21 days or until extubated. Overall, there was no difference in the incidence of death or BPD between groups. However, iNO therapy reduced the incidence of BPD for infants with birth weight >1000 g by 50% (p = 0.001). Low-dose iNO therapy reduced the incidence of PVL (p = 0.048), as well as the combined endpoints of ICH, PVL and ventriculomegaly for the entire study population (p = 0.032). INO therapy did not increase the incidence of adverse events, including mortality, ICH, PVL, pulmonary hemorrhage, and PDA treatment in any subgroup. In this trial there was no relationship between OI and brain injury risk, in contrast to the findings of Van Meurs et al. Mechanisms through which iNO therapy might provide neuroprotection in the premature newborn are uncertain, and warrant further study. Based on laboratory studies, several possibilities exist which include modulation of circulating cells (including neutrophils, monocytes and platelets) that may occur during NO exposure as they transit the pulmonary circulation. Alternatively, iNO induced down-regulation of lung derived cytokines may also reduce distant organ injury [60–62]. Another possible mechanism may relate to distal delivery of NO or NO-related metabolites through the systemic circulation through red blood cell or protein mediated pathways [63, 64].

The effects of iNO in the premature newborn may depend on the timing, dose, and duration of therapy, and the nature of the underlying disease. The available evidence from clinical trials suggests that low-dose iNO may be safe and effective in reducing the risk of death/BPD for a subset of premature newborns, in particular infants with birth weights > 1000 g. A neuroprotective effect of iNO has been demonstrated in large RCTs, but the relationship of disease severity and ICH/PVL risk is uncertain. Treatment of premature newborns with respiratory failure between 7–14 days after birth appears to be safe and effective in reducing the incidence of BPD.

Extracorporeal Membrane Oxygenation for Neonates

Anne Greenough, Munir Agha and Adam P.R. Smith

72.1 Introduction

Extracorporeal membrane oxygenation (ECMO) is a form of cardiopulmonary bypass, modified such that patients can be supported for a prolonged period of time, even weeks. ECMO is not a treatment, but rather supports the patient until their lung and/or cardiac function improves. ECMO was developed for use in adult patients, but abandoned when initial trials failed to demonstrate that it improved survival advantage over that achieved by conventional respiratory support [1]. Subsequently, Bartlett and colleagues demonstrated the potential of ECMO for neonates with severe respiratory failure. Now, many thousands of neonates have been recorded on the Extracorporeal Life Support Organisation (ELSO) database as having received ECMO. In this chapter, the techniques used and the management of a neonate on ECMO are described. In addition, the indications for ECMO and the results achieved are discussed.

72.2 Techniques

There are two methods of providing ECMO; veno-arterial (VA) and veno-venous (VV). In VA ECMO, blood is drained from the right jugular vein and returned via the right carotid artery. The major advantage is that it provides support for both lung and heart function, as 80% cardiopulmonary bypass is achieved. Thus, the level of additional respiratory support can be reduced, decreasing the likelihood of further barotrauma. VA ECMO, however, has disadvantages, which include the potential for clots or air to enter the arterial circulation. In addition, the carotid artery is cannulated and arterial reconstruction may be difficult, particularly in small infants. In VV ECMO, the artificial lung is in series with the patient's lung and pulmonary and systemic perfusion relies on the patient's ventricular function. Venous blood is drained from the internal jugular vein and returned to the inferior vena cava via the femoral or, less commonly, the umbilical vein. Alternatively a double lumen catheter may be sited in the right atrium via the right jugular vein, venous blood is drained from one lumen into the ECMO circuit and oxygenated blood returned through the other cannula into the right atrium. VV ECMO obviates the need for carotid artery cannulation, but leg edema can occur following femoral vein ligation after decannulation.

72.3 ECMO Circuit

Venous blood is pumped through an oxygenator, which has blood and gas compartments separated by semi-permeable membranes, through which diffusion of oxygen and carbon dioxide occur. Oxygen transfer is dependent on the surface area of the membrane, pump flow and the degree of saturation of the venous blood. Carbon dioxide (CO_2) elimination is affected by the flow rate. Heat is lost, particularly due to the large surface are of the oxygenator, hence a heat exchanger is used to warm the blood prior to returning to the infant.

72.4 Management During ECMO

Heparin, usually as a continuous infusion (20–50 U/kg/hr) is given to maintain an activated clotting time of 180–200 seconds to prevent clotting in the circuit or cannulae. As a result of anticoagulation bleeding complications occur, most commonly at cannulation and surgical wounds. These risks can be minimized by maintaining adequate platelet counts (>100,000 cells/mm^3), a normal international normalized

Birth weight > 2 kg
No lethal congenital anomalies
No irreversible brain injury
Mechanical ventilation < 14 days

ratio of prothrombin time (INR) and adequate levels of fibrinogen. Neuromuscular paralysis is necessary during cannula insertion, analgesia and sedation are continued throughout ECMO. Additional respiratory support is required during ECMO, but it is important to use settings that minimize further lung injury, but avoid atelectasis. Typical "lung rest" settings are peak pressures less than 30 cmH_2O, PEEP levels of 8–10 cmH_2O, rates of 10–25 breaths per minute and inspired oxygen concentrations of 0.21–0.40. Weaning is achieved by gradually reducing the pump flow rate.

72.5 Eligibility for ECMO

Prematurely born infants and those of low birth weight have an increased risk of intracranial hemorrhage and thus have been excluded from ECMO in most centers. ECMO, as it is a method of support rather than treatment, is inappropriate for infants with severe co-morbidities. Furthermore, the underlying pathology should have short-term reversibility, hence receiving more than 14 days of aggressive conventional ventilation is considered a relative contraindication to ECMO (Table 72.1). In the past, ECMO was generally reserved for infants with a predicted mortality of at least 80%; this has been defined as:

- oxygenation index (OI) > 40
- alveolar-arterial oxygen gradient ($AaDO_2$) ≥ 620 torr

$$OI = \frac{\text{mean airway pressure} \times FO_2}{PaO_2 \text{ (postductal)} \times 100}$$

$$AaDO_2 = FiO_2 \times (P_{atm} - 47) - PaO_2 - PaCO_2$$

where P_{atm} = atmospheric pressure (mmHg) and 47 mmHg reflects water vapor pressure.

In the UK ECMO trial [2] however, an OI >40 was associated with a mortality of only 41% on conventional ventilation.

72.6 Outcome

72.6.1 Mortality

The largest randomized neonatal ECMO trial recruited 185 neonates with severe respiratory failure from 55 neonatal intensive care units in the UK [2]. Parental consent to entry into the trial was requested if OI was greater than 40 or arterial partial pressure of CO_2 was >12kPa for three hours. Infants were then randomized to either remain on conventional therapy at their neonatal unit or be transferred for ECMO at one of five UK centers. Overall, there was a significant reduction in mortality for the ECMO group (relative risk (RR) 0.55, 95% CI 0.39–0.77; p = 0.0005). There was a benefit for ECMO in all diagnoses, although the effect in CDH infants was marginal; 17 CDH infants supported conventionally died before discharge and 14 of 18 supported with ECMO died before one year of age. Meta-analysis of the only four neonatal ECMO randomized trials demonstrated a benefit of ECMO on mortality (RR 0.44, 95% CI 0.31–0.61) [3].

Table 72.2 Survival rates to hospital discharge or transfer *

Primary Diagnosis	Total Cases	Survivors to discharge	% Survival
MAS	7,152	6,705	94
CDH	5,270	2,724	52
PPHN	3,452	2,681	78
Sepsis	2,506	1,884	75
RDS	1,437	1,209	84
Other	1,559	994	64

* Adapted from [10].

Up to July 2007, 21500 neonates supported for respiratory causes had been reported to the ELSO Registry [4]. The overall survival to hospital discharge or transfer was 76%; infants with MAS having the best results and those with CDH the poorest (Table 72.2). Approximately 10% of cases reported to the ELSO Registry have a primary cardiac problem, overall survival is 38%. ECMO may also be used during cardiopulmonary resuscitation.

72.6.2 Morbidity

Chronic respiratory, neurological and growth problems have been reported following ECMO. The only long-term data on outcome following randomization to ECMO or conventional management comes from follow-up of the UK ECMO trial. Follow-up at one year revealed that ECMO was associated with a reduction in mortality without an increase in severe disability (defined as having a Griffiths quotient less than 50 or being unable to participate in quantitative developmental assessment due to severity of disability). At four years of age, more of the ECMO surviving infants had no disability (50% versus 37%) [5]. Ninety of the infants (56 ECMO; 34 conventional) were seen at seven years, there were no significant differences in overall cognitive ability between the two groups; 76% of infants had overall performance within the normal range [6]. Overall, the study showed a continuing benefit of ECMO for the primary outcome of death or severe

disability (relative risk 0.64, 95% CI 0.47–0.86; p = 0.004). At one year of age, the ECMO-supported infants had better lung function [7]. At seven years of age, more children from the "conventional" group had evidence of respiratory morbidity, 32% had intermittent wheeze during the 12 months prior to questioning, and 41% regularly used inhalers, compared to 11% and 25% respectively of the ECMO group [6].

72.6.3 Cost-Effectiveness of ECMO

The costs of ECMO at one year are dominated by the expense of initial hospital care, partly reflecting the cost of ECMO provision itself, but also that the reduced mortality led to an increased average duration of stay in conventional neonatal intensive care. Cost-effectiveness improves over time, with the seven year follow-up analysis from the UK ECMO trial estimating the incremental cost per life year gained was £13,385 (2002–3 prices) [8]. Whilst treatment of infants was cost-effective in most diagnostic groups, the cost/ ratio for infants with CDH was far poorer.

72.7 Changes in ECMO Requirements with Time

Advances in other respiratory support techniques for term and near-term infants have reduced the number of cases referred for ECMO and altered the profile of these patients. Data from the ELSO registry highlight that neonatal respiratory cases fell from a peak of 1516 ECMO runs in 1992 to 751 runs in 2003 and that the proportion of cases with MAS fell from 35% to 25%, while CDH cases rose from 18% to 28% of neonatal respiratory cases. Similarly, a comparison of infants with severe respiratory failure treated at a single centre during two time periods showed a decrease in ECMO utilization from 42.8% to 27.7% [9]. There were concomitant increases in the use of HFOV (36.7% to 87.2%), surfactant (26.5% to 89.3%) and iNO (0% to 44.7%). One potential concern with the institution of newer methods of respiratory support is that it may delay ECMO treatment, which in non-randomized studies has been associated with prolongation of both ECMO and conventional treatment, as well as increased mortality [10].

Lung Diseases: Problems of Steroid Treatment of Fetus and Newborn

Henry L. Halliday

73.1 Introduction

Corticosteroids given in the perinatal period have a multitude of biologic effects on the developing lung [1]. These include reduced alveolarization, increased production of surfactant lipids and proteins, increased absorption of lung fluid and increased antioxidant activity. Clearly some of these will be beneficial to the immature fetus or neonate whilst others will be detrimental. Thus administration of corticosteroids in the perinatal period must be based upon clinical judgment of the balance of benefits and risks.

The first true randomized trials of corticosteroids in the perinatal period were both published in 1972 in the same issue of a pediatric journal. They were aimed at either preventing or treating respiratory distress syndrome (RDS) a condition of predominantly preterm infants, which then had a high mortality rate. RDS is due to primary deficiency of pulmonary surfactant [2] and Liggins, an obstetrician in New Zealand had shown that an infusion of cortisol into fetal lambs seemed to prevent RDS [3]. He and a colleague from pediatrics performed a large randomized trial of prenatal betamethasone and showed that this not only decreased the risk of RDS in neonates but also reduced mortality. Since 1972 many randomized trials confirmed the benefits of prenatal corticosteroids [4] and long-term follow-up of the original cohort at age 31 years has been published [5]. Detrimental effects of prenatal corticosteroids and the controversy over any additional benefit of repeat courses will be discussed in this chapter.

The trial of Baden et al recruited only 44 infants with RDS to test the effects of hydrocortisone on blood gases, need for assisted ventilation and survival. Unfortunately, there were no beneficial effects of hydrocortisone and the authors also concluded that there were no immediate detrimental effects of the therapy. However, two subsequent follow-up publications raised concerns about an excess of severe intraventricular hemorrhage (IVH) and neurosensory and electroencephalographic abnormalities [6, 7] in hydrocortisone treated infants. Despite these early concerns dexamethasone was used to treat infants with bronchopulmonary dysplasia (BPD) and ventilator-dependence less than a decade later [8, 9]. The rationale for dexamethasone therapy was to reduce inflammation in the lung, an important precursor to the development of BPD. However, the doses of dexamethasone used in these trials were very large (about 0.5 mg/kg/day as a starting dose) giving pharmacologic rather than physiologic effects. It was not surprising that the acute beneficial effects on lung function [8, 9] would later be shown to have had adverse long-term effects on the developing central nervous system [10].

73.2 Results from Randomized Trials of Prenatal Corticosteroids

The most recent systematic review of a single course of prenatal steroids for accelerating fetal lung maturation includes 21 studies and 4269 infants [4]. The authors conclude that prenatal steroid treatment does not increase risk to the mother of death, chorioamnionitis or puerperal sepsis. However, treatment was associated with an overall reduction in neonatal death (RR 0.69; 95%CI 0.58–0.81), RDS (RR 0.66; 95%CI 0.59–0.73), IVH (RR 0.54; 95%CI 0.43–0.69), necrotizing enterocolitis (NEC) (RR 0.46; 95%CI 0.29–0.74), respiratory support and intensive care admissions (RR 0.80; 95%CI 0.99) and systemic infections in the first 48 hours of life (RR 0.56; 95%CI 0.38–0.85). Prenatal steroid use is also effective in women with premature rupture of membranes and pregnancy related hypertension syndromes [4]. The authors concluded that a single course of prenatal steroids should be considered routinely for preterm delivery with few exceptions. Further information is needed concerning optimal dose to delivery interval, optimal steroid to use, effects in multiple pregnancies and to confirm the long-term effects into adulthood [4]. The most recent systematic review of repeat doses of prenatal

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

steroids for women at risk of preterm birth for preventing RDS included 5 trials and involved over 2000 women [11]. Treatment with repeat dose(s) of steroids was associated with a reduction in both occurrence (RR 0.82; 95%CI 0.72–0.93) and severity of any neonatal lung disease (RR 0.60; 95%CI 0.48–0.75) and serious infant morbidity (RR 0.79; 95%CI 0.67–0.93). Mean birth weight was not significantly different between treatment groups, although in one trial, treatment with repeat dose(s) of steroids was associated with a reduction in birth weight Z score and in two trials with an increased risk of being small for gestational age (SGA) at birth (RR 1.63; 95%CI 1.12–2.37). The authors concluded that repeat dose(s) of prenatal steroids reduce the occurrence and severity of neonatal lung disease and the risk of serious health problems in the first few weeks of life. The short-term benefits for babies support the use of repeat dose(s) of prenatal steroids for women at risk of preterm birth. However, these benefits are associated with a reduction in some measures of weight and head circumference at birth, and there is still insufficient evidence on the longer-term benefits and risks [11].

Since this repeat dose systematic review was published another important large study reported that multiple courses of prenatal steroids, every 14 days, do not improve preterm birth outcomes and are associated with decreased weight, length and head circumference at birth [12]. These authors concluded that a repeat treatment schedule of every 14 days until week 33 weeks or delivery was not recommended. Recently, a balanced view has emerged stating that weekly repeat doses of prenatal steroids compared with a single course seem to reduce neonatal respiratory morbidity and some of its complications, particularly when delivery occurs at less than 32 weeks' gestation [13]. The major concern about repeat doses of steroids is that they may be associated with adverse effects on the brain and that long-term outcome data are currently lacking. A compromise may be to consider repeated doses of steroids for women who remain at very high risk of extreme preterm delivery (for example < 29 weeks), where a 20% reduction in composite severe morbidity may outweigh the theoretical concerns of risks in later childhood [13].

73.3 Results from Randomized Trials of Postnatal Steroids

The most recent systematic reviews of postnatal steroids for preventing [14] and treating chronic lung disease (CLD) [15] in preterm infants were published in the Cochrane Library in 2009. Twenty-eight trials enrolling 3740 infants were included in the systematic review of postnatal steroids given in the first week of life to try to prevent CLD in preterm infants [14]. There were significant benefits of early postnatal steroids as regards earlier extubation and decreased risks of CLD at both 28 days (RR 0.87; 95%CI 0.81–0.93) and 36 weeks' postmenstrual age (PMA) (RR 0.79; 95%CI 0.71–0.88). There were also decreases in persistent ductus arteriosus (PDA) (RR 0.78; 95%CI 0.72–0.85), retinopathy of prematurity (ROP) (RR 0.88; 95%CI 0.80–0.97) and severe ROP (RR 0.79; 95%CI 0.65–0.97). There were no significant differences in rates of mortality, infection, severe IVH, periventricular leukomalacia, NEC or pulmonary hemorrhage. Important adverse effects included gastrointestinal bleeding (RR 1.86; 95%CI 1.35–2.55), intestinal perforation (RR 1.81; 95%CI 1.33–2.48), hyperglycemia (RR 1.34; 95%CI 1.21–1.48), hypertension (RR 1.85; 95%CI 1.55–2.22), hypertrophic cardiomyopathy (RR 4.33; 95%CI 1.40–13.4) and growth failure (RR 6.67; 95%CI 2.27–19.6). Twelve trials reported late outcomes and several adverse effects were found including developmental delay (RR 1.94; 95%CI 1.30–2.88), cerebral palsy (RR 1.50; 95%CI 1.13–3.59) and abnormal neurological examination (RR 1.81; 95%CI 1.33–2.47). However, the rates of the combined outcomes of death or cerebral palsy, and death or major neurosensory disability were not significantly increased [14].

Dexamethasone was used in 20 studies and hydrocortisone in eight. In a subgroup analysis most of the beneficial and harmful effects were attributable to dexamethasone although with hydrocortisone there was an increase in intestinal perforation (RR 2.02; 95%CI 1.13–3.59) and a borderline reduction in PDA (RR 0.85; 95%CI 0.73–0.99) [14]. The authors concluded that the benefits of early postnatal steroid treatment (< 8 days), particularly with dexamethasone, may not outweigh the known or potential adverse effects of this treatment. There is a compelling need for the long-term follow-up and reporting of late outcomes, especially neurological and developmental outcomes, among surviving infants who participated in all randomized trials of early postnatal steroids. Hydrocortisone in the doses and regimens used in these trials had few beneficial or harmful effects and cannot be recommended for prevention of CLD [14]. One randomized trial of a 4-week course of early dexamethasone reported outcomes at school age [16]. The authors' conclusion was that early postnatal dexamethasone therapy should not be recommended for the routine prevention or treatment of CLD because it leads to substantial adverse effects on neuromotor and cognitive function at school age [16].

Nineteen trials enrolling a total of 1345 infants were included in the systematic review of late (after 7 days) postnatal steroids for CLD in preterm infants [15]. Late steroid treatment was associated with a reduction in neonatal mortality (RR 0.49; 95%CI 0.28–0.85) but not at discharge (RR 0.87; 95%CI 0.65–1.17). Other beneficial effects included earlier extubation and reductions in CLD at both 28 days (RR 0.87; 95%CI 0.81–0.94) and 36 weeks' PMA (RR 0.72; 95%CI 0.61–0.85), need for late rescue treatment with dexamethasone (RR 0.46; 95%CI 0.36–0.58), discharge home on oxygen therapy (RR 0.71; 95%CI 0.54–0.94) and death or CLD at both 28 days (RR 0.84; 95%CI 0.78–0.89) and 36 weeks' PMA (RR 0.72; 95%CI 0.63–0.82). There was a trend towards an increased risk of infection and gastrointestinal bleeding but not NEC. Short-term adverse effects included hyperglycemia (RR 1.52; 95%CI 1.25–1.84), glycosuria (RR 8.03; 95%CI 2.43–26.5) and hypertension (RR 2.66; 95%CI 1.58–4.49). There was an increase

in severe ROP (RR 1.38; 95%CI 1.07–1.79) but no significant increase in blindness. There was a trend towards reduction in severe IVH (RR 0.44; 95%CI 0.19–1.02) and trends towards an increase in cerebral palsy and abnormal neurological examination were partly offset by a trend in the opposite direction in death before late follow-up. The combined rate of death or cerebral palsy was not significantly different between steroid and control groups. Major neurosensory disability and the combined rate of death or major neurosensory disability were not significantly different between groups. There were no substantial differences between groups for other outcomes in later childhood, including respiratory health or function, blood pressure or growth [15]. The authors concluded that the benefits of late steroid therapy (after 7 days) may not outweigh actual or potential adverse effects. Although there continues to be concern about an increase in adverse neurological outcomes in infants treated with early postnatal steroids, this review of late steroids suggests that this may reduce neonatal mortality without significantly increasing the risk of adverse long-term neurodevelopmental outcomes. However, the methodological quality of the studies determining long-term outcomes is limited in some cases and no study was sufficiently powered to detect increased rates of important long-term outcomes. Given the evidence of both benefits and harms of treatment and the limitations of the evidence at present it appears prudent to reserve use of late postnatal steroids to infants who cannot be weaned from mechanical ventilation and to minimize the dose and duration of any course of treatment [15].

73.4 Conclusions

There are some problems with steroid treatment of the fetus and newborn but on the whole if used according to accepted guidelines the benefits outweigh the risks. For the fetus at risk of preterm birth a single course of betamethasone leads to lung maturity and reduces the risk of RDS, neonatal mortality and other important complications of prematurity [5]. The current recommendation is to give 2 doses of 12 mg betamethasone, 24 hours apart, to women who may deliver within 7 days and are less than 35 weeks pregnant [17].

There remains some controversy about repeat courses of prenatal steroids as they are associated with reduced fetal growth but consensus seems to support their use when there is a high risk of preterm birth before 29 weeks' gestation [13].

The beneficial pulmonary effects of early postnatal dexamethasone, in the first week of life, do not outweigh the adverse effects on neurodevelopment [14]. However, late postnatal steroid therapy, after the first week of life, seems to be associated with similar beneficial pulmonary effects without significant increase in neurodevelopmental sequelae [15]. Late steroid therapy, with low dose, short duration dexamethasone is probably still indicated for preterm infants with CLD who remain ventilator dependent and have severe respiratory disease [15, 18].

The role of inhaled steroids needs further evaluation in randomized clinical trials [19].

Apnea of Prematurity and Sudden Infant Death Syndrome

Christian F. Poets

74.1 Apnea of Prematurity

74.1.1 Introduction

Apnea of prematurity (AOP) is a developmental and thus self-resolving disorder, which nonetheless can cause serious problems. Almost every infant born at less than 29 weeks gestation exhibits AOP. No study, however, has yet identified a threshold in either frequency or severity of accompanying bradycardia or hypoxemia above or below which there is an increased risk for neurodevelopmental impairment. Most even suggested that within the frequency and severity of AOP tolerated in their institution, there is little indication that AOP, by itself, leads to impaired neurodevelopment [1].

Given the lack of good outcome data, indications for treatment or a step-up in its intensity are bound to be arbitrary. From a physiological point of view it is not the apnea but its effect on oxygenation and/or heart rate that is relevant to the well-being of an infant. Although never systematically investigated, it is unlikely that a desaturation to 79% for 2 s will pose the same risk on neurodevelopment as one to 20% requiring vigorous stimulation. In the author's institution, an apnea severity score has therefore been developed to encompass this situation (Fig. 74.1).

This score however, is as yet unvalidated and can only serve as an example of how apnea severity may be assessed more objectively even without documentation via continuous recordings. It also has to be kept in mind that any treatment threshold strongly depends on the averaging time used by the instrument with which SpO_2 and heart rate are monitored (Fig. 74.2).

74.1.2 Treatment

Interventions to improve AOP can be grouped according to 3 underlying pathophysiologic mechanisms: interventions aimed at (i) reducing work of breathing, (ii) increasing respiratory drive, and (iii) improving diaphragmatic contractility (Table 74.1).

74.1.2.1 Interventions Aimed at Reducing Work of Breathing

Prone Head-Elevated Positioning

In the prone position, the chest wall is stabilized and thoracoabdominal asynchrony reduced. Several studies have demonstrated that the prone position reduces apnea rate in preterm infants, with some also reporting a decrease in desaturation rate. An extension of the prone position is the prone, head-elevated tilt position, which was associated with a 49% reduction in desaturations to <85% in one study. Recently, however, 2 studies re-investigated the issue, triggered by the observation that infants appear more comfortable when only the chest rather than the entire body is being tilted. Both found a slight (–13%) reduction in the frequency of desaturation/bradycardia compared to the horizontal position; one even found no advantage for the head-up tilt position [2]. This much less clear advantage of the head-up tilt postion may be due to the fact that infants in the earlier study had received no other treatment, whereas in the more recent ones, all had received caffeine and most continuous positive airway pressure (CPAP) [2].

Thus, the effect of head-up positioning on bradycardia and intermittent hypoxia may be less pronounced in infants already receiving other treatments for AOP. The prone, head-up tilt position should therefore be considered as a first-line intervention for infants with AOP, but will likely offer little additional effect in infants already treated with caffeine or CPAP.

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

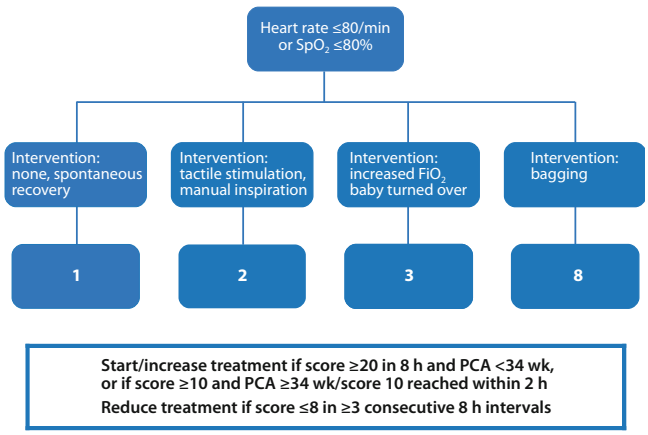

Fig. 74.1 Apnea Score to assess apnea severity similarly across different raters/infants. The value in the lower row of boxes indicates the respective score

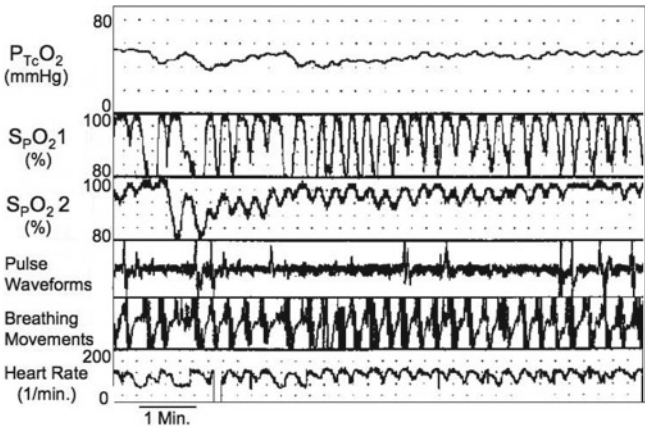

Fig. 74.2 Influence of averaging time of the pulse oximeter on rates of intermittent hypoxia. Two pulse oximeters (Nellcor N200) are attached to the right and left foot of a preterm infant during periodic apnea. The upper pulse oximeter saturation trace (SpO_2 1) was recorded in a beat-to-beat mode, the lower one (SpO_2 2) in a 6-s averaging mode. Note that with the oximeter set in a non-averaging mode, 15 alarms to ≤80% SpO_2 would have been counted, in contrast to only two with the 6-s averaging mode. Unaccounted for, this purely technical difference might have resulted in different treatment decisions. *$PTcO_2$*, partial pressure of transcutaneous oxygen tension, *SPO_2* pulse oximeter saturation. Table 74.1 Suggested incremental treatment plan for AOP

1st Step:	Prone, 15° head-up tilt position
2nd Step:	Caffeine*
3rd Step:	Variable flow CPAP or synchronized N-IPPV
4th Step:	Intubation and mechanical ventilation**

*Consider caffeine as first-line treatment in infants <28 weeks GA. **Doxapram may be considered as an alternative in infants who continue to exhibit recurrent hypoxia and bradycardia despite mechanical ventilation.

Continuous Positive Airway Pressure and Nasal Ventilation

CPAP has been shown to reduce extubation failure in preterm infants, despite the fact that most systems currently available do not reduce work of breathing. CPAP can be applied via a nasopharyngel tube or (bi-)nasal prongs. Reintubation rates are 40% lower with the latter (relativ risk (RR) 0.59 [0.41;0.85], number needed to treat 5 [NNT]) [3], which is why this should be the preferred mode when applying CPAP. An extension of CPAP is nasal intermittent positive pressure ventilation (N-IPPV), which has a high effectiveness over CPAP in preventing extubation failure (RR 0.21 [0.10–0.45], NNT 3) [4].

Typically, an inspiratory pressure of 15–20 cm H_2O, applied at a rate of 10–20/min, is combined with a CPAP level of 5–6 cm H_2O. There is theoretical concern that this might result in gastric distension, but this has not been confirmed [4]. Both studies showing superiority of N-IPPV over CPAP in the meta-analysis, however, used synchronized nasal ventilation [4]. When we compared non-synchronized N-IPPV with N-CPAP delivered via a variable flow device that reduces work of breathing, the rate of bradycardia and desaturation was 50% lower with the latter device [5]. Thus, a reduced work of breathing may be key to success for nasal ventilatory support to improve AOP, which can be achieved via either synchronized N-IPPV or variable flow N-CPAP devices [5].

74.1.2.2 Interventions Aimed at Increasing Respiratory Drive

Oxygen Administration

That oxygen stabilizes neonatal respiration was first observed in 1923. Several crossover trials in infants with and without BPD have since shown that the application of low-flow oxygen results in a reduced rate of intermittent hypoxia and apnea [6]. Application of this therapy, however, has to be weighed against side effects potentially resulting from oxygen toxicity. Thus, before the data from randomized controlled trials (RCT) currently underway are available, no ideal oxygen level can be recommended.

Increased Inspiratory CO_2 Concentration

Respiratory drive also depends on CO_2. If CO_2 levels fall to below the eupneic baseline value, apnea occurs. Recently, an inspiratory CO_2 concentration of 0.8% for 2 h was as effective as theophylline in reducing apnea duration and rate [7]. It is likely, however, that infants will quickly accommodate to a higher inspiratory CO_2 concentration; thus, data on the longer-term effectiveness of this treatment modality are required.

Red Blood Cell Transfusions

An increase in respiratory drive resulting from an increased tissue oxygenation is also one of the proposed mechanisms for red cell transfusions to potentially ameliorate AOP, and anemia has indeed been implicated in the pathophysiology of AOP. It would thus seem logical to hypothesize that blood transfusions are an effective treatment modality in infants with AOP who are anemic. Data on the effect of blood transfusions on the frequency of these episodes, however, are conflicting. In 2 crossover-studies, focussing on bradycardia and intermittent hypoxia, we found no effect of transfusion [8, 9]. Recently, however, Bell et al published the results of a RCT comparing a liberal with a more restrictive transfusion policy in 100 VLBW infants [10]. Mean rate of apneas requiring stimulation was 0.23/h in the liberal *vs* 0.46/h in the restricted transfusion group, but significantly more infants in the restrictive transfusion group happened to have brain lesions and may thus have been more likely to develop AOP. Based on these conflicting data, blood transfusion to anemic VLBW infants with AOP as their only symptom cannot be recommended.

Caffeine

Methylxanthines increase chemoreceptor sensitivity as well as respiratory drive and can also improve diaphragmatic contractility. Of the substances available, caffeine has a wider therapeutic range and fewer side effects than theophylline. There were concerns, however, that caffeine, being an adenosine antagonist, could reduce tolerance to hypoxia and thus might be harmful to infants with recurrent hypoxia. Thus, it is most commendable that Schmidt et al performed a large placebo-controlled RCT enrolling over 2000 infants [11]. Caffeine (or placebo) was started during the first 10 days of life in infants of 500–1250 g birth weight at a dose of 5–10 mg/kg caffeine citrate until no longer needed for AOP treatment. Mechanical ventilation, CPAP, and oxygen could all be discontinued approximately one week earlier in infants treated with caffeine. Somewhat unexpectedly, and not a primary endpoint, was the finding of a 40% lower risk of bronchopulmonary dysplasia (BPD; 36% *vs* 47%; OR 0.6; 95% CI 0.5;0.8) and a 30% lower risk of developing a symptomatic patent ductus arteriosus (OR 0.7; [0.5;0.8]) in the caffeine group [11]. Most important, however, are the data on the primary outcome, i.e., death or disability at 18 month corrected age. These showed that caffeine was associated with a 23% reduction in this outcome (OR 0.77; 95% CI 0.64–0.93). This benefit was particularly strong for cerebral palsy: 4.4% *vs* 7.3% of infants had this outcome (RR 0.58; 0.39–0.87) [12].

In a subgroup analysis, the effect of caffeine on the primary outcome was found to be restricted to those requiring ventilatory support at randomization; i.e., caffeine had no effect on death or disability in infants not requiring CPAP or IPPV. Interestingly, the reduced duration of the need for ventilatory support was only evident in those who were randomized within the first 3 days of life. Thus, caffeine appears to be the only drug yet identified to reduce cerebral palsy. Given that this effect appears to be restricted to those receiving ventilatory support, it is most likely that it was mediated via a reduced need for mechanical ventilation rather than a reduced rate of bradycardia and desaturation, but this has yet to be proven. In any case, caffeine administration should be started within the first 3 days of age in infants <1250 g requiring respiratory support who suffer from or are likely to develop AOP.

Doxapram

Doxapram stimulates peripheral chemoreceptors at low and central ones at high doses. It shows a dose-response curve. Most studies used a continuous intravenous (i.v.) infusion, although some suggest that the i.v. solution may also be given orally at twice the dose. Short-term side effects become quite common at doses above 1.5 mg/kg/h and include irritability, myoclonus, elevated blood pressure and gastric residuals. Of concern is the fact that the long-term effects of doxapram are unknown. This is particularly worrying given that in a study on factors associated with poor motor development in extremely low birthweight infants, the only difference found was that infants with developmental delay had received a mean cumulative doxapram dose of 2233 mg, compared to 615 mg in controls ($p<0.01$) [13]. Although such a retrospective analysis cannot distinguish whether this reflects sequelae of severe AOP (for which doxapram had been given), or a direct drug effect, it clearly raises concern. In the caffeine study [12], infants in the placebo group had not only been more likely to develop cerebral palsy, but were also 3 times more likely to receive doxapram. Given these data (or lack thereof), doxapram cannot be recommended as a standard treatment for AOP.

74.1.2.3 Interventions Aimed at Improving Diaphragmatic Strength

If muscle fatigue is involved in AOP, then improvements in diaphragmatic strength should be beneficial, but this has hardly been tested yet. Fifteen years ago, an enriched total parenteral nutrition (TPN) solution with branched-chain amino acids, which improve diaphragmatic function *in vitro*, was associated with a decrease in the average number of episodes of apnea from 58 during standard TPN to 11 with the enriched solution infusion during matched 12-hour periods ($p < 0.01$) in an unblinded cross-over study design [14]. This interesting approach to the treatment of AOP should be investigated further.

In summary, treatment for AOP may follow an incremental approach, starting with infant care procedures such as prone

positioning, followed by methylxanthines and CPAP/N-IPPV. We urgently need data on how much intermittent hypoxia/bradycardia can be tolerated in an individual infant without putting her/him at risk of developmental impairment.

74.2 Sudden Infant Death Syndrome (SIDS)

Sudden deaths in infants have been known since biblical times, but it was only in 1970 that Bergman et al coined the term SIDS. It was recently re-defined by an expert panel as "the sudden unexpected death of an infant <1 year of age, with onset of the fatal episode apparently occurring during sleep, that remains unexplained after a thorough investigation, including performance of a complete autopsy and review of the circumstances of death and the clinical history". To facilitate research, this definition was stratified into cases with the "classic" features of SIDS present and completely documented (so-called Category 1A SIDS), those with these features present, but incompletely documented (IB), and those meeting Category I criteria except for one or more of the following: Age <3 wk or >270 d, similar deaths in siblings, close relatives or infants in the custody of the same caregiver, perinatal conditions such as a history of premature birth, suspected mechanical suffocation, or marked inflammatory changes not sufficient to be assigned a cause of death (Category II) [15]. According to this definition, all cases not meeting criteria for category I or II SIDS, including those for which an autopsy has not been performed, are now called "Unclassified Sudden Infant Death" [15]. The practicality of this new definitory approach remains to be seen.

74.2.1 Epidemiology

74.2.1.1 Incidence

Despite a recent decline in incidence, SIDS continues to be the leading cause of postperinatal mortality in developed countries (Table 74.2). There is now a trend to classify many deaths previously diagnosed as SIDS into other categories such as (positional) asphyxia. In fact, a recent analysis of US mortality data showed that concurrent increases in post-neonatal mortality rates for unknown and unspecified causes and suffocation accounted for 90% of the decrease in SIDS rates in 1999 to 2001 [16]. Thus, it is important always to report changes in both, SIDS and post-neonatal mortality rates (to which SIDS contributes substantially).

Table 74.2 SIDS and post-neonatal mortality (PNM) rates in different countries, 1990 *vs* 2003 [27]

Country	PNM 1990	PNM 2003	Change (%)	SIDS 1990	SIDS 2003	Change (%)
Netherlands	2.3	1.2	–48	0.56	0.10	–82
Sweden	2.4	0.96	–60	1.0	0.23	–77
Germany	3.3	1.4	–58	1.42	0.43	–70
USA	3.38	2.67	–31	1.30	0.54	–58
New Zealand	4.21	1.90	–55	2.90	0.80	–72

74.2.1.2 Age and Time of Death

One of the most striking epidemiological features in SIDS is its characteristic age distribution. Some 75% of deaths occur between 2–4 months of age, and 95% before 9 months of age [1]. Early beliefs that SIDS is extremely rare in the neonatal period cannot be maintained: 6–7% of SIDS victims are younger than 1 month of age, and 11% of all neonatal deaths are due to SIDS [1]. There are even several reports of sudden death in apparantly healthy neonates occurring while sleeping on their mother's abdomen shortly after delivery.

Throughout the year, there used to be a preponderance of deaths in the cold season, but this has almost disappeared following the back-to-sleep campaigns. In a study from the UK, only 27% of deaths occurred between December and February [17].

74.2.1.3 Risk Factors

A large number of factors associated with an increased risk of SIDS have been identified (Table 74.3) [1]. Many underline the importance of social factors in the pathogenesis of SIDS; others, like maternal smoking or anemia during pregnancy, suggest that there must already be a disturbance during intrauterine life that poses a risk to the infant. Factors that are potentially amenable to modification include maternal

Table 74.3 Risk factors for SIDS. Derived from [1], with permission

Maternal factors	Infantile factors
Young age	Male gender
Multiparity	Low birth weight
Smoking during pregnancy	Low birth length
Maternal drug abuse	Premature birth
Previous fetal deaths	Blood type B
Anemia during pregnancy	Low Apgar scores
Placenta praevia	Low hematocrit at 48 hours
Premature rupture of membranes	Not using a pacifier
Low social class	Prone or side sleeping position
Low family income	Bed-sharing
Short inter-pregnancy interval	Overheating
Unmarried mother	Not breastfed
Partner unemployed	Siblings in family
Late attendance of antenatal clinic	Sleeping in own room
Postnatal depression	Previous SIDS in family
Attendance to psychiatrist	Previous cyanotic episode
Urinary tract infection in pregnancy	

smoking, not breast feeding, not using a pacifier, overheating, and a non-supine sleeping position, and these are the factors targeted by most intervention campaigns. Recently, however, "new" modifiable risk factors have been identified. These include head covering, which has a pooled adjusted OR of 16.9 (95% CI 13.6–22.7) and a population-attributable risk (PAR) of 27% [18], and prone sleeping in preterm and low birth weight infants [19]. Parents of the latter infants may get confused by the common use of the prone position in hospital; it is thus particularly important to place these infants on their back before hospital discharge and to explain the importance of supine sleeping to their parents. Bed-sharing is also a relatively "new" risk factor, at least in infants <11–13 wk, where it is associated with a 10- to 19-fold increase in SIDS risk [20, 21]. It should thus be strongly discouraged in the first 3 months of life. Thereafter, no increased risk has been found.

74.2.2 Pathology

74.2.2.1 Intrathoracic Petechial Hemorrhages

As implied by its definition, there is no morphological finding in SIDS that sufficiently explains death. There are, however, a number of characteristic findings in these infants, such as serosal petechiae, which are so consistent that they appear to support the concept that SID may indeed form a specific disease entity. Other characteristic findings in SIDS include the occurrence of (often bloody) froth around the nose and mouth. Both may result from high transpulmonary pressure swings, such as occurring during breathing against an obstructed upper airway [1].

74.2.2.2 Abnormalities in Brainstem Serotonergic System

Serotonin is a neurotransmitter involved in regulating various processes potentially related to SIDS, e.g., sleep and arousal, control of breathing, airway reflexes, and autonomic function [22]. Endogenously released serotonin is also required for gasping. Comparative studies on the binding properties of neurotransmitter receptors in SIDS found multiple brainstem abnormalities in SIDS compared to control infants, suggesting that such abnormalities may be involved in some SIDS cases [22].

74.2.2.3 Genetic Studies in SIDS

For many years, it has been known that some infants who die suddenly and unexpectedly do so because they have an inherited disease such as the A984G mutation in the medium-chain acyl-CoA dehydrogenase (MCAD) gene. More recently, mutations in genes encoding cardiac ion channels have been identified. These well-defined diseases, however, contribute only a few percent to all cases of SIDS (and, by definition, prohibit defining SIDS as the cause of death). More relevant to SIDS are recent data on gene polymorphisms that may predispose infants to SIDS under certain circumstances, such as those found in the serotonin transporter gene. The reader is referred to a recent review on this exciting new field of research [23].

74.2.3 Pathophysiology

There are now a number of recordings from cardiorespiratory monitors that were obtained during SIDS. Despite some limitations, these recordings have for the first time provided us with objective data on the pathophysiological mechanisms immediately preceding SIDS. In an analysis of 9 recordings of chest wall impedance and heart rate from infants who had an autopsy diagnosis of SIDS or mild BPD, gasping was the predominant pattern, being already present at the time of the monitor alarm in 3 infants and occurring within 3 min after it in a further 4 (Fig. 74.3) [24]. Primary trigger for the monitor alarm had been bradycardia in all but two infants, but there was no indication of heart block or ventricular tachycardia. These observations, confirmed by a similar, more recent study [25], suggest that prolonged apnea is unlikely to be a primary mechanism in the sequence of events leading to most cases of SIDS, while the "primary" bradycardia is most likely caused by hypoxemia. In addition, there seems to be some failure or depression of arousal and gasping. The

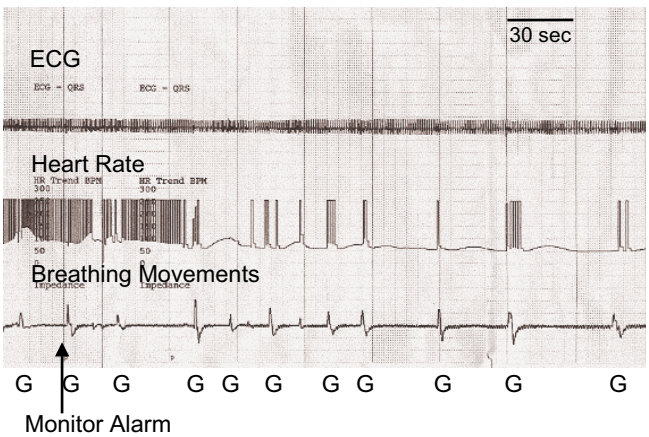

Fig. 74.3 Section from a memory monitor printout of a 1-month old infant born at 34 wk gestation and with an autopsy diagnosis of SIDS. There are 11 gasps, which progressively decrease in amplitude. There is an increase in heart rate from 72 to 140 bpm during the first 20 s of recording, followed by several smaller increases in heart rate that appear to occur in response to the gasps and are also decreasing in amplitude over time. *G*, gasp. From [24], with permission

underlying causes of both the hypoxemia and the failure of these infants to resuscitate themselves from this hypoxemia remain to be determined.

74.2.4 Prevention

74.2.4.1 Primary Prevention

Dissemination of advice on safe sleeping has been one of the most effective health interventions ever performed. Recommendations are reviewed at regular intervals to incorporate new data. The current advice given by the American Academy of Pediatrics includes the following (abbreviated) [26]:

- infants should be placed for sleep in a supine position for every sleep;
- use a firm sleep surface. pillows or sheepskins should not be placed under a sleeping infant;
- keep soft objects and loose bedding out of the crib;
- let your baby share your room for sleep, but not your bed;
- do not smoke during pregnancy, and keep him/her smoke-free after birth;
- consider offering a pacifier at nap time and bed time;
- avoid overheating. Bedroom temperature should be comfortable for a lightly clothed adult.

74.2.4.2 Secondary Prevention

For many years, the use of home monitors in specific risk groups, i.e., secondary prevention, has been the only method to prevent SIDS, but its effectiveness in reducing its incidence has never been proven. Nonetheless, home monitoring may be prescribed as a diagnostic tool or as an early warning of potentially dangerous pathophysiology. The first group comprises infants after an apparent life-threatening event (ALTE) and infants from families who had 2 or more sudden unexpected infant deaths. The second group involves technology-dependent infants (e.g., with a tracheostomy), infants with respiratory control disorders and preterm infants with persistent AOP. AOP is not associated with an increased risk of SIDS, but monitoring may be indicated to prevent potential sequelae, e.g., cerebral palsy. Whatever the indication, a pulse oximeter with motion-resistant technology to reduce the frequency of false alarms is currently the preferred monitoring device. Although there are no controlled trials on this issue, there is evidence to suggest that apnea and hypoxemia may occur too late during the events leading to death always to allow for successful resuscitation. Monitoring should continue for 4 weeks after the last (true) monitor alarm except for siblings from families with multiple deaths who should be monitored until the age of the oldest infant who died.

Cardiovascular Physiology, Pathology, and Clinical Investigation

Luciane Piazza, Angelo Micheletti, Diana Negura, Carmelo Arcidiacono, Antonio Saracino and Mario Carminati

75.1 Introduction

Congenital heart defects (CHD) are a heterogeneous entity, representing the most common malformations in the fetal and neonatal period. The incidence of moderate to severe structural CHD that will require expert cardiologic care is 2.5 to 3 per 1000 live births. Moderately severe forms of CHD probably account for another 3 per 1000 live births. Specialised cardiologic care is not needed for most minor forms of CHD, such as tiny ventricular septal defect (VSD) or atrial septal defect (ASD) [1]. Most infants with congenital heart disease are identified by the end of neonatal period.

75.2 The Fetal and Neonatal Circulation

Fetal circulation is shown in Fig. 75.1.

In the fetal circulation, the right and left ventricles work in a parallel circuit. Three cardiovascular structures, unique to the fetus, are important for maintaining this circulation: ductus venosus, foramen ovale and ductus arteriosus. The umbilical vein carries oxygenated blood (PO_2 of about 30–35 mmHg) from the placenta to the inferior vena cava (IVC) through the ductus venosus, where it partially mixes with poorly oxygenated IVC blood derived from the lower part of the fetal body. When it reaches the right atrium (RA), oxygenated blood preferentially streams across the foramen ovale (FO) and enters the left atrium (LA), where it mixes with the pulmonary venous return before entering the left ventricle (LV). From the LV, the ascending aorta supplies fully oxygenated blood (PO_2 about 28 mmHg) to the coronary arteries, the head, and the upper extremities. Only a small portion of the LV cardiac output streams through the aortic arch and supplies flow to the thoracic aorta. Superior caval vein blood, which is considerably less oxygenated (PO_2 12–14 mmHg), enters the RA where it is directed preferentially across the tricuspid valve into the right ventricle (RV). Just about 10% of RV output is ejected into the pulmonary arteries (PA) because the fetal lungs are still not expanded

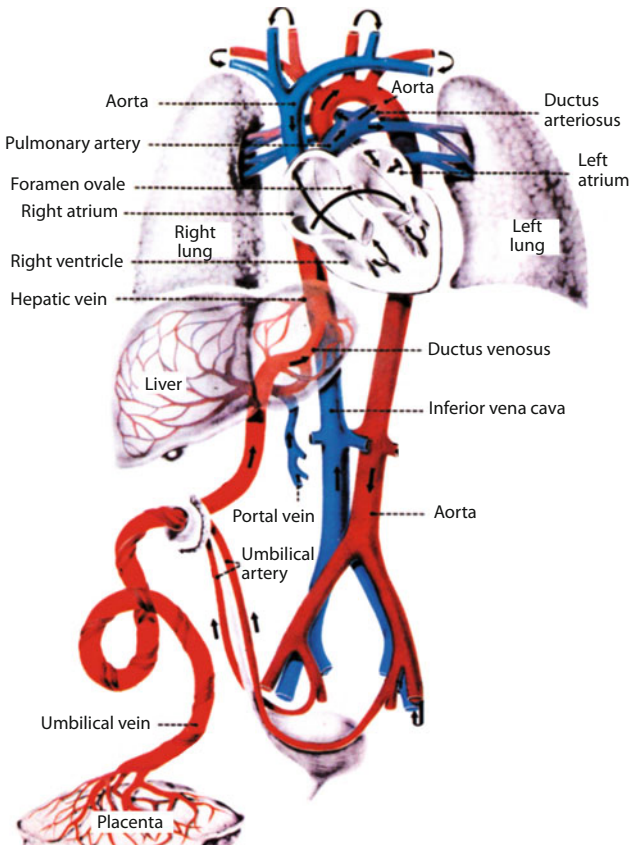

Fig. 75.1 Diagram of fetal circulation showing the four sites of shunt: placenta, ductus venosus, formanen ovale and ductus arterious (modified with permission from Fesslova V. Ecocardiografia fetale. Raffaello Cortina Editore, Milano 2008, p. 39)

and ventilated, and pulmonary vascular resistances is therefore very high. Most RV output bypasses the lungs and flows through the ductus arteriosus into the descending aorta and the inferior part of the fetal body, after which it returns to the placenta via the two umbilical arteries.

A distinctive feature of fetal circulation is the role of the placenta, low-resistance vascular bed, where oxygenation and metabolites exchange occur. The placenta is not only an organ for a gas exchange, and the fetus adapts by producing fetal hemoglobin which has a higher affinity for oxygen, compared to adult hemoglobin.

The dimensions of fetal cardiac chambers reflect the difference between right and left sided blood volume, with the RV and pulmonary artery being larger respectively than the LV and ascending aorta, although the pressure in both circuits is equal due to the patency of the ductus arteriosus.

75.3 Changes in Circulation after Birth

At birth, the main changes in circulation occur as follows: first the placental circulation disappears and the pulmonary circulation is established due to (i) a rapid increase in systemic vascular resistance (SVR) as a result of very-low-resistance placenta circulation removal and (ii) closure of the ductus venosus. Second, physical expansion of the lungs results in: (i) reduction of the pulmonary vascular resistance (PVR), fall in PA pressure and increment of pulmonary blood flow; (ii) mechanical and passive closure of the FO due to a difference between left and right atrial pressure; pressure in the left exceeds that in the right because of increased pulmonary venous return to the LA and decreased venous return to the RA after ductus venosus closure; (iii) closure of patent ductus arteriosus (PDA) secondary to increased arterial oxygen saturation.

75.4 Regulation of Pulmonary Vascular Resistance and Pulmonary Blood Flow

In fetal life the PVR is high and the oxygen concentration, at the level of smooth muscle cells in the pulmonary arteriolar walls, is low. At birth, since lung ventilation occurs, PVR promptly decreases and simultaneously pulmonary blood flow increases. Those events are associated with thinning of the medial layer of the pulmonary arterioles as well as hyperplasia of alveolar units and their own circulatory vessels. After the initial sudden decrease in PVR and pressure, there is a slow progressive decrease within 2–6 weeks. Several factors may interfere with the pulmonary flow or pulmonary vascular resistance, causing conditions such as persistent pulmonary hypertension or delay in PVR normalization process:

- hypoxia and/or altitude;
- acidosis;
- severe hyaline membrane disease or other pulmonary diseases;
- congenital heart defects such as large VSD or PDA, which are characterized by high PA pressure, secondary to direct transmission of the systemic pressure to the PA through the large defect;
- increased pressure in the LA or pulmonary veins.

75.5 Closure of the Ductus Arteriosus

During fetal life, the ductus arteriosus is fully patent and pulmonary and aortic pressures are therefore equal. Once the duct closes, pulmonary artery pressure decreases as the resistance in the pulmonary vascular bed falls. The functional closure of the PDA occurs because of constriction of the medial, smooth muscle cells within 10 to 15 hours after birth. The following factors are relevant to ductal closure:

- *Oxygen* A postnatal increase in systemic circulation oxygen saturation is the strongest stimulus for smooth muscle cell constriction.
- *Gestational age of the newborn* The ductus arteriosus is more likely to remain open in preterm infants because of immaturity of the constrictor response to oxygen by ductal smooth muscle cells.
- *Prostaglandin E (PGE)* An acute decrease in PGE levels results in ductal constriction. This event is determined by placenta removal, since the placenta is a significant source of PGE. Drugs like indomethacin, a prostaglandin synthetase inhibitor, can be used to effect closure of a significant PDA in premature infants.
- *Hypoxia and acidosis* relax the duct but constrict pulmonary arterioles which are also constricted by sympathetic stimulation and α-adrenergic stimulation.
- *Oxygen* constricts the duct but relaxes pulmonary arterioles.

75.6 Persistence of the Fetal Circulation

Persistent pulmonary hypertension of the newborn (PPHN) or persistence of fetal circulation occurs in approximately 1 in 1500 live births. This neonatal condition is due to failure of pulmonary vascular transition to extrauterine life. This clinical syndrome is characterized by persistence of pulmonary hypertension which causes varying degrees of cyanosis depending on the amount of right-to-left blood flow (shunting) through the PDA or patent foramen ovale (PFO). No underlying congenital heart defect is present. In this situation, PVR exceeds the systemic vascular resistance; in postnatal life it causes reduced pulmonary perfusion and systemic hypoxemia. There is often some degree of myocardial dysfunction with elevated pulmonary vascular resistance characterized by decreased contractility or tricuspid regurgitation. These abnormalities are caused by global or subendocardial ischemia and are aggravated by hypoglycemia and hypocalcemia.

The most common precipitating disease is meconium-aspiration syndrome, sepsis/pneumonia, perinatal acidosis, abnormal pulmonary vascular development, or pulmonary hypoplasia.

The differential diagnosis includes: congenital heart disease, sepsis, pulmonary parenchymal disease, polycythemia, intrauterine or perinatal asphyxia and metabolic disease, myocardial dysfunction due to intrauterine constriction of the ductus arteriosus.

Diagnostic evaluation of the cyanotic newborn infant includes the gradient in oxygenation, chest X-ray and echocardiography. The aim is to rule out CHD. The only structural abnormality is the presence of a large PDA with right-to-left or bidirectional shunt. The RV is enlarged, with flattening of the interventricular septum. The RA is also enlarged with the atrial septum bulging towards the left with or without an interatrial communication. Left ventricular systolic and diastolic dysfunction may also be present.

Initial treatment includes an immediate attempt to reverse hypoxemia, improving pulmonary and systemic perfusion. Respiratory support, correction of any metabolic disorder and hemodynamic support should be provided.

75.7 Clinical Presentation

In spite of a wide spectrum of CHD, clinical presentation does not vary much. Signs and symptoms of severe heart disease in the newborn period include cyanosis, discrepancy of the arterial pulses and/or four limb blood pressure, and congestive heart failure. Circulatory collapse is uncommon but the emergency treatment of shock and clinical stabilization should precede definitive anatomic diagnosis.

75.7.1 Cyanosis

Cyanosis is a blue discoloration of the skin caused by deoxygenated blood within the capillary network. Detection of cyanosis depends on the skill and experience of the physician and environmental light (it is more evident in natural than in artificial light). Cyanosis does not always indicate hypoxemia: a neonate may be severely hypoxemic but not clinically cyanotic. Cyanosis can be detected on many parts of the body: lips, fingernails, toenails, tip of the nose, oral mucous membranes, conjunctivae and tip of the tongue.

By definition cyanosis is determined by deoxygenated hemoglobin (Hb) concentration exceeding 3 g/dL in arterial blood and/or 5 g/dL in capillary bed.

Fetal and adult hemoglobin are different in terms of oxygen affinity, which is indicated by the P50 value. P50 is the level of PaO_2 (partial pressure of oxygen) at which 50% of hemoglobin is bound to O_2. It is about 27 mmHg in adults. The P50 of fetal hemoglobin is about 20 mmHg, the venous oxygen saturation (O_2 sat) is therefore higher in the neonate (about 80%) than in the adult (about 70% or less). As a consequence, cyanosis in neonates becomes clinically evident at lower level of PaO_2 than in adults or children, about 38–39 mmHg and 52–54 mmHg respectively.

The level of hemoglobin greatly influences the appearance of cyanosis. In patients with polycythemia, cyanosis is detectable at a higher level of oxygen saturation; conversely in patients with anemia, cyanosis appears at lower level of oxygen saturation. In polycythemic neonate (Hb 22 g/dL) cyanosis becomes evident when O_2 sat approaches 85–92%. In a normal neonate the usual level of Hb is about 17 g/dL and cyanosis becomes evident when O_2 sat approaches 82% and PaO_2 38–39 mmHg. Often preterm babies have a reduced Hb concentration, about 12 g/dL or less, in which case cyanosis appears at O_2 sat level of about 75%.

Cyanosis may be either peripheral or central. Peripheral cyanosis is a bluish discoloration limited to the extremities, associated with normal arterial O_2 saturation and pink color of mucous membranes; it can be seen with acrocyanosis or exposure to cold. The blue color may reflect intermittent vasomotor changes in the skin. A pathological cause of acrocyanosis is cutaneous arterial constriction resulting from low cardiac output state with sluggish peripheral blood flow. Central cyanosis is cyanosis associated with arterial oxygen desaturation.

Generally cyanosis related to CHD is not associated with respiratory distress, unlike cyanosis due to lung disease. Exceptions to this rule are:

- Central cyanosis with low PaO_2 in the 20s or less, in which cases hyperpnea is stimulated.
- Cyanosis associated with low cardiac output. This is commonly seen with left heart obstructive lesions if the ductus arteriosus becomes restrictive. The pulse volume will be poor and the extremities cool.
- Cyanosis associated with obstruction of pulmonary venous drainage resulting in pulmonary edema, such as is seen in obstructed total anomalous pulmonary venous return.

75.7.1.1 Differential Cyanosis

Differential cyanosis in neonates occurs when cyanosis is more evident in the lower extremities than the upper or viceversa.

- Upper limb saturation higher than the lower limb: deoxygenated blood coming from the RV shunts from pulmonary artery to distal aorta through the ductus arteriosus because of either elevated PVR or aortic obstruction proximal to the ductus such as in critical aortic coarctation or interrupted aortic arch.
- Lower limb saturation higher than upper limb: typical of this condition is a reversed flow into the ascending aorta and aortic arch from pulmonary artery through a large ductus arteriosus, such as in transposition of great arteries, large PDA and pulmonary hypertension.

Differential cyanosis is fairly uncommon and is of little practical diagnostic use.

75.7.1.2 Differential Diagnosis

Cyanosis is one of the most common clinical presentations of diverse disease processes, including cardiac, lung and central nervous system abnormalities. Table 75.1 summarizes the differential diagnosis of cyanosis.

A suggested plan for investigation of the cyanotic newborn baby includes:

1. Clinical evaluation of cyanosis: central or peripheral, extension, localization. Heart rate, arterial pulses, blood pressure, respiratory rate, presence of respiratory distress.
2. Chest X-ray: may reveal a pulmonary or cardiac cause, and the severity of the problem.
3. Arterial blood gas analysis in room air: confirms or excludes central cyanosis.
4. Hyperoxia test: helps in differentiating pulmonary or central nervous system causes from cardiac causes.
5. ECG if a cardiac cause of cyanosis is suspected.
6. Umbilical arterial line: PaO_2 in a preductal artery (e.g. a radial artery) 10 to 15 mmHg higher than the PaO_2 in a postductal artery (e.g. from an umbilical arterial line) suggests a right-to-left ductal shunt.
7. Prostaglandin E_1: to be commenced if a cyanotic defect is suspected as a result of investigations.

Table 75.2 summarizes the differential diagnoses of CHF in the neonate.

Table 75.1 Differential diagnosis of cyanosis

Newborns with CHD	
CHD with increased pulmonary vascularity	*CHD with decreased pulmonary vascularity*
– D-Transposition of great arteries	– Tetralogy of Fallot
– Total anomalous pulmonary venous return	– Double outlet right ventricle with PS
– Taussig-Bing anomaly	– Ebstein's anomaly
– PPHN	– Pulmonary atresia
– Truncus arteriosus	– Tricuspid atresia
– Single ventricle without PS	– Single ventricle with PS
– TGA and VSD	– TGA and PS
Pulmonary disease	
– Pneumothorax or pleural effusion	
– Diaphragmatic hernia	
– Persistent fetal circulation syndrome	
– Perinatal asphyxia	
Central nervous system	
Cyanosis with normal PaO_2	

PS pulmonary stenosis, *PPHN* persistent pulmonary hypertension of the newborn, *TGA* transposition of the great arteries, *VSD* ventricular septal defect.

75.7.2 Heart Failure in the Newborn

Congestive heart failure (CHF) as clinical presentation accounts for about 30% of infants and children with CHD [2]. CHF is a clinical syndrome in which cardiac output is insufficient to meet the metabolic demands of the tissues, including oxygen and nutrient delivery and waste removal.

In early stages infants may be tachypneic, tachycardic with increased respiratory effort, and there may be hepatomegaly and delayed capillary refill. In worsening CHF dyspnea with grunting, intercostal and subcostal recession may appear. Feeding difficulties, failure to thrive and diaphoresis may occur later.

An acute presentation as cardiorespiratory collapse may occour with "left sided" lesions.

75.7.2.1 Differential Diagnosis

When heart failure develops in the first weeks of life, the differential diagnosis includes:

– structural heart disease causing significant volume and/or pressure overload;
– myocardial disease;
– arrhythmia.

Table 75.2 Causes of heart failure in newborns

Structural Heart Disease	
– Anomalies of coronary circulation – Ebstein's anomaly of tricuspid valve – Hypoplasic left heart syndrome	*At birth*
– Transposition of the great arteries – Premature infants with large patent ductus arteriosus – Total anomalous pulmonary venous return	*First week*
– Critical aortic or pulmonary stenosis – Coarctation of the aorta – Structural cardiac disease with left-to right shunt at level of ventricles – Tetralogy of Fallot or Pulmonary atresia with aorto-pulmonary collaterals	*1-4 weeks*
Myocardial Disease	
A *Primary* – Myocarditis – Transient myocardial ischemia (with or without birth asphyxia) – Cardiomyopathy (as seen in infants of diabetic mothers)	
B *Secondary* – Sustained tachyarrhythmias (atrial flutter or fibrillation) – Congenital heart block – Birth asphyxia resulting in transient myocardial ischemia – Severe anemia (as seen in hydrops fetalis) – Overtransfusion or fluid overload – Metabolic causes: hypoglycemia, hypocalcaemia – Neonatal sepsis	

75.7.3 Heart Murmur

To determine the sensitivity and specificity of clinical assessment of murmurs in neonates, as performed by a pediatric cardiologist, and to identify clinical features that predict the presence of CHD, Mackie et al [3] reported that clinical assessment detected most complex CHD whereas some simple lesions were missed. The murmur quality, location, and timing were predictive of CHD. The prevalence of the heart murmur in premature infants is higher than in full-term infants.

There are three common innocent murmurs in the newborn period:

1. A pulmonary flow murmur of the newborn is the most common. It is best heared at the upper left sternal border and transmits well to both sides of the chest. The murmur is soft, grade 2/6 in intensity. It is transient, usually disappearing by six months of age.
2. A transient systolic murmur of PDA is heared at the upper left sternal border and the infraclavicular area on the first day, and it usually disappears shortly thereafter.
3. A transient systolic murmur due to tricuspid regurgitation (TR) is indistinguishable from that of VSD and is maximally audible at the lower left sternal border. This murmur is more common in infants who had fetal distress or neonatal asphyxia, because they tend to maintain a high PVR for a longer period.

Most pathologic murmurs should be audible during the first month of life. However, the time of appearance of heart murmur depends on the nature of the defect.

1. Heart murmurs of stenotic lesions, i.e. aortic stenosis, pulmonary stenosis and coarctation of the aorta, are audible after birth and persist because they are not affected by the degree of PVR.
2. Heart murmurs that depend on the reduced PVR, e.g. heart murmurs due to left-to-right shunt lesions, such as VSD. The onset of a loud VSD murmur may be delayed until 1–2 weeks of age.
3. The continuous murmur of a large persistent PDA. This is a crescendo systolic murmur with a slight or absent diastolic component.

Even in the absence of a murmur, a newborn infant may have a serious heart defect that requires immediate attention, for instance when there is transposition of the great arteries (TGA) or severe CHF, in which the murmur appears only when myocardial function has improved because of medical treatment.

75.7.4 Arrhythmias

For a detailed description of identification and management of neonatal arrhythmias, see Chapter 77.

75.8 Clinical Evaluation of the Neonate with CHD

Congenital heart diseases with early presentation account for a significant proportion of all neonatal emergencies; early diagnosis is vital to achieve correct treatment and favorable prognosis. Critical CHD includes all cardiovascular lesions that would result in neonatal death without immediate intervention to palliate or correct the anatomic defect. The initial assessment of the newborn with possible CHD should include timing of presentation and severity of symptoms. These depend on: (1) the nature and severity of the anatomic defects; (2) the impact of the alterations to normal physiology that occur during the first week of life with the closure of ductus arteriosus and fall of PVR; (3) intrauterine effects of the structural lesions.

75.8.1 Initial Evaluation

75.8.1.1 History

The history can provide useful information leading to the suspicion of CHD: (1) maternal disease during first trimester of gestation due to viral infections, X-ray exposure, drug intake, alcohol abuse, diabetes; (2) problems in the perinatal period (low Apgar score and/or the need of cardio-pulmonary resuscitation).

75.8.1.2 Physical Examination

Physical examination of the neonate can provide important clues to the anatomic diagnosis.

Inspection: to look for the presence of cyanosis with or without respiratory distress, respiratory pattern including the effort of breathing and use of accessory muscles. A general appearance typical of a syndrome, chromosomal abnormalities or malformations which may be associated with CHD.

Palpation: reduced or absent distal pulses are highly suggestive of obstruction of the aortic arch. Weak arterial pulses are characteristic of critical aortic valve stenosis, hypoplastic left heart syndrome or cardiogenic shock. Palpation of the precordium may detect the presence of a thrill that usually indicates at least moderate outflow tract obstruction or a restrictive VSD with low right ventricular pressure. Hyperdynamic precordium suggests heart disease with high volume overload such as left-to-right shunt lesions and/or severe valvular regurgitation. A cool neonate with prolonged capillary refill time should always raise the possibility of severe CHD.

Auscultation: it is rarely conclusive for CHD diagnosis. More than 50% of full-term newborn infants have an innocent murmur at some time during the first week of life (see § 75.7.3).

Most pathological murmurs should be audible during the first month of life. Heart murmurs audible immediately after birth are due to stenotic lesions (e.g. aortic stenosis, pulmonary stenosis, and coarctation of aorta), or left-to-right shunt lesions (e.g. a small VSD). The onset of a murmur due to a large VSD may be delayed until first or second week of life. The continuous murmur due to a PDA may not appear for two to three weeks. Diastolic murmurs are always indicative of cardiovascular disease. During the auscultation, the physician must pay attention to the heart rate, noting its regularity and/or variability.

75.8.1.3 Four-limb Blood Pressure

Blood pressure should be measure in the upper and lower limbs. A difference between arms and legs of more than 10 mmHg is suggestive of coarctation of the aorta, aortic arch hypoplasia or interrupted aortic arch. Blood pressure measurements are highly specific but not sensitive for the diagnosis. Moreover, coarctation cannot be ruled out even in absence of significant blood pressure gradient as it may occur when a large ductus arteriosus is still patent.

75.8.1.4 Chest X-ray

Chest X-ray can give important clues leading to the diagnosis of CHD and/or associated lung disease. The cardiothoracic ratio of normal newborn infants is > 0.5; the normal value in older children and adults is < 0.5. Therefore, the evaluation of heart size should take into consideration the degree of inspiration, judged by the level of the diaphragm. Particularly in newborns, the heart size may be difficult to determine due to an overlying thymus. In addition to the heart size, its position within the chest should be considered to assess visceral and cardiac situs (e.g. dextrocardia, right or left isomerism is frequently associated with CHD).

Cardiac silhouette may be typical in some CHD as the "egg shape" in transposition of the great arteries (Fig. 75.2).

Evaluation of pulmonary vascular markings in neonates can be difficult. It is often hard to distinguish between increased pulmonary blood flow and pulmonary venous congestion. A poorly perfused lung field suggests decreased pulmonary blood flow and indicates serious cyanotic congenital heart defects or significant left atrial hypertension.

In neonates with infracardiac total anomalous pulmonary venous drainage (which is almost always "obstructed") the chest-X-ray shows a small heart, upper lobe blood diversion, fluid in the fissures (signs of pulmonary edema). Differentiating between primary pulmonary disease and respiratory distress syndrome is sometimes difficult.

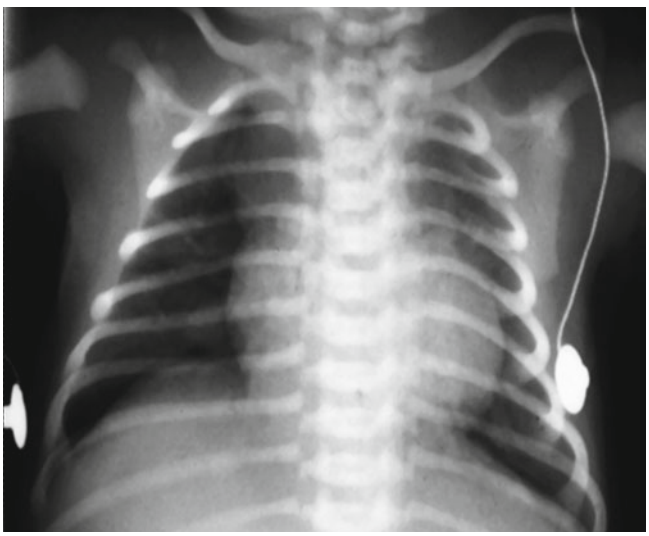

Fig. 75.2 Trasposition of the great vessels. The heart is enlarged and has an egg-shaped configuration

75.8.1.5 Electrocardiogram (ECG)

The normal ECG of a newborn is different from that of an older child because it reflects the hemodynamic relations existing in utero. Usually it shows: (1) ainus tachycardia with a rate as high as 160 beats/minute; (2) right-sided deviation of the QRS axis with a mean of +125 degrees and a maximum of +180 degrees; (3) relatively small QRS complex voltages and T wave; (4) right ventricular dominance with tall R waves in V4R, V1 and V2; (5) occasional Q waves in V1. Diagnostic value of ECG in the newborn period is highly non specific and the precise diagnosis of CHD is generally obtained by other diagnostic tools, in particular echocardiography.

75.8.1.6 Hyperoxia Test

In newborns with suspected CHD, a hyperoxia test should be considered to make the differential diagnosis between oxygen desaturation due to heart disease and that due to pulmonary disease. Although this test does not give a complete diagnosis, it remains useful, especially when an echocardiogram is not easily or quickly available. The hyperoxia test is obtained by measuring the oxygen tension in room air (if tolerated), followed by repeated measurements with the patients receiving 100% inspired oxygen for 5 minutes. If possible, the arterial partial pressure of oxygen (PO_2) should be measured directly by arterial puncture, although PO_2 values obtained from a properly applied transcutaneous oxygen monitor (TCOM) are also acceptable. The measurements should be taken at both "preductal" and "postductal" sites.

- When a baby breathes 100% oxygen, an arterial PO_2 of 250 mmHg in both upper and lower limbs virtually eliminates critical structural cyanotic heart disease (positive test).

- Patients with pulmonary disease only will show a significant increase in PO_2.
- Stable intracardiac right-to-left shunting (failed or negative test). An arterial PO_2 of <100 mmHg in absence of lung disease is most likely due to intracardiac right-to-left shunting. There is only a mild increase of oxygen saturation, but it is usually below basal levels.
- Patients with large left-to-right shunting and systemic hypoxemia. In this situation there is a high level of oxygenation, because the inspired oxygen normalizes the saturation of pulmonary venous blood, which can be low due to pulmonary edema and oxygen diffusion gradient (an example of this situation is represented by an unobstructed total anomalous pulmonary venous return).
- Patients with PO_2 between 100 and 250 mmHg may be affected by a structural cardiac lesion with intracardiac mixing and greatly increased pulmonary blood flow as seen when there is a single ventricle.
- Markedly higher oxygen content in the upper versus the lower part of the body. This is an important diagnostic clue to lesions that include all forms of critical aortic arch obstruction or left ventricular outflow tract obstruction.
- Reverse differential cyanosis. This occurs in neonates with transposition of the great arteries and those with abnormal pulmonary to aortic shunting due to coarctation, interruption of the aortic arch, or suprasystemic pulmonary vascular resistence (persistent fetal circulation).

Patients with a positive hyperoxia test are likely to have a duct dependent CHD and prostaglandin E_1 should be given, until anatomic abnormality can be defined.

75.8.1.7 Stabilization and Transport

After the initial evaluation, attention should continue to be focused on the basic neonatal life support and maintaining patency of ductus areriosus. Airways should be stabilized, vascular access secured, volume status, and inotropic support maintained and systemic and pulmonary circulation kept in balance. The neonate may need to be transferred to a medical center with full pediatric cardiological facilities.

75.8.1.8 Prostaglandin E_1

When systemic perfusion depends on patency of the ductus arteriosus, a continuous infusion of PGE_1 may be lifesaving. PGE is indicated for the treatment of ductal dependent lesions. Indications and treatment recommandations are reported in Tables 75.3 and 75.4.

The mechanism of PGE_1 action consists of relaxation of the smooth muscle fibers forming the ductal tissue. In other tissues PGE_1 has been shown to result in increased levels of nitric oxide and nitric oxide syntethase [2]. When ductal dilatation occurs, systemic perfusion increases (peripheral vasodilatation) and pulmonary congestion may decrease. This change is accompanied by a rise in PH and a decrease in lactate accumulation because of improved tissue perfusion.

Table 75.3 Indications for prostaglandin E_1

Cyanotic heart disease with severely limited or no pulmonary blood flow
- Tricuspid atresia
- Pulmonary atresia and critical pulmonary stenosis

Children with obstructed systemic blood flow may depend on ductal patency, e.g. in the following conditions
- Aortic atresia
- Critical aortic stenosis
- Critical coarctation of the aorta
- Interrupted aortic arch
- Hypoplastic left heart syndrome

Patients with transposition of great arteries benefit from patency of the ductus arteriosus because the pulmonary and systemic circulation is in parallel.

Table 75.4 Recommandations for treatment with prostaglandin E_1

- The usual starting dose is 0,05 mcg/kg/min
- When the desired effect is achieved, reduce to 0.025 mcg/kg/min
- Secure vascular access

Adverse effects include respiratory depression; PGE can cause apnea in 10–12% of the neonates and a stable airway must be maintained. Generally all neonates receiving PGE_1 infusion should be intubated for transport. Systemic hypotension and bradycardia have also been seen. Sometimes additional side effects are observed, e.g. bradycardia (7%), tachycardia (3%), edema and cardiac arrest (1%) [4]. PGE_1 inhibits platelet aggregation and may impair clotting. Prolonged use of PGE_1 has been associated with gastric obstruction and cortical hyperostosis of the long bones. Patients receiving PGE_1 need to be monitored for vital signs, including pulse oximetry, and arterial blood gas analysis.

Following the initial diagnosis and medical stabilization, the neonate can be transferred to a tertiary pediatric cardiac center fully equipped for any required additional treatment.

75.8.2 Confirming the Diagnosis

To confirm the diagnosis, two-dimensional and color Doppler echocardiography is used to define the anatomy, physiology and myocardial function.

Echocardiography is the most commonly used non-invasive diagnostic tool. It is harmless, but some precautions have to be taken if the patient is very sick: for example temperature stability should be maintained, extension of the neck for suprasternal views of the arch may be problematic, particularly in neonate with respiratory distress. Careful specialized nursing assistance is recommended.

Table 75.5 Indications for neonatal interventional catheterization

– Atrial septostomy (Rashkind)	
– Balloon valvuloplasty	Pulmonary valvular stenosis
	Aortic valvular stenosis
– Balloon angioplasty of native coarctation of the aorta	
– Transcatheter radiofrequency perforation and valvuloplasty	→ Atretic pulmonary valve
– Miscellaneous	Coil embolization of abnormal vascular communications
	Stenting of a PDA
	Stenting of the right ventricle outflow

75.8.2.1 Cardiac Catheterization

Cardiac catheterization is reserved for special cases where echocardiography is not diagnostic, as in definition of the anatomy of peripheral pulmonary branches, aorto-pulmonary collaterals, some complex pulmonary venous anomalies or in other situations where the decision making process can be hampered by an incomplete or incorrect diagnosis. Echocardiography is fully diagnostic for intracardiac anatomy, in virtually all the cases.

Interventional catheterization: nowadays, a wide range of interventional procedures can be carried out in very small babies (Table 75.5). These procedures include a pre-operative palliation, for instance by balloon atrial septostomy, or an alternative to surgery, e.g. by balloon dilatation of a pulmonary or aortic stenosis. Interventional catheterization can also play a role in a wide spectrum of postoperative sequelae, such as residual pulmonary branch stenosis. See the following text for further details on catheter interventional procedures.

Cardiac catheterization of newborns, either interventional or diagnostic, carries more risks than when performed on children. Basic medical stabilization, airway management, sedation and body temperature control are crucial. The baby's hemodynamic condition should be as stable as possible. Intravenous lines should be secured and intravenous infusion pumps adequately prepared. For example a prostaglandin infusion should be given by a dedicated intravenous line; flushing of this line should be avoided because bolus injection can cause apnea and hypotension.

75.9 CHD in the Newborn

The types of CHD that may present during the newborn period differ from those recognized later in infancy. During the neonatal period, CHD can be classified according to anatomy, physiopathology or timing of presentation. In each of the following sections, specific lesions will be discussed focusing on pathophysiology and clinical presentation.

75.9.1 Duct-Dependent Pulmonary Blood Flow

This group of CHD is characterized by obstruction of pulmonary blood flow due to severe pulmonary stenosis or pulmonary atresia. In this situation pulmonary blood flow depends mainly on the patency of the duct (Table 75.6).

75.9.1.1 Critical Pulmonary Valve Stenosis

Congenital obstruction to RV outflow can be classified as valvar, subvalvar or involving pulmonary trunk and peripheral pulmonary artery branches. This pathology (pulmonary stenosis, PS) is relatively common; the frequency approaches 8–10% of all cardiac defects. There are many anatomical descriptions about the pulmonary valve: dome-shaped valve; dysplastic hypertrophy of the pulmonary valve leaflets; unicommissural, bicuspid, tricuspid valve; hypoplastic annulus with dysplastic valve [5, 6]. The main cardiac consequence of PS is an elevated RV pressure because of obstruction to right ventricular cardiac output. The rise in pressure causes RV hypertrophy which is proportional to the degree of obstruction. This hypertrophy is particularly evident in the infundibular region, producing dynamic narrowing of the outflow tract. Because the ventricular septum is intact, the systolic pressure generated in the RV may exceed the LV systolic pressure. Moreover, the higher diastolic pressure in the RV caused by muscular hypertrophy results in a non compliant RV and increased right atrial filling pressure. When the right atrial pressure exceeds the left atrial pressure, a right-to-left shunt at the foramen ovale appears, resulting in central cyanosis or hypoxemia. There may be associated RV dysfunction and/or tricuspid regurgitation.

In critical pulmonary stenosis or pulmonary atresia the pulmonary flow is duct-dependent, as previously explained.

Newborns with critical PS present within the first week of life with cyanosis and hypoxemia and signs of CHF with peripheral vasoconstriction. Cardiac auscultation reveals a single second heart sound. The systolic murmur of PS may be soft or even absent, reflecting diminished flow across the right ventricle outflow tract. More often, a systolic regurgitant murmur due to tricuspid insufficiency is heard at the left midsternal border.

ECG reveals RV hypertrophy and right axis deviation.

Chest X-ray reveals reduction of pulmonary blood flow. Normal or severe cardiomegaly is present, as in case with severe tricuspid regurgitation.

75.9.1.2 Pulmonary Atresia with Intact Ventricular Septum

Pulmonary atresia with intact ventricular septum (PA-IVS) is a rare lesion occurring in an estimated 8 of 1000 live births [6].

PA-IVS is characterized by abnormalities proximal to the RV-PA junction. This pathology includes a spectrum of disease ranging from imperforate pulmonary valve with a well-developed RV to a severely hypoplastic-rudimentary RV with RV coronary fistulae and absent infundibulum. Focusing on pathophysiology, in the case of rudimentary RV, systemic venous blood, brought to the right atrium from caval veins and coronary sinus, passes mainly into the left side of the heart across the foramen ovale without passing the lungs. Anatomically, the pulmonary valve is often well formed with definable fused commissures. There is also a form when the valve is more dysmorphic with unicuspid or quadricuspid configurations, as well as complete absence of some valvular architecture with a fibrous ventriculoarterial junction [7]. Typically, the tricuspid valve (TV) is smaller than normal. The TV is commonly dysplastic and variably regurgitant. The size of the TV correlates with the RV cavity size, and this is important in the prognosis of PA-IVS. The RV is hypertrophied with a small cavity in 90% of cases and severely hypoplastic in more than 50%. RV may be unipartite (inlet only), bipartite (inlet and outlet), or tripartite (inlet, outlet and trabecular portions). Coronary artery abnormalities are common, including areas of stenosis or complete atresia. Retrograde blood flow from the hypertensive RV into coronary circulation through ventriculo-coronary connections (sinusoids) may be necessary for myocardial perfusion (Fig. 75.5). Ventriculo-coronary fistulae are not present in cases of significant tricuspid regurgitation, presumably because RV hypertension does not develop. After birth, with ductal runoff, diastolic pressure is relatively low and in competition with the suprasystemic RV pressure for coronary artery perfusion. The pulmonary arteries are usually confluent, supplied by a left-sided ductus arteriosus. Usually, because of the obligatory right-to-left shunt at the atrial level, these patients have a foramen ovale or an atrial septal defect (ASD).

Newborns with this malformation become cyanotic and hypoxemic immediately after functional closure of the PDA. When the ASD is restrictive, the cardiac output may be affected. Cyanosis is usually apparent within hours of birth, worsening progressively. In the absence of significant acidosis and reduced cardiac output, tachypnea may be evident. Cardiac examination reveals single first and second heart sounds. A soft pansystolic murmur is often audible at the left lower sternal border. Sometimes the murmur of TR is prominent.

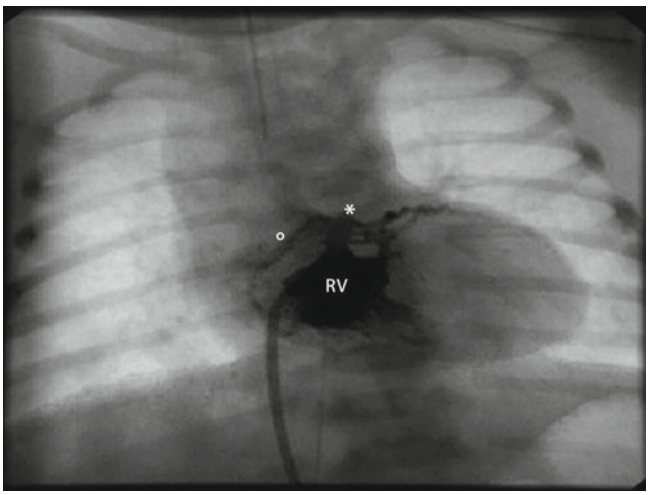

Fig. 75.5 Angiogram of a newborn with pulmonary atresia with intact ventricular septum. The right outflow tract (*asterisk*) ends blindly at the level of the atretic pulmonary valve (*circle*). Coronary sinusoids. *RV* right ventricle

Chest X-ray reveals a variable degree of cardiomegaly. Pulmonary vascular markings are decreased.

ECG reveals an LV dominance or significant LV hypertrophy. There is right atrial enlargement and ST-T abnormalities, consistent with some degree of subendocardial ischemia.

Echocardiography is effective in making the diagnosis. Catheterization is indicated for precise assessment of possible presence of sinusoids, RV to coronary fistulae, stenosis of the coronary vessels when there is a severely hypoplastic RV ("RV dependent coronary circulation"). However, when there is a tripartite RV, perforation of the atretic pulmonary valve followed by balloon dilation can be performed as an alternative to surgical valvulotomy.

75.9.1.3 Tetralogy of Fallot

Tetralogy of Fallot (TOF) occurs in 3–6 infants per 10,000 live births [8]. The etiology is multifactorial but reported associations include untreated maternal diabetes, phenylketonuria and an increased intake of retinoic acid. Some associated chromosomal anomalies have been described: trisomies of chromosomes 21, 18 and 13; however, the most frequent association is with 22q11 chromosome microdeletion [9]. This deletion, manifested by varying degrees of palatal abnormalities, dysmorphic facies, learning difficulties, immune deficiencies and hypocalcemia, is typical of DiGeorge syndrome.

Anatomically, TOF results from anterior and cephalad deviation of the infundibular portion of the ventricular septum. This deviation causes: (1) aortic overriding over the crest of interventricular septum; (2) a malaligned subaortic ventricular septal defect; (3) obstruction of right ventricular outflow tract (RVOTO) (the level of the obstruction can be subvalvular, valvular, supravalvular, in the pulmonary artery or its branches, and either isolated or in combination); and (4) systemic pressure in the RV with secondary hypertrophy (Fig. 75.6).

In case of TOF with pulmonary atresia (PAVSD), the right and left pulmonary artery are confluent in approximately 50%, with blood to the pulmonary arteries flowing through the PDA. In the other 50%, pulmonary supply is multifocal. In these patients the pulmonary blood supply may originate partly from the "true" pulmonary arteries and partly from aorto-pulmonary collateral arteries (MAPCAS). If the pulmonary arteries are discontinuous or absent, pulmonary supply is only from MAPCAS or from a combination of MAPCAS and PDA.

Other associated lesions include atrial septal defects, additional ventricular septal defects and anomalous origin of coronary arteries. A right aortic arch is present in one-quarter of patients with TOF.

The initial presentation of TOF depends on the severity of obstruction of the right ventricular outflow tract.

Neonates with the most severe forms of TOF present with marked cyanosis. Pulse oximetry is equal in all limbs and demonstrates oxygen saturation of 70–80% in air. Arterial blood gas analysis demonstrates hypoxemia. Patients with less severe variants present during the neonatal period with mild-to-moderate cyanosis, but typically without respiratory distress.

The neonatal ECG usually shows right ventricular hypertrophy and right QRS axis deviation. A chest X-ray classically shows a small or absent main pulmonary artery with decreased pulmonary blood flow and, over time, a "boot-shaped" heart silhouette.

Diagnosis is confirmed by echocardiography and cardiac catheterization is not usually required.

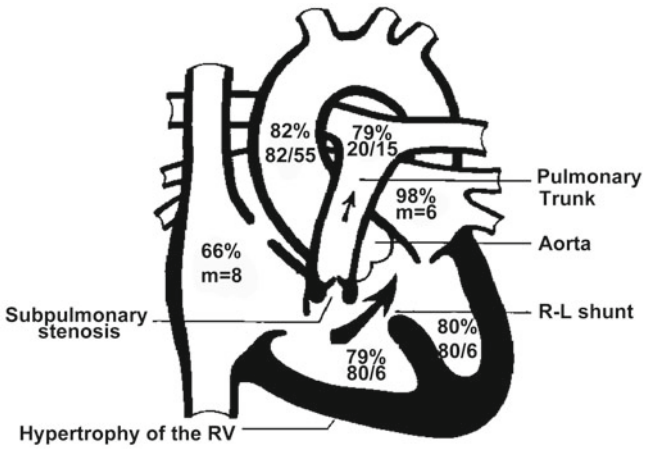

Fig. 75.6 Schematic diagram of oxygen saturation (%) and pressures in anatomy of Tetralogy of Fallot. The findings include: equal right and left ventricular pressures; a right-to-left (R-L) shunt at ventricular level; an anteriorly displaced infundibular septum resulting in subpulmonary stenosis

75.9.1.4 TOF with Absent Pulmonary Valve

Approximately 2–6% of patients described as TOF also have absent pulmonary valve leaflets [10]. The presence of rudimentary valvar leaflets results in free pulmonary regurgitation throughout fetal life. This chronic phenomenon produces chronic RV overload which is transmitted to the pulmonary arteries, with concomitant dilatation of these vessels.

There may be cyanosis in a neonate when the RV pressure is relatively high and when relatively low compliance of the RV decreases the antegrade flow towards the pulmonary circulation and causes right-to-left shunting through the VSD. As the RV pressure decreases, the cyanosis becomes less evident, and more left-to-right shunt develops. Congestive heart failure signs might appear when PVR drops, causing an increased pulmonary blood flow. Some babies can present with inspiratory and expiratory stridor due to tracheobronchial tree compression by aneurysmal pulmonary arteries. In most of these cases PDA is absent.

75.9.1.5 Severe Ebstein's Anomaly

Ebstein's anomaly (EA) is an uncommon but severe anatomic lesion when it presents in the neonatal period. Some familial cases have been reported. Overall, recognized EA is rare, accounting for less than 1% of CHD [11].

Ebstein's anomaly is characterized by abnormal attachment of the posterior and septal tricuspid leaflets in the RV cavity far from a normally positioned tricuspid valve annulus. The degrees of leaflet displacement are variable. The anterior leaflet is large, often with abnormal cordal attachments. This leaflet may obstruct the RV outlet. The inlet portion of the RV is usually functionally integrated into the right atrium ("atrialization of the RV") and the functional RV cavity is small. Nearly all patients have a coexisting ASD or PFO. Ebstein's anomaly can be associated with accessory atrioventricular conduction pathways (Wolff-Parkinson-White syndrome).

Clinical presentation depends on the type and severity of EA. At birth, pulmonary vascular resistance is high and the degree of cyanosis can vary with the degree of right-to-left shunting at the atrial level. In neonates with relatively mild tricuspid valve displacement and no RV outflow tract obstruction, right-to-left shunting usually decreases over the first weeks of life due to pulmonary vascular resistance decrease, with a concomitant reduction in cyanosis. If there is a significant portion of RV atrialized or if the tricuspid valve anterior leaflet obstructs the outflow tract, cyanosis persists and the severity of CHF increases. Ebstein's anomaly is one of the few disorders that may cause a thrill in a neonate.

There are several characteristic ECG appearances: right QRS axis deviation, right bundle branch block, low-voltage QRS complex in the right precordial leads, right atrial enlargement, and first degree AV block. Arrythmias can occur in more than 50% of patients; most frequently they are tachyarrhythmias, including paroxysmal supraventricular tachycardia, atrial fibrillation and atrial flutter.

Cardiac size may vary from nearly normal to extreme cardiomegaly, which is rather typical of EA.

75.9.1.6 Complex CHD with Severe Pulmonary Stenosis or Pulmonary Atresia

Some patients with tricuspid atresia, single ventricle and transposition of the great arteries may have severe pulmonary valve stenosis or pulmonary valve atresia. Postnatally, the degree of restriction to pulmonary flow will determine the clinical presentation and physical findings. Most babies present with cyanosis or murmur. In some of these neonates restrictive ASD may be an important problem, especially in neonates with single ventricle and atrioventricular valve stenosis.

75.9.2 Duct-Dependent Systemic Blood Flow

In this group there is a unique physiology related to left ventricular outflow obstruction (LVOTO) characterized by total or partial arterial duct dependent systemic perfusion (Table 75.7). During intrauterine development, systemic perfusion is not compromised, being maintained by the ductal flow from the right ventricle to aorta. Postnatally, acute impairment of systemic perfusion follows ductal constriction. When the PDA closes, infants present with cardiovascular collapse and symptoms of CHF.

75.9.2.1 Aortic Stenosis

The normal aortic valve has three leaflets of approximately equal size with a semilunar shape at the level of the free margins. Abnormalities of the aortic valve account for 70–80% of left ventricular outflow tract obstruction. In severe neonatal aortic stenosis (AS) the valve is often unicuspid or bicuspid (Fig. 75.7).

During fetal development, normal growth and development of the fetus is generally maintained in spite of valvar aortic stenosis. LVOTO exposes the left ventricle to increased

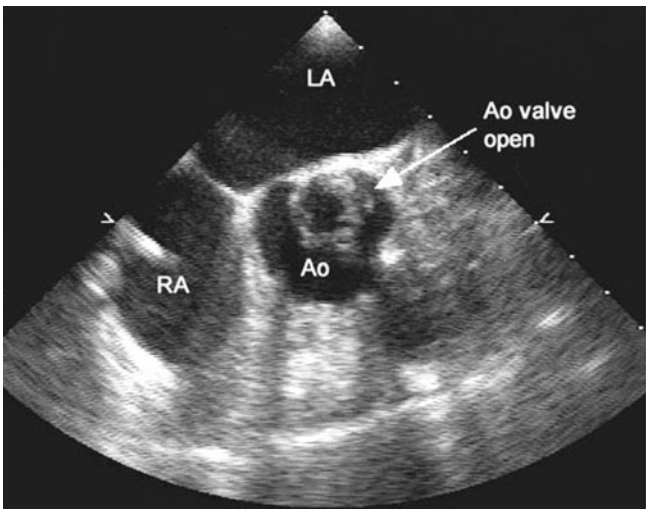

Fig. 75.7 Two dimensional echocardiogram (parasternal short axis) demonstrates an uncuspid and thickened aortic valve

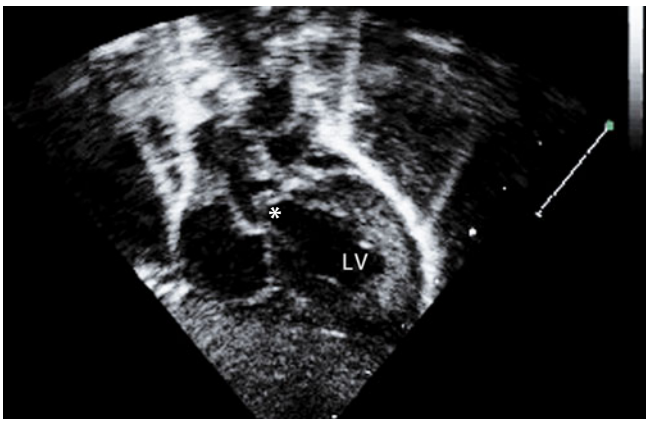

Fig. 75.8 Subcostal coronal view: Neonate with aortic valvar stenosis, concentric left ventricle (LV) hypertrophy. Aortic valve (*asterisk*)

afterload and results in ventricular hypertrophy and myocardial dysfunction. Moreover, chronic in-utero subendocardial ischemia secondary to hypertrophy and increased intracavitary pressure can lead to coronary ischemia and development of endocardial fibroelastosis which further impairs the ventricular function. Additionally, reduced antegrade blood flow through the aortic valve will predispose to underdevelopment of the left heart structures and hypoplasia of the mitral valve, left ventricle, and aortic arch. The RV supplies an increased proportion of systemic blood flow via the PDA because LV output is reduced.

Neonates with critical aortic stenosis present dramatically soon after birth. As the ductus arteriosus begins to close, severe systemic hypoperfusion occurs resulting in decreased coronary perfusion, acute hemodynamic deterioration with cardiovascular collapse, acidosis, organ injury and shock. Once the baby is stabilized, a complete echocardiographic evaluation is required to assess the severity and levels of the obstruction, associated cardiac abnormalities and related hypoplasia of the aortic arch and left heart structures.

Neonates and infants with less severe obstruction may present with failure to thrive and tachypnea due to increased work of breathing in association with pulmonary vascular congestion due to left atrial hypertension.

ECG findings vary widely in newborns and infants with AS. The right ventricular hypertrophy is the predominant pattern in neonates.

Chest X-ray reveals global cardiomegaly in most of the cases. Pulmonary vascular markings are usually normal, but in 30–50% of cases congestion may be evident.

Following the anatomic definition by echocardiography (Figs. 75.8 and 75.9) treatment strategy depends on: (i) the degree of aortic stenosis and the presence of aortic regurgitation; (ii) associated cardiac lesions; (iii) the severity of lesions involving other organs e.g necrotizing enterocolitis.

75.9.2.2 Coarctation of the Aorta

Coarctation of the aorta (CoAo) occurs in 8–10% of all cases of CHD. It is a hemodynamically significant narrowing of the aorta located mostly at the insertion of the ductus arteriosus. It could be isolated or associated with other abnormalities, e.g. tubular hypoplasia of the aortic arch, left ventricular outflow obstruction, bicuspid aortic valve, VSD and ASD. CoAo has been classified as preductal, ductal and postductal. It is frequently seen in some chromosomal syndromes such as Turner syndrome. In newborns or young infants, the presentation is often dramatic as shock or severe congestive heart failure. A concomitant large PDA may make the diagnosis difficult. The most common signs and symptoms are: tachypnea, diaphoresis at feeding, poor perfusion, hepatomegaly and metabolic acidosis. If the duct is partially open, preductal saturation is higher than postductal saturation; there is upper limb hypertension and weak palpable femoral pulses. If the duct is completely closed, there is no discrepancy between upper and lower limb saturation, femoral pulses are absent, cyanosis or lower limb mottling and upper limb hypertension are present.

CoAo and absence of four limb systolic pressure gradient can occur in the following anatomical and physiological conditions. (i) The duct is still patent, so the RV provides flow to the lower part of the body; these neonates have a differential cyanosis with lower O_2 saturation taken from lower limbs. (ii) LV dysfunction and systemic hypotension so severe that it becomes impossible to detect a pressure gradient. (iii) Aberrant right subclavian artery arising distally to the coarctation site; therefore right arm pressure reflects post-coartctation pressure.

The key point is not to exclude diagnosis of CoAo solely through the absence of a gradient in pulse volume or systolic pressure between upper and lower limbs.

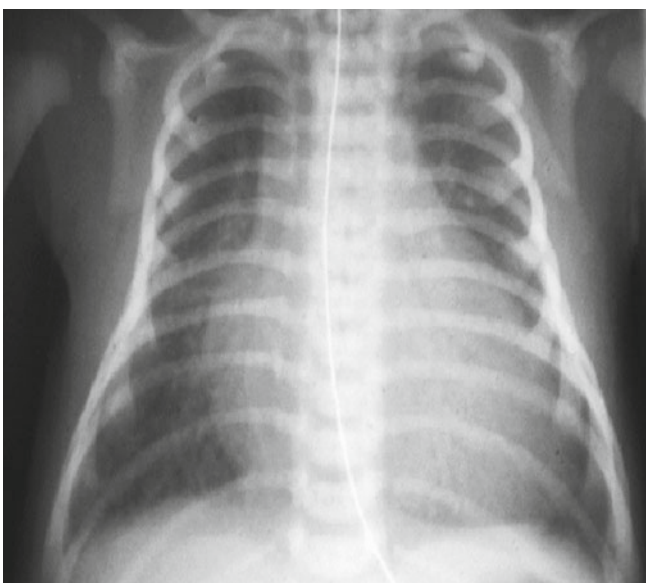

Fig. 75.10 Severe coarctation of the aorta. Heart is enlarged. Pulmonary arterial markings are normal, but there are distended pulmonary veins

The most common ECG pattern shows right ventricular hypertrophy initially, while biventricular hypertrophy usually appears later. Chest X-ray reveals the hallmarks of cardiomegaly and pulmonary congestion (Fig. 75.10). Echo color Doppler is the most sensitive and specific method for making the diagnosis (Figs. 75.11 and 75.12).

75.9.2.3 Interrupted Aortic Arch

Interrupted aortic arch (IAA) is an uncommon congenital cardiovascular malformation. The incidence is 1% of all congenital heart diseases, carrying a mortality rate higher than 90% in the neonatal period [12].

IAA is defined as either a complete discontinuity or nonpatent fibrous strand in the trasverse arch or aortic isthmus. It is classified into three types according to the site of interruption: type A, the interruption is distal to the left subclavian artery origin; type B, between the origin of left subclavian and left common carotid artery; type C, which is the rarest one, between the origin of the right brachiocephalic and the left common carotid artery.

Its hemodynamic condition is totally dependent on PDA patency that supplies the lower part of the body. Furthermore, most patients have only an isolated VSD but IAA can be associated with a variety of complex cardiovascular anomalies (Table 75.8) [13].

In most of the cases the pathophysiology of interrupted aortic arch is similar to critical CoAo in the newborn. Systemic blood flow is dependent on PDA patency. When the PDA closes, the baby develops poor perfusion, acidosis, shock and renal failure. On physical examination, tachycardia, systolic murmur, hepatomegaly and weak femoral pulses are present. Differential cyanosis between the upper and lower limbs is usually difficult to appreciate when there is a VSD. If there is a concordant ventriculo-arterial connection, the pulse oximetry may show higher oxygen saturation in the pre-ductal upper limbs compared with post-ductal lower limbs. If the great arteries are transposed, the oxygen saturation could be higher in the lower limbs (reversal differential cyanosis).

IAA type B is commonly associate with DiGeorge syndrome (broad nasal bridge, malar hypoplasia, narrow palpebral fissures, hypertelorism, low-set posteriorly rotate ears, retrognathia, small mouth, and submucosal palatal cleft, variable thymus and parathyroid deficiencies). These physical features are difficult to recognize in neonates, therefore all neonates with IAA should be genetically investigated to confirm DiGeorge syndrome. The major risk in these patients is graft-versus-host disease after blood transfusion with non-irradiated blood.

ECG and chest X-ray are not specific. Echocardiography is fundamental to make the diagnosis and to detect coexisting defects.

75.9.2.4 Hypoplastic Left Heart Syndrome

Hypoplastic left heart syndrome (HLHS) represents a group of defects characterized by varying degrees of underdevelopment of left sided heart structures. Most of the patients have combinations of aortic and mitral valve atresia or stenosis [14]. The severity is determined by the severity of outflow tract obstruction and the degree of aortic hypoplasia. This syndrome accounts for 1–3.8% of all CHD [15].

The LV is a rudimentary non pumping chamber; the pulmonary venous return goes to the RA through a foramen ovale or atrial septal defect, causing complete venous blood mixing. The RV maintains the pulmonary and systemic output in a parallel fashion. The pulmonary arteries receive blood from the RV, while cerebral and cardiac perfusion are supplied retrogradely through the arterial duct into the transverse arch and ascending aorta.

During fetal life, the PVR is higher than the systemic vascular resistance and the RV maintains normal perfusion in the aorta and placenta through the duct. After birth, there is reversal of vascular resistance in the two circuits, with systemic pressure being higher than pulmonary, and PDA closure occurs. Additionally, an important anatomic element is the presence of an appropriately restrictive interatrial communication. With pulmonary and systemic parallel circulation, the ratio of pulmonary to systemic flow (Qp:Qs) depends on the balance between pulmonary and systemic vascular resistances. At birth, PVR is elevated but eventually decreases even in children with HLHS, resulting in increasing pulmonary blood flow and increasing RV overload, to preserve adequate systemic output. As Qp:Qs increases, more saturated blood passes from the LA to the RA across a non restrictive ASD; consequently systemic oxygen saturation approaches normal values despite progressive clinical signs of CHF. This mechanism represents the most common cause of CHF in the first weeks of life [6]. A different clinical presentation occurs when the pathophysiology is characterized by reduced pulmonary blood flow secondary to a small or restrictive interatrial communication. These babies always present critically with deep cyanosis, marked tachypnea, metabolic acidosis, hypoxemia characterized by PaO_2 values of 20 mmHg or less, and cardiovascular collapse.

All infants with HLHS should be promptly commenced on a prostaglandin infusion to ensure ductal patency and sysytemic perfusion. Clinical stabilization includes endotracheal intubation, vascular access placement, correction of metabolic acidosis, and oxygen delivery. After the diagnosis is made by echocardiography, prompt left atrial decompression is necessary by a balloon transcatheter or surgical procedure (atrial septostomy).

Newborns with HLHS are generally full-term babies who initially appear well and healthy; only a few are affected by extracardiac anomalies, like structural brain malformations typical of chromosomal abnormalities [16, 17]. The magnitude and distribution of acquired vital organ dysfunction usually

relates to the circulatory impairment at the time of diagnosis. All the interventions in the preoperative period should be done in order to: (i) preserve ductal patency and (ii) set or maintain Qp:Qs ratio of 1:1.

Differential diagnosis should include all the other left-sided obstructive lesions characterized by arterial duct dependent systemic circulation (Table 75.7) and other non-structural cardiac diseases with shock-like state clinical presentation such as neonatal sepsis or neonatal myocarditis; these conditions can be easily differentiated by echocardiography.

75.9.3 Parallel Circulation/Trasposition of the Great Arteries

Transposition of the great arteries (TGA) is a common form of cardiac anomaly, accounting for approximately 75–80% of all congenital heart defects [6]. TGA is defined anatomically as concordant atrioventricular (AV) connection and discordant ventriculoarterial connection. In this setting the morphological RA is connected to the morphological RV which gives rise to all or most of the aorta; the morphological LA is connected to the morphological LV from which the pulmonary trunk emerges (Fig. 75.13) [18]. This condition is known as simple transposition. By contrast, complex transposition includes VSD, left ventricular outflow tract obstruction, aortic arch anomalies and anomalous venous return.

Ventricular septal defect is present in 20% of TGA [19, 20], typically in the outlet portion. Malalignment of the outlet septum deviated to the right results in variable degrees of PA overriding representing an anatomical entity called double-outlet right ventricle with subpulmonary ventricular septal defect (Taussig-Bing anomaly).

Left ventricular outflow tract obstruction can be demonstrated in over 30% of the patients with TGA [21]. Aortic arch obstruction is rare in TGA without VSD. Coronary anatomy may show different patterns [22]. In 10% of the cases, this cardiac defect is associated with other noncardiac malformations [23].

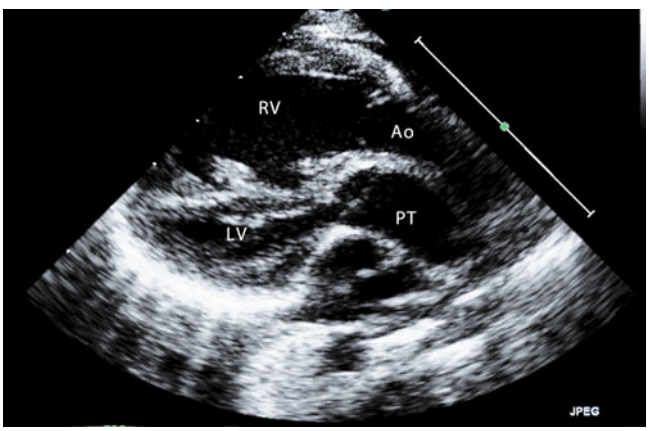

Fig. 75.13 Echocardiography; long-axis view demonstrating the anterior aorta arising from the right ventricle (RV) and the pulmonary trunk (PT) arising from the left ventricle (LV)

75.9.3.1 Transposition Physiology

Systemic blood goes from RA to RV and then into the aorta without being oxygenated in the lungs. On the contrary, fully oxygenated pulmonary venous blood returns from the pulmonary veins into LA and LV and returns to the lungs via the pulmonary artery: in this setting the systemic and pulmonary circulations describe parallel loops. Survival depends on the presence of one or more mixing sites between these two circulations such as atrial septal defect, ventricular septal defect or PDA, to achieve arterial oxygen saturation compatible with life.

Following separation of the placenta, newborns with TGA without VSD and small PFO or ASD have severe cyanosis (a very low PaO_2: 15–20 mmHg) on the first day of life, associated with high $PaCO_2$ and metabolic acidosis due to a severely decreased effective pulmonary blood flow.

75.9.3.2 Diagnosis

The hyperoxia test is suggestive of a cyanotic congenital heart condition [24]. Chest X-ray and ECG may be helpful, but findings are not specific. The definitive diagnosis relies on echocardiography.

The initial management aims at increasing FiO_2 and maximizing mixed venous oxygen saturation opening the arterial duct with prostaglandin. Resuscitation with mechanical ventilation can be necessary and the foramen ovale should be emergently enlarged by ballon atrial septostomy. This procedure is usually performed under fluoroscopy in the cardiac catheterization laboratory. Balloon atrial septostomy, also known as the Rashkind procedure, consists of placing a balloon tipped catheter in the LA, via the foramen ovale; the balloon is then inflated and pulled back into the RA, tearing the atrial septum. Echocardiographic guidance is mandatory. The aim of this procedure is to create an interatrial communication big enough to cause an increase in oxygen saturation due to improved blood mixing. In addition to these measures, medical support is usually necessary to optimize the clinical condition: correction of metabolic acidosis with hyperventilation and sodium bicarbonate to promote alkalosis, lower pulmonary vascular resistance and increase pulmonary blood flow.

In case of good atrial septostomy but persisting desaturation, oxygen saturation could be improved by: (i) decreasing the whole body oxygen consumption (muscle relaxants, sedation, mechanical ventilation); (ii) increasing cardiac output with inotropic agents; (iii) increasing oxygen-carrying capacity by treating anemia.

The arterial switch operation is the procedure of choice and it is used to achieve complete physiological and anatomical correction.

75.9.4 Lesions with Complete Intracardiac Mixing

75.9.4.1 Total Anomalous Pulmonary Venous Return

Total anomalous pulmonary venous return (TAPVR) is a congenital defect in which the pulmonary veins drain anomalously into the systemic venous circulation causing a complete blood mixing. TAPVR is classified in four types based on the anatomical sites of the abnormal connection: supracardiac, cardiac, infracardiac and mixed.

1. *Supracardiac*: the veins drain into a common confluence behind the LA which drain through an anomalous vein into the systemic venous circulation, usually in the right-sided superior vena cava or the innominate vein through a persistent vertical vein.
2. *Cardiac*: the common venous confluence drains either into the coronary sinus or posterior portion of RA.
3. *Infracardiac*: the common venous confluence passes across the diaphragm through the esophageal hiatus and drains either into the portal vein or ductus venosus or hepatic vein or inferior caval vein.
4. *Mixed type*: this anatomical configuration is the result of combination of different forms of TAPVR. It is commonly associated with other major cardiac anomalies.

In addition, drainage can be obstructed or unobstructed. The majority of supracardiac TAPVR cases have some degree of obstruction which could be secondary to: (i) ascending vein compression between bronchi and pulmonary artery or aorta, (ii) vertical vein orifice stenosis or (iii) a small and restrictive atrial communication.

Heterotaxy syndrome, especially right isomerism, is usually associated with TAPVR [25]. TAPVR is associated with other cardiac anomalies such as single ventricle, truncus arteriosus, transposition of the great arteries, pulmonary atresia and coartaction of the aorta [26].

There is an obligatory left-to-right shunt from pulmonary veins to the right heart and an obligatory right-to-left shunt from RA to the left heart to maintain the systemic output. The factors that determine blood flow distribution in these two circuits include: (i) relative size of the atrial communication and (ii) severity of any obstruction in the extracardiac pulmonary venous channel.

In the most common form of TAPVR, pathophysiology is a combination of pulmonary vein obstruction and increased pulmonary blood flow. This situation results in RV volume overload. Neonates with significant pulmonary vein obstruction present with severe cyanosis, tachypnea and hemodynamic instability. These babies are frequently misdiagnosed as having persistent fetal circulation or sepsis or severe respiratory distress syndrome [27].

The clinical presentation of TAPVR varies with the degree of obstruction and pulmonary blood flow. Frequently the newborns present with tachypnea due to RV volume overload, whereas babies with the important pulmonary vein obstruction show frank respiratory distress, pulmonary edema, poor peripheral perfusion, hypotension and metabolic acidosis. Identification of this pathology is crucial in critically ill neonates and the diagnosis is usually made by echocardiography.

75.9.4.2 Truncus Arteriosus

This defect consists of a single great artery arising from the heart which gives rise to systemic arteries, pulmonary and coronary arteries. Depending on the anatomical origin of the pulmonary arteries, four types of truncus arteriosus exist [28].

1. Type I, pulmonary trunk arises from common arterial trunk.
2. Type II, right and left pulmonary arteries arise separately but close to one another from the left postero-lateral aspect of common arterial trunk.
3. Type III, each pulmonary artery arises from the ipsilateral aspect of common arterial trunk.
4. Type IV, the main pulmonary artery is absent with the lungs receiving their blood supply through aortopulmonary collaterals.

The common arterial trunk overrides a VSD which is often large, nonrestrictive, with the superior border being formed by the truncal valve. The truncal valve may have a variable number of cusps, most commonly three; it is often anatomically abnormal showing different grade of regurgitation and/or stenosis. The pulmonary arteries are usually of normal caliber although stenosis of the origin and diffuse hypoplasia can occur. Coronary anomalies, in terms of origin and epicardial course, can coexist. Truncus arteriosus may also be associated with a right-sided aortic arch. The extracardiac anomalies are common and can contribute to the mortality; association with DiGeorge syndrome, chromosome 22q11 deletion [29], is reported in about 30% of cases [30].

In most cases the dominant physiology is a left-to-right shunt at the level of the great arteries. The pulmonary and the systemic blood flow is determined respectively by pulmonary vascular resistance and systemic vascular resistance. Newborns affected by truncus arteriosus generally have an elevated pulmonary vascular resistance and are therefore asymptomatic. As pulmonary resistance gradually decreases and PBF increases, signs of CHF occur. Subsequently the volume and pulmonary pressure overload leads to pulmonary vascular disease. Furthermore, signs of CHF can be worsened by concomitant significant truncal valve regurgitation or stenosis. Echocadiography provides accurate diagnosis (Figs. 75.14 and 75.15). Definitive repair of truncus arteriosus consists of PA branches separation, RV-PA conduit implantation and VSD closure.

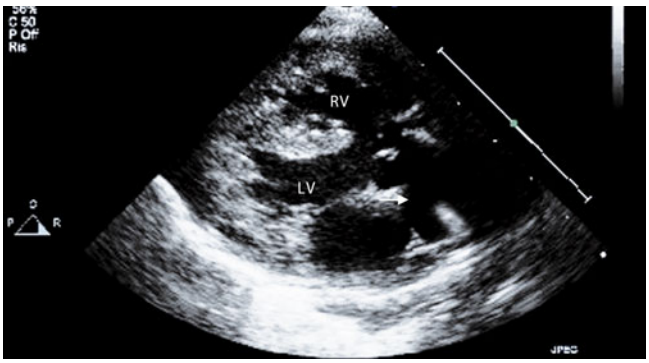

Fig. 75.14 Echocardiogram (long-axis parasternal view) of truncus arterious. Truncal vessel gives rise to the aorta and the pulmonary arteries (*arrow*). *RV* right ventricle, *LV* left ventricle

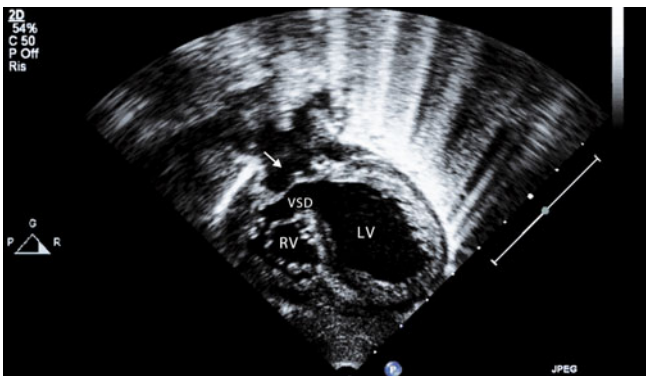

Fig. 75.15 Subcostal view demonstrating the ventricular septal defect (*VSD*) overriding the truncal valve. *RV* right ventricle, *LV* left ventricle

75.9.4.3 Complex Single Ventricle

Physiology of complex single ventricle is characterized by complete mixing of systemic and pulmonary venous circulation. An anatomical definition describes single ventricle as a malformation in which both atrioventricular valves enter one ventricle and there is only one identifiable ventricular sinus [31]. A large variety of anatomic lesions exist, generally associated with atresia of an atrioventricular or semilunar valve. The great vessels usually arise from the heart in an abnormal fashion; frequently variable degrees of pulmonary or aortic obstruction may be present. Most complex single ventricles are associated with heterotaxy syndrome: polysplenia or asplenia, systemic venous return anomalies, anomalous pulmonary venous connection, visceral situs abnormalities, atrioventricular septal defect.

The hemodynamic characteristics and the clinical presentation depend on the balance of anatomy and/or resistance in the systemic and pulmonary circulation. Patients without pulmonary stenosis show increased pulmonary blood flow and soon develop signs of congestive heart failure. In cases with pulmonary stenosis, the cyanosis is present according to the degree of osbstruction.

Patients with pulmonary or aortic atresia or severe hypoplasia of the aortic arch have a ductal-dependent circulation and they need treatment with PGE_1 as long as palliative surgical procedure is performed.

75.9.5 Left-to-right Shunt Lesions

In the group of left-to-right shunt lesions, the most common in the neonates are: PDA, ventricular septal defect, atrioventricular septal defect and atrial septal defect. PDA will be widely described in Chapter 80.

75.9.5.1 Ventricular Septal Defect

Ventricular septal defect (VSD), is one of the most common isolated congenital cardiac malformations. A ventricular septal defect is a hole in the interventricular septum resulting in direct communication between the left and right ventricles. A clinical useful classification schema divides VSD in four types, considering interventricular septum from the RV aspect:

1. Perimembranous, which partially or totally involves the membranous septum. It can extend into the inlet, trabecular or outlet portions of the septum. This accounts for the majority of the cases.
2. Subarterial, located just beneath the pulmonary valve. This defect, also known as "doubly committed", occurs most often amongst Asians.
3. Inlet defect, beneath the septal cusp of the tricuspid valve.
4. Muscular defect, located anywhere in the muscular septum with all muscular margins (Fig. 75.16).

VSD could be either isolated or part of complex CHD as in TOF, truncus arteriosus, double outlet RV.

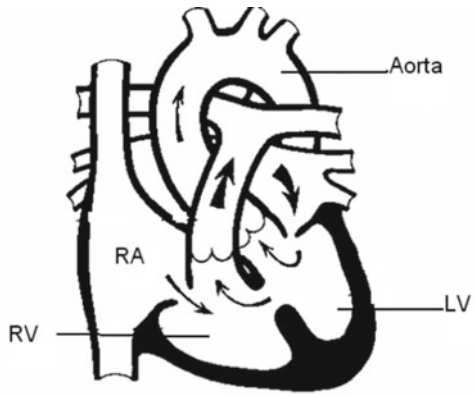

Fig. 75.16 Ventricular septal defect: VSD may occur anywhere in the ventricular septum. This defect is located in the muscular portion of the septum. *RV* right ventricle, *LV* left ventricle

The common atrioventricular valve is indicated (*arrow*). *RA* right atrium, *LA* left atrium, *RV* right ventricle, *LV* left ventricle

75.9.5.2 Atrioventricular Septal Defect

Atrioventricular septal defect (AVSD) is a malformation involving the structures normally derived from the endocardial cushion tissue: ostium primum atrial septal defect, inlet VSD and the common atrioventricular valve (Fig. 75.17). Different forms of AVSD exist but two are the most common: partial and complete. Partial AVSD indicates an atrioventricular septal defect with interatrial communication (ostium primum ASD), common AV valve but not inlet VSD; the term complete atrioventricular septal defect describes an AVSD with both ostium primum ASD and inlet VSD. There is a strong association between complete AVSD and Down syndrome whereas partial AVSD is more seen in DiGeorge and Ellis-Van Creveld syndromes.

Most neonates with left-to-right shunt defects present with signs of cardiac failure after 2 weeks of age. During fetal life even large defects do not have major physiological effects because of high PVR. After birth the normal decline of PVR occurs within the first 2 weeks. In the presence of a large shunt, this decline may be delayed by 1–3 months. When this phenomenon happens, pulmonary artery blood flow increases resulting in left heart volume overload.

Babies with small left-to-right shunt defects usually come to the attention of pediatricians because of cardiac murmurs without symptoms. Children with moderate left-to-right shunt defects show varying degrees of growth retardation. Large defects cause signs and symptoms of cardiac failure as tachypnea, nasal flaring, rib and sternal retraction, feeding difficulties, irritability, excessive sweating. It is extremely rare for partial AVSD to cause abnormal physical signs during neonatal period, unless there is significant AV valve regurgitation.

All the neonates with signs of cardiac failure should be investigated by echocardiography.

Early Diagnosis of Congenital Heart Disease: When and How to Treat

Luciane Piazza, Angelo Micheletti, Diana Negura, Carmelo Arcidiacono, Antonio Saracino and Mario Carminati

76.1 Introduction

Cardiovascular malformation is the most common group of congenital malformations. The prevalence is 5.3 cases per 1000 live births [1–3]. These malformations represent a significant cause of neonatal morbidity and mortality. Advances in medical and surgical treatment of congenital heart disease (CHD) have resulted in a trend towards an improved outcome in conditions which previously carried high mortality. The antenatal diagnosis of CHD, by fetal echocardiography carries important advantages: 1) prenatal diagnosis is associated with less hypoxia, preoperative acidosis, fewer neurologic events, and early age to surgery [4]; 2) it provides opportunities for parental counseling; 3) it may optimize perinatal care in terms of changes in obstetric and neonatal management with multidisciplinary approach which should reduce mortality and morbility [5,6]. Routine neonatal examination fails to detect many affected babies, because a normal examination does not exclude serious cardiac malformation, including hypoplastic left heart syndrome or other pathologies such as interruption or coarctation of the aortic arch. Considering that about half of the babies with cardiac murmur, detected over the first few days of life, have a structural heart disease [7], these patients should be referred for early pediatric cardiological evaluation and definitive diagnostic echocardiography. Unrecognized neonatal cardiac malformation carries a serious risk of avoidable mortality, morbidity and handicap [8]. Regardless of this, all syndromic babies such as Down syndrome-affected babies who have a high prevalence of congenital heart disease, should be referred for early echocardiographic examination [1]. The key point is that echocardiography is an essential tool in the evaluation of neonates and has dramatically improved the accuracy of diagnosis of congenital heart disease.

76.2 When and How to Treat – Preoperative Management of Neonates with CHD

The preoperative management of patients with critical congenital heart defects has a dramatic impact on overall outcome; it requires a coordinated, multidisciplinary approach with pediatric cardiologist, pediatric intensivist, surgeon, anesthesiologist, pediatric nurses, respiratory therapists, and family members. The major goal is to provide supportive care, clinical stabilization, and adequate cardiac output to ensure adequate tissue delivery. Advances in the surgical repair of congenital heart defects have allowed a trend toward a single stage repair. Nevertheless there are still two palliative procedures used for specific indications (Table 76.1): systemic-to-pulmonary artery shunt and pulmonary artery banding.

76.2.1 Systemic-to-Pulmonary Artery Shunt

The systemic-to-pulmonary artery shunt is a palliative procedure that is used to increase pulmonary blood flow in cardiac defects characterized by pulmonary outflow obstruction and clinical cyanosis. In these conditions, before surgery, the

Table 76.1 Indications for palliative procedure

1. Systemic-to-pulmonary arterial shunt
   - Right-sided obstructive lesion varying in severity from moderate pulmonary stenosis to pulmonary atresia
   - Tetralogy of Fallot
   - Single ventricle with pulmonary stenosis
   - Tricuspid atresia
   - Atrioventricular septal defect with severe pulmonary stenosis
2. Pulmonary artery banding
   - Tricuspid atresia with unrestrictive VSD
   - Single ventricle with unrestrictive pulmonary blood flow
3. Norwood procedure
   - Hypoplastic left heart syndrome

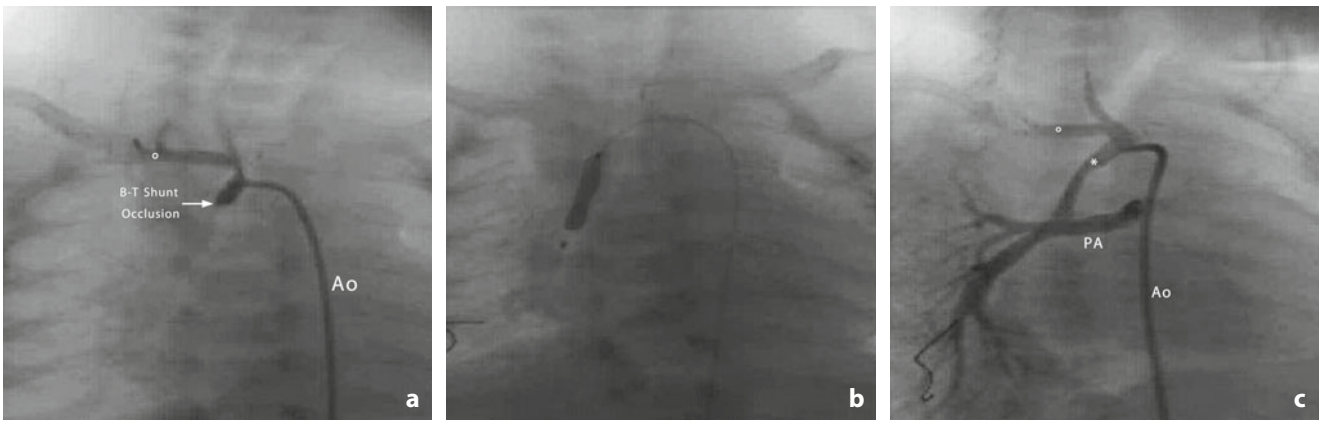

Fig. 76.1 **a** Injection in the right Blalock-Taussig shunt; the shunt is completely occluded. **b** Recanalization of the shunt with a balloon catheter. **c** Post balloon angioplasty: injection in the right modified Blalock-Taussig shunt; complete recanalization (*asterisk*). Right subclavian artery (*circle*), *AO* catheter in the aorta, *PA* pulmonary artery

ductus arteriosus is the main source of pulmonary blood flow; as the ductus closes spontaneously, severe hypoxemia, metabolic acidosis and death can occur. That is why prostaglandin (PGE_1) should be administrated by continuous intravenous infusion to maintain patency of the ductus arteriosus. In many cases supporting therapy is necessary to prevent vasoconstriction and avoid hypoxia, acidosis and hypercapnia which may increase pulmonary vascular resistance (PVR). It is important to maintain normal blood glucose, calcium levels and preservation of a neutral thermal environment [9]. The modified Blalock-Taussig shunt (MBTS) is the most commonly created systemic-pulmonary shunt in neonates [10]. This procedure consists of a polytetrafluoroethylene (Gore-Tex) graft placement between the innominate or subclavian artery and the ipsilateral pulmonary artery [11]; it aims at increasing pulmonary blood flow (PBF) and making pulmonary arteries grow in order to achieve a favorable anatomic condition for future correction. In particular situations such as Ebstein's Anomaly, pulmonary atresia with intact ventricular septum or hypoplastic left heart syndrome, transcatheter arterial duct recanalization and stenting can be considered as an alternative technique to a surgical shunt [12–14]. The postoperative management after Blalock-Taussig shunt insertion in neonates is generally uncomplicated. The saturation is about 75–80% in most of the cases. The extubation is deferred until pulmonary blood flow is adequate and the arterial saturation is stable. When the saturation is not adequate, following problems should be excluded: hypotension, shunt narrowing or occlusion, pulmonary edema and lung disease. If shunt narrowing or obstruction is detected, feasible treatment could be percutaneous balloon angioplasty (Fig. 76.1a,b,c), thrombolysis or surgery. Immediate postoperative anticoagulation with heparin is used, followed by daily aspirin therapy as long as the shunt is open.

Pulmonary edema can occur in cases of overcirculation, requiring if necessary reoperation to narrow the shunt size.

76.2.2 Pulmonary Artery Banding

Pulmonary artery banding is a palliative procedure performed in neonates affected by CHD associated with high pulmonary

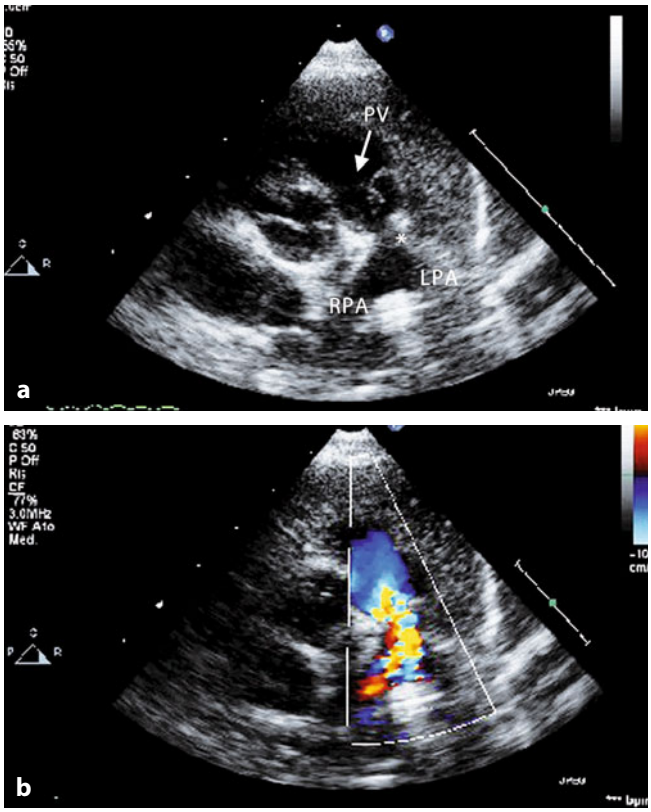

Fig. 76.2 Echocardiogram picture of pulmonary artery banding. **a** Pulmonary valve (PV); Pulmonary banding (*asterisk*). *LPA* left pulmonary artery, *RPA* right pulmonary artery. **b** Color flow picture showing flow acceleration across the banding

blood flow and CHF poorly controlled by medical therapy. The aim is to control the symptoms, to make the child grow properly and to prevent the development of pulmonary vascular disease.

The banding procedure consists of surrounding the main pulmonary artery with a synthetic band in order to create a stenosis limiting the pulmonary blood flow (Fig. 76.2) It can be performed either through sternotomy or anterolateral thoracotomy.

76.2.3 Norwood Procedure

The Norwood procedure is performed to treat the conditions that result in single ventricle circulation. Since in these conditions, the most urgent problem is that the heart is unable to pump blood to the systemic circulation, the object of the Norwood procedure is to connect the single ventricle to the systemic circulation. This procedure is prescribed in the treatment of hypoplastic left heart syndrome (HLHS), an association of anatomical anomalies involving the left side of the heart. HLHS includes varying degrees of hypoplasia of the left ventricle, critical stenosis or atresia of the mitral and/or aortic valve, along with some degree of hypoplasia in the aortic arch [4].

The surgical treatment for HLHS consists of three steps:

1. initial palliative reconstruction (STAGE I- Norwood procedure);
2. bidirectional Glenn shunt;
3. Fontan operation.

The first stage is performed to provide a systemic perfusion independent from the arterial duct, to preserve function to the single ventricle by minimizing excess pressure and volume work, and to allow normal maturation of the pulmonary vasculature. An atrial septectomy is performed to avoid obstruction of pulmonary venosus return and to allow blood flow from the left atrium (LA) to the right atrium (RA). The pulmonary artery and aorta are used to create the "neoaorta". Either a modified Blalock–Taussig (MBT) shunt or Sano shunt (right ventricle [RV] to main pulmonary artery [PA] conduit) is placed in order to supply pulmonary circulation [16]. The Sano shunt, compared with the BT shunt, results in a higher elevation of the diastolic blood pressure. Because the coronary arteries are perfused in diastole, the advantage expected in the Sano strategy is supposed to be a better coronary perfusion [17].

A new approach to the HLHS is known as "hybrid" procedure which consists of transcatheter stent implantation in the ductus arteriosus as well as surgical bilateral PA branches banding. The stent maintains systemic perfusion whereas the bands limit pulmonary blood flow [18, 19]. This procedure should be performed either in a catheterization laboratory or in a theatre where both angiographic as well as surgical capabilities and equipment should be available.

76.3 Pathologies which Require Correction in the Neonatal Period

76.3.1 Truncus Arteriosus

Complete mixing at the ventricular and arterial levels, with blood flow to the systemic and pulmonary circulation determined by pulmonary and systemic resistance is the consequence of truncus arteriosus. In the absence of pulmonary artery stenosis the normal fall in pulmonary vascular resistance (PVR) results in significant left-to right shunting, pulmonary overcirculation and symptoms of CHF. Due to the rapid development of pulmonary overcirculation, pulmonary hypertension and subsequent vascular obstructive, disease can occur as early as 3 months of life. Based on these data, the policy of many centers is to perform complete correction during the neonatal period [20]. The surgical repair consists of ventricular septal defect (VSD) patch closure, pulmonary artery removal from the common arterial trunk and RV to PA conduit implantation.

The combination of other cardiac malformations and truncus arteriosus, such as aortic arch interruption, outflow tract obstruction and multiple VSDs, carries high mortality with high risk of reintervention in survivors [21].

76.3.2 Transposition of the Great Arteries (TGA)

Most infants with TGA are diagnosed shortly after birth. Usually the babies need a balloon atrial septostomy (Fig. 76.3). Additional medical support is necessary to optimize clinical conditions.

The arterial switch operation (ASO) is the procedure of choice used to achieve complete physiological and anatomic correction. Current indications for ASO in newborns and infants must be taken into account in planning operative strategy, because the optimal time depends on anatomic features such as multiple VSDs or unbalanced ventricles. The key point is the morphologically left ventricular pressure at the time of presentation. Currently the optimal timing of ASO for babies with TGA without VSD varies from 5 to 15 days. Occasionally, newborns with TGA do not undergo early surgery because of later presentation, later diagnosis or both, or coexisting medical problems such as septic conditions or necrotising enterocolitis (NEC). In the ASO operation, the aorta and pulmonary artery are sectioned and their distal extremities are transposed and anastomosed; coronary arteries are then translocated to the neo aorta [22]. An alternative procedure is an atrial switch operation (Senning or Mustard operation) leaving the morphologically right ventricle in the systemic circuit. Despite the technical difficulties associated with the arterial switch operation and the problems related to postoperative management,

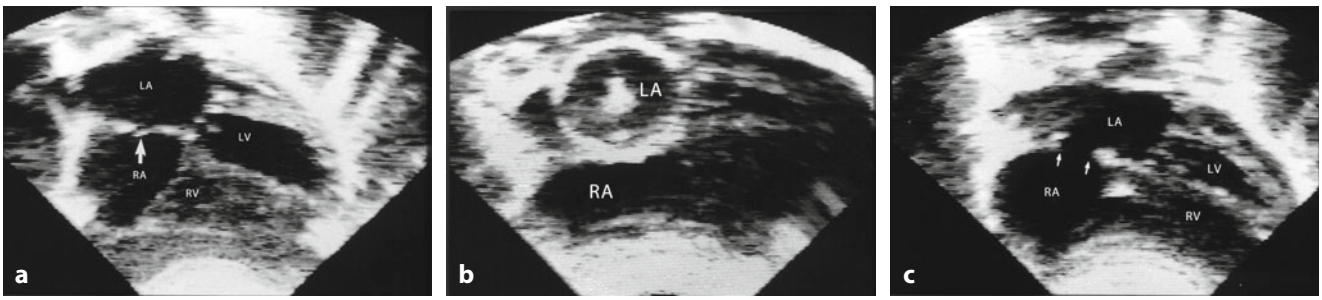

Fig. 76.3 Cross-sectional echocardiography from the subcostal approach demonstrating the septostomy procedure. **a** Short frame demonstrating the interatrial septum before the septostomy. **b** Catheter in the left atrium across the interatrial septum. **c** The interatrial communication (*arrows*) after balloon septostomy. *LA* left atrium, *RA* right atrium, *RV* right ventricle, *LV* left ventricle

early mortality is now similar to that of the atrial switch operation, whereas long-term results are better [23–25].

76.3.3 Total Anomalous Pulmonary Venous Return (TAPVR)

TAPVR is a congenital defect in which the pulmonary veins drain anomalously into a systemic venous structure (see Chapter 75). In obstructed TAPVR, correction is usually performed at the time of presentation, especially when the child is markedly cyanotic [26]. In unobstructed TAPVR, timing of correction varies with the severity of the clinical features: generally babies present with symptoms of CHF later in infancy, at that time correction should be carried out.

76.3.4 Ebstein's Anomaly

Hemodynamic abnormalities in this malformation are related to the severity of tricuspid regurgitation, the size of the functional RV, and the degree of the right-to left shunting across the atrial septal defect (ASD). Ebstein's anomaly can be associated with ASD and pulmonary outflow obstruction. If there is a severe tricuspid regurgitation in utero, massive cardiomegaly, secondary pulmonary hypoplasia, hydrops fetalis or a combination of these can occur [27]. The Ebstein's anomaly has a clinical spectrum that varies from severe cyanosis and circulatory collapse in the newborn to minimal or no symptoms in child or adult. Once the diagnosis is made, the newborn may require support with PGE_1 infusion and nitric oxide, and definitive surgical management is undertaken. For neonates, therapy is tailored to the severity of the malformation and the degree of RV outflow tract obstruction. Surgery may involve ligation of the duct, placement of a systemic to pulmonary shunt, creation of a functional tricuspid atresia or tricuspid valve repair [28]. Mortality is strongly related to severe tricuspid regurgitation and pulmonary hypoplasia.

76.3.5 Right-sided Obstructive Lesions

76.3.5.1 Tetralogy of Fallot (TOF)

There is a wide spectrum of anatomical variability in TOF with and without pulmonary atresia (TOF/PA). Clinical presentation depends on the severity of the anatomical defects, particularly on the degree of right ventricular outflow tract obstruction, the amount of right-to-left shunt through the ventricular septal defect and the size of pulmonary arteries, as noted in the previous section. Echocardiographic examination provides all the information required to plan surgical strategy (Figs. 76.4 and 76.5). Therefore cardiac catheterization is needed only when the diagnostic dilemma is still not sorted out like pulmonary or coronary artery anatomy, presence of aorto-pulmonary collateral arteries.

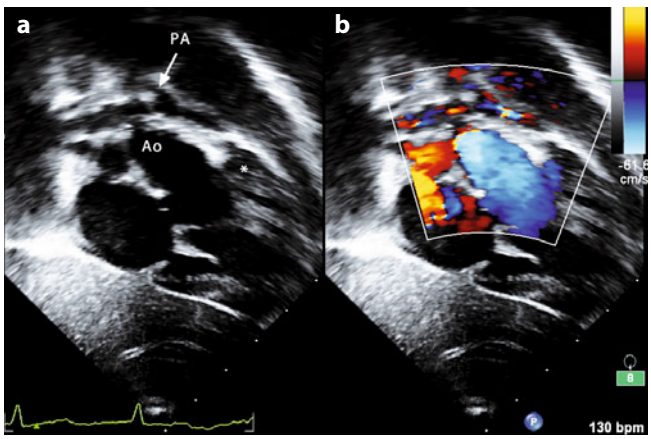

Fig. 76.4 **a** Right subcostal anterior oblique view in tetralogy of Fallot demonstrating the antero-cephalad deviation of the outlet septum into the right ventricular outflow tract. Infundibular pulmonary stenosis (*asterisk*). Significant hypoplasia of the pulmonary trunk and pulmonary arteries. **b** Color Doppler imaging showing turbulence and flow acceleration in the right ventricular outflow tract. The turbulence continues into the pulmonary trunk and pulmonary arteries. *AO* aorta, *PA* pulmonary artery

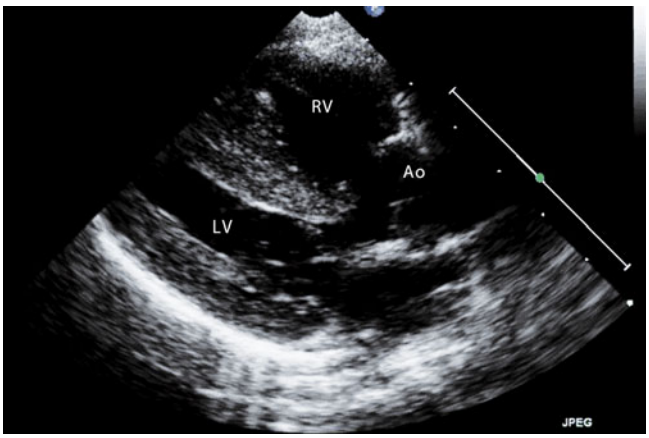

Fig. 76.5 Two-dimensional echocardiogram (modified parasternal long axis view) demonstrating large ventricular septal defect, aortic override and the right ventricular hypertrophy typical of tetralogy of Fallot

All patients with TOF and TOF/PA require surgical intervention. Initial medical management depends on clinical presentation which also depends on the severity of right ventricular outflow tract obstruction (RVOTO). When RVOTO is significant, neonates present with cyanosis, hypoxemia and metabolic acidosis: prostaglandin infusion should be started to maintain ductal patency and surgical palliation or repair after stabilization should be planned. Most commonly palliation consists of a subclavian artery-pulmonary shunt such as the modified Blalock-Taussig shunt, performed without cardio-pulmonary bypass. Due to the advances in neonatal cardiac surgery, some centers have been performing complete repair in neonatal period [29, 30]; major concerns remain regarding cardiopulmonary bypass complications, associated risk of longer stay in the intensive care unit, neurobehavioral abnormalities [30, 31], and anatomical issues. Other concerns include VSD patch closure, subpulmonary obstruction relief and pulmonary artery reconstruction through a transventricular approach [32, 33]. The ideal age for complete correction is still under discussion [29, 30, 34] although it is a common practice to proceed to complete correction within 4–6 months of age.

76.3.6 Pulmonary Valve Stenosis (PS)

PS is characterized by thickened, doming pulmonary valve leaflets with hypertrophied RV and normal tricuspid valve annulus. In critical PS, transcatheter balloon dilatation is the procedure of choice. The procedure is also recommended when RV pressure exceeds half the systemic pressure. Angiography and invasive pressure measurements during cardiac catheterization confirm the echocardiography diagnosis and allow measurement of the pulmonary valve which is fundamental to perform balloon valvuloplasty (Fig. 76.6). An oversized balloon, 1.2–1.4-fold the size of the annulus is used. Balloon valvuloplasty is effective and restenosis is uncommon [35]. In the presence of dysplastic valves such as in Noonan syndrome, valvuloplasty is less effective, requiring subsequently surgical valvotomy. Quite often, after critical PS balloon dilatation, cyanosis persists due to a persistent right to left shunt at the level of foramen ovale as a result of significant RV hypertrophy and diastolic dysfunction; in this situation an adequate pulmonary flow should be guaranteed either by keeping the arterial duct open with PGE_1 infusion or stent implantation or by performing a MBT shunt between the aorta and pulmonary artery.

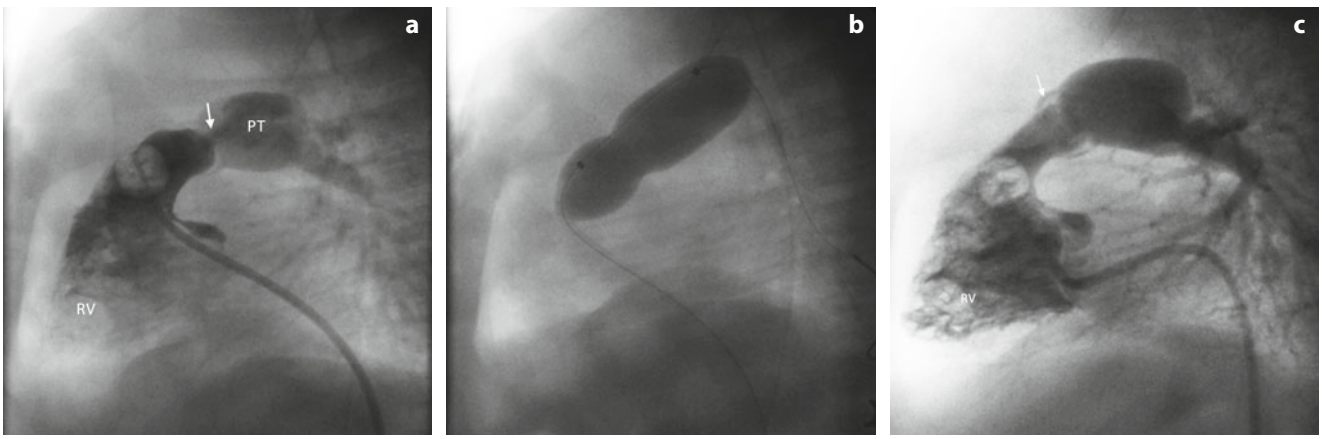

Fig. 76.6 A right ventriculogram in neonate with pulmonary valve stenosis. **a** A lateral view demonstrating systolic doming of the stenotic leaflets and narrow jet of contrast into PA (*arrow*). Right ventricle (RV); pulmonary artery (PA). **b** A guidewire is passing through the catheter from the right ventricle (RV). The balloon is inflated with diluted contrast until the balloon "waist" disappears. **c** A repeat right ventriculogram showing markedly improved antegrade flow through the stenotic pulmonary valve (*arrow*)

76.3.7 Pulmonary Atresia with Intact Ventricular Septum (PA/IVS)

PA/IVS represents a congenital heart defect with a wide spectrum of morphological heterogeneity. The morphologic aspects vary with respect to tricuspid valve size, RV hypoplasia, infundibular development and presence of coronary stenosis or coronary-RV cavity fistulas, called sinusoids. These connections are considered persistent communications which do not involute during intrauterine life due to the development of RV suprasystemic pressure; they might be found in up to 50% of the cases [36]. All the morphological aspects could be fully investigated by echocardiography and cardiac catheterization. Complete hemodynamic and angiographic study is essential even if a detailed diagnosis is carried out by echocardiography.

Transcatheter pulmonary valve radiofrequency perforation followed by pulmonary valve balloon dilatation is an effective procedure (Fig. 76.7) in order to decompress the right ventricular cavity and to reduce tricuspid valve regurgitation [38]. Subsequent postcatheterization management could be challenging because arterial duct stenting or MBT shunt insertion might be necessary in order to optimize the effective pulmonary blood flow.

Another alternative approach could be surgical pulmonary valvotomy with or without MBT shunt at the same time.

Babies with sinusoid-coronary artery dependent circulation should not undergo right ventricular decompression as this procedure could cause myocardial infarction due to an acute reduction of RV cavity pressure and consequently in the coronary artery perfusion pressure [37]. Therefore a palliative surgical approach (MBT shunt and atrial septostomy in case of restrictive ASD) could be a good option for these cases.

76.3.8 Left-sided Obstructive Lesions

76.3.8.1 Aortic Valve Stenosis (AS)

The treatment of AS depends on the degree of obstruction and the presence of systemic hypoperfusion. Neonates presenting with collapse or congestive heart failure need emergency treatment. PGE_1 infusion should be started to maintain ductal-dependent systemic flow. In many cases inotropic support is also required. The treatment of choice for neonatal congenital aortic stenosis is transcatheter balloon valvuloplasty (Fig. 76.8). Vascular access is usually retrograde using the carotid artery. However an antegrade approach using the

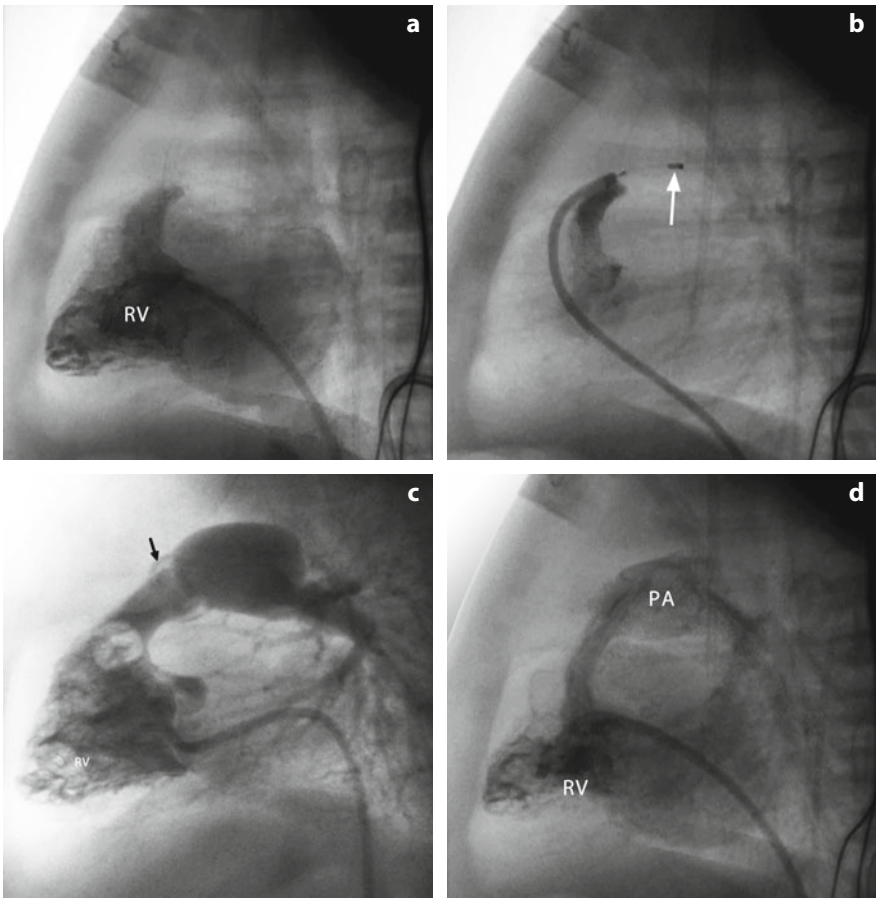

Fig. 76.7 Transcatheter intervention for pulmonary atresia. **a** Lateral view of a right ventricular (*RV*) injection in neonate with pulmonary atresia and intact ventricular septum. The RV outflow tract ends blindly at the level of the atretic pulmonary valve. No contrast crosses the pulmonary valve plate. **b** The lateral view angiography in the infundibulum: the tip of the radiofrequency perforation wire just positioned below the atretic pulmonary valve (*arrow*). **c** A balloon catheter submaximally inflated across the atretic valve. **d** Injection in the right ventricle (*RV*) demonstrating the continuity created between the RV and the pulmonary artery (*PA*)

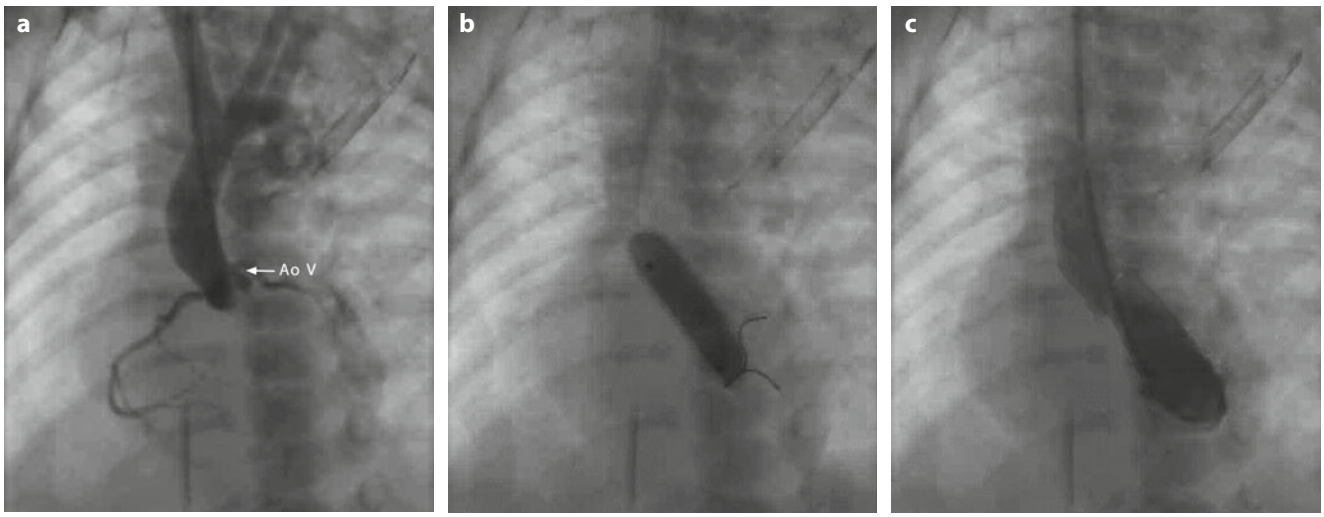

Fig. 76.8 **a** Carotid artery injection showing bicuspid aortic valve. **b** Balloon inflated across the aortic valve for valvuloplasty. **c** Injection in the left ventricle (*LV*) after valvuloplasty

umbilical or the femoral arteries has been described. The antegrade approach is associated with lower morbidity compared with the retrograde approach [39, 40]. Balloon valvuloplasty in neonates may be markedly effective; however limited long-term data have shown development of significant aortic valve regurgitation in up to 25% of patients treated with this technique [41].

76.3.8.2 Coartaction of the Aorta (CoAo)

The most common type of coarctation is located at the level of the isthmus, in the thoracic aorta, distal to the origin of the left subclavian artery. Neonates with CoAo develop symptoms once the duct closes. At that time systemic perfusion fails, and hypotension and acidosis occur. PGE_1 infusion should be given to keep ductal patency and supply systemic circulation as a palliative measure until surgical intervention is performed.

Treatment options vary from surgery to transcather intervention. Surgery with coarctation resection and end-to-end anastomosis or the subclavian artery flap technique is currently the first choice. However balloon angioplasty may be performed in circumstances where the infant is a poor candidate for surgery because of cardiovascular collapse [16]. Surgery for neonatal CoAo is associated with fewer reinterventions, improved aortic arch growth, no aortic aneurism formation, and a decreased need for antihypertensive medications when compared with neonates treated primarily with balloon angioplasty [42].

76.3.8.3 Interrupted Aortic Arch (IAA)

IAA consists of a disconnection between the ascending and descending aorta. Clinical presentation, preoperative management and timing of surgery are similar to critical CoAo. A VSD and patent ductus arteriosus are present in more than 90% of the cases [43]. VSD patch closure could be approached either during the same operation or in a second stage after having performed pulmonary artery banding at the same time as IAA repair.

Arrhythmias and Heart Muscle Diseases

Fabio Mosca, Federico Schena and Anna Maria Colli

77.1 Arrhythmias

77.1.1 Introduction

Physiological cardiac electrical activity is characterized by sinus rhythm consisting of a regular sequence of activation of the atria (shown on the surface electrocardiograph [ECG] as a P wave), the atrioventricular (AV) node (PR interval), the ventricular myocardium (the QRS complex) and return to electrical rest (the T wave). The heart-beats show a regular cadence and the morphology of the EKG does not vary.

Arrhythmia is defined as the loss of regularity of sequence or morphology [1].

Arrhythmias are quite common in the neonatal period as both the regulatory systems and the neonatal myocardium are quite immature. Moreover the neonatal myocardium contains several bundles of potentially conducting tissue connecting the atrial to the ventricular myocardium, which may become surreptitiously active and allow rapid antegrade or retrograde conduction. On the other hand, conduction from the atria to the ventricles may be impaired and the regulatory interplay between the sympathetic and vagal mechanisms may produce variable responses compared to the adult [1, 2]. As ranges of normality for heart rate (HR) and ECG intervals differ at different age, Table 77.1 summarizes the normal ranges [1].

From a practical standpoint it is useful to approach arrhythmias based on both heart rate and ECG features. We therefore recognize tachyarrhythmias of atrial and ventricular origin and bradiarrhythmias which may originate form abnormally slow intrinsic pacemaker activity or be the consequence of a conduction defect at any level. Electrolyte disturbances, thyroid dysfunction and beta mimetic drugs all have an impact on cardiac rhythm and heart rate [1, 2].

77.1.2 Ectopic Beats

Ectopic beats occur prematurely and may originate form the atrial (premature atrial contraction [PAC]) or ventricular myocardium (premature ventricular contraction [PVC]). They are extremely common in the fetus and newborn and their incidence in an otherwise healthy heart decreases with age.

PACs are characterized by a P wave occurring after an RR interval shorter than the previous one and a narrow QRS complex (Fig. 77.1). They originate from the right or left atrium or the proximal AV node. They are extremely common in the newborn population, are generally idiopathic and benign, and usually disappear within a few weeks. Occasionally, because the neonatal myocardium contains several bundles of conducting tissue connecting the atrial to the ventricular myocardium, a PAC reaching the ventricular myocardium may surreptitiously find one of these bundles in a conductive state and a short circuit ensues (reentry mechanism) generating a rapid sequence of beats known as supraventricular tachycardia (SVT). Occasionally, conduction through the ventricular myocardium does not follow the conduction bundles (aberrant conduction) and the ensuing QRS is wide resembling a PVC. Sometimes the PAC occurs very early and is not conducted beyond the atrial myocardium determining significant bradycardia.

PVCs are the most common arrhythmia in the pediatric age group and are usually benign if the heart is normal and the QT interval is normal for heart rate. They are characterized by an early and wide (> 80 msec) QRS complex not preceded by a P wave and followed by a compensatory pause, the sum of the preceding and subsequent RR intervals being equivalent to the sum of two sinus RR intervals. Occasionally they may occur regularly every other, third or fourth beat: in this case we speak of bi, tri and quadrigeminy. PVCs commonly occur in the presence of electrolyte imbalances, especially hypokalaemia.

Isolated PACs or PVCs require no treatment other than correction of electrolyte imbalances and withdrawal of cardioactive drugs (caffeine, theophylline, inotropes) unless they

Table 77.1 Normal values of heart rate and ECG intervals according to age

Age	Heart Rate beats/min	PR interval	QRS interval	QTS axis (degrees)
Newborn	120–180	0.08–0.14 sec	<0.065 sec	+59 – +192 (+135)
1–12 months	120–180	0.08–0.14 sec	<0.080 sec	+31– +114 (+75)

QT interval requires correction for heart rate according to Bazett's Formula (QTc = measured QT (msec)/ √preceding RR interval (msec). Normal < 440 msec.

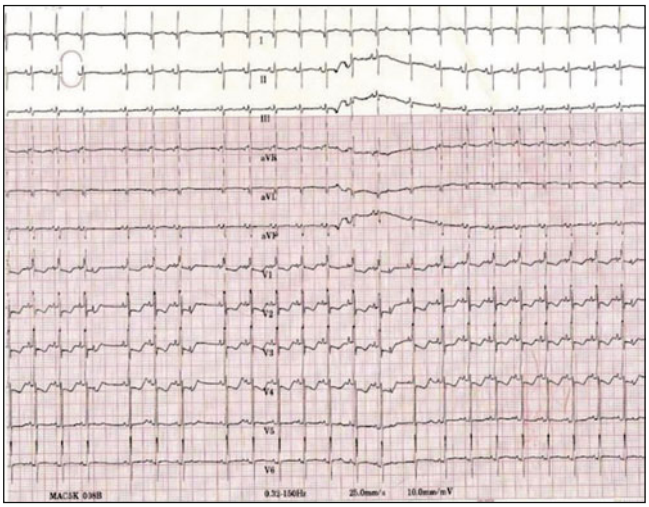

Fig. 77.1 ECG tracing showing supraventricular ectopic beats

are blocked and the ensuing heart rate is too slow or they occur in the context of long QT syndrome. When they occur during the vulnerable phase of myocardial electrical activity (the descending limb of the t wave) they may spark runs of ventricular tachycardia (VT) [1, 2].

77.1.3 Atrial Tachycardias

77.1.3.1 Sinus Tachycardia

Sinus tachycardia is actually not an arrhythmia in itself, the normal sinus activation occurs at a higher rate than normal for age. Always secondary, it is characterized by the variability of the RR interval as well as by the gradual onset and resolution. Treatment is based on the correction of the cause (e.g., fever, anemia, respiratory failure however slight, hyperthyroidism, sepsis, drug effect) [1, 2].

77.1.3.2 Supraventricular Tachycardia (SVT)

SVT is the most common atrial arrhythmia in the neonate with an incidence of 1–2:1000. It may occur in the absence of any myocardial disease and, amongst the congenital cardiac defects, the ones where it most commonly occurs are Ebstein's anomaly, congenitally corrected transposition of the great arteries, hypertrophic cardiomyopathy, tricuspid atresia and mitral valve prolapse (usually not a neonatal problem). It may complicate the long-term follow-up of extensive atrial surgery such as Mustard or Senning procedures for transposition of the great arteries.

SVT is characterized by a rapid heart rate (> 200/min). On the ECG it is characterized by narrow regular QRS complexes and the P wave is usually retrograde (it follows the QRS and is inscribed on the T wave) (Fig. 77.2). If the episode is long standing the repolarization may show myocardial suffering. SVT may be due to a reentry mechanism through an accessory pathway (commonly known as Wolff-Parkinson-White syndrome) with the circuit starting from the natural pathway and the return through the accessory pathway (orthdormic) or viceversa (antidromic) or sometimes through a permanent reentry in the AV node (permanent junctional reentry tachycardia [PJRT]).

Another mechanism is reentry in the absence of an accessory pathway (reciprocating reentry tachycardia and intra-atrial reentry) and the third possible mechanism is the presence of an abnormal automaticity with or without a specific focus (ectopic atrial tachycardia, polymorphic atrial tachycardia and junctional ectopic tachycardia).

Episodes of SVT may be short lived and completely asymptomatic (e.g., a casual finding on the monitor or ECG) or sustained, and if so they may lead to heart failure and shock especially if HR > 250/min for > 24–48 hours. In fact,

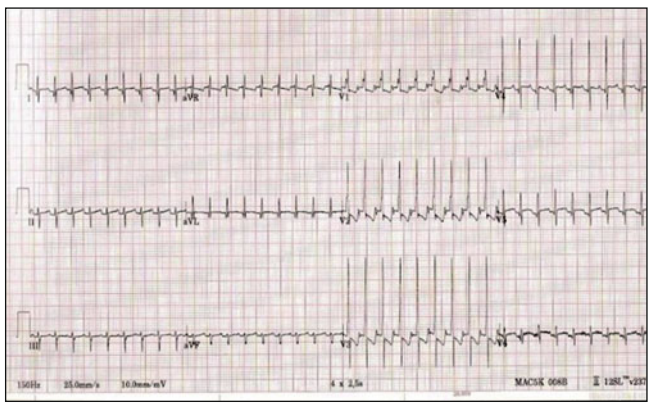

Fig. 77.2 ECG tracing of the same neonate during an episode of STV. Note the P waves inscribed on the T wave (retroconduction)

tachycardia occurs at the expense of diastole and this is the time when coronary flow to the myocardium occurs. Typically SVT has an abrupt onset sometimes prompted by a PAC and an equally abrupt end, distinguishing it from sinus tachycardia (the HR in the newborn may be similar) where both onset and resolution are gradual [1–5].

77.1.3.3 Atrial Flutter and Atrial Fibrillation

Atrial flutter (AFl) is characterized by rapid atrial reentry with atrial rates > 300/min. There is a variable degree of associated heart block so ventricular rate may be almost normal and occasionally, as the degree of block may vary in the same patient, irregular. It is rare, occurs more commonly in the fetus, is associated in most cases with a normal heart and the prognosis is good, recurrences being quite the exception.

Atrial fibrillation (AF) is virtually unknown in the newborn and is usually associated with either surgical scars or myocardial disease. Atrial activity is completely disorganized and ventricular rate is consequently irregularly irregular [1–5].

Treatment of SVT requires interruption of the reentry circuit. Unless it has been sustained and longstanding, when it may become refractory to treatment, SVT commonly responds to vagal maneuvers, the safest and most common of which consists of eliciting the diving reflex (apnea induced by stimulating the airways by placing a bag full of ice at melting temperature on the nose and mouth, just as if the baby was diving in cold water) or the rapid intravenous infusion of adenosine sulphate. Adenosine blocks the AV node and either interrupts the circuit or allows atrial flutter to become evident. If adenosine fails to interrupt the SVT permanently it is appropriate to use an antiarrhythmic such as flecainide or propafenone both as a bolus and as maintenance therapy. Digoxin, amiodarone and sotalol are also used alone or in combination with flecainide and propafenone. If the patient is hemodynamically unstable synchronized D/C shock with energy delivered at 0.5–4 Joules/kg is indicated. Ablation of abnormal pathways is not indicated in the newborn period and, once instituted, drug treatment must be continued for one year to prevent recurrences. Atrial flutter and fibrillation do not respond to vagal manoeuvres but require drugs or D/C shock depending on hemodynamics. Table 77.2 summarizes the dosages of the most common antiarrhythmic drugs used in pediatrics [2–15].

77.1.4 Ventricular Tachycardias

Ventricular tachycardias (VT) originate below the His bundle. They are characterized by a wide QRS complex on the ECG. Clinical presentation includes syncope and palpitation but it may be completely asymptomatic. VT are extremely uncommon in the newborn and when present are usually secondary to primary cardiac muscle diseases (including arrhythmogenic right ventricular dysplasia), ion channel

Table 77.2 The most common antiarrhythmic drugs and the currently accepted pediatric dosages

Drug	Attack dose (i.v.)	Maintenance dose i.v.	Maintenance dose per os
Adenosine	0.05–0.25 mg/kg Rapid bolus	N/A	N/A
Amiodarone	5mg/kg over 30’	10 mg/kg/day May be repeated	Attack dose p.o. 10 mg/kg/day for 10 days followed by 5 mg/kg/day
Atenolol	N/A	N/A	1mg/kg/day q.i.d. or b.i.d
Digoxin	20mcg/kg/day in 3 doses subdivided as ½ dose, ¼ dose + ¼ dose	1/3 of the attack dose (b.i.d)	Attack p.o. 30 mcg/kg/day in in 3 doses subdivided as ½ dose, ¼ dose + ¼ dose Maintenance 10 mcg/kg/day
Flecainide	1–2 mg/kg over 30’	2–6 mg/kg/day	2–7 mg/kg/day as b.i.d., t.i.d. or q.i.d.
Lidocaine	1 mg/kg as a single dose to be repeated every 5–10 minutes to effect up to max dose 3 mg/kg It may be given by endotracheal route at 1 mg/kg	20 + 50 mcg/kg/min	
Propafenone	0.3–1mg/kg over 30’ or 2 mg/kg over 2 hours	1–2mg/kg/day	10–15 mg/kg/day t.i.d.
Metoprolol	N/A	N/A	1 mg/kg/day q day or b.i.d.
Propranolol	0.01–0.1mg/kg/dose as a slow bolus	N/A	2–5 mg/kg/day t.i.d. or q.i.d.
Nadolol	N/A	N/A	1 mg/kg/day
Sotalol	N/A	N/A	4–9 mg/kg/day b.i.d. or t.i.d.
Verapamil	Not used in the first year of life because of risk of electro mechanical dissociation	N/A	2–6 mg/kg/day b.i.d. or t.i.d

Notes:
Flecainide and propafenone must be used in the hemodynamically stable patient and when systolic function is preserved.
Digoxin is usually considered a second choice and/or in association with another drug.
Amiodarone requires serial checks of thyroid function.
Lidocaine must be given cautiously in patients with low cardiac output. It is contraindicated in complete heart block and in wide complex tachycardia secondary to accessory conduction pathways.

diseases (e.g., Long QT syndrome: LQTS), cardiac tumors (e.g., rhabdomyomas), myocarditis, surgical scars or problems involving the coronaries (e.g., Kawasaki disease) electrolyte imbalances or drugs. The most common form in the newborn is the "torsade de pointe" or polymorphic VT, typically found in carriers of LQTS as a result of abrupt sympathetic stimulation or extreme bradycardia. LQTS is a genetic disorder of the ion channels of the myocardial membrane, causing electrical instability and malignant ventricular arrhythmias. The two best known variants are autosomal dominant (Romano-Ward, incidence of 1/5000–10,000 live births) and autosomal recessive, associated to deafness (Jervell-Lange-Nielsen). At a molecular level there are several genotypes identified, differing not only by the location of the responsible gene but also by clinical and EKG characteristics. The best known genotypes are:

- LQTS1 (K channels, gene located on chromosome 11) where VT occurs in response to stress or emotion. VT occurs frequently but mortality is low and response to beta blockade (metoprolol) excellent
- LQTS2 (K channels, gene located on chromosome 7) VT occurs in response to auditory stimulation. Mortality is high and treatment includes association of beta blockade and KCl supplements
- LQTS3 (Na channels, gene located on chromosome 3) VT occurs mostly during sleep or extreme bradycardia. Events are rare but mortality is high. Treatment includes implant of a pacemaker with defibrillator capabilities to counteract extreme bradycardia as well as arrhythmic events.

LQTS is one of the mechanisms underlying Sudden Infant Death Syndrome and the only one for which a simple screening method is available. In fact patients with LQTS fail to adjust QT length according to heart rate and this is detected by an abnormally long QT interval on the ECG. Finding a long QT on the ECG prompts not only evaluation of the variations over the 24 hours by Holter monitoring, but search of relevant mutations, especially if family history is positive [1, 2].

77.1.5 Bradyarrhythmias

Bradyarrhyhtmias considered physiological in the pediatric age group include:

- in the term baby: transient sinus bradycardia (HR 80–90 beats per minute) especially common after birth asphyxia;
- in the preterm baby sinus bradycardia associated with apnea;
- throughout childhood transient junctional rhythm and wandering pace maker, especially occurring during sleep.

Sustained bradycardias on the other hand are usually due to conduction disturbances such as sino-atrial block or various degrees of AV block.

Of these the so called 2nd degree block with Wenckebach phenomenon, in which the atrioventricular conduction time (measured by the PR interval) progressively lengthens until one P wave is not conducted at all, is physiological during sleep and requires no treatment.

The most common pathological bradycardia is complete AV Block (CHB), characterized on the ECG by independent atrial and ventricular activity. In the fetus and newborn it is usually congenital, either associated with congenital heart disease, especially corrected transposition of the great arteries, left isomerism or univentricular heart, or isolated.

Congenital CHB on the other hand shows ventricular rates well below normal and may lead to heart failure or sudden death. The most common cause of perinatal AV block is the presence of anti Rho antibodies in mother's blood, (which may well predate onset of full blown clinical picture of lupus), although other forms of myocarditis may affect the conduction tissue [1, 2].

77.2 Heart Muscle Diseases

77.2.1 Introduction

The term cardiomyopathy defines primary heart muscle disorders, where "primary" indicates that the changes are not due to congenital cardiac lesions, valvular diseases or hypertension. They are characterized by an often progressive systolic or diastolic dysfunction of the left ventricle, or both.

Classically we recognize three different forms: dilated, hypertrophic and restrictive, although the evolution from one to the other has been recognized and described. The most recent classifications also include arrhytmogenic right ventricle (RV) dysplasia (virtually unknown in the newborn for its degenerative nature) and non compaction of the left ventricular myocardium (NCLVM). The incidence of cardiomyopathies in the first year of life is 5–9/100,000 infants (much higher than the overall incidence in the pediatric group (1–2/100,000 per year before 18 years of age) [16, 17].

In a significant proportion of patients the onset of the clinical picture is at birth or within the first month of life. It is noteworthy that diagnostic criteria used by the major international registries exclude some secondary forms such as the cardiac hypertrophy in the infants of diabetic mothers (IDM), a common finding in the newborn.

Besides the different epidemiology, cardiomyopathies occurring in infants have a more severe prognosis. In fact they are mostly part of a more generalized metabolic, neuromuscular or genetic problem with multisystem involvement (determining the overall prognosis) compared with the later onset, primitive familial forms [18].

We shall discuss in detail hypertrophic and dilated cardiomyopathies, which are more common in newborns and infants, while we shall only briefly discuss NCLVM because its onset is usually well into infancy.

77.2.2 Etiology and Pathogenesis

77.2.2.1 Hypertrophic Cardiomyopathy (HCM)

Table 77.3 summarizes most pathologies associated with HCM. The most common syndromes associated with HCM are Noonan and Leopard (due to a defective PTPN11 gene) and Beckwith-Wiedemann, accounting for a large proportion of neonatal onset HCM [19].

Familial HCM is usually autosomal dominant and is due to a defect in one of the genes encoding for any one of the sarcomeric proteins. Most commonly the defect involves the myosin heavy chains, myosin binding protein 3, troponin I, tropomyosin and troponin T. Amongst these only the mutations of gene MHC7 may manifest themselves (in the heterozygous form) during the neonatal period while all the others usually appear beyond infancy. There are in the literature, however, cases of composite heterozygosis for two defects of the same gene or two different genes giving rise to extremely early onset and extremely severe forms.

The histological hallmark of HCM is myocardial fibres disarray associated with variable degrees of fibrosis. This picture is common to many of the cases occurring in the context of a syndrome or metabolic (e.g., mytochondrial) disorders.

In glycogen storage disorders such as pompe's, cardiomyocytes appear enlarged and show extensive sarcoplasmic vacuoles from lysosomal glycogen accumulation.

Macroscopically HCM is characterized by increased ventricular wall thickness, left ventricoular (LV) internal diameter may be normal or reduced and contractility is enhanced. Hypertrophy may involve either or both ventricles or involve only the interventricular septum asymmetrically. Septal hypertrophy may cause LV outflow tract obstruction (hypertrophic obstructive cardiomyopathy, HOCM) which is in turn enhanced by the systolic anterior motion (SAM) of the mitral valve. Also hypertrophy may be so massive as to reduce the LV to a virtual chamber and interphere with LV filling (diastolic dysfunction).

The unfavorable fiber/capillary ratio in severe hypertophy may cause myocardial ischemia and arrhythmias are the next most common complication.

Table 77.3 Etiology of hypertrophic cardiomyopathy in newborns and infants

Malformation syndromes
Noonan syndrome

CDG type Ia
Neuromuscular disorders
Myotonic dystrophy
Nemaline myopahty
Other congenital myopathies
Familial isolated cardiomyopathy
Familial HCM with autosomal dominant inheritance
X-linked isolated cardiomyopathy
Familial HCM autosomal recessive inheritance
Familial HCM with Wolff-Parkinson-White syndrome

* Rarely seen in the newborn period.

77.2.2.2 Dilated Cardiomyopathy (DCM)

Forty percent of cases of DCM occurring in infancy present in the first year of life. In the majority of cases etiology remains unknown and we speak of idiopathic DCM. DCM as a sequela of viral myocarditis represents approximately 10–15% of cases, much rarer than in later ages and the same is true for DCM related to neuromuscular disorders. Another 10% of cases occur as familial, syndromic (e.g., Alstom's syndrome) or secondary to metabolic disorders (carnitine deficit, Barth syndrome).

In familial forms the autosomic dominant modality of transmission is prevalent; the majority of genes identified thus far encode for sarcomeric or cytoskeletal proteins, responsible for generating contractile force or transmitting mechanical impulses between adjacent cells [19].

Macroscopically the mechanical dysfunction at cellular level leads to reduced LV contractility, reduced LV ejection fraction and progressive LV dilatation. LV wall thickness may be reduced or increased and secondary AV valve regurgitation leads to atrial dilatation with its incumbent risk for atrial arrhythmias and thromboembolism.

77.2.3 Clinical Aspects

77.2.3.1 Hypertrophic Cardiomyopathy

In the forms with early onset, myocardial hypertrophy is present since fetal life and may be diagnosed in the course of a routine obstetric ultrasound. After birth, symptoms are generally due to diastolic dysfunction and include dyspnea, sometimes cyanosis (mostly acrocyanosis), feeding difficulties and failure to thrive. Physical examination may show a variably harsh ejection systolic murmur if LV outflow tract obstruction is present. Peripheral pulses are usually normal. Sometimes the diagnosis is incidental in a completely asymptomatic baby being investigated for suspected syndrome or metabolic disorder or because of family history of cardiomyopathy. Rarely, sudden death is the first manifestation of the disease. ECG shows LV hypertrophy (represented by high voltages in the left or all precordial leads), LV overload (ST–T changes), atrial hypertrophy and conduction disturbances. Chest X ray is relatively aspecific but may show cardiomegaly and pulmonary venous congestion. Two dimensional (2D) echocardiography establishes the diagnosis. Diagnostic criteria include increased thickness of the interventricular septum and the posterior wall in diastole (> 2SD for age or BSA), increased LV fractional shortening (FS), evidence of LV outflow tract obstruction and SAM of the mitral valve [19].

77.2.3.2 Dilated Cardiomyopathy

Presenting symptoms of DCM in the newborn are essentially those of cardiac failure and low output: tachypnea or dyspnea, sweating, tachycardia, pallor and poor peripheral perfusion, feeding difficulties, vomiting.

Cardiac auscultation is characterized by gallop rhythm and a systolic murmur from mitral regurgitation, peripheral pulses may be weak and the liver is often enlarged. Exceptionally the first alarm is an episode of acute life threatening event (ALTE). In a minority of cases diagnosis is made before the onset of symptoms in the course of evaluation for positive family history or prenatal diagnosis of multiple malformations (syndromic picture) or metabolic disorders.

Chest X-ray shows cardiomegaly and pulmonary venous congestion which may reach pulmonary edema, occasionally the left atrium may be so enlarged as to cause left lower lobe atelectasis.

ECG findings are often aspecific and may show sinus tachycardia, flat or inverted T waves in the left precordial leads or left atrial enlargement, and, as the disease progresses, ventricular arrhythmias, especially ventricular tachycardia or polymorphic ventricular tachycardia (torsade de pointe), may occur. Diagnosis is easily established by echocardiography which shows increased LV diastolic diameter, reduced systolic function indices (shortening and ejection fractions). Wall thickness may be normal or reduced and there may be intracavitary thrombus. Color doppler may show mitral regurgitation [20].

77.2.4 Differential Diagnosis

77.2.4.1 Hypertrophic Cardiomyopathy

Left ventricular hypertrophy secondary to poorly controlled maternal diabetes is a relatively common finding in infants of diabetic mothers (IDM), cardiac dysfunction may be severe and mimic primitive HCM, but natural history is good with gradual resolution of the morphologic and clinical picture within the first few weeks of life. Cardiac hypertrophy secondary to hypertension (e.g., from renal disease) and left ventricular outflow tract obstruction (especially coarctation of the aorta). Severe RV hypertrophy may be caused by premature ductal constriction which may be the consequence of maternal ingestion of non steroidal anti inflammatory drugs in the latter weeks of pregnancy. In addition myocardial hypertrophy in the premature baby may be secondary to steroids (for chronic lung disease) or long-term inotropic drugs administration. Correct differential diagnosis is paramount, as the latter forms are usually reversible once the drug is withdrawn.

Once a primary cause for myocardial hypertrophy has been ruled out, the finding of HCM in a newborn mandates an accurate and specific family history to establish whether there is a recurrence of HCM, accurate search for even subtle physical findings suggestive of a genetic (syndromic) picture and a complex workup for inborn errors of metabolism which must include blood and urinary screening for amino or ketoacids and even muscle or skin biopsy for study of mitochondrial DNA and search for specific histological picture of certain myopathies [21].

77.2.4.2 Dilated Cardiomyopathy

Ventricular dilatation with associated clinical signs of cardiac failure may be the consequence of congenital viral infections as well as of severe chronic fetal anemia and both mimic DCM. Specific IgG and IgM and hemoglobin levels are usually diagnostic in those cases. Amongst structural congenital anomalies CMD may be secondary to severe chronic myocardial ischemia secondary to anomalous origin of the left coronary artery from the pulmonary artery, in which the neonatal myocardium receives deoxygenated blood. Therefore when approaching a newborn or an infant the origins of the coronary arteries from the ascending aorta must be clearly established as the origin of a coronary artery from the pulmonary artery is difficult to be univocally established by 2D echo, but surgery may allow a normal left ventricular function to be reestablished.

Neonatal HIV infection may determine LV dysfunction in children but rarely in infants.

The finding of DCM, just like HCM, requires an accurate and specific family history inquiring for cases of inheritable metabolic or neuromuscular disorders. Timely detection of carnitine deficiency must be actively sought as the clinical picture is often curative. On the other hand post–myocarditis DCM may not be easily diagnosed on serology and endomyocardial biopsy may be required [21, 22].

77.2.5 Prognosis

77.2.5.1 Hypertrophic Cardiomyopathy

Prognosis of HCM diagnosed in the first year of life is much worse than that diagnosed later on: in fact mortality reaches 25–30% in most published series. For those infants who survive the first year of life, the per year mortality rate slowly drops and realigns itself with that of cases diagnosed later in life. Cases diagnosed in utero or at birth appear to have an even higher mortality, although specific epidemiologic data are missing.

Prognosis is heavily influenced by the underlying cause with a one year survival of 30% in inborn errors of metabolism, 65–70% when a syndrome is present and 85% in idiopathic HCM [19].

77.2.5.2 Dilated Cardiomyopathy

Prognosis of DCM is variable but overall severe. Forty to forty-five percent of patients die or are transplanted after an average of 3 months after diagnosis.

Negative prognostic factors are presence of heart failure at onset, lowest LV ejection or shortening fraction. Post-myocarditis DCM has a slightly better prognosis while the onset secondary to inborn errors of metabolism has the worst. Improved survival in recent years is mostly due to the increasing number of patients reaching cardiac transplantation [20, 23].

77.2.6 Therapy and Treatments

77.2.6.1 Hypertrophic Cardiomyopathy

Very few cases (thus far only patients with pompe's disease) benefit from enzymatic replacement treatment; in all cases in which carnitine deficiency or other derangements of beta oxidation are suspected it is recommendable that supplementary carnitine be administered.

Heart failure treatment is based mostly on ACE inhibitors and diuretics; cases with LVOTO and diastolic dysfunction are treated with beta blockers (propranolol or atenolol) and in some cases with Ca antagonists (verapamil) despite it being generally held as contraindicated in the newborn. In a recent series of pediatric patients, administration of high dose beta blockers (propranolol 5–20 mg/kg/day) was associated with improved survival [24]. Inotropes are usually contraindicated as they enhance the degree of obstruction. Occasional cases of asymmetric septal hypertrophy are suitable candidates for surgical resection of septal hypertrophy. When there is no or no longer responsiveness to medical treatment, cardiac transplantation is indicated.

77.2.6.2 Dilated Cardiomyopathy

Treatment is based on common antifailure drugs (diuretics, ACE inhibitors, digoxin, inotropes). Many patients require additional antiarrhythmic drugs and anticoagulant or antiaggregant treatment; just like HCM, some cases associated with metabolic disorders respond well to treatment with carnitine at pharmachological dosages [23].

Ventricular assist devices, pacemakers for resynchronizing ventricular contraction, automatic implantable cardioverters, intraaortic balloon or extracorporeal membrane oxygenation have all been used as a bridge to transplantation though not in the newborn period.

Cardiomyopathies represent the indication to cardiac transplantation in 35% of cases in the first year of life and > 70% in older ages.

Current average survival after pediatric cardiac transplantation is approx 18 years, though some centers are investigating genetic therapy and stem cell treatment in some forms of cardiomyopathy.

77.2.7 Non-Compaction of the Left Ventricular Myocardium (NCLVM)

NCLVM is a recently identified form of cardiomyopathy characterized by the presence of deep muscular trabeculations in the LV wall establishing the presence of deep sinuses that determine the sponge-like appearance of the myocardium. Fifteen to eighteen percent of cases are familial although the specific genetic basis is far from established and is likely quite composite [25]. The gene encoding for tafazzin (responsible for Barth syndrome) has been involved in some cases and in others the cardiac picture was associated with dysmorphic features. The majority of pediatric cases are diagnosed in the first year of life, representing almost 10% of pediatric cases with an estimated incidence of 0.12 cases per 100,000 children, clinically NCLVM is characterized by variable degrees of systolic and diastolic LV dysfunction. Arrhythmias may also occur as well as intracavitary thrombi. Symptoms at onset include tachypnea, cyanosis, failure to thrive or weight loss, syncope or thromboembolic events. Chest X-ray may show cardiomegaly, ECG high ventricular voltages and ST-T wave changes.

Diagnosis is established by 2D echo and requires the following criteria: multiple LV wall trabeculations and multiple

deep recesses between trabeculae in continuity with the LV cavity usually visible by color Doppler, mostly at the level of the apex or mid ventricle. LV myocardium shows a two layered structure with an uncompacted/compacted ratio > 2 (or 1.4 in infants according to some authors). In some cases this evolves into echo pictures almost undistinguishable from either DCM or HCM. In selected cases magnetic resonance imaging (MRI) may be useful if echo is not diagnostic. Prognosis is very variable but may be serious with death or severe disability leading to transplantation as early as one year after diagnosis. Some forms show an undulating course with initial improvement and subsequent deterioration even years later.

Treatment is based on anti failure drugs, beta blockers for hyperkinetic arrhythmias and thromboembolic prophylaxis (acetylsalicylic acid) which is advised in all cases.

Some patients have benefitted form carnitine, coenzyme Q, thiamine and riboflavine supplementation, while others have been sent to cardiac transplantation [26].

Blood Pressure Disorders in the Neonate: Hypotension and Hypertension

Jonathan M. Fanaroff and Avroy A. Fanaroff

78.1 Introduction

Blood pressure (BP) disorders are a common problem in neonates admitted to the neonatal intensive care unit (NICU). Additionally, there is an association between systemic hypotension and neonatal morbidities such as intraventricular hemorrhage [1]. Hypertension, while less common, can also lead to significant short and long-term morbidities. There remains, however, no standard definition of hypotension or hypertension in the neonatal period. Indeed, there is convincing evidence that wide variations exist among NICUs in both practice styles and approaches to blood pressure disorders. Barrington notes "The treatment of shock and hypotension in the preterm infant may be the area of neonatology where there is the greatest "intervention/data imbalance"; more babies receive more treatments with less supportive evidence than in virtually any other domain" [2].

In this chapter the current status of hypotension and hypertension in the neonatal period is reviewed. First we examine the measurement of neonatal blood pressure and then review the definitions of blood pressure disorders. Subsequently the causes, consequences and treatment of neonatal hypotension are presented. Finally the causes, clinical features, diagnostic studies and an approach to clinical management of neonatal hypertension are discussed.

78.2 Measurement of Neonatal Blood Pressure

The technical goal for measurement of blood pressure would be a method that is simple, reliable, non-invasive, painless, and gives a continuous measurement. Unfortunately this goal has not yet been obtained. Direct invasive measurement (via an arterial or peripheral artery catheter) is currently considered the optimum method. Usually, mean blood pressure rather than systolic pressure is used when judging the normality of data obtained from the indwelling arterial line because it is thought to be free of the artifact caused by resonance, thrombi, and air bubbles, but this may not always be true. The downside of invasive measurement relate to the risks of an indwelling catheter, such as thrombus formation, hemorrhage, or infection. Noninvasive indirect measurement includes oscillometric and automated Doppler techniques. Provided that cuff size is standardized, oscillometric measurement seems to be accurate within the normal range. However, concern has been expressed that, at the lower levels, it consistently overestimates the blood pressure providing false reassurance.

78.3 Definition of Hypotension and Hypertension

While many studies have looked at blood pressure ranges in neonates, there remains no standard definition of truly pathologic hypotension and hypertension. Fig. 78.1 shows data obtained in a study of 608 newborns admitted to Philadelphia area NICUs during the first 99 days of life [3]. One way to define abnormal blood pressure is based on normative values. Hence hypertension is often defined as sustained systolic (SBP) and/or diastolic (DBP) blood pressure more than two standard deviations above the mean values (≥ 95%) [4]. However, blood pressure varies significantly, in a linear fashion, with gestational age and birth weight. Gender may also be significant on the first day of life when extremely low birth weight (ELBW) (< 1000 g) males have lower blood pressure than females [5]. Blood pressure also increases daily during the week of life. Hence the definition of hypotension in the newborn has remained elusive and treatment algorithms are

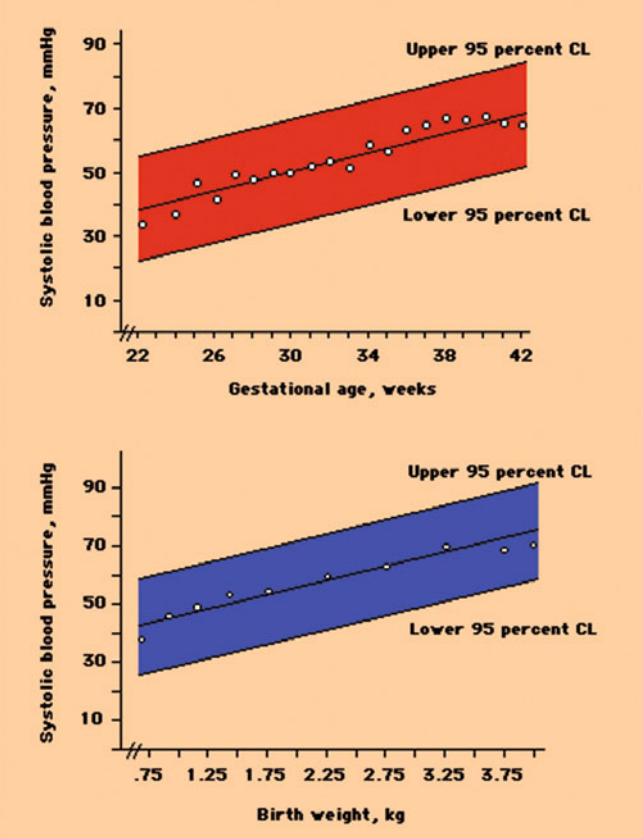

Fig. 78.1 Neonatal blood pressure. Linear regression of mean SBP on gestational age and birth weight in 329 infants admitted to NICU on day 1 of life. The mean SBP and 95 percent confidence limit (CL) for incremental gestational age and birth weight are plotted about the respective regression lines. Reproduced with permission from Zubrow AB, Hulman S, Kushner H, Falkner B. Determinants of blood pressure in infants admitted to neonatal intensive care units: a prospective multicenter study. Philadelphia Neonatal Blood Pressure Study Group. J Perinatol 1995; 15:470–479. Copyright 1995 Nature Publishing Group

based upon statistically defined gestational age-dependent normative blood pressure values and clinical judgment.

The dilemma remains when to treat and how. The traditional "two standard deviations below the norm" can be applied to the term neonate, but for preterm infants "normal for age" is a challenge. Furthermore, while almost a quarter century has elapsed since Versmold published his classic paper on blood pressure in the smallest premature infants, there is particular controversy over when to treat abnormal blood pressures in ELBW infants [6]. Whereas in adults and children normative data for systolic, diastolic and mean blood pressure is available, in infants most data sets have used "mean blood pressure" to define hypotension and determine when to intervene. Empirically the gestational age in weeks has been used to define the lower limits of mean blood pressure during the first day of life. But this is unreliable and the blood pressure should be looked at in the context of the clinical condition. Normal blood pressure in newborns varies with gestational age, birth weight and postnatal age, increasing by 1–2 mmHg per week for the first month. Blood pressure rises significantly during the first 72 hours of life irrespective of gestational age so that all preterm infants should have a mean pressure above 30 mmHg by this time [7].

Oxygen delivery to the tissues is influenced by cardiac output and blood flow more so than blood pressure, and, hence, values of blood pressure that are statistically abnormal are not necessarily pathologic. Shock is a complex clinical syndrome caused by acute circulatory failure. Hypotension (i.e., lower than expected blood pressure) frequently, but not always, accompanies shock. Shock is characterized (and defined) by inadequate tissue and organ perfusion, which may involve a single organ or all organ systems. Impaired perfusion not only results in inadequate delivery of oxygen and nutrients but also inadequate removal of metabolic waste products. Cellular function is disrupted and eventually there is cell death. Few data are available on the relation between blood pressure and systemic flow, cardiac output and neonatal morbidity and mortality but shock remains a major cause of neonatal morbidity and mortality [7]. In most very low birth weight (VLBW) neonates, cerebral blood flow autoregulation is indeed lost when blood pressure reaches the fifth percentile [8].

The incidence of hypotension is relatively high, especially in ELBW infants. Between 16 and 98% of extremely preterm infants receive treatment for hypotension in the first few days of life. This enormous variation has arisen because of a lack of reliable information to create an evidence base for intervention [9–11]. There is a significant variation among NICUs in the incidence, diagnosis, and approach to hypotension.

Al-Aweel et al [12] in a multi-center report found an almost three-fold variation among sites in the odds of hypotension [12]. Even more concerning, two of the six sites had a 5- to 30-fold higher use of vasopressors than other sites after risk adjusting for the occurrence of hypotension [12].

78.4 Clinical Features

In addition to low blood pressure the clinical features of hypotension in the neonate include varying combinations of tachycardia, bradycardia, and tachypnea, mottling of the skin, prolonged capillary refill time, cool extremities, and decreased urine output. A difference between the central and peripheral temperature may be indicative of hypovolemia or sepsis. Volume expansion will rapidly reduce the differential between central and peripheral temperature.

78.5 Causes of Hypotension

There are many causes of neonatal hypotension and shock syndromes. Therapy must be specifically directed at the

Table 78.1 Causes of neonatal shock

A. *Hypovolemia*
- a. Placental hemorrhage;abruption placenta previa
- b. Feto-maternal hemorrhage
- c. Twin to twin transfusion
- d. Birth trauma – subaponeurotic bleed
- e. Ruptured liver/spleen
- f. Massive pulmonary hemorrhage
- g. Disseminated intravascular coagulopathy
- h. Third space losses – Necrotizing entero-colitis

B. *Cardiogenic shock*
- a. Asphyxia
- b. Arrhythmias
- c. Congenital heart disease
  - i. ductal dependent lesions when ductus closes
  - ii. total anomalous pulmonary venous drainage
- d. Cardiomyopathy
- e. Myocarditis
- f. Air leak syndromes
  - i. Pneumothorax
  - ii. Inadvertent positive end expiratory pressure (PEEP)

C. *Sepsis and septic shock*

D. *Endocrine*
- a. adrenal hemorrhage
- b. adreno-genital syndrome

E. *Drug-induced hypotension*

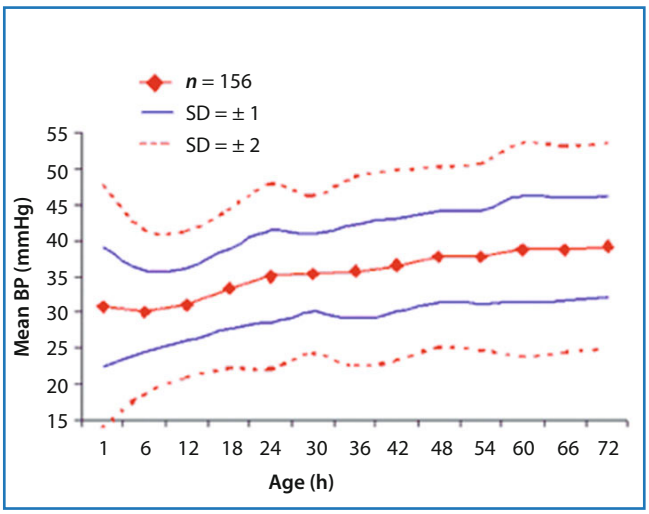

Fig. 78.2 Mean blood pressure of all ELBW infants in the first 72 hours of life

underlying cause. Table 78.1 lists the various causes of hypotension. Note that there are many other causes than hypovolemia, and, indeed in ELBW infants hypovolemia is relatively uncommon compared to other causes.

Cardiac output is the product of heart rate and stroke volume. Because of a limited ability to increase stroke volume, neonatal cardiac output is more dependent upon heart rate. Hence prolonged tachycardia or bradycardia compromise cardiac output. Stroke volume is dependent upon preload (ventricular filling), after load (systemic and pulmonary vascular resistance), and myocardial contractility. The treatment of hypotension is based upon manipulation of these parameters [9].

78.6 Significance of Blood Pressure Requiring Treatment in ELBW Infants

To explore the relationship between short and long term morbidity and neonatal blood pressure Fanaroff et al [7] performed a chart review of the 156 infants with birth weight between 401 and 1000 grams who were born during the period 1998–1999 and admitted to the NICU at Rainbow Babies & Children's Hospital. Blood pressure, obtained predominantly (81%) by umbilical arterial catheter (or by oscillometer 19%) was recorded hourly for the first 24 hours and then every 6 hours until 72 hours of life. Infants were then divided into two groups – those who received no treatment to support blood pressure (n = 97) and those who were treated for hypotension (n = 59). Infants receiving treatment weighed less at birth and were a week less mature than those who received no blood pressure support. They were also less likely to have been exposed to antenatal corticosteroids. Patients were considered to have treated hypotension if they received fluid pushes and/or pressors (dopamine and/or dobutamine) during the first 72 hours of life to elevate blood pressure. The infants underwent neurologic, developmental and formal audiologic testing. Fig. 78.2 shows the plot of the mean blood pressure, as well as one and two standard deviations above and below the mean during the first week of life. Overall there is a spontaneous increase in mean arterial pressure (MAP) from 32 at age 1 hour to 41 mmHg by the end of the first week of life. Infants requiring blood pressure support were more likely to have severe intracranial bleeds and had a higher mortality rate. Logistic regression analyses controlling for maternal socioeconomic status and coexisting neonatal morbidity was performed and at follow-up treated hypotension was significantly associated with delayed motor development (β: −6.0, SE: 3.1) and hearing loss (OR 8.9, CI 0.92-86.3) [7].

78.7 Treatment

Successful management of neonatal hypotension and shock mandates understanding the etiology and patho-physiology of the cardiovascular compromise. The ability to establish the etiology of the condition (hypovolemia, myocardial dysfunction or abnormal vasoregulation) at the bedside is limited. Management, despite efforts to use all the available evidence, often remains empiric. Volume replacement (fluid boluses) vasoactive medications and corticosteroids in various

combinations are the foundations of therapy. It is important not to be treating a number, but to consider the blood pressure in the context of the infant's total clinical condition. Frequent evaluation of vital signs, blood pressure, perfusion, urine output and neurologic status are used to guide the interventions. Although many hypotensive babies are hypovolemic, there are many other causes for hypotension and they should all be considered, including defining the hemodynamics echocardiographically, before pushing excessive volume.

The optimal means of restoring normal circulating blood volume, blood pressure and cardiac output have yet to be determined. Whether crystalloids or colloids are preferable is also unclear in newborns. In their Cochrane review, Osborn and Evans commented: "There is no evidence from randomized trials to support the routine use of early volume expansion in very preterm infants without cardiovascular compromise. There is insufficient evidence to determine whether infants with cardiovascular compromise benefit from volume expansion. There is insufficient evidence to determine what type of volume expansion should be used in preterm infants (if at all) or for the use of early red cell transfusions" [13].

Normal saline has been shown to be equally effective to albumin in restoring blood pressure in hypotensive preterm infants. Because it is efficacious, safer, readily available and inexpensive normal saline has become the crystalloid of choice for volume expansion [14]. Furthermore, in a follow-up of a randomized trial comparing crystalloid and colloid Greenough reported that 19/131 survivors had abnormal neuro-developmental status [15]. Although these infants differed from the normal group in birth weight, magnitude of colloid infusion received and oxygen exposure in addition to intraventricular hemorrhage, periventricular leukomalacia and postnatal corticosteroid exposure, regression analysis demonstrated that only colloid infusion related significantly to abnormal neuro-developmental outcome independent of other variables. Thus colloid infusions should be used with caution in the perinatal period and normal saline is the preferred fluid for volume repletion.

Although volume expansion is liberally used in newborn intensive care, little is known about its effects on hemodynamics or outcomes. Ewer et al [16], using data that were obtained from anonymized regional case notes of Project 27/28, a British National case-controlled study run by the Confidential Enquiry into Stillbirths and Deaths in Infancy, reported that newborns who received 30 mL/kg volume expansion in the first 48 h of life were more likely to die than those who received <30 mL/kg (OR 4.5, 95% CI 1.2, 17.2). More is not necessarily better!

Mayock and Gleason [17], by studying the effects of volume expansion with and without hypoxia in immature lambs provide some insight into this problem. They note that rapid volume expansion in normovolemic preterm fetal sheep did not affect blood pressure or cerebral blood flow but was associated with decreased cerebral oxygen delivery. This was further compromised when oxygen content was decreased. We can but speculate on the long-term consequences of these findings in humans, but should be cautious about over aggressive volume correction using crystalloids or colloids which might cause hemodilution and reduce O_2 delivery to the brain.

Because systemic hypotension is associated with increased mortality as well as both short- and long-term morbidity volume expansion, dopamine and dobutamine have been the agents most commonly used to treat hypotension. Norepinephrine is preferred by some clinicians. Dopamine is the most widely used sympathomimetic amine in the treatment of neonatal hypotension, and a Cochrane review confirmed that it is more effective than dobutamine in raising blood pressure [18]. Volume administration is less effective in the immediate postnatal period, and its extensive use is associated with significant untoward effects, especially in preterm infants. During the course of their disease, some of the sickest hypotensive newborns become unresponsive to volume and pressor administration. This phenomenon is caused by the desensitization of the cardiovascular system to catecholamines by the critical illness and relative or absolute adrenal insufficiency.

Corticosteroids have added a new wrinkle to the management of hypotension. Many hypotensive preterm infants have low cortisol levels, and corticosteroids are being used increasingly to prevent or treat hypotension in these babies. Steroids rapidly up-regulate cardiovascular adrenergic receptor expression and serve as hormone substitution in cases of adrenal insufficiency which explains their effectiveness in stabilizing the cardiovascular status and decreasing the requirement for pressor support in the critically ill newborn with volume-and pressor-resistant hypotension. Although corticosteroid therapy has resulted in improved blood pressure and circulation, many complications including unanticipated spontaneous gut perforation, hyperglycemia, hypertension and the long-term problem of increased cerebral palsy and intellectual impairment necessitates judicious use of corticosteroids to support blood pressure in preterm infants [19].

When the etiology of the hypotension is primary cardiac dysfunction (arrhythmia, structural heart disease, myocarditis, asphyxia) the infants may manifest the classical clinical features of congestive heart failure with edema, cardiomegaly, and hepatomegaly. Inotropic agents, with or without peripheral vasodilators, are the treatments of choice. Prostaglandin E1 to restore ductal patency is vital for infants with ductal dependent lesions Structural heart disease or arrhythmia often requires specific pharmacologic or surgical therapy. Fluid boluses may aggravate the condition.

78.8 Hypotension Outcomes

Batton defined low BP as ≤ 25 mmHg in the first 72 hours of life [20]. He followed 67 infants with normal BP, 31 infants with untreated low BP, and 70 infants with treated low BP. Untreated infants with low BP had similar survival rates, but

more cerebral palsy, deafness, or any neuro-developmental impairment when compared with infants with normal BP. Treated infants with low BP had more mortality, and less survival without neuro-development impairment compared with infants who had normal BP. Kiunt also reported that the early need for BP support related to intraventricular hemorrhage, periventricular leukomalacia and major neurodevelopment impairment [21]. On the other hand Pellicer in a prospective evaluation of the effect vasopressors/inotropes for early systemic hypotension on neurodevelopment, found no differences in the rates of abnormal neurologic status, developmental delay, or combined adverse outcome (death or cerebral palsy or severe neurodevelopmental delay between the hypotensive and normotensive groups) [22]

Finally, despite recent advances in our understanding of the pathophysiology and management of neonatal hypotension, there are few data from well conduced trials on the impact of the treatment on organ blood flow and tissue perfusion and on neonatal morbidity and mortality. In view of these significant problems with therapy there is an imperative to better study this problem, define hypotension (based on hemodynamic measurements which are feasible and reproducible) and determine optimal therapy. Such trials are ongoing.

78.9 Hypertension

Hypertension, while not as common as hypotension, can be seen in up to 3% of NICU admissions. As noted earlier, neonatal hypertension is defined as a sustained blood pressure above the 95th percentile using available normative data. BP in newborns increases with both gestational and post-conceptional age as well as with birth weight and the data generated by Zubrow et al [3] provides useful parameters to define hypertension. It is important to ensure that the correct cuff size has been used, with the cuff bladder measuring 2/3 the length of the extremity. Furthermore, the diagnosis should be made based on repetitive measurements (at least three) or consistent elevation of pressure over a 2–3 day period if the infants are asymptomatic.

The estimated incidence of hypertension ranges from 0.2–3% and it is frequently an indicator of other renal or cardiovascular abnormalities [23]. In Cleveland in 1983 hypertension, defined as mean blood pressure greater than 70 mmHg on three separate determinations, was noted in 2% of all neonatal admissions to the intensive and intermediate care nurseries [24]. As most infants are asymptomatic, and the onset is insidious, only by paying close attention to the vital signs, including measurement of blood pressure, will neonatal hypertension be recognized. Measures are then necessary to determine the underlying cause and institute appropriate therapy. In healthy neonates, systolic blood pressure increases rapidly during the first 6 weeks of life with the most rapid rise observed during the first 5 days. A similar pattern is observed for diastolic pressures. The observed increases in blood pressure are positively correlated with birth weight and both gestational and postnatal age [25].

78.10 Clinical Features

In most newborns, hypertension is discovered on routine monitoring of vital signs. These infants are asymptomatic or present with the usual non-specific features in the newborn such as hematuria, feeding difficulties, unexplained tachypnea, apnea, lethargy, irritability, or rarely seizures. Symptomatic infants are often mottled with florid features of congestive heart failure. Skalina in Cleveland reported the rapid onset of a retinopathy identical to that seen in hypertensive adults in neonates with hypertension [26]. Eleven of 21 patients with elevated blood pressure demonstrated some or all of the following abnormalities: increased ratio of venous to arterial caliber, vascular tortuosity (including arteriovenous crossing changes), superficial and deep hemorrhages, and exudates. These findings appeared to resolve after control of the hypertension [26].

78.11 Causes of Hypertension

There are many causes of hypertension (Table 78.2) but in the newborn period, hypertension is primarily is of renovascular origin, although cardiac, endocrine, and pulmonary causes must be considered as well. Neonatal hypertension may be secondary to congenital malformations or due to acquired disease states.

Congenital etiologies include: renal artery stenosis/ hypoplasia, coarctation of the aorta, and abdominal aortic atresia. Renal artery stenosis has also been noted secondary to congenital rubella. Furthermore, there are a number of congenital renal parenchymal abnormalities which have been associated with hypertension in the newborn period. Both autosomal dominant or autosomal recessive polycystic kidney disease (PKD) may present in the newborn period with enlarged kidneys and hypertension. Severely affected infants with PKD are at risk of developing congestive heart failure due to severe malignant hypertension. Hypertension has also been reported in infants with unilateral multicystic dysplastic kidneys. Renal obstruction and hydronephrosis may also lead to hypertension, secondary to impingement on the renal vessels or via the renin-angiotensin system.

Acquired renal parenchymal causes of hypertension in the newborn period include severe acute tubular necrosis and cortical necrosis usually secondary to severe asphyxia. Other acquired causes of neonatal hypertension include: thromboembolic renal artery and renal vein complications secondary to umbilical artery catheterization or to thrombosis associated

Table 78.2 Causes of hypertension

Renovascular conditions
Thromboembolism

Mid abdominal aortic coarctation
Renal venous thrombosis
Compression of renal artery
Idiopathic arterial calcification
Congenital rubella syndrome
Renal parenchymal disease
Polycystic kidney disease
Multicystic dysplastic kidney disease
Uretero-pelvic junction obstruction
Acute tubular necrosis (birth asphyxia)
Cortical necrosis
Cardio-Pulmonary conditions
Coarctation of thoracic aorta
Bronchopulmonary dysplasia (BPD)
Pneumothorax
Endocrine conditions
Congenital adrenal hyperplasia
Hyperaldosteronism
Hyperthyroidism
Pseudo hypoaldosteronism Type II
Medications/Intoxications
Corticosteroids e.g., dexamethasone
Adrenergic agents
Vitamin D intoxication
Xanthenes – Theophylline/Caffeine
Pancuronium
Phenylephrine
Maternal cocaine or heroin use
Tumors
Wilms' tumor
Mesoblastic nephroma
Neuroblastoma
Pheochromocytoma
Neurologic conditions
Pain
Intracranial hypertension
Seizures
Familial dysautonomia
Subdural hematoma
Miscellaneous conditions
Closure of abdominal wall defect
Adrenal hemorrhage
Hypercalcemia
Extracorporeal membrane oxygenation (ECMO)

with polycythemia or hypercoagulable states. Almost 10% of the infants with indwelling umbilical arterial catheters develop hypertension [27].

Hypertension is also more common in infants with bronchopulmonary dysplasia (BPD), patent ductus arteriosus, or intraventricular hemorrhage as well as those who receive postnatal corticosteroids. Endocrinologic disorders that may produce hypertension in the newborn period include congenital adrenal hyperplasia, hyperaldosteronism, and hyperthyroidism. Salt and water overload and hypercalcemia may also be associated with hypertension in the neonate. Other factors include pain, closure of abdominal wall defects, adrenal hematoma with renal artery compression, seizures, central nervous system disorders including those associated with inherited metabolic disorders, drug-induced hypertension, and infants of drug- dependent mothers with symptoms of withdrawal.

Medications to be aware of include aminophylline, high doses of adrenergic agents, prolonged use of pancuronium, or administration of phenylephrine ophthalmic drops. Hypertension induced by medications typically resolves when the offending agent is discontinued or its dose is reduced. Patients with certain tumors, including neuroblastoma, Wilms' tumor, and mesoblastic nephroma, may also present in the neonatal period. The hypertension results from either compression of the renal vessels or ureters by the tumor or secretion of vasoactive substances such as catecholamines associated with a phaeochromocytoma or neuroblastoma.

There is also a rare disorder, known as hypertension-hyponatremia syndrome, with elevated levels of renin observed in neonates. Renal ischemia from possible microthrombi has been postulated as the precipitating cause and with sodium supplementation and antihypertensive therapy the condition resolves and renin levels return to normal [28].

78.12 Diagnostic Approach

In hypertensive neonates it is important to determine whether any reno-vascular anomalies were detected prior to birth. The history may include drug abuse, perinatal asphyxia, umbilical catheter placement or medications administered to the neonate. It is important to confirm the elevated blood pressure and measure the BP in all four extremities to rule out coarctation of the aorta. The pressures are usually higher in the lower extremity and a differential pressure between the upper and lower extremity would suggest coarctation. During the physical examination a careful search for anomalies, dysmorphic features and careful cardiac evaluation are mandatory. Tachycardia and flushing may indicate a secreting tumor such as a neuroblastoma.

Careful abdominal examination and auscultation over the renal vessels is important as well as a thorough search for features of congenital adrenal hyperplasia, such as sexual ambiguity or hyperpigmentation. Asymmetrical growth (hemi-hypertrophy) together with aniridia would suggest a Wilms' tumor. Remember that BPD is a common non-renal cause of hypertension and these infants tend to manifest the increased blood pressure late in the course of the disease unless they have been treated with corticosteroids [29]. The combination of dexamethasone or aminophylline, together with repeated high doses of adrenergic agents, may all contribute to hypertension.

Table 78.3 Selected drugs for the treatment of neonatal hypertension

Drug	Dose	Comments
Chlorothiazide (diuretic)	IV/PO: 20–40 mg/kg/day divided q 12 hours	Monitor electrolytes
Furosemide (diuretic)	IV: 1 mg/kg/dose q 12–24 hours PO: 1–2 mg/kg/dose q 12–24 hours	Better for short-term use. Monitor electrolytes, Long-term use can lead to osteopenia and renal calculi.
Hydralazine (vasodilator)	IV: 0.1–0.5 mg/kg/dose q 6–8 hours PO: 0.25–1 mg/kg/dose q 6–8 hours	May lead to tachycardia or tachyphylaxis
Amlodipine (Calcium channel blocker)	PO: 0.1–0.3 mg/kg/dose q 12–24 hours	Monitor for arrhythmias, monitor calcium and magnesium
Captopril (ACE inhibitor)	PO: Initial: 0.05 mg/kg/dose, then 0.1–0.4 mg/kg/dose q 6–24 hours	Monitor renal function and blood pressure closely; contraindicated in infants with bilateral renovascular disease
Propranolol (beta blocker)	IV/PO: 0.5–1 mg/kg/dose q 6–12 hours	Monitor blood pressure, heart rate, glucose

The initial evaluation of neonatal hypertension includes determination of serum electrolytes, creatinine, blood urea nitrogen (BUN), and a urinalysis in order to look for renal parenchymal disease. Plasma renin levels are warranted, but are normally high in neonates. Endocrinologic studies including serum and urinary measurements of cortisol, 17 hydroxy-progesterone, aldosterone and thyroxin are carried out when pertinent.

In addition to a chest radiograph, which is helpful to determine cardiomegaly and congestive heart failure, renal ultrasonography is necessary in all hypertensive infants. This will identify arterial and or venous thrombi in addition to renal anomalies. Echocardiography is also useful. Cysto-urethrography is performed when indicated. In selected infants aortography used to be performed but with magnetic resonance imaging and spiral computed tomography (CT) scans this should no longer be necessary. In neonates, nuclear scanning has limited use to determine abnormalities of perfusion because of immature renal function.

78.13 Treatment

Therapy of neonatal hypertension should be tailored to the severity of the blood pressure elevation, and to the underlying cause of hypertension as appropriate. A wide range of therapeutic agents are now available for management of neonatal hypertension in both acute and chronic settings. In most cases hypertension will resolve, but some infants may require prolonged treatment. Pharmacologic management of hypertension in the neonate includes use of beta-blockers, angiotensin-converting enzyme inhibitors, calcium channel blockers, and/or diuretics. Essential elements of therapy also include the avoidance of fluid overload (judicious diuretic therapy may be warranted or fluid restriction if renal function is impaired), relief of pain and discontinuation of medications possibly contributing to the hypertension such as corticosteroids, aminophylline and inotropic agents. Every effort should be made to choose the antihypertensive agent most appropriate for the clinical situation. Blood pressure must be closely monitored as with intravenous therapy the BP may drop precipitously. Examples of available drugs for the treatment of hypertension are listed in Table 78.3. Awareness of their mechanisms of action and side effects are vital in treating these challenging patients. For example, angiotensin-converting enzyme inhibitors such as captopril are excellent antihypertensive agents but are contraindicated in the treatment of babies with coarctation of the aorta, unilateral renal artery disease and hyperkalemia [30]. They must also be used with care in babies with chronic hypertension because an abrupt drop in BP may adversely affect the brain and kidneys,

78.14 Follow-up

The long-term outcomes of neonatal hypertension depend upon the underlying etiology. Although blood pressures can be controlled with antihypertensive medications, infants with parenchymal renal disease may remain hypertensive. When the hypertension is secondary to acquired reno-vascular disease the blood pressure often normalizes over time and medications can be discontinued. However significant structural or functional renal abnormalities may persist. Appropriate follow-up with a pediatrician or pediatric nephrologist must be arranged.

78.15 Conclusions

Although many sick newborns are treated for hypotension and hypertension, the normal physiologic BP range ensuring appropriate organ perfusion is uncertain. Treatment decisions are based on statistically defined gestational and postnatal age-dependent normative BP values, combined with clinical

intuition, because of difficulties evaluating organ perfusion and adequacy of cerebral oxygen delivery. Early onset hypotension is usually due to the combined effects of abnormal peripheral vasoregulation, myocardial dysfunction, and hypovolemia. Volume administration is the primary initial therapy but its use may be associated with significant untoward effects, especially in preterm infants, and should be limited to 10–20 mL/kg of isotonic saline. If the BP cannot be normalized dopamine should be added, sometimes followed by epinephrine and corticosteroids. Hypertension, most often caused by congenital or acquired renovascular disease or volume overload, needs a thorough search for the etiology and cautious treatment so the BP does not fall too quickly or too low.

78.16 Practice Points

- Blood pressure norms are based on statistically defined gestational and postnatal age-dependent normative blood pressure values. Blood pressure increases with increasing gestational age, weight, and postnatal age.
- Treatment decisions for hypotension should be based on a combination of low blood pressure and clinical symptoms. Too much volume is associated with increased morbidity and mortality
- Care must be taken not to drop the blood pressure too quickly in hypertensive neonates as cerebral perfusion pressure will be adversely effected.

Polycythemia and Hyperviscosity

Otwin Linderkamp

79.1 Introduction

The term hyperviscosity cannot be understood without some knowledge of how blood viscosity is defined and measured. Viscosity (V) is a flow property defined as resistance (R) to the movement of blood: R = VZ, where Z is the resistance resulting from the vessel geometry [1]. Blood viscosity is usually measured in flow devices with fixed geometry (e.g., in a rotational viscometer with a defined gap or in a tube viscometer with defined tube diameter and length). In these devices, the blood flow resistance increases linearly with the blood viscosity, and blood flow resistance is measured as pressure (P) or force required to achieve a defined blood flow (F) in the device (V ≈ R = P/F). Blood viscosity decreases with increasing shear forces due to red blood cell (RBC) aggregation at low shear rates and ellipsoidal deformation of RBCs at high shear. In tube viscometers with diameters below 300 μ, blood viscosity decreases linearly with decreasing tube diameter. Without this so called Fåhræus-Lindqvist effect, blood with a hematocrit of 50% and higher could probably not pass through arterioles and capillaries with diameters below 50 μm.

Hyperviscosity is frequently used synonymously with polycythemia (i.e., high hematocrit). However, blood viscosity increases with increasing hematocrit, plasma viscosity and RBC aggregation and with decreasing red blood cell deformability. Neonatal blood has several favorable properties including lower plasma viscosity and RBC aggregation (due to lower concentrations of high molecular weight proteins) and increased RBC deformability [2, 3]. Plasma viscosity is about 20% lower in the neonate compared with adults, thereby decreasing blood viscosity at given hematocrit by 20% [3]. The reduced RBC aggregation decreases blood viscosity at low shear stress and facilitates blood flow at slow flow (e.g., in veins).

Division of Neonatology, Department of Pediatrics
University of Heidelberg, Heidelberg, Germany

RBC deformability is not a mathematically defined mechanical parameter, but the result of various geometric (shape, volume and excess surface area) and mechanical (membrane elastic moduli, membrane and internal viscosity) properties. Filtration techniques demonstrated decreased filterability of neonatal RBCs due to their large volume [4]. The deformability of neonatal RBCs studied in counter-rotating devices and the RBC membrane elasticity were found increased compared with adult RBCs [5, 6]. However, neonatal RBCs appear to be more sensitive than adult cells to agents that can impair RBC deformability such as acidosis, hypoxemia and bacterial toxins [7–9]. Moreover, neonatal blood contains more RBCs with irregular shape and impaired deformability than adult blood [10].

The viscosity reduction in narrow tubes (Fåhræus-Lindqvist effect) is more pronounced for neonatal RBCs than that of adults (Fig. 79.1) due to their larger volume and increased membrane elasticity. The extent of the viscosity reduction increases with rising hematocrit. Compared to blood viscosity in 500 μm tubes, viscosity reductions of blood with a hematocrit of 0.70 L/L in 50 μm tubes were 50% in term neonates and 39% in adults, whereas the viscosity reductions at a hematocrit of 0.30 L/L were only 29 and 19%, respectively [11]. Because of the enhanced Fåhræus-Lindqvist effect and decreased plasma viscosity, blood viscosity in 50 μm tubes is similar in neonates who have a hematocrit of 0.70 L/L as in adults with a hematocrit of 0.50 L/L (Fig. 79.1). These findings may explain why circulation in neonates is less affected by a high hematocrit than circulation in adults.

79.2 Definition of Polycythemia and Hyperviscosity in Neonates

In the majority of newborn infants, the hematocrit shows marked changes from cord blood levels through the first 24 hours of birth. The changes in the hematocrit depend on the blood volume at birth. In neonates with low blood volume

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

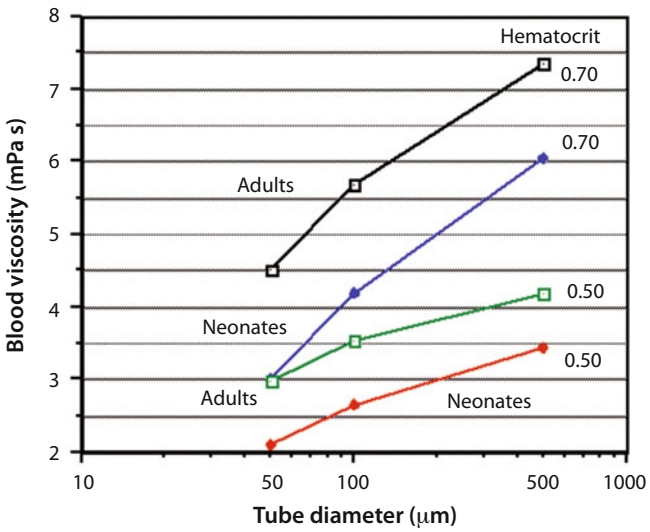

Fig. 79.1 Blood viscosity in adults and full-term neonates measured in tubes with diameters of 50, 100 and 500 μm. The hematocrit was adjusted to 0.50 and 0.70 L/L. Note that in 50-μm tubes the viscosity of neonatal blood with a hematocrit of 0.70 L/L was similar as the viscosity of adult blood with a hematocrit of 0.50 L/L. Adapted from [11]

(e.g., due to early cord-clamping), the hematocrit changes little, whereas in neonates with high blood volume (e.g., after late cord-clamping), the hematcrit rises considerably after birth, reaches the highest values at two hours of postnatal age, and decreases slowly over the next 24 hours [12–14]. Thus, the frequency of polycythemia depends strongly on the time of blood sampling.

The most commonly used definition for neonatal polycythemia is a venous hematocrit of 0.65 L/L or more [15–18]. Screening programs for the detection of neonatal polycythemia are usually based on hematocrit measurements in cord, skin prick or venous blood. Umbilical blood is the preferred source for screening since it is routinely collected for blood gas studies and does not require vessel puncture in the infant. In unselected neonates, the umbilical hematocrit is on average 0.10 L/L higher than that of venous or arterial blood in the infant at 2 hours of birth [12, 13]. Since approximately 50% of unselected infants with an umbilical hematocrit of 0.55 L/L or more develop venous hematcrit values of 0.65% or greater, this value is usually used as indication for peripheral venous blood sampling at 2 hours of birth. However, the umbilical hematocrit is similar in healthy term infants with early and late cord-clamping and, therefore, fails to detect polycythemia after late cord-clamping [14]. The capillary hematocrit measured in unwarmed skin prick blood is on average 0.10 L/L (warmed skin: 0.05 L/L) higher than the venous hematocrit over a wide range of hematocrit values [16, 17]. This has been explained by impaired peripheral circulation and red blood cell trapping in skin vessels [19]. If the capillary hematocrit is 0.70 L/L or greater, a venous specimen should be analyzed.

The definition of polycythemia as a venous hematocrit of 0.65 L/L or more is based on clinical observations in adults who are at high risk of cardio-circulatory disorders such as stroke and heart attack if their hematocrit exceeds this critical value [15]. However, as outlined in the Introduction, neonatal blood demonstrates several beneficial flow properties such as decreased plasma viscosity and increased RBC deformability when compared with adult blood. Moreover, otherwise healthy neonates with hematocrit values of 0.65–0.69 L/L may show some clinical manifestations of polycythemia, but long-term sequelae are rare [3]. For clinical practice the following definitions of polycythemia may be used: 1) a hematocrit of 0.70 L/L or more independent of clinical signs, and 2) a hematocrit of 0.60–0.69 L/L with clinical signs of polycythemia.

Hyperviscosity is usually defined as a blood viscosity (measured by means of a Wells Brookfield Microviscometer) that is two standard deviations greater than the mean of a normal population [12, 16, 17]. Blood viscosity techniques are not generally available. However, blood viscosity in narrow tubes that have diameters of 50 or 100 μm can be calculated from published formulas [11].

79.3 Causes of Polycythemia and Hyperviscosity in the Neonate

Polycythemia in neonates defined as a hematocrit of 0.65 L/L or greater occurs in about 1–5% of all newborn infants [12, 13, 16–18]. Hyperviscosity defined as blood viscosity of more than two standard deviations above population mean of screened neonates occurs in 5% of infants. The frequency of neonatal polycythemia diagnosed in various hospitals depends on whether a screening program is performed, on the mode of cord-clamping and the prevalence of neonates with a high risk for polycythemia. Table 79.1 summarizes causes of and risk factors for polycythemia and hyperviscosity in the neonate.

In infants with late cord-clamping, the incidence of polycythemia is about 25% at two hours, but less than 10% at 24 hours after birth [14, 19–20], since the hematocrit decreases spontaneously after the early postnatal hours (Table 79.2). Blood transfusion from the placenta to the neonate occurs when the umbilical cord is clamped at some time after 5 seconds of birth. Before birth, the fetal blood volume is approximately 70 mL/kg of blood [19, 20]. Late cord-clamping may increase the neonatal blood volume by 35 mL/kg if the newly born infant is kept at or below the level of the placenta. The rapid blood volume expansion is counteracted by extravasation of plasma so that the hematocrit rises from approximately 50% at birth to 58–70% at 2 hours after birth. This increase in hematocrit is associated with a 50% rise in blood viscosity. The Leboyer birth method, which requires placement of the newly born infant on the mother's abdomen and clamping of the cord when it stops pulsating, results in a smaller blood volume expansion due to the smaller pressure

Table 79.1 Causes of polycythemia and hyperviscosity in the fetus and neonate

Increased hematocrit (≥ 0.65 L/L)
- Red cell transfusion:
  - Placenta-to-fetus transfusion: late cord-clamping,* intrauterine asphyxia*
  - Twin-twin transfusion (monochorionic twins)*
  - Maternal-fetal transfusion
  - Transfusion of a large volume of blood or erythrocytes*
- Increased fetal erythropoiesis:
  - Chronic intrauterine hypoxia,* placental insufficiency,* maternal gestosis* or smoking*
  - Small for gestational age* and large for gestational age* infants
  - Endocrine disorders: Hyperinsulinism (diabetic mother,* Beckwith-Wiedemann syndrome*), neonatal thyrotoxicosis,* adrenal hyperplasia*
  - High altitude*
  - Trisomy 13,* 18,* 21*
  - Congenital erythrocytosis
- Dehydration

Increased plasma viscosity and RBC aggregation
- Septicemia (increase in fibrinogen)
- Diabetic mother
- Transfusion of adult plasma or immunoglobulins

Decreased RBC deformability
- Septicemia
- Diabetic mother (glycosylated membrane proteins)
- Hypoxia, acidosis
- Nutritional deficiencies (vitamin E, iron, protein)
- Transfusion of ATP-depleted RBCs

* Discussed indications of screening for polycythemia.

gradient between the placenta and the infant [21]. A recent meta-analysis on effects of late cord-clamping revealed little evidence of harmful effects of late-clamping, but an increased risk for anemia after early cord-clamping [22]. Moreover, neonatal polycythemia resulting from late-cord clamping did not cause developmental or neurologic sequelae during 20 months follow-up [23]. In preterm infants, late cord-clamping appears to result in smaller hematocrit rises than in full-term infants, whereas infants with intrauterine growth restriction or diabetic mothers are at higher risk of developing severe polycythemia after late cord-clamping due to increased intrauterine erythropoiesis [24].

In some disorders such as maternal diabetes and asphyxia, increased plasma viscosity, decreased RBC deformability and increased RBC aggregation may contribute to increased blood viscosity in addition to polycythemia [3]. In septicemia, impaired RBC deformability, increased RBC aggregation and a large number of rigid neutrophils may contribute to impaired micro- and macro-circulation [9].

Transfusion of blood components may cause symptomatic hyperviscosity if the hematocrit rises above a critical limit or the plasma viscosity and RBC aggregation increase as a result of treatment with high doses of immunoglobulins [25]. Because of the higher plasma viscosity of adult plasma, fresh frozen plasma should not be used for hemodilution in polycythemic neonates [26]. RBCs from adult donors are less deformable than neonatal RBCs. Transfusion of adult RBC should, therefore, not result in a hematocrit of more than 0.55 L/L (see Fig. 79.1). Uncontrolled erythropoietin treatment can cause polycythemia if the infant responds particularly well to erythropoietin. However, erythropoietin treatment improves RBC deformability, due to the increased formation of young well-deformable RBC [27].

79.4 Symptoms and Signs of Polycythemia and Hyperviscosity

Increased blood viscosity can increase the flow resistance in various organs, thereby impeding their blood and oxygen supply. Polycythemia in the neonate decreases cardiac output, and blood flow to the brain, the gastrointestinal tract, the kidneys, the lungs, the limbs and the skin [28]. There is concern that this may increase the risk of pulmonary hypertension, renal failure, necrotizing enterocolitis, cerebral ischemia, intracranial hemorrhage, and developmental retardation. However, systemic RBC transport (calculated as product of cardiac output times hematocrit) and RBC transport to the brain (blood flow velocity times hematocrit) remain stable in the neonate over a hematocrit range of 0.40 to 0.70 L/L [29]. Moreover, cerebral oxygenation does not decrease in the neonate up to a hematocrit of 0.70 L/L [30]. At hematocrit of 0.70 L/L and greater, systemic and cerebral RBC transport decrease markedly. This agrees with studies of blood flow in narrow tubes [11].

Clinical consequences of a high blood viscosity are principally a result of impaired circulation and oxygen supply in affected organs (Table 79.3). Central nervous system symptoms such as hypotonia or irritability are of particular

Table 79.2 Effect of cord-clamping on hemorheology in full-term infants at 2 h after birth [14, 21]

	Early [a]	Leboyer [b]	Late [c]	P < 0.05
Hematocrit [L/L]	0.48 ± 0.06	0.58 ± 0.06	0.63 ± 0.05	a < b < c
Plasma viscosity [mPa s]	1.04 ± 0.09	1.06 ± 0.08	1.09 ± 0.09	a = b = c
RBC aggregation	4.2 ± 1.0	4.2 ± 1.8	4.0 ± 1.4	a = b = c
RBC deformation (at 3 Pa)	0.42 ± 0.04	0.41 ± 0.05	0.42 ± 0.05	a = b = c
Blood viscosity [mPa s]	2.8 ± 0.5	3.7 ± 0.5	4.2 ± 0.4	a < b < c

Table 79.3 Clinical features ascribed to polycythemia and hyperviscosity

Central nervous system
- Early effects: hypotonia and sleepiness, irritability and jitteriness
- Neurodevelopment: long-term neurologic and developmental problems
- The reported long-term sequelae are mostly caused by underlying condition as intrauterine and perinatal asphyxia or maternal diabetes

Heart and lungs
- Tachycardia, tachypnea, respiratory distress
- Cyanosis, plethora
- Chest radiography: cardiomegaly, pulmonary plethora
- Echocardiography: increased pulmonary resistance, decreased cardiac output

Gastrointestinal tract
- Poor suck, vomiting
- Necrotizing enterocolitis

Kidneys
- Oliguria (depending on blood volume)

Metabolism
- Hypoglycemia
- Hypocalcemia
- Jaundice

Hematology
- Mild thrombocytopenia
- Thrombosis

concern, since they may indicate increased risk for long-term neurological and developmental sequelae. Peripheral or systemic cyanosis and plethora are merely signs of a high hematocrit, but not of compromised circulation. A decrease in platelet count has been suggested as an indicator of polycythemia [31], but is also observed in infants with growth retardation and in infants of mothers with gestosis or smoking during pregnancy.

Reported frequencies of clinical manifestations in polycythemic neonates vary widely. This may be explained by inclusion of neonates who have a high risk of perinatal complications independent of the occurrence of polycythemia (e.g, asphyxia, intrauterine growth restriction, diabetic mother, malformations), and by inclusion of different numbers of neonates who have venous hematocrits of 0.70 L/L or greater. Wiswell et al. [32] observed clinical signs and symptoms in 50% of neonates who had hematocrits of 0.65 L/L or greater. Van der Elst et al. [33] found most polycythemic infants healthy and unaffected. Moreover, most clinical signs and symptoms of polycythemia are of minor importance and can be observed in neonates who do not have polycythemia. Moreover, some complications such as thromboses or necrotizing enterocolitis may be caused by the exchange transfusion procedure rather than by the polycythemia.

Long-term studies of the incidence of developmental and neurological abnormalities at 1–7 years also reach conflicting conclusions [3, 34]. Goldberg et al [35] reported a high incidence of neurological problems at 9 months among infants who had polycythemia. Black et al [36, 37] observed that neonatal polycythemia was associated with a high risk of neurologic and developmental problems at 1 and 2 years. At 7 years only small (insignificant) differences were observed between children with and without neonatal polycythemia. However, both groups included infants who had additional risks for developmental problems. Moreover, hemodilution did not influence the results significantly. A study performed in Thailand demonstrated that impaired outcome at 1–2 years of age was caused by intrauterine hypoxia rather than by neonatal polycythemia [38]. Investigators who included only polycythemic infants without additional risks found no effect of polycythemia and hemodilution on long-term outcome [23, 39–40]. Drew et al [41] reported that increased blood viscosity was a better predictor of poor outcome than was a high hematocrit.

79.5 Prevention and Treatment of Polycythemia and Hyperviscosity

Prevention of polycythemia includes prevention of risk factors such as poor control of maternal diabetes and intrauterine asphyxia. If the risk of polycythemia is increased, the umbilical cord should be clamped immediately after birth to avoid placental transfusion [24]. However, late cord-clamping in otherwise healthy neonates should not be avoided for concern of polycythemia, since overall late cord-clamping is more beneficial for the normal neonate than early cord-clamping [20, 22].

Since the hematocrit decreases spontaneously subsequent to the peak value at 2 hours of birth, it appears reasonable to accelerate this natural hemodilution by infusion of normal saline. Although several text books recommend “liberal fluid intake” for polycythemic infants, no study using the efficacy of this approach has been found in the literature. According to our own experience, the infusion of 10 mL/kg of normal saline over 1 hour decreases the hematocrit below the critical level in approximately 50% of infants.

The general recommendation for the treatment of polycythemia is partial exchange transfusion (isovolemic hemodilution) via an umbilical vein catheter or using a radial artery for blood withdrawal and a scalp or peripheral vein for blood replacement [42]. Isovolemic hemodilution in neonates is performed via an umbilical venous catheter using 5% human serum albumin, serum (free of activated clotting factors), or crystalloids (normal saline or Ringer solution). Adult plasma increases the plasma viscosity and the RBC aggregation and, therefore, should not be used for hemodilution [26]. De Waal et al [43] conducted a systematic review to determine the efficacy of crystalloid (normal saline or Ringer solution) versus colloid (plasma or 5% albumin) for hemodilution. No meaningful differences in effectiveness (decrease in hematocrit, relief of symptoms) between plasma, 5% albumin and

crystalloid solutions were observed in six studies. Plasma expanders such as hydroxyethyl starch and Hemaccel have been used for hemodilution in neonates [44], but little is known about their distribution and metabolism in the neonate.

The use of umbilical vein catheterization for partial exchange transfusion may cause severe complications including septicemia, vasospasm, vessel perforation with hemoperitoneum or intrahepatic hematoma, air embolism, arrhythmia, thrombosis, portal hypertension and necrotizing enterocolitis [42]. The exchange transfusion itself may cause blood volume and pressure fluctuations, electrolyte abnormalities, hypoglycemia, thrombocytopenia and hemolysis. The stress resulting from the procedure may explain that the heart rate [17, 29] and energy expenditure [45] may rise after hemodilution for neonatal polycythemia. Exchange transfusion with plasma via the umbilical vein increases the risk of necrotizing enterocolitis [16].

Since the central hematocrit is 0.65 L/L or greater in about 3% of all neonates, several thousand otherwise healthy neonates may be exposed to this potentially harmful invasive procedure of partial exchange transfusion if this threshold is used as indication, although long-term studies of children who had neonatal polycythemia failed to show the benefits of exchange transfusion for hemodilution [3, 34, 46]. Hemodilution, therefore, is presently recommended if the hematocrit is 0.70 L/L or higher or if symptoms of compromised circulation are present at hematocrits of 0.60 to 0.69 L/L.

The following recommendations for the treatment of neonatal polycythemia are widely used.

- Screening for polycythemia may be done in small and large for gestational age infants, infants of diabetic mothers and some of the rarer risk factors listed in Table 79.1. It can be performed in umbilical blood, in skin prick ("capillary") blood, venous blood taken without prolonged tourniquet or excessive squeezing, and in arterial blood.
- If symptoms of polycythemia are observed, other explanations should be explored before an exchange transfusion is performed. The laboratory work-up includes measurements of hematocrit, blood gases, leukocyte and platelet count, CRP, serum glucose and calcium (Table 79.2). Pulse oximetry and echocardiography may be indicated. Hypoxia, acidosis, hypoglycemia and electrolyte abnormalities should be corrected.
- If the venous or arterial hematocrit is 0.65–0.69 L/L and signs of impaired circulation are present or if the hematocrit is 0.70 L/L or greater with or without signs, an infusion with 10 mL/kg of normal saline is given in 1 hour, and the venous hematocrit is determined again.
- If the hematocrit remains above the critical level, exchange transfusion is performed with normal saline or Ringer solution. Cristalloids are as efficacious as colloids (plasma, 5% albumin and plasma expanders) for hemodilution.
- In infants with high risk of impaired RBC deformability (e.g., diabetic mother), hemodilution may be indicated in some symptomatic infants with a hematocrit of 0.60–0.64 L/L.
- Informed consent of the parents must be obtained as efficacy and safety of exchange transfusions for polycythemia are uncertain.
- The exchange transfusion can be performed via an umbilical vein catheter or a radial artery for blood withdrawal and a routine venous infusion for blood replacement.
- The volume of serum exchanged is:

  $$\text{Volume} = 100\ \text{mL/kg} \times (\text{observed} - \text{desired hematocrit})$$

  where 100 mL/kg is the total blood volume in polycythemic infants and the desired hematocrit is usually 0.55 L/L. Usually an exchange volume of 20–30 mL is satisfactory. In each single withdrawal 1–1.5 mL/kg of blood is removed over 2–3 minutes and replaced over another 2–3 minutes.
- Infants should be monitored during the procedure and for several hours thereafter.

Patent Ductus Arteriosus

Bart Van Overmeire

80.1 Epidemiology

Patent ductus arteriosus (PDA) is the most common cardiac abnormality of the preterm infant. Its incidence is inversely related to gestational age, such that it affects almost 60% of infants less than 28 weeks' gestation. Data published in 2007 demonstrated that spontaneous closure of the ductus occurs in 30% of infants with birthweights below 1500 g (very low birth weight [VLBW]) [1]. It is obvious that percentages are decreasing for each lower birthweight category (Table 80.1), but also that a markedly wide variation exists among centers. This may reflect the influence of varying factors on the closure of the ductus.

Higher closing rates, and as a consequence lower incidences of PDA, have been reported in several papers for European infants. A randomized comparative multicenter trial that compared early (day 3) versus late (day 7) indomethacin treatment for PDA in preterm infants with gestational ages between 26 and 31 weeks and suffering from respiratory distress syndrome (RDS), revealed that 281 of 380 (74%) spontaneously closed their duct by the age of 7 days [2]. In 210 infants who received placebo in a double blind randomized trial of ibuprofen prophylaxis, high spontaneous closing rates on the 3rd to 4th day of life were confirmed by echocardiographic assessment [3]. Data are displayed for five birthweight and gestational age categories (Table 80.2).

Data from the neonatal registry of the Belgian college of physicians, demonstrate a closed or non-symptomatic PDA in 46.7% of 2635 VLBW infants for the years 2007-2009 [4]. As compared to these numbers, the closure rates described by Koch et al [5] in the United States seem lower, e.g., 34% on the third day of life in a group of 122 infants with birth weights below 1000 g. Other US data report 31% closure below 1000 g and 67% in a group of 65 VLBW infants [6]. It is clear that a wide variation exists in spontaneous ductal closure in preterm infants. In addition to immaturity, which is the factor that contributes most to PDA, various cofactors affect the occurrence of PDA. For many years, the presence of severe RDS has been recognized as a delaying factor for closure [7], as is the association with sepsis [8]. Intrauterine growth restriction also affects the behavior of the ductus [9]. The group of Rakza demonstrated convincingly that hypotrophic infants had significantly larger left to right shunts appearing earlier after birth and needing earlier treatment than eutrophic controls [10]. The authors explain that chronic hypoxia in utero may have caused a faster decrease of the pulmonary vascular resistance through the production of higher noradrenaline levels. Additionally, major anomalies of both the intima and media of the ductal vessal wall have been described [11]. It is a common belief that excessive fluid administration during the first days of life is associated with the occurrence of PDA. Unfortunately, poor evidence exists to support this view. A systematic meta-

Table 80.1 Closed or non-symptomatic PDA among VLBW infants surviving >12 hours

501–750 g	750–1000 g	1001–1250 g	1251–1500 g
n = 4,046	n = 4,266	n = 4,557	n = 5,284

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

analysis on this topic was last updated in 2008. Four of the five included trials date from the era before antenatal steroids and exogenous surfactant therapy and the one from 1999 shows very weak evidence. Nevertheless, the authors conclude that the practice of restricting water intake to physiological needs in preterm infants might be expected to decrease the risk of PDA [12]. The role of cortisol was highlighted by the studies of Watterberg demonstrating an inverse relationship between serum cortisol levels on postnatal days 3–4 and 5–6 and the occurrence of PDA [13]. It is known that both antenatal [14, 15] and postnatal steroid administration are associated with lower incidences of PDA [16, 17]. The prenatal use of NSAIDs as tocolytics has an impact on the postnatal reactivity of the ductus. Indomethacin and ibuprofen freely cross the placenta [18, 19]. During pregnancy they have a vasoconstrictive effect on the ductus and fetal pulmonary circulation which increases with advancing gestational age. Antenatally induced changes in the fetal ductal wall lead to a decreased reactivity of the ductus to postnatal NSAID treatment with an increased rate of treatment failure [20, 21]. The use of magnesium sulfate in pregnant women has been associated with a higher risk of developing PDA in extremely low birth weight infants [22] and with a reduced responsiveness to indomethacin prophylaxis [23]. Other large studies did not confirm these observations [24].

Many pharmacologic agents that are commonly used in the early neonatal period may influence the behavior of the ductus. Although caffeine has no direct effect on preterm sheep ductus' contractility [25], markedly less treatment for PDA was observed in the group of infants who received caffeine in a large multicenter clinical trial including 2,006 subjects [26]. In contrast to what was suggested years ago, there actually seems less evidence for a reducing effect of the postnatal administration of thyroid hormone [27] and the shielding of the thorax during phototherapy [28] on the occurrence of PDA. The administration of furosemide, by increasing circulating prostaglandin E2 levels, has been associated with an increased incidence of PDA in a study of 66 infants with RDS [29]. Six of seven studies that investigated the use of furosemide in preterm infants with RDS of less than 5 days of age were performed before the systematic application of prenatal steroids, surfactant or fluid restriction. However, a systematic review combining the trials indicated an increased risk of PDA and hypovolemia [30]. More recent data on the concomittant use of furosemide during NSAID treatment for PDA underscore the risk of inducing transient renal failure [31] but do not confirm the clinical effect of delaying the closure of the ductus [32, 33].

Various other frequently used drugs in the NICU may have unexpected vasodilatory actions on the ductus. To date, no clinically relevant effect on the behavior of the ductus has been described by the inhalation of nitric oxide [34–36]. Aminoglycosides, cimetidine, ranitidine and heparin are other possible candidates with dilating effects on the ductus meriting further prospective evaluation [37].

80.2 Physiology and Pathogenesis

During fetal life the patency of the ductus is essential. It allows 90% of the right ventricular output to bypass the high-resistance pulmonary vascular bed. Fetal patency of the ductus before birth and the closure after birth is the result of a balanced interaction of locally produced and circulating mediators, low oxygen tension and the unique structure of the vessel wall. Prostaglandins, converted from arachidonic acid by COX enzymes, play a major role in maintaining ductal patency in utero. There are two separate genes encoding COX proteins, COX-1 and COX-2, and a variant of COX-1 informally termed COX-3 has also been identified [38]. COX-1 is mostly constitutive whereas COX-2 is highly expressed during inflammation. COX-2 has been found to be increasingly expressed in the fetal ductus arteriosus with advancing gestation and is the main contributor to local PGE_2 generation in the ductus at term [39]. Of the five major prostanoids (PGE_2, $PGF_{2\alpha}$, PGD_2, PGI_2 and TXA2), predominantly PGE_2 and PGI_2 have high levels in the fetus because of high placental production and low clearance by the fetal lungs. They are the most potent ductal relaxants.

The increase in postnatal oxygen tension along with a decreased sensitivity of the ductus to PGE_2 as the fetus approaches term, initiate the closure of the ductus [40]. In the term infant constriction begins within the first few hours after birth and functional closure is usually completed within 24–48 hours of age.

After the initial functional constriction, a phase of neointimal thickening and remodeling occurs, leading to anatomical occlusion after several days [41]. Recent experiments have shown that platelets play a crucial role by promoting a thrombotic sealing and supporting luminal remodeling for the definite closure of the ductus [42, 43].

In the preterm infant the closure usually takes longer. The immature ductus has an increased sensitivity to PGE_2 and its constriction after birth is weaker. At comparable O_2 concentrations the ductus of the very immature fetus generates far lower tensions than those observed in the near-term fetus precluding definitive closure. NO synthase expression in the vasa vasorum of the vessel media is further increased and impedes the critical degree of contraction which is essential to elicit tissue hypoxia, initate remodeling and ultimately definitive closure of the ductus [44]. This carries an increased risk of reopening. A similar mechanism is believed to contribute to the failure of ductal closure of fetus previously exposed to maternal indomethacin [45]. In addition, there is evidence that the major vasorelaxant nitric oxide (NO) plays a role in the very immature ductus. Inhibition of NO synthase was found to exert a greater effect in closing the ductus of the more immature fetus whereas COX inhibition exerted a greater effect in the near-term fetus. The combined treatment with NO synthase and COX inhibitors was more effective than simply using COX inhibitors, but severe side effects precluded the introduction of this approach in clinical practice [46].

80.3 Pathophysiology

Almost all morbidity associated with PDA in preterm infants may be explained by the persistent left to right shunt through the vessel, causing a systemic hypoperfusion and a pulmonary hyperperfusion. In most infants, the heart can cope with the increasing demands by increasing left ventricular stroke volume and heart rate.

80.3.1 Pulmonary Effects

The lungs receive an increased perfusion which may lead to decreased lung compliance, lung edema, and increased risk of pulmonary hemorrhage [47, 48]. Symptoms and signs appear as the limits of compensatory mechanisms are reached. An association between the duration of the left to right shunt and the development of bronchopulmonary dysplasia has been demonstrated [49], although the simultaneous presence of an infection largely increases the risk [8]. Unfortunately, in studies of prophylactic treatment of PDA the incidence of BPD was not reduced. This may be explained by the study design, as all infants in the control group were given a back-up treatment only 1–3 days after the randomization. Alternatively, indomethacin may promote BPD in itself by inducing moderate renal dysfunction leading to increased lung fluid [50]. Experiments in baboons confirmed that a negative influence of a moderate left to right shunt increases clearly pulmonary to systemic flow ratio and exerts a negative effect on pulmonary mechanics. The most striking observation was an arrested alveolar growth and a reduced alveolar branching causing a significantly lower alveolar surface area and complexicity in the subjects that were exposed to persisted shunting [48].

80.3.2 Systemic Effects

Other organ systems may suffer hypoperfusion, including the gut, kidneys and the brain. A persistent patency of the ductus has been shown to be a risk factor for increased mortality. [51, 52]. Disturbances in renal perfusion have been shown [53]. The decrease in mesenteric blood flow [54, 55] has been associated with increased risk of gut ischemia, necrotizing enterocolitis [56], and causing a prolonged interval to full feeds [57]. In infants with PDA the superior mesenteric artery flow velocities were significantly lower postprandially as compared to those with closed duct [55].

80.3.3 Cerebral Effects

Already in the early 1980s hypoperfusion of the neonatal brain as a result of ductal left to right shunt was demonstrated by Doppler flow studies [58] and confirmed repeatedly on many occasions with other imaging techniques [59, 60].

More recently, an impressive lowering of the regional oxygen saturation in the brain could be visualized in infants with a moderate ductal shunt by use of near infrared spectroscopy (NIRS), and a prompt amelioration after closure of the ductus [61]. Although PDA has been clearly associated with all above-mentioned morbidities, in many situations, its causal role is not straightforward.

80.4 Pharmacological Treatment

Because left to right shunt through the ductus is associated with increased morbidity and mortality and because prostaglandins play a major role in patency of the ductus, for decades cyclooxygenase inhibitors have been used to treat PDA [62]. Successful closure of the duct has been reported to occur in 40–80% of treated infants. The risk of reopening increases to above 20% in the smallest infants. Because the process of intimal cushion formation during closure of the duct is inhibited by blockade of prostaglandins in the most immature infants, COX inhibitors are paradoxically less effective in extremely preterm neonates [63, 64]. Until 2004, indomethacin was the only COX inhibitor approved for treatment of PDA in most countries. Since late 1990s ibuprofen has been studied as an alternative for the treatment and prophylaxis of PDA.

The decision to start with pharmacological treatment in an individual infant depends on many factors. It is obvious that if factors in favor of a spontaneous closure of the duct are present, many clinicians will postpone pharmacological treatment by a few days. The appearance of signs and symptoms in the lungs or other organ systems should motivate to the initiation of more prompt treatment.

Schematically, three approaches are possible. Firstly, a conservative management with restriction of fluids combined with optimized respiratory support including positive end expiratory pressure; secondly, the pharmacological treatment with either ibuprofen or indomethacin; and finally surgical ligation of the ductus. Benefits and risks of each approach should be balanced, taken into account the specific characteristics of the infant such as birth weight, postnatal age, antenatal exposure to corticosteroids or NSAIDs, and the presence of comorbidities or infection.

80.4.1 Hemodynamic Significance of the PDA-shunt

Because invasive catheterization is not possible in small preterm infants, echocardiographic assessment is the method of choice to evaluate ductal patency and magnitude of PDA

shunting [65]. The technique allows monitoring the effects of intervention and has been used to guide both doses and the duration of pharmacological treatment [66–68]. It is generally accepted that a left atrium-to-aortic-root diameter ratio of ≥ 1.4 in the parasternal long axis view, a ductal diameter of 1.4 mm/kg body weight, and flow reversal in diastole in the descending aorta, indicate a hemodynamically significant left to right shunt [69]. When the mean end diastolic flow velocity in the left pulmonary artery exceeds 0,2 m/sec, there needs to be an additional high index of suspicion of significant left to right shunt [70].

Because frequent echocardiographic studies may destabilize the infant and in some NICUs it is not easy to obtain a bedside cardiac ultrasound, biomarkers such as B-type natriuretic peptide (BNP), NT-pro-BNP and cardiac troponin T (cTNT) are now more frequently used to detect "symptomatic" PDA and to guide treatment [71–74]. BNP is a vasoregulatory peptide that is released by the ventricles in response to increases in cardiac volume and pressure [75]. BNP levels did correlate very well with the magnitude of the left to right shunt as examined by echocardiography and reflected the moment of closure. Nevertheless, the high variability in the BNP measurements preclude their use as monitoring for changes in shunt magnitude [76]. The combination of measurement of biomarkers as a screening tool in those centers where echocardiography is not readily available, a high clinical suspicion and a comprehensive cardiac ultrasound and Doppler assessment, is probably an optimal approach to guide timely treatment of PDA [77].

80.4.2 Prophylaxis

A vast amount of studies have investigated the timing of pharmacological treatment of PDA. Prophylactic, early pre-symptomatic and symptomatic treatment strategies have been compared [78]. More than 30 studies and reviews addressed prophylaxis with non-steroidal anti-inflammatory drugs (NSAIDs) in preterm infants. The last updated meta-analyses available demonstrate that both prophylactic indomethacin and ibuprofen reduce significantly the risk of developing a symptomatic PDA and the need for ductal ligation [79, 80]. Nineteen prophylactic indomethacin trials were eligible in which 2,872 infants were included. The incidence of symptomatic PDA was very significantly reduced: typical relative risk (RR) 0.44; 95% confidence interval (CI) 0.38–0.50. In the studies eligible for the ibuprofen review the ductus had closed spontaneously in 58% of the infants of the control group by the third day of life. Based on available data the prophylactic administration of ibuprofen cannot be recommended. Indomethacin offers the additional effect of reducing the occurrence of intraventricular hemorrhage (IVH) (typical RR 0.66 95% CI 0.53–0.82). No positive effect on any other outcome parameter could be demonstrated. In particular, no decrease in the rates of bronchopulmonary dysplasia, death, necrotizing enterocolitis, or white matter disease. Notwithstanding the decrease of IVH, no improved neurodevelopmental outcome has been demonstrated [80, 81].

80.4.3 Treatment

Indomethacin and ibuprofen have also been extensively studied for the treatment of PDA. Ibuprofen disturbs significantly less regional circulations, which may offer less dysfunction of kidney, intestines, and brain [82–84]. Urine production was less affected in preterm infants (n = 148) that were treated on day 2–3 of life with ibuprofen than in those receiving indomethacin [85]. This observation resulted in ibuprofen being introduced for clinical use in preterm infants. Necrotizing enterocolitis was diagnosed twice as often in the indomethacin group (8 versus 4; p = 0,37) [85]. Cerebral oxygen availability has repeatedly been shown to be less affected with ibuprofen [83, 86]. Systematic reviews of the trials that evaluated indomethacin or ibuprofen for early treatment of a non-symptomatic or symptomatic PDA confirmed a comparable efficacy of both drugs [87]. The most recently updated systematic meta-analysis included 20 studies [88]. There was no statistically significant difference between indomethacin and ibuprofen efficacy or in failure to close the ductus in 19 comparative studies including 956 infants with a typical relative risk (RR) of 0.94 (95% CI 0.76–1.17). Infants receiving ibuprofen treatment have less evidence of transient renal failure and less risk of developing necrotizing enterocolitis: 15 studies including 865 infants; typical RR 0.68 (95% CI 0.47–0.99). No other differences were noted, e.g., mortality, reopening of the ductus, need for ligation, duration of ventilatory support, duration of supplementary oxygen and development of BPD.

The conventional doses of indomethacin and ibuprofen are different, based on their respective pharmacokinetic parameters. Adapted dosing schemes have been tried to augment efficacy/side effect ratio of indomethacin, however, with variable success [89] (see also § 80.4.5).

80.4.4 Risks of Treatment

Indomethacin and ibuprofen are not devoid of adverse drug reactions. Due to their vasoconstrictive effects, both drugs affect the perfusion of various organ systems to a certain extent, e.g., the gut, kidney and brains. Although ibuprofen initially seemed to have a more favorable safety profile with less disturbance of regional circulations [82–86], the occurrence of unexpected hypoxemia caused a lot of concern. Acute pulmonary hypertension developed in three preterm infants immediately after the infusion of ibuprofen THAM-buffered solution [90]. A clear explanation for this phenomenon is lacking. One infant of 169 treated with ibuprofen-lysine presented

the same adverse effect, but no causal relationship could be found between PPHN and ibuprofen-lysine in another 229 treated infants [3, 91, 92]. Additional studies could not confirm a clear association between the use of ibuprofen-lysine and severe hypoxemia. Although the trial that first reported this serious adverse effect was halted by the national authorities [93], the ibuprofen formulation under investigation became registered for clinical use in Europe in 2004. Ibuprofen-lysine was registered for treatment and prophylaxis of PDA in preterm infants in the US in 2006. Ibuprofen is insoluble in water and more than 90% bound to serum albumine [94]. An *in vitro* model demonstrated that at higher ibuprofen concentrations (750 micromol/L or 150 mg/L) in infant serum containing bilirubin, the fraction of unbound bilirubin increases fourfold [96]. This displacement of bilirubin from albumin binding sites may be clinically relevant in jaundiced preterm infants, as high levels of free bilirubin are associated with brain damage, hearing loss and kernicterus [96, 97]. When ibuprofen is administered in the recommended dosages of 10, 5 and 5 mg/kg at 24 hourly intervals to neonatal infants, ibuprofen serum peak levels of 20–40 mg/L are reached [98]. According to the *in vitro* model, an increase of 10% of the free fraction of bilirubin can be expected at such ibuprofen levels. Three smaller studies exploring the rise of unbound bilirubin were rather reassuring [99–101].

Additional risks of NSAID use for closing PDA in preterm infants are the occurrence of an isolated ileal perforation, particularly when there is concomitant use of steroids [102, 103]. Although predominantly reported for indomethacin, the risk may be similar for ibuprofen as its mechanism is related to microvascular changes and not to disturbances of the regional perfusion of the gut [104]. Increased bleeding tendency has been described after indomethacin use [105], but except for some increased occult blood appearing in stools this does not seem to cause clinically relevant problems. Some neonatal intensive care units are reluctant to continue or introduce enteral feedings during NSAID treatment. Eighty percent of the infants that participated in the European trials of prophylactic and early therapeutic NSAID for PDA were receiving trophic feedings without any apparent untoward effect [2, 3, 85, 93]. The most recent meta-analysis showed that necrotizing enterocolitis is less likely to occur post ibuprofen than post indomethacin treatment [88].

80.4.5 NSAID Dosing Schemes

The pharmacokinetic parameters vary widely in preterm infants due to physiological changes that occur after birth. Studies have shown large prolonged half-life for indomethacin (11–36 h) and reduced clearance rate in the preterm infant, both of which reveal marked interindividual variations [106, 107]. The volume of distribution also varies and is influenced by the patency of the ductus [108]. Accordingly, optimal therapeutic dosing is difficult to establish [109]. The most widely used doses for indomethacin are three times 0.1 to 0.25 mg/kg administered every 12–24 hours. The lower dose with longer interval is recommended when treatment is initiated on the first day. The registered dosing scheme for ibuprofen consists of a first dose of 10 mg/kg followed by a second and third dose of 5 mg/kg at 24 hourly intervals.

In order to improve efficacy/side effect ratio of NSAID during treatment for PDA, a variety of adapted dosing schemes have been studied. As it has been observed that PGE2 production resurges within 5 days of indomethacin treatment [110], a prolonged course consisting of additional indomethacin doses has been tried [89]. Unfortunately, no significant benefit for closure rates, not less reopenings or ligations, and no improvement for BPD, IVH or mortality rates has been obtained. A lower proportion of infants with diminished urine output was observed (typical RR 0.27; 95%CI 0.13 –0.6) but at the expense of an increased risk of NEC (RR 1.87; 95% CI 1.07–3.27) [89].

The continuous infusion of indomethacin has been advocated to avoid disturbances in cerebral perfusion [111], but was reported later to be less effective in extremely low birthweight infants [112]. Interestingly, by applying a stepwise increasing dosage of indomethacin based on echographic evaluation, the group of Sperandio et al [66] obtained ductal closing rates up to 80% without apparently increasing side effects. After an initial standard treatment, subsequent doses were given if the ductus persisted as assessed by echocardio-Doppler. Cumulative indomethacin doses were as high as 6 mg/kg [66]. As the efficacy of ibuprofen at extremely low gestational ages is comparably reduced to indomethacin [113], the administration of additional doses has been investigated. In a group of 25 VLBW infants that received a second course of three doses of ibuprofen the additional closure was 48 % [114]. Su et al [113] obtained an additional closure rate of 50% by administrating up to six doses of ibuprofen. Similar efficacy was demonstrated after the first and second course in a study population of 160 infants with birthweight below 1000 g with a cumulative closure rate of 65% [115]. In order to optimize the efficacy of ibuprofen, an adapted dosing scheme based on postnatal age has been proposed [116]. Further studies are warranted to investigate whether an individualized ibuprofen dosing scheme would result in an increased benefit/risk ratio.

80.5 Surgical Treatment

Since the introduction of indomethacin in the 1980s, surgical ligation has been reserved for those infants for whom treatment with NSAIDs fails or is contraindicated [117]. Beyond the third to fourth week of life, efficacy of COX-inhibitors rapidly declines as the patency of the ductus is less regulated by prostaglandins. Ligation then becomes an option, however

it remains nonetheless associated with a number of complications such as pneumothorax, bleeding, IVH, chylothorax as a result of thoracic duct injury, vocal cord paralysis, wound infection, hypotension, and left ventricular dysfunction in the days after the procedure [118–122]. The morbidity rate ranges form 1 to 16% and mortality from 0 to 10%. In a large retrospective study, surgical ligation and indomethacin treatment for significant PDA were associated with a comparable risk for NEC or NEC-related gastrointestinal complications [123] but mechanics of breathing significantly improved after ligation [124]. However, there are no recent controlled comparisons between pharmacological, conservative and surgical methods of PDA closure. Only one trial in 1983 enrolling 154 infants, compared initial surgical ligation versus medical treatment [117]. No statistically significant difference was found between the groups for mortality, chronic lung disease, NEC or IVH. An increase in pneumothorax (RR = 2.68; CI 1.45–4.03) and retinopathy of prematurity (RR = 3.80; CI 1.12–12.93) was observed in the ligated group. The use of prophylactic ligation cannot be recommended based on the limited current evidence [125]. Additional data from the TIPP study indicated that ligation of the ductus was associated with a higher risk of BPD, severe retinopathy of prematurity and neurosensory impairment [126]. A retrospective analysis of 446 infants showed that ligation was significantly associated with chronic lung disease [127]. In a group of 20 infants, a further decrease of oxygenation of the brain was observed by use of near infra red spectroscopy [128]. No increased brain injury, however, was noted in a preterm baboon model [129]. Because of the associated risks of ductal ligation in preterm infants in recent papers and the absence of recent comparative clinical trials, the primary surgical closure of the ductus does not seem advisable (130).

80.6 Conclusions

PDA continues to be a frequent complication of extremely premature birth, despite the more generalized use of antenatal steroids, postnatal surfactant administration and the improvement of non-invasive ventilatory strategies. Many perinatal factors influence the development of a symptomatic PDA. A large left to right shunt may cause profound hemodynamic disturbances to local organs and the brain. From the NSAIDs studied, ibuprofen actually seems to be the preferred drug for pharmacological treatment because of its more favorable benefit/risk ratio. The therapeutic response of the most immature infants, however, is limited for all investigated COX-inhibitors. Surgical ligation of the duct should be considered as a back-up treatment, because it carries the risk of serious complications and destabilization of the infant. Unfortunately, in spite of many studies, investigations and trials, there is no generally accepted and conclusive evidence to decide at which moment and to which infants the treatment of the ductus should be pursued in order to improve their long-term outcome.

Bilirubin Metabolism, Unconjugated Hyperbilirubinemia, Physiological Neonatal Jaundice

Giovanna Bertini and Carlo Dani

Jaundice is the most frequent condition identified in a newborn. Recent data show that about 25% of neonates have visible jaundice during their hospitalization, and 5.1% have a serum total bilirubin (STB) concentration >12.9 mg/dL (220.59 μmol/L) [1].

81.1 Bilirubin Metabolism

Hyperbilirubinemia is defined as a STB >20 mg/dL. It is caused by a high rate of production of bilirubin or reduced hepatic clearance or increased intestinal absorption. Bilirubin is mainly produced from the catabolism of hemoglobin, and partially from non-erythroid heme-proteins, myoglobin, and ineffective erythopoiesis (Fig. 81.1). The site of conversion of heme to bilirubin is the reticulo-endothelial system, and together with bilirubin, a molecule of carbon monoxide (CO) and an atom of iron are the products of the catabolism (Fig. 81.1). The determination of CO in the expired air or the measurement of CO-hemoglobin are able to quantify the production of bilirubin in a newborn [2]. Bilirubin production in a normal neonate is 2 or more times greater that in the adult per kg bodyweight. In addition, a transient deficiency of bilirubin conjugation is present at birth (during fetal life bilirubin is cleared by the mother through the placenta), and disorders of hepatic uptake and intrahepatic circulation have been demonstrated [3].

Bilirubin is insoluble in water, but in the blood is transported bound to albumin at 2 binding sites (one at very high affinity) in equilibrium with a very low concentration of unbound or free bilrubin [4]. About 8 mg of bilirubin is bound to each gram of albumin. Bilirubin is conjugated to monoconjugate and diconjugated bilirubin by the enzyme system UDP-Glucuronosyltransferase (UGT) 1A1 codified by the UGT 1A1 gene complex. When bilirubin load in newborns is high, bilirubin is mainly conjugated with only one molecule of glucuronic acid. In the intestines, monoconjugated bilirubin is more easily deconjugated by β-glucuronidase and reverted to native bilirubin which can be absorbed by the gut. In fact, the intestine of neonates is almost sterile, and bilirubin is not yet degraded to sterco- and uro-bilinogen.

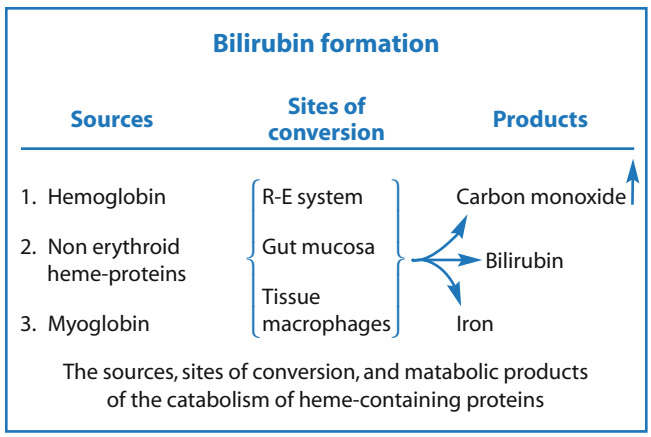

Fig. 81.1 The conversion of heme produces a molecule of carbon monoxide, a molecule of bilirubin and an atom of iron

81.2 Unconjugated Hyperbilirubinemia

Neonatal jaundice is currently defined as hyperbilirubinemia, and bilirubin is 99% unconjugated. In routine laboratory determinations, unconjugated bilirubin is reported as indirect-reacting bilirubin. The only reason for measuring the bilirubin fractions (direct and indirect) concentrations, is the suspicion of cholestatic jaundice, e.g., biliary atresia.

Elevated STB can lead to bilirubin encephalopathy and subsequently to kernicterus with risk of death or permanent

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

severe neurodevelopmental disabilities. Jaundice in the absence of a hemolytic disease is frequently and erroneously considered a physiologic or developmental event with very low risk. In fact, in recent years the right emphasis given to breastfeeding has convinced many health personnel that is important to say to mothers "feed the baby on demand, forget the balance and weight gain, and remember that any mother produces the right amount of milk for his baby". Unfortunately, insufficient breastfeeding and starvation increases the activity of heme-oxygenase, the key enzyme in bilirubin production. Thus, in recent times many infants are admitted to hospital after their discharge with a severe dehydration, hypernatremia and hyperbilirubinemia as a consequence of insufficient feeding. Two important papers reported breastfed infants at high risk of kernicterus due to very high hyperbilirubinemia consequent to insufficient nutrition [5, 6]. In the paper of Meisel et al [5] the six infants had a SBC of 39.0–49.7 mg/dL, four had a gestational age of 37 weeks, one of 38 and another of 39 weeks. All had a negative direct Coombs test. They were treated with exchange transfusion but, unfortunately, all resulted as being affected by kernicterus. Three of the four neonates reported by Hansen [6] had a gestational age of 36 weeks while the fourth was born at 40 weeks, but their SBC ranged from 32.1 to 36.3. Three of them were only treated with intensive phototherapy and formula feeding ad libitum while the fourth received an exchange transfusion when SBC was already decreased to approximately 23 mg/dL. All the infants had a normal follow-up.

81.3 Bilirubine Conjugation Genetics

Recently, new research has contributed in clarifying the reason why some healthy infants have a severe jaundice without evident signs of hemolysis, and other infants who are breastfed have a prolonged neonatal jaundice, the so called breast milk jaundice. An important study of Kaplan et al [7] has shown that white neonates with a polymorphism of the gene encoding UGT, in which an additional TA base pair is inserted in TATAA box of the gene promoter (Gilbert's syndrome), could develop hyperbilirubinemia. Affected individuals who are homozygous for the variant promoter, and have 7 TA repeats—$(TA)_7TAA$ (7/7) instead of the more usual 6 repeats—$(TA)_6TAA$ (6/6), have a higher serum total bilirubin (STB) concentration, an increased blood carboxyhemoglobin corrected for inspired CO (COHbc), index of heme catabolism and bilirubin production, a decreased total conjugated bilirubin (TCB) showing a decrease efficacy of enzyme system UDP-Glucuronosyltransferase 1A1 and an increased production/ conjugation rate (COHbc/(TCB/STB [%]), represented by bilirubin production divided by conjugation. In synthesis, newborns with Gilbert's syndrome not only have a diminished enzyme activity which results from decreased expression of normally structured UGT, but also an increased hemolysis which exacerbates neonatal hyperbilirubinemia. This condition is also important because, in the white population, it is frequently associated with prolonged hyperbilirubinemia associated with breastfeeding; after cessation of breastfeeding, the infant's bilirubin level became normal [7]. In the oriental population, a mutation of the UGT 1A1 is responsible of Gilbert's syndrome and prolonged unconjugated hyperbilirubinemia associated with breast milk. The most frequent missense mutation is a G → A transition at nucleotide 211. Arginine replaces glycine at position 71 of the corresponding protein product (G71R) [8].

Identification of genetic mutations of bilirubin conjugation requires a full genetic consultation and laboratory analysis. A detailed genetic work-up should include details of ethnic background, risk factors, previous infants with jaundice, either in the neonatal period or later. This is particularly important because studies have shown that Gilbert's syndrome is a determining factor for the development of neonatal hyperbilirubinemia due to ABO incompatibility [9], and also in G-6-PD deficiency (Mediterranean mutation) [10]. Moreover, Maruo et al, studying Japanese hyperbilirubinemic infants with no obvious cause for their jaundice, found the allele frequency of a mutated UGT 1A1 (G71R) more than double than in controls [8]. Both hetero- and homozygosity for the G71R mutation were associated with hyperbilirubinemia [8]. It is possible that the high incidence of hyperbilirubinemia in Japanese newborns may be a function of the frequency of the G71R mutation in that population. In addition, a case of kernicterus in a breast-fed infant with hereditary spherocytosis and Gilbert's syndrome has been recently reported [11].

Crigler-Najjar (C-N) syndromes are very rare. However, while type 1 C-N is rarely undetected by neonatologists, C-N type 2 is more insidious. In fact, jaundice is very often confused with non-hemolytic jaundice and infants with C-N type 2 could be discharged after phototherapy without any short-term follow-up. Infants often return to the hospital with intense jaundice and signs of bilirubin encephalopathy. C-N type 1 presents with very high hyperbilirubinemia during the first few days of life, and generally phototherapy only transitorily reduces TSB below 20 mg/dL [12]. The treatment with Sn-proto- or mesoporphyrin, heme-oxygenase inhibitors, has been attempted [13, 14] but it is only capable of reducing the time spent under the lamps. However, this treatment could be useful during diseases or starvation when SBC increases over 20–25 mg/dL. By now, the only treatment that could give to these infants a normal life is liver transplant.

81.4 Physiological Neonatal Jaundice

The term "physiological jaundice" is no longer generally used because most neonatologists prefer to describe the level of TSB in relation to time and to treat infants according to a graph of TSB plotted against the baby's age in hours.

Risk zones for near-term (35–37 weeks of gestational age) and term (38–42 weeks of gestational age) newborns have been prepared according to the percentile tracks based on the hour-specific serum bilirubin values [15]. On the age-specific nomogram, the zone >95th percentile was labeled as high risk, and that <5th percentile was labeled as low risk. Serum total bilirubin values between the 5th and 30th, 30th and 60th, and 60th and 95th percentiles were designated as being in the low-intermediate, intermediate, and high-intermediate risk zones, respectively. The 5th and 95th percentiles on the nomogram had the highest sensitivity (100%) and specificity (98.2%), respectively, in predicting the subsequent development for term newborns in the approach to management of hyperbilirubinemia. Infants of 35–37 weeks' gestation had significantly lower birth weights, significantly higher serum total bilirubin levels on days 5 and 7, and were 2.4 times more likely to develop significant hyperbilirubinemia than those of 38–42 weeks' gestation [15]. In near-term newborns of 35–37 weeks' (245–265 days') gestation, the decision to diagnose and treat significant hyperbilirubinemia should be made on the basis of risk status (percentile distribution of the serum bilirubin values on postnatal age) rather than using birthweight-based thresholds. A nomogram constructed from daily serum bilirubin values of each population can be used in assessing the age (hour)-specific jaundice risk (high, intermediate, or low) of each near-term newborn [15].

What is the outcome in a population of healthy term and near-term infants with TSB ≥19 mg/dL (≥325 μmol/L)? To answer this question Jangaard et al [16] have prospectively studied 56,019 infants at ≥35 weeks of gestation who were born between January 1 1994 and December 31 2000 in Nova Scotia, Canada. They did not find cases of kernicterus and no significant differences in rates of cerebral palsy, deafness, or visual abnormalities were observed between infants with hyperbilirubinemia (≥325 μmol/L) and infants with less severe or no hyperbilirubinemia. However, at the follow-up associations with developmental delay, attention-deficit disorder, and autism were observed in the group of hyperbilirubinemic infants [16]. These associations require additional studies to ascertain whether a causal relationship exists.

Pathologic Unconjugated Hyperbilirubinemia, Isoimmunization, Abnormalities of Red Cells and Infections

Michael Kaplan, Ronald J. Wong and David K. Stevenson

82.1 Introduction

Unconjugated hyperbilirubinemia in the newborn after birth is a normal phenomenon, transitional in nature, and harmless. It may be protective for the human neonate exposed to increased levels of oxygen and light in the environment outside the womb before antioxidant enzymatic defenses are fully upregulated. The phenomenon is called "physiologic neonatal jaundice" and the contributing biochemistry has been described in the preceding chapter (see Chapter 81).

Physiologic neonatal jaundice implies benignity, but also a causation that is developmental in nature. That is, newborn infants have normally increased bilirubin production (two–three times the adult on a body weight basis) [1, 2] because of their relatively increased red cell mass responsive to their fetal state and shortened red blood cell lifespan, combined with transitionally impaired uptake and conjugation. This imbalance between bilirubin production and bilirubin elimination is the major determinant of transitional hyperbilirubinemia after birth.

Although pathologic unconjugated hyperbilirubinemia could be defined on the basis of exacerbation of increased bilirubin production or impairment of conjugation, the diagnosis would not even be considered if the pattern of transitional hyperbilirubinemia did not deviate from the normal one. For example, an infant might have markedly increased bilirubin production, but better than usual elimination and therefore, not deviate from the usual course of hyperbilirubinemia. Conceivably, it would also be possible to have greater impairment of uptake or conjugation, but have counter-balancing lower bilirubin production, for example, because of anemia, so that the trajectory of bilirubin levels would not deviate from the expected course. Thus, pathologic unconjugated hyperbilirubinemia is probably best defined epidemiologically, using a nomogram [3], which defines the normal trajectory of hour-specific bilirubin levels, even defining risk zones that reflect the likelihood that a particular infant tracking in that zone might deviate enough from the general population to warrant further diagnostic workup or treatment. Notably, increased bilirubin production is a contributing cause of all kinds of neonatal jaundice. Moreover, all neonates have temporarily impaired elimination of bilirubin. Disorders of hepatic uptake, conjugation, and intrahepatic circulation contribute to the pathologic exacerbation of transitional neonatal jaundice and are discussed in the following chapter (see Chapter 83).

Treatment of pathologic jaundice is also discussed separately. It depends less on the cause (although there may be some consideration of risk in this regard) and more on the extent to which an individual infant has deviated from the normal transitional pattern of hyperbilirubinemia and is at more risk for injury because of the absolute level, binding capacity, and clinical circumstances that might alter binding affinity of albumin for bilirubin.

Thus, pathologic unconjugated hyperbilirubinemia is defined as an hour-specific bilirubin exceeding the 95th percentile for a population-based house-specific bilirubin nomogram, appropriate for the particular ethnic and cultural circumstances [3]. Because all neonates have relatively impaired elimination of the pigment after birth, one of the most common causes of pathologic unconjugated hyperbilirubinemia is increased bilirubin production from any cause. Such causes are the focus of this chapter, and include hemolysis resulting from isoimmunization, abnormalities of red cells and infections, but also many other conditions. Some of these other conditions are quite common, such as closed-space bleeding, most often encountered by the pediatrician in the form a cephalohematoma or bruising. Depending upon the volume of extravascular blood, bilirubin production can be increased to a rate comparable to that observed in hemolytic conditions. Thus, such infants may have a transitional trajectory of bilirubin levels in one of the higher risk zones of the

hour-specific nomogram or even cross zones depending upon their conjugating capacity and the magnitude of the increase in bilirubin production. Premature infants also have increased production relative to the full term infant, perhaps because of even shorter red cell life spans. The latter is mitigated by less of an increase in the red cell mass among infants born at earlier gestation. Nonetheless, the more mature and larger of the premature infants are likely to deviate from the full-term hour-specific nomogram because of an exaggerated imbalance between increased bilirubin production and impaired elimination [4].

Finally, the infant of a diabetic mother has increased bilirubin production as a major contributing cause to their propensity for pathologic unconjugated hyperbilirubinemia [5, 6]. This increased bilirubin production may be the result of polycythemia, but often reflects ineffective erythropoiesis in the presence of a normal hemoglobin or hematocrit level. The likelihood of a pathologic trajectory of bilirubin levels in the transitional period after birth is further exacerbated by impaired elimination in these infants. This latter compounding factor was revealed by higher bilirubin levels in infants of diabetic mothers compared to infants of normal mothers while controlling for bilirubin production on a body weight basis.

The most important phenomenon contributing to pathologic unconjugated hyperbilirubinemia is hemolysis from any cause. The rapid destruction of red cells in the circulation with the consequent degradation of heme is the predominant source of bilirubin in most pathologic unconjugated hyperbilirubinemia requiring diagnostic workup and treatment. Hemolysis can occur from a variety of specific causes, including isoimmunization (Rh disease, ABO heterospecificity, and other immune globulin mediated hemolytic conditions); red cell enzyme deficiencies (glucose-6-phosphate dehydrogenase [G6PD] deficiency, hexokinase deficiency, and other less common enzymatic deficiencies); and red cell membrane defects (hereditary spherocytosis, elliptocytosis, and other less common red cell membrane defects) [7].

Finally, there are now recognized polymorphisms of the HO-1 (heme oxygenase-1) promoter involving GT expansions [8]. An increase in the number of GT expansions in the promoter can alter the expression of HO-1 and lead to clinically important decreases in bilirubin production [9, 10]. This may have other biological consequences, including risk for vascular disease, and among pregnant women, idiopathic recurrent miscarriages, intrauterine growth restriction, and preeclampsia [8, 11].

What is important to understand in the context of pathologic unconjugated hyperbilirubinemia is the fact that there may be native variation in bilirubin production rates. In the context of impaired elimination in the transitional period after birth or in conditions which further limit uptake or conjugation, these variations might contribute to pathologic unconjugated hyperbilirubinemia without other apparent environmental or acquired exigencies [12–15].

82.2 Hemolytic Conditions

82.2.1 Increased Risk Associated with Hemolysis

Neonates with hemolytic disease appear to be at a higher risk of developing bilirubin induced-brain damage compared with those without hemolysis. Indeed, the first link to be established between increasing bilirubin levels and the risk of kernicterus was in newborns with hemolytic disease due to Rh isoimmunization [16]. Subsequent reports suggested that the incidence of kernicterus in hyperbilirubinemic newborns with hemolytic disease may be higher than that in counterparts without evidence of hemolytic disease, as reviewed by Newman and Maisels [17]. In a survey of the literature up to 1983, Watchko and Oski [18] reinforced the concept that hyperbilirubinemia among neonates without hemolytic disease was less dangerous with regard to the development of kernicterus than in cases where hemolysis was present. A similar stand was taken by Newman and Maisels [19] several years later. However, there is little data on which to base this view. A study shedding some light on this question was performed by Ozmert et al [20]. In 102 children aged 8–13 years, who had been treated for indirect hyperbilirubinemia ranging from 17–48 mg/dL, a positive direct Coombs test, presumed to identify ongoing hemolysis, was associated with lower IQ scores and a higher incidence of neurologic abnormalities. They also found, in these same children, that the incidence of detected neurologic abnormalities increased proportionately to the time of exposure to high bilirubin levels. Similarly, Nilsen et al [21] found that of 55 Norwegian males born in the early 1960s who had neonatal hyperbilirubinemia, those who had a positive Coombs test and hyperbilirubinemia for greater than 5 days had significantly lower IQ scores than average.

Although there is to date no evidence demonstrating higher levels of unbound bilirubin in hemolyzing neonates, it is still generally accepted that hemolysis is a potential factor increasing the risk for bilirubin-related brain damage. While a total serum (or plasma) bilirubin (TSB) concentration of 20–24 mg/dL (342–410 μmol/L) may be associated with kernicterus in a neonate with Rh isoimmunization, a healthy, term non-hemolyzing infant will rarely be endangered by TSB concentrations in this range. Hemolysis due to direct Coombs positive Rh and ABO immunization, other isoimmunizations and G6PD deficiency may therefore pose an increased threat to an otherwise healthy newborn. The Subcommittee on Hyperbilirubinemia of the American Academy of Pediatrics (AAP) includes jaundice developing within the first 24 hours, blood group incompatibility with a positive direct antiglobulin test (DAT) (also known as the Coombs test), other known hemolytic disease including G6PD deficiency, all associated with increased hemolysis, as major risk factors for the development of severe hyperbilirubinemia [22]. The Subcommittee recommends initiating phototherapy or performing exchange transfusions at lower levels of TSB in neonates

with hemolytic conditions than in non-hemolyzing counterparts. However, one should not be lulled into a sense of false security that a hyperbilirubinemic, but non-hemolyzing newborn, will not develop kernicterus. Cases of kernicterus have been reported in which there was no evidence of hemolysis [23]. Crigler-Najjar syndrome, a condition not associated with increased hemolysis, is frequently complicated by bilirubin-induced neurologic dysfunction (BIND).

Unfortunately, there is currently no bedside technique available to determine the presence or absence of increased heme catabolism. Red blood cell (RBC) indices, useful as indicators of hemolysis in older children or adults, are not reliable for this purpose in newborns [24]. Hemolysis, while ongoing, may not be readily determinable. For example, in a multinational, multicenter study of 1370 newborns, the level of corrected end-tidal carbon monoxide (ETCOc), an index of heme catabolism, in 92 of 120 (76%) neonates who were hyperbilirubinemic was greater than the mean value for the cohort [25]. In a male cohort of G6PD-normal, otherwise healthy African American neonates born to non-smoking mothers, ETCOc values were significantly higher among hyperbilirubinemic neonates than among those who did not develop hyperbilirubinemia [26]. Also using ETCOc, Maisels and Kring [27] demonstrated that, before hospital discharge, most infants with TSB levels >75th percentile [3] produced significantly more bilirubin than those with lower bilirubin levels. Because bedside ETCOc testing is no longer available, and blood typing, DAT determination, and G6PD screening are not universally performed, it is possible that an infant not actually classified as having a hemolytic condition, may, in fact, be actively hemolyzing. The potentially increased risk for hyperbilirubinemia and kernicterus may therefore go unrecognized.

Hemolytic conditions in the newborn are generally divided into 2 major etiologic groups: immune and non-immune. The former group includes Rh isoimmunization, although today Rh disease is largely preventable by antenatal and postnatal Rh_oD globulin (of which the best known commercial preparation is Rh_oGAM) administration. Rh disease will, nevertheless, be discussed in some detail, because much of our knowledge of the pathophysiology of kernicterus derives from studies of babies with this condition. ABO immune disease (mother blood group O, baby group A or B) is the most common immune condition currently encountered. Of the non-immune causes, G6PD deficiency is by far the most important, and is highly associated with the development of extreme hyperbilirubinemia and kernicterus.

82.3 Immune Hemolytic Disease

82.3.1 Rh Isoimmune Hemolytic Disease

Rh disease in pregnancy is highly associated with both intrauterine hemolysis as well as severe hemolytic disease following delivery. Untreated, the condition can lead to intrauterine anemia and severe hydrops fetalis, with rapid postnatal evolvement of hyperbilirubinemia with the potential of kernicterus.

82.3.1.1 Background: the Immunization Process

The Rh group of antigens comprises the C, D, and E pairs of antigens. While each of these antigens may result in isoimmunization, anti-D isoimmunization is the most common and has the greatest degree of clinical significance. There is some effect of racial distribution of Rh negativity. In Caucasian populations about 13–15% of individuals are Rh-negative. About half of that number is encountered in African Americans, while Rh negativity is very rare in individuals of Asian background. The incidence of Rh isoimmunization is infrequent, and is reported to be 6.8 cases per 1000 live births [28].

The immunization process may begin if an Rh-negative woman, usually D-negative, is exposed to a D antigen. This may occur by antepartum or intrapartum transplacental fetomaternal transfusion of fetal RBCs containing a D antigen. Similar transfusion of Rh-positive RBCs may occur during abortion, blood administration, or procedures including amniocentesis, chorionic villus sampling, or fetal blood sampling. The mother's immune system may respond by forming anti-D IgG antibodies. These then cross the placenta and adhere to the fetal RBCs containing the D antigen. The antigen-antibody response leads to hemolysis and anemia. Because the mother's immune system becomes primed, the immune response may become more severe and more rapid with progressive pregnancies. In cases of prolonged and severe anemia, bone marrow stimulation may result in increased numbers of circulating immature RBCs (erythroblastosis) and even extramedullary hematopoiesis with hepatosplenomegaly. Fetal hydrops, including generalized tissue edema and pleural, pericardial and peritoneal effusions, may result from hypoproteinemia, tissue hypoxia, and capillary leak, combined with congestive cardiac failure due to anemia, and venous congestions due to poor myocardial function with diminished cardiac output [29].

82.3.1.2 Management of the Pregnancy

Hydrops fetalis is associated with a very high mortality rate and major efforts should be made to prevent this occurrence. The mainstay of the management of a pregnancy complicated by Rh isoimmunization includes active surveillance of the fetus to detect fetal anemia. Once the fetus does become anemic, the decision to perform an intrauterine transfusion or to deliver the infant will depend on the gestational age: the potential complications of delivering a premature infant will have to be weighed against those involved in performing an intrauterine transfusion. In the recent past, amniocentesis was the primary method of fetal monitoring [30]. The degree of hemolysis was assessed by determinations of the amount of

bilirubin in the amniotic fluid by measuring the deviation from linearity at 450 nm, the wavelength at which bilirubin absorbs light. The measurements were divided into 3 zones plotted on the Liley chart. Readings in Zone III were indicative of severe hemolysis with a high likelihood of fetal death. The Liley chart was improved upon by the Queenan curve [31]. This regimen has been largely replaced in the last few years by a combination of advancing ultrasonographic techniques and developing genetic technologies. Because this condition is now rare, and therapeutic technologies are advancing at a rapid rate, Rh-immunized women and their fetuses should be managed in a tertiary center capable of adequately managing the fetus. As the neonatologist not actively involved in this field may be unfamiliar with many of these recent advances, an outline of current management of affected pregnancies follows.

A general principle is that all pregnant women should have an antibody screen performed early in pregnancy. If a woman is RhD-negative and there is no evidence of anti-D alloimmunization, rhesus immune globulin should be administered at 28 weeks gestation [29]. By doing so, the incidence of antenatal immunization will be reduced to 0.1% [32]. The globulin should also be administered following spontaneous or elective abortion, amniocentesis, chorionic villus sampling, or fetal blood sampling. Within 72 hours of delivery, another dose should be administered, should the woman have delivered an RhD-positive infant.

The RhD gene has been localized to the short arm of chromosome 1 [33]. Approximately 55% of individuals will be heterozygous at the RHD locus, in which case only 50% of their fetuses will be RhD-positive. Because an RhD-negative fetus requires no further testing, it is important to assess the chance of an at risk fetus having a D antigen. Gene frequency tables, combined with the history of RhD-positive or -negative infants fathered by any individual have been used to estimate the likelihood of the father being heterozygous. Recent advances in DNA technology, however, allow for accurate determination of whether the father is heterozygous or homozygous for the RHD gene [34]. Should the father be heterozygous, steps should be taken to determine the Rh type of the fetus. This can be done accurately by retrieving fetal DNA via amniocentesis [35]. Amniocentesis for this purpose may be replaced by free fetal DNA techniques, which allow the presence of fetal RHD in the maternal plasma to be detected [34]. Further advances in this field may enable fetal Rh typing to be performed noninvasively in the future.

Determination of the maternal anti-D titer is an important step in the monitoring of an RhD-sensitized woman. A critical titer is that associated with a high risk of severe hydrops. The critical titer varies from center to center, but a titer ranging from 8–32 is usually used [29].

Doppler assessment of the blood flow velocity in the fetus' middle cerebral artery (MCA) is replacing amniocentesis as a means of detecting fetal anemia. In an anemic fetus, the blood velocity may increase due to decreased viscosity and increased cardiac output. In one study, a value of more than 1.5 multiples of the median identified all cases of moderate to severe anemia [36]. In a recent study comparing diagnostic amniocentesis with MCA flow, Doppler measurements improved on optical density determinations by 9% [37]. Should fetal anemia be detected by either Doppler or amniocentesis, fetal blood sampling may be obtained (cordocentesis) to determine hematocrit, direct antibody titer, fetal blood type, reticulocyte count, and total bilirubin values. Intravascular intrauterine transfusion may be considered if the hematocrit value is less than 30%, however, should the pregnancy have reached 35 weeks gestation or more, the advantages of induction of delivery may outweigh the dangers of intrauterine transfusions. Repeated intrauterine transfusion may cause fetal bone marrow suppression, and in a repeatedly transfused fetus, the RBC mass at the time of delivery may be comprised almost entirely of donor cells. In this situation exchange transfusion may be unnecessary, although "top-up" transfusions for anemia may be required [38]. In capable hands, the outcome of intrauterine transfusion should be good. In the Netherlands, the survival rate in 254 treated fetuses was 89% [39].

82.3.1.3 Postnatal Management of the Newborn

Management of a hydropic, severely anemic neonate, especially if complicated by respiratory and other problems of prematurity, is a major neonatal challenge requiring a degree of expertise available only at a tertiary center. The infant may be generally swollen because of soft tissue edema, and in addition may have large collections of fluid in the pleural, pericardial, and peritoneal spaces. Intubation may be difficult because of the soft tissue swelling. Ventilation may be difficult, and the need for emergency drainage of the fluid collections, sometimes in the delivery or operating room, may add to the challenge. Anoxic myocardial damage may necessitate use of inotropes, and respiratory ventilatory support may have to be complemented by surfactant and nitric oxide (NO) administration. High frequency ventilation may be necessary. Metabolic acidosis should be corrected [40].

Because the circulatory system may be overloaded, and myocardial function poor, it may be preferable to correct the anemia by performing a partial exchange transfusion, rather than by simple blood transfusion. Following insertion of an umbilical venous or arterial catheter, small amounts of anemic blood should be removed and replaced with donor blood in the form of packed cells. This procedure may be titrated until the desired hematocrit value is obtained.

In the fetus, most bilirubin formed from increased heme catabolism will be eliminated via the placenta. Severe intrauterine hyperbilirubinemia is therefore not usually not a problem. Once delivered, however, the placenta no longer participates in the bilirubin elimination process, and continued hemolysis combined with immature conjugation and excretion may precipitate a rapid rise in TSB values with the potential, if untreated, of causing extreme hyperbilirubinemia.

Once the baby has been stabilized, attention should be paid to preventing this from occurring, and rectifying this situation should it occur. This is achieved by instituting intense phototherapy as soon as possible, closely monitoring TSB levels, and performing an exchange transfusion in cases where the TSB continues to increase despite intensive phototherapy.

Some studies have demonstrated that intravenous immune globulin (IVIG) administration may be effective in preventing or limiting the number of exchange transfusions in Rh disease [41]. A recent Cochrane report suggested that more information, based on well designed studies, are needed before IVIG can be routinely recommended for isoimmune hemolysis [42]. Nevertheless, the recent AAP guideline recommends the use of IVIG in order to prevent exchange transfusion in cases of failing phototherapy [22]. In general, the principles of the AAP guideline should be adopted to guide the management of the hyperbilirubinemia. The reader is referred to Chapter 84 for further details on the treatment of hyperbilirubinemic newborns.

Very few studies have reported the long-term neurodevelopmental outcome of fetuses treated with intrauterine transfusion. Overall, the results to date are encouraging, although future long-term follow-up studies will be necessary to fully evaluate the current therapeutic modalities offered to the fetuses and newborn infants of Rh-immunized pregnancies [40]. Fetal exposure to moderately increased bilirubin levels for prolonged periods of time may result in sensorineural hearing loss because of the effect of bilirubin on the developing auditory neural system [43].

82.3.2 ABO Immune Disease

82.3.2.1 Background: Blood Group Incompatibility and DAT Positivity

Now that the occurrence of Rh isoimmunization has been reduced by anti-D immune prophylaxis, ABO incompatibility has become the single most frequent cause of immune hemolytic disease causing jaundice in the neonate. Despite its increased frequency, the clinical picture, though, is usually milder than that of Rh disease.

ABO blood group heterospecificity refers to the situation in which the mother has O blood and the baby has blood group A or B. This setup is present in approximately 12% of pregnancies. In some instances, women with blood group O have a high titer of naturally occurring anti-A or anti B antibodies. In contrast to Rh isoimmunization, in which immune sensitization occurs progressively with subsequent pregnancies, high titers of anti-A or anti-B antibodies can sometimes be found in blood group O women before their first pregnancy or even in girls [44]. Unlike blood group A or B individuals, in whom their respective anti-B or anti-A antibodies are IgM molecules, and therefore unable to cross the placenta in significant quantities, the respective antibodies of blood group O people are predominantly IgG molecules. Being smaller than IgM, IgG molecules may cross the placenta and attach to the corresponding fetal RBCs, provided that these cells have the A or B antigen. This isoimmunization process may cause hemolysis commencing in utero. Extravascular hemolysis of the IgG-coated RBCs is probably mediated by Fc-receptor-bearing cells within the reticuloendothelial system. Prior to delivery, there is little danger of severe hyperbilirubinemia and the immune process is usually not sufficiently severe to cause hydrops. Babies may sometimes be born moderately anemic, and there is a potential danger of hyperbilirubinemia in the first days following delivery.

The hallmark of isoimmunization is a positive DAT. The test is termed direct if the antiglobulin is detected on the RBCs. An indirect test refers to the antibody being detected in the serum. About one-third of blood group A or B neonates born to a blood group O mother will have a positive DAT [45]. Measurements of endogenous formation of CO, reflective of heme catabolism, have demonstrated an increased rate of heme catabolism in hyperbilirubinemic DAT-positive, ABO-incompatible neonates compared with controls [2, 46, 47]. In a multicenter, international study of bilirubin production using ETCOc determinations, DAT positive babies (not necessarily hyperbilirubinemic) had significantly higher ETCOc values than the total population studied [25]. While hyperbilirubinemic, DAT positive babies had even higher ETCOc values than the general DAT positive population, these were not significantly higher than hyperbilirubinemic babies of other categories.

Not all DAT positive neonates will develop severe hyperbilirubinemia. In one study, although a positive DAT was predictive of an elevated TSB value, only 20% of DAT positive neonates actually developed TSB values >12.8 mg/dL (218 μmol/L), and even fewer had severe jaundice [45]. In another study, only 19.6% of DAT positive, ABO-incompatible infants required phototherapy [48]. Despite this apparent clinical mildness, the authors occasionally encounter newborns with severe hyperbilirubinemia of early onset, occasionally warranting exchange transfusion. To complete this clinical spectrum, kernicterus has been described in association with ABO hemolytic disease [49, 50].

The reasons for absence of clinical disease in the majority of DAT-positive newborns may include the paucity of A and B antigenic sites on neonatal RBCs compared with adult RBCs, or weak expression of these antigens in neonates. Non-RBC A or B antigenic sites may exist and bind with transplacentally-acquired antibody without affecting the RBC. ABO blood group incompatibility with a negative DAT, not usually predictive of hemolysis or hyperbilirubinemia, may sometimes cause early and rapidly progressing jaundice, reminiscent of DAT-positive, hemolytic disease.

ABO heterospecificity with a positive DAT does not necessarily indicate ABO hemolytic disease as many ABO incompatible, DAT positive neonates have no evidence of

ongoing hemolysis and do not develop early jaundice or hyperbilirubinemia. In order to support the diagnosis of ABO hemolytic disease, some or all of the following criteria are necessary:

- Indirect hyperbilirubinemia, especially during the first 24 hours of life
- Mother with blood group O, baby with blood group A or B
- Spherocytosis on blood smear
- Increased reticulocyte count
- Evidence of hemolysis based on increased endogenous production of CO. Unfortunately, a readily available clinical too for determining ETCOc levels is no longer available.

An interaction between DAT negative ABO incompatibility and polymorphism for the (TA)7 sequence in the promoter of the UDP-glucuronosyltransferase 1A1 (UGT1A1) gene, which encodes the corresponding bilirubin conjugating enzyme, has been described. Neonates who were both ABO incompatible as well as homozygous for the variant gene promoter had a significantly higher incidence of TSB ≥ 15.0 mg/dL (257 μmol/L) than counterparts not bearing this combination [51].

82.3.2.2 Clinical Manifestations of ABO Hemolytic Disease

Most blood group A or B neonates born to blood group O mothers will not develop any signs of hemolytic disease. Routine blood group and DAT determination on umbilical cord blood is an option, but not mandatory. It is essential to closely observe any newborn born to a blood group O mother for the development of jaundice. A TSB measurement should be performed at the first sign of visible jaundice. Phototherapy and exchange transfusions are indicated according to the 2004 AAP guidelines [22], using the lower level of TSB intended for newborns with risk factors. IVIG may be helpful in modifying the rate of rise of bilirubin and may be particularly useful in situations in which the TSB is approaching the indications for exchange transfusion, despite a trial of intense phototherapy. It is thought that IVIG blocks the Fc receptors in the reticuloendothelial system, thereby inhibiting hemolysis and limiting bilirubin formation.

82.3.3 Isoimmunization Due to Antibodies Other than RhD

More than 50 RBC antigens may cause hemolytic disease of the newborn [52]. The most important of these with regard to prenatal hemolysis and the need for intrauterine infection include anti-c, anti-Kell, and anti-E [53–55], although others may also, infrequently, be problematic. Alloimmunization due to these autoantibodies can sometimes cause severe hemolytic disease of the fetus requiring prenatal intervention. Fetal surveillance protocols and clinical strategies developed for Rh D alloimmunization are useful in monitoring all alloimmunized pregnancies. Similarly, the postnatal management should be based on the principles outlined in the management of the RhD-immunized newborn. Anti-Kell isoimmunization warrants special mention as fetal anemia often predominates the clinical picture. This may be due to erythropoietic suppression in addition to a hemolytic process [56].

82.4 Non-Immune Hemolytic Disease

82.4.1 Glucose-6-Phosphate Dehydrogenase (G6PD) Deficiency

G6PD deficiency is one of the most common enzyme deficiencies known and is estimated to affect hundreds of millions of people worldwide [57, 58]. Immigration patterns have transformed this condition from one limited to its indigenous distribution, including areas in south Europe, Africa, the Middle East, and Asia, to one which may now be encountered virtually in any corner of the globe. G6PD deficiency is a major factor in the pathogenesis of hyperbilirubinemia and is highly associated with extreme hyperbilirubinemia and kernicterus [59, 60]. The condition is overrepresented in a recent series of neonates with extreme hyperbilirubinemia and bilirubin encephalopathy, relative to the overall frequency of this condition in the United States, Canada, United Kingdom and Ireland [49, 50, 61]. For example, in the US-based Pilot Kernicterus Registry [49], over 20% of reported neonates had G6PD deficiency, whereas the overall frequency of G6PD deficiency in that country is estimated at less than 3% [58]. Because G6PD deficiency has major public health implications as far as the neonate is concerned, it will be discussed below in some detail.

82.4.1.1 Function of G6PD

G6PD plays a major part in stabilization of the RBC membrane. The enzyme catalyzes the first step in the hexose monophosphate pathway, oxidizing glucose-6-phosphate to 6-phosphogluconolactone, thereby reducing NAPD to NADPH. NADPH is essential for the regeneration of reduced glutathione from oxidized glutathione, a substance that plays an integral part in the body's antioxidative mechanisms. The pathway is also instrumental in stimulating catalase, another important antioxidant. In the absence of G6PD, NADPH will not become available, reduced glutathione will not be regenerated, and cells may be rendered susceptible to oxidative stress. The RBC is especially vulnerable to the G6PD deficiency state, as, unlike other body cells, no alternative source of NADPH is available in that cell. Oxidative membrane damage incurred may manifest as hemolysis [58].

82.4.1.2 Genetics of G6PD Deficiency

G6PD deficiency is an X-linked condition. Males may therefore be normal hemizygotes or deficient hemizygotes. Females may be either normal or deficient homozygotes, or heterozygotes. The most common mutations are G6PD A^-, found in Africa and southern Europe and in African Americans. G6PD Mediterranean, regarded as a more severe type than G6PD A^-, is encountered in Mediterranean countries, the Middle East and India. Another variant encountered primarily in Asia is G6PD Canton. Many other mutations have been documented [57].

82.4.1.3 G6PD Deficiency and Hemolysis

Most G6PD-deficient individuals will lead perfectly normal lives and for the most part be unaware of their inherited condition. However, G6PD deficiency is notoriously associated, in children and adults, with severe hemolytic episodes, associated with jaundice and anemia, which may occur following exposure to a hemolytic trigger. Classically, these episodes often occur following ingestion of or contact with the fava bean (favism). Beutler [57] has emphasized the role of infections in the pathogenesis of acute hemolysis.

The most extreme form of G6PD deficiency associated hemolytic jaundice in neonates is typified by acute and unpredictable onset of jaundice. Some identifiable substances which may trigger hemolysis include naphthalene used to store clothes, herbal medicines, henna applications, or menthol-containing umbilical potions. Frequently, however, no identifiable trigger can be found. Extreme jaundice may develop suddenly and with no prior warning, and the TSB concentration may increase exponentially to dangerous levels. G6PD deficiency may therefore by the one reason that kernicterus may not be completely preventable. The hemolysis may be severe and exchange transfusion may be the only recourse.

Frequently hematologic indices typical of hemolysis in older children and adults, including falling hemoglobin and hematocrit values and increasing reticulocyte count may be absent, despite a clinical picture of hemolysis. However, studies of endogenous CO formation, reflective of the rate of heme catabolism, have demonstrated an important role of increased hemolysis in association with this condition [62, 63]. Slusher et al [63] for example, demonstrated significantly higher levels of carboxyhemoglobin (COHb) in Nigerian G6PD-deficient neonates who developed kernicterus, compared with neonates who were hyperbilirubinemic, but did not develop signs of kernicterus.

More frequently and less life-threatening, G6PD-deficient neonates may have a more moderate form of jaundice. The incidence of this form of jaundice occurs at a rate several-fold over that of controls. The jaundice usually responds to phototherapy, although exchange transfusion may also be necessary. These infants have a low-grade hemolysis, which cannot be implicated as the primary icterogenic factor [64, 65]. Diminished bilirubin conjugation has been shown to be of major importance in the pathogenesis of the jaundice [66]. A intriguing interaction has been noted between G6PD deficiency and the non-coding area $(TA)_7$ promoter polymorphism in the gene encoding the bilirubin conjugating enzyme, UGT1A1 [67]. This polymorphism, also known as UGT1A1*28, is associated with Gilbert's syndrome. The incidence of hyperbilirubinemia, defined as a TSB ≥15.0 mg/dL (257 μmol/L), increased in a stepwise, dose-dependent fashion, in G6PD-deficient neonates who were either heterozygous or homozygous for the polymorphism. This effect was not seen in the G6PD-normal control group. Furthermore, G6PD deficiency alone, in the absence of the promoter polymorphism, did not increase the incidence of hyperbilirubinemia over and above that of G6PD-normal counterparts. In contrast, in Asians, in whom the (TA)7 polymorphism is rare, a similar interaction was noticed between G6PD deficiency and coding area mutations of the UGT1A1 gene [68].

Unlike the acute hemolytic form of jaundice, this milder form of jaundice can be predicted by predischarge TSB testing. Neonates who had a predischarge TSB concentration below the 50th percentile on the bilirubin nomogram [3] had a very small likelihood of subsequent hyperbilirubinemia. As the predischarge TSB increased above the 50th percentile, however, the chance of subsequent hyperbilirubinemia increased significantly [69].

82.4.1.4 Testing for G6PD Deficiency

Many qualitative or quantitative screening tests are available which should accurately determine the hemizygous state in males or the homozygous state in females. However, being an X-linked condition, a large section of the female population may comprise heterozygotes. Because of X-inactivation, heterozygotes have two RBC populations: G6PD-deficient, and G6PD-normal. Non-random X-inactivation may result in unequal ratios of normal and enzyme deficient RBCs. Heterozygotes may, as a result, have either a normal, intermediate or deficient phenotype rendering the heterozygote state difficult to determine using standard biochemical tests [70]. It was previously thought that heterozygotes had sufficient enzyme activity to protect them from the dangers of G6PD deficiency [58]. However, more recent reports suggest that heterozygotes may not be without risk [71–73]. Females of high risk groups should be closely followed-up according to the development of jaundice, a normal reading screen notwithstanding. Also, biochemical tests may give a falsely normal result if performed during an acute hemolytic episode, as older RBCs may be destroyed, leaving younger cells, with higher enzyme activity, intact [74]. In such cases, G6PD testing should be performed several weeks after the acute hemolysis has subsided. An alternate method is to analyze DNA for the specific suspected mutation.

Some countries have introduced neonatal screening for G6PD deficiency combined with parental education. There is

little data demonstrating whether screening will actually be instrumental in reducing the incidence of kernicterus. Parents of screened newborns and their medical attendants should, however, be made more aware of the condition by the screening process. Parental education should lead to avoidance of potentially offending substances. Hopefully, knowledge that an infant is G6PD-deficient should speed the process of evaluation and treatment of a jaundiced neonate.

The treatment of neonatal hyperbilirubinemia associated with G6PD deficiency should follow the guideline of the AAP [22] for neonates with hemolytic risk factors. In the event an infant presents with neurological signs commensurate with bilirubin encephalopathy, exchange transfusion should be immediately performed.

82.4.2 Pyruvate Kinase Deficiency

Pyruvate kinase catalyzes the conversion of phosphoenolpyruvate to pyruvate and the formation of adenosine triphosphate (ATP) from adenosine diphosphate in the Embden-Meyerhof pathway. Pyruvate kinase deficiency, a condition inherited in an autosomal recessive manner [75], results in a lack of ATP, an important source of energy for RBC metabolism [76]. As a result, in the newborn period, anemia, reticulocytosis, and severe jaundice may ensue. Exchange transfusion may be required. This RBC enzyme defect is much less frequently encountered than G6PD deficiency. Four isozymes are encoded by 2 genes, among which 180 mutations have been described [77]. Diagnosis is determined by enzyme assay, which should be performed in cases of hemolysis and hyperbilirubinemia not associated with a positive DAT or spherocytosis. Molecular studies may also confirm the diagnosis.

82.4.3 Hereditary Spherocytosis

Of the hereditary RBC membrane defects which may lead to acute hemolysis and hyperbilirubinemia in the newborn, hereditary spherocytosis is probably the most common [78, 79]. Hereditary spherocytosis is also one of the few causes of hyperbilirubinemia which does not resolve in the neonatal period. This condition may be inherited both in an autosomal dominant and recessive fashion, and frequently there may be a history of acute hyperbilirubinemia in a sibling or a parent. It is thought that protein deficiencies in the RBC membrane, including ankyrin, band 3, α-spectrin, β-spectrin, and protein 4.2, leave microscopic patches of the lipid bilayer inner surface bare of proteins, at which points microvesiculization occurs. These osmotically fragile RBCs are trapped in the spleen, the microvesicles aspirated by macrophages, and the cell destroyed. Hemolysis may result in jaundice, anemia, and splenomegaly. The diagnosis can be made microscopically by demonstrating spherocytes in the peripheral blood smear, with confirmation by the osmotic fragility test. The latter test may be especially important in differentiating babies with hereditary spherocytosis from those with DAT positive ABO isoimmunization, a condition that may also result in microspherocytosis. Mutations of at least 5 genes encoding the above-mentioned proteins have been recognized.

Hereditary spherocytosis is frequently associated with neonatal hyperbilirubinemia. Of 178 affected Italian, term, predominantly breastfed newborns, 112 (63%) developed neonatal hyperbilirubinemia requiring phototherapy. The incidence of hyperbilirubinemia was even higher in those who also had a genetic variation in the promoter of the bilirubin UGT1A1 gene, similar to that described in G6PD deficiency [78]. Kernicterus has been described [10]. Treatment comprises intense phototherapy with resort to exchange transfusion in cases unresponsive to light therapy. Splenectomy may become necessary later during childhood in order to control the anemia resulting from ongoing hemolysis.

82.4.4 Hereditary Elliptocytosis, Pyropoikilocytosis, Ovalocytosis, and Stomatocytosis

These are rare conditions affecting the erythrocyte membrane. The diagnosis may be made by microscopic examination of the peripheral blood smear. Hemolysis may occur in the neonatal period and result in anemia and hyperbilirubinemia.

82.4.5 Infection

Infection is often associated with pathologic unconjugated hyperbilirubinemia. The presence of infection also creates increased risk for injury caused by bilirubin, probably related to alterations in binding of bilirubin to albumin, but also through other mechanisms that may not be well-defined, related to the inflammatory process [80]. The likelihood of injury caused by bilirubin is increased for a given level of bilirubin in the presence of infection. Moreover, an infant is more likely to deviate from the normal trajectory of bilirubin levels because of increased bilirubin production in the presence of infection. The cause of this increased production may be hemolysis, but also upregulation of heme oxygenase (heat shock protein 32), which may respond to oxidative stress associated with the infected state.

82.5 Summary

In summary, pathologic unconjugated hyperbilirubinemia is best defined epidemiologically. Although some pathologic unconjugated hyperbilirubinemia can be understood in terms

of primary problems with uptake and conjugation, most pathologic unconjugated hyperbilirubinemia encountered by the pediatrician after birth and requiring treatment is associated with increased bilirubin production, often further exacerbated by environmental or acquired factors. Thus, a treatment strategy designed to modulate bilirubin production remains rational and potentially important, if a drug with the appropriate safety profile and efficacy is approved. Meanwhile, phototherapy is the mainstay of treatment and is reviewed in Chapter 84.

Kernicterus, Bilirubin Induced Neurological Dysfunction and New Treatments for Unconjugated Hyperbilirubinemia

Deirdre E. van Imhoff, Frans J.C. Cuperus, Peter H. Dijk, Claudio Tiribelli and Christian V. Hulzebos

83.1 Introduction

In the 19th century it was already known that unconjugated hyperbilirubinemia could potentially harm the central nervous system of jaundiced newborn infants. Yellow staining of deep brain nuclei in jaundiced infants was first reported in 1847. The term kernicterus (in German, *kern* = nucleus; in Greek, *ikterus* = yellow) was first denoted in 1903 to describe the pathological findings of this specific yellow staining pattern [1]. Nowadays, kernicterus is not only used to describe the pathological findings, but also to describe the clinical findings of acute and/or chronic bilirubin encephalopathy in jaundiced infants [2, 3]. Although acute kernicterus is an unambiguous clinical disorder in severely jaundiced newborn infants with the possibility of permanent sequelae, subtle forms of bilirubin encephalopathy referred to as bilirubin-induced neurological dysfunction, also known as BIND have evolved more recently [4]. This chapter aims to describe the pathophysiology of bilirubin neurotoxicity, its clinical spectrum and diagnostic tools. Novel treatment modalities to prevent infants from developing severe unconjugated hyperbilirubinemia and bilirubin neurotoxicity will be highlighted.

83.2 Pathophysiology – Risk Factors

The risk of kernicterus and BIND may be in part determined by the concentration of Total Serum Bilirubin (TSB), which in neonates consists almost exclusively of unconjugated bilirubin (UCB), but is primarily determined by the concentration of non-albumin bound free bilirubin (B_f). B_f can easily pass the blood-brain barrier, and may better reflect the bilirubin load distributed in the brain [5]. Several cellular mechanisms of the brain protect the brain against bilirubin accumulation. One of these protective regulating mechanisms is UCB export from the brain to the blood by multidrug resistance P-glycoprotein 1 (MDR1) and most importantly by the multidrug resistance-associated protein 1 (MRP1) [5, 6]. Data from *in vitro* and *in vivo* experiments have suggested that B_f, and not TSB, is the principal determinant of bilirubin neurotoxicity [7–9]. A number of pathophysiological factors are related to the variable clinical spectrum of bilirubin neurotoxicity. First, several mechanisms including necrosis and apoptosis are involved in bilirubin-induced neuronal damage, resulting in specific types of cellular damage and dysfunction [5, 6, 10]. Second, neural susceptibility to bilirubin neurotoxicity is not comparable in all cell types of the brain, neurons being more susceptible than glia cells with the exact mechanisms involved remaining speculative [5, 6, 10]. Third, the amount of UCB that enters the brain is dependent not only on the B_f concentration, but also on the intactness of the blood brain barrier. The B_f concentration in plasma is determined by the concentration of unconjugated bilirubin bound to albumin, at a specific plasma pH, in relation to the affinity of bilirubin to bind albumin. Conditions associated with low albumin concentrations, or with displacement of bilirubin from albumin (e.g., by sulfonamides or free fatty acids) increase B_f concentrations. Conditions that decrease intactness of the blood-brain barrier (e.g., hyperosmolality, hypercapnia, asphyxia, prematurity, infection, and sepsis) can result in a net increase of UCB uptake in the brain [4].

Multiple other factors (i.e., cerebral blood flow, vascular permeability, cellular efflux pumps and cellular recovery capacity) may affect the development of neurotoxicity at any given B_f concentration [6]. Some of these factors are incorporated as risk factors in management guidelines of jaundiced infants. Clinical evidence of most of these risk factors is limited. Most factors are based on anecdotal clinical evidence or theoretical and experimental animal data. Although imperfect, these factors are used by many clinicians to determine TSB thresholds before starting treatment [2, 3, 11–15]. The risk factors that increase the susceptibility for bilirubin neurotoxicity

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

Table 83.1 Risk factors used in addition to TSB to assess the risk of bilirubin neurotoxicity in the management of jaundiced infants

Risk factors
– Acidosis
– Asphyxia
– Hemolysis
– Hypothermia
– Hypoalbuminemia or less albumin available to bind bilirubin
– Intracranial hemorrhage
– Low birth weight
– Meningitis
– Prematurity
– Sepsis

and risk factors that predispose to develop hyperbilirubinemia are shown in Table 83.1. Risk assessment of bilirubin neurotoxicity for each individual newborn infant involves more than measurement of the TSB concentration, and appears to be a dynamic process affected by continuously changing individual conditions. Unfortunately, B_f cannot be routinely measured so that concentration of TSB and the currently used risk factors are the principle parameters that determine treatment thresholds.

83.3 Clinical Symptoms

The clinical spectrum of signs of bilirubin neurotoxicity relates to the bilirubin-induced damage to specific brain areas. Specific brain stem nuclei (auditory, vestibular and oculomotor), cerebellar Purkinje cells, basal ganglia (i.e., globus pallidus and subthalamus) and the hippocampus are particularly vulnerable to bilirubin neurotoxicity [6, 16]. In the initial phase, acute bilirubin encephalopathy is characterized by lethargy, hypotonia and poor sucking. In the second or intermediate phase, most commonly within 2–3 days after the initial phase, hypertonia (retrocollis, opistotonus), discomfort and irritability dominate. The infant may develop fever, a typical high-pitched cry, and seizures, which may alternate with drowsiness and hypotonia. Exchange transfusion at this stage might reverse the central nervous system damage in some cases. When left untreated, this second phase progresses into a more advanced stage characterized by pronounced retrocollis-opisthotonus, shrill cry, apnea, fever, sometimes seizures, deep stupor to coma and even death [3, 17]. Choreoathethosis, vertical gaze paralysis, auditory dysfunction, and dental dysplasia (Perlstein's tetrad) and motor delay are the most commonly described permanent neurologic sequelae in infants who survive the acute phase of kernicterus. Intelligence is usually normal in these infants [5, 17]. Less severe hyperbilirubinemia can result in subtle bilirubin encephalopathy referred to as "bilirubin-induced neurological dysfunction" (BIND) or as "bilirubin-associated neurological dysfunction" (BAND) [18]. Subtle permanent bilirubin encephalopathy can present with auditory dysfunction and/or mild neurologic abnormalities such as mild impairment in neurologic and/or cognitive performance [4, 19]. Involvement of the auditory nervous system dysfunction may result in sensorineuronal hearing loss or deafness. Alternatively, auditory dysfunction referred to as auditory neuropathy (AN) or auditory dys-synchrony (AD) may occur. AN/AD is defined as a normal neurophysiological test of the inner ear, i.e., normal cochlear microphonic responses and otoacoustic emissions, but an abnormal or absent auditory brainstem response (ABR) resulting in abnormal sound processing. AN/AD is clinically characterized by problems in sound localization and speech discrimination. Hearing loss is not present per se and a normal audiogram is often seen [4].

Several studies have evaluated effects of moderate and severe degees of hyperbilirubinemia with respect to neurodevelopmental outcome in later childhood [20]. Considering the differences in incidence and severity of neurologic dysfunction in infants with a comparable severity of neonatal hyperbilirubinemia, it seems impossible to predict outcome by TSB levels in jaundiced newborn infants. In general, preterm infants and infants suffering hemolytic disease seem to have an increased risk of neurologic sequelae of neonatal hyperbilirubinemia [20]. Isolated movement disorders such as athetosis or distonia are sometimes seen and in a retrospective analysis of extremely low birth weight infants a significant association between peak concentrations of TSB during the first two weeks of life and neurodevelopmental impairment was found [4, 17, 19, 21, 22].

83.4 Epidemiology

In the past century, kernicterus was almost exclusively seen in the context of high concentrations of TSB related to Rh hemolytic disease. When Rh disease became rare due to the introduction of Rh-immune globulin, and phototherapy appeared an effective treatment for unconjugated hyperbilirubinemia, the incidence of kernicterus decreased. Subsequently, treatment criteria were liberalized. As a combined result of the more liberal treatment criteria, a trend towards earlier hospital discharge (before the maximal TSB concentration is reached), and higher survival rate of preterm infants, kernicterus remains a serious threat for jaundiced newborn infants. Nowadays, the exact incidence of kernicterus and BIND is unknown. This is, at least in part, related to differences in the definition of severe hyperbilirubinemia and in methods of assessing neurodevelopmental outcome among studies. In a prospective study investigating severe hyperbilirubinemia (defined as maximum TSB >510 μmol/L) of the newborn in the UK, the incidence of bilirubin encephalopathy was ~ 1 case per 100,000 live births [23]. It is estimated that 1–3 per 100,000 live births are at risk of developing kernicterus when untreated and that 5–10% of infants surviving severe hyperbilirubinemia suffer permanent sequelae [6, 20].

83.5 Diagnosis

Current management guidelines for jaundiced infants are actually based on the total serum bilirubin (TSB) concentrations. Because exact neurotoxic TSB concentrations are unknown and risk factors for imminent bilirubin neurotoxicity are not evidence based, other diagnostic tools, in addition to TSB, may be valuable to detect imminent BIND in jaundiced newborn infants (Table 83.2).

To evaluate the risk of BIND, the history of the infant is important. Information about the gestational age, physical examination and the presence of risk factors for bilirubin neurotoxicity as well as the duration of the hyperbilirubinemic period, the presence of acute symptoms and whether the child has previously been treated or not is crucial data to diagnose BIND at a later age [24].

Although preliminary clinical series and *in vitro* data point to a correlation between B_f and BIND, the difficulty of clinically measuring B_f has prevented its introduction in clinical practice. Alternatively, the Bilirubin/Albumin ratio (B/A ratio) could be used as a surrogate parameter to indicate B_f concentrations [25, 26]. However, due to the presence of bilirubin displacers, i.e., drugs that interfere with the bilirubin-albumin binding, B_f may reach values much higher than suggested by the calculated B/A ratio. In addition, the individual variability in the binding affinity of the albumin for bilirubin should also be taken into account. Alternatively, other plasma constituents such as apolipoproteins may bind UCB, and decrease B_f. Consequently, the B/A ratio seems an imperfect surrogate to estimate B_f. It needs to be outlined however, that B_f may also be an imperfect predictor of bilirubin neurotoxicity, since many factors affect the development of bilirubin neurotoxicity at any given B_f level.

The theoretical considerations and clinical evidence for the concept that additional use of the B/A ratio, i.e., next to TSB, in jaundiced premature infants might improve the prediction of BIND has been recently reviewed. Although no prospective clinical trials exist, it is suggested that the additional use of the B/A ratio may be valuable in evaluating jaundiced premature infants [27–31]. A randomized controlled trial investigating the additional use of the B/A ratio in the treatment of hyperbilirubinemia in preterm infants (ISRCTN74465643) is underway and will hopefully provide the answer to this important question.

Table 83.2 Diagnostic tools to evaluate the severity of hyperbilirubinemia and/or risk of imminent bilirubin neurotoxicity

Diagnostic tool
Anamnestic
– History of hyperbilirubinemic period
– Treatment for neonatal hyperbilirubinemia
– Gestational age
– Risk factors present in hyperbilirubinemic period
– Symptoms of kernicterus during hyperbilirubinemic period
– Abnormal physical examination
Total serum bilirubin concentration
Free bilirubin concentration
Bilirubin/albumin ratio
Auditory brainstem response
Magnetic resonance imaging
BIND score

The possibility that biochemical markers, i.e., use of Tau and S100B protein concentrations, are useful in the diagnosis of bilirubin-induced neurotoxicity has been studied in hyperbilirubinemic newborn infants [32]. Tau is a microtubule-associated structural protein of central nervous system neurons. S100B protein, a neurotrophic factor, is synthesized in astroglial cells in the central nervous system and Schwann cells. Previous data showed increased Tau and S100B protein concentration in plasma and/or cerebrospinal fluid in patients with cerebral injury (e.g., hypoxia and trauma). In a prospective study of 92 hyperbilirubinemic non-asphyxiated infants, Tau and S100B protein concentration was positively correlated with TSB concentration. Tau and S100B concentration increased at TSB concentration above 327 μmol/L, as observed in 46 infants. At lower TSB concentrations, protein concentrations remained unchanged. Above a TSB concentration of 327 μmol/L, clinical symptoms of bilirubin encephalopathy (i.e., auditory neuropathy, minor neurologic dysfunction and electroencephalographic abnormalities) were present in 22 of 46 of the infants. Compared to TSB concentrations, measurement of Tau and S100B protein concentration did not improve sensitivity or specificity for any of the described clinical symptoms. The use of Tau and S100B protein concentration in the assessment of BIND is not recommended.

The neural auditory pathway is very susceptible to bilirubin toxicity putatively resulting in sensorineurinal hearing loss or auditory neuropathy also known as auditory dys-synchrony. A frequently used, non-invasive and very sensitive tool to determine bilirubin neurotoxicity, is the Auditory Brainstem Response (ABR), which allows for determination of electrophysiological activity of the neural auditory pathway. The ABR consists of a sequence of positive waves (numbered I–V) representing the auditory pathway from inner ear to brainstem. Wave I and II represent the peripheral auditory nerve and waves III–V represent the activity in the auditory centers at the brain stem level of the pathway (cochlear nucleus and lateral lemniscus, respectively) [33]. Bilirubin-induced ABR changes mainly involve waves III and V and may progress from reversible increased interwave latencies to the loss of wave amplitude. ABR changes can be transient, but may also progress into permanent wave changes or even loss of any recognizable wave [7, 27]. A bedside method to evaluate the intactness of the auditory pathway is the Automated Auditory Brainstem Response (AABR) with an ALGO hearing screening system (Natus Medical, San Carlos, CA, USA). AABR measurements are simplified ABR measurements and able to identify infants with abnormal cochlear or auditory function. A pass or refer result is shown on the ALGO machine for each ear of the infant. In an observational study of

191 patients of variable birth weight (406–4727 g) and variable gestational age (24–42 weeks), an abnormal ALGO result (bi-or unilateral refer) was associated with increased B_f concentrations and B_f/TSB ratios, but not with TSB concentrations alone [34].

Another tool to identify acute and chronic bilirubin neurotoxicity in jaundiced infants is Magnetic Resonance Imaging (MRI) [18]. MRI changes include bilateral hyperintensity of globus pallidus on T1-weighted scans in the early phase (first 3 weeks of life) and most commonly subtle but persistent pallidal hyperintensity, suggestive of permanent gliosis, on late T2-weighted scans (with disappearance of hyperintensity on T1-weighted scans). The subthalamic nucleus and hippocampus are affected less frequently (approximately 40% and 5% of reported cases, respectively). Bilateral damage of the globus pallidus and the subthalamic nucleus are specific signs of bilirubin neurotoxicity, which sometimes can also be visualized with ultrasonography, and is a key in the differentiation between hypoxic-ischemic encephalopathy or metabolic disorders, which predominantly affect the thalamus [30]. The additional value of MR spectroscopy to MRI is not completely clear, but acute changes in cerebral metabolism have been shown in bilirubin encephalopathy [35].

In 1999, a clinical scoring system was developed to evaluate the risk of exposure to unconjugated hyperbilirubinemia. Clinical signs of bilirubin encephalopathy include mental status, muscle tone and cry of the infant. Dependent on the level of abnormality, 0-3 points are obtained for each clinical sign, resulting in an overall score between 0 and 9, representing no toxicity or advanced toxicity, respectively. Validation of this scoring system is in progress [36, 37].

83.6 Treatment

To identify newborns at risk for severe hyperbilirubinemia and to prevent bilirubin neurotoxicity, guidelines have been developed for the management of jaundiced infants. The American Academy of Pediatrics' Subcommittee on Hyperbilirubinemia adapted a guideline for hyperbilirubinemic infants of 35 or more weeks of gestation in 2004 [3].

Currently, this guideline is adapted by many countries worldwide for the management of jaundiced "near-term" and term newborn infants. However, international guidelines for preterm infants are lacking and rather local or national guidelines for preterm infants are used, such as the consensus-based guideline on hyperbilirubinemia for preterm infants of 35 or less weeks of gestational age in The Netherlands (www.neonatologiestudies.nl/main/richtlijnen) [38].

Few prospective studies have analyzed effects of different TSB-thresholds on long-term outcome (Table 83.3). In a group of 95 low birth weight infants, hyperbilirubinemia was treated either with prophylactic phototherapy (starting 12 hours after birth, n = 46) or conservative phototherapy (starting at fixed TSB threshold concentrations of 150 μmol/L, n = 49). The maximum TSB concentrations were comparable in both groups, but in a subgroup of extreme low birth weight infants (ELBW, < 1000 g), the maximum TSB concentrations were significantly higher in the conservative group (171 μmol/L versus 139 μmol/L, conservative versus prophylactic treatment) with a concomitant higher incidence of cerebral palsy. However, since the study was not originally powered for this outcome, it failed to demonstrate significant differences in long-term neurodevelopmental outcome [39]. Another randomized controlled trial assigned 1974 ELBW preterm infants to a prophylactic phototherapy group (started immediately postnatal) or a conservative phototherapy group (based on predefined TSB threshold concentrations: 137 μmol/L for infants weighing 501–750 g and 171 μmol/L for infants weighing 751–1000 g). The primary outcome of this study was a combination of neurodevelopmental impairment (defined as blindness, severe hearing loss, moderate of severe cerebral palsy, or a score below 70 on the mental or psychomotor developmental index of the Bayley Scale of Infant Development II) or death. In this

Table 83.3 Long-term outcome of randomized controlled trials on TSB thresholds

Author/Year	Population	Phototherapy		Long-term outcome
		Prophylactic	Conservative	
Morris, 2008 [40]	ELBW infants (<1000 g) n = 1974	Direct postnatally	TSB threshold 137 μmol/L (501–750 g) or 171 μmol/L (751–1000 g)	No significant difference for the combination of death or neurological impairment. Prophylactic phototherapy reduced the risk of neurodevelopmental impairment (RR = 0.86, 95% CI: 0.74–0.99) Non-significant higher mortality among infants of 501–750 g (RR = 1.13, 95% CI: 0.96–1.34)
Jangaard, 2007 [39]	LBW infants (<1500 g) n = 95	12 hours postnatally	TSB threshold 150 μmol/L	Non-significant increase in cerebral palsy and death in a subgroup of ELBW infants (<1000 g) in the conservative group

ELBW extreme low birth weight, i.e., birth weight less than 1000 g; *LBW* low birth weight, i.e., birth weight less than 1500 g, *RR* relative risk, *CI* confidence intervals, 17.1 μmol/L = 1 mg/dL bilirubin.

study, maximum TSB concentrations were significantly higher in the conservative group: 168 μmol/L versus 120 μmol/L in the prophylactic group. Prophylactic phototherapy significantly reduced the risk of neurodevelopmental impairment (relative risk [95% confidence intervals]: 0.86 [0.74–0.99]). This benefit of prophylactic phototherapy seems questionable for infants with a birth weight of 501–750 g, because in this group a non-significant trend of increased mortality was found [40].

83.7 New Treatments for Unconjugated Hyperbilirubinemia

Conventional treatment for severe unconjugated hyperbilirubinemia consists of phototherapy and exchange transfusion. Although phototherapy is considered effective and safe, it does not always prevent toxic accumulation of bilirubin in neonates. Long-term phototherapy, as required by Crigler-Najjar patients, may take up to 16 hours per day and becomes less effective with age. In spite of this intensive treatment regimen, approximately 30% of the patients with Crigler-Najjar disease type I develop mild to severe brain damage. In addition, patients still die resulting from complications related to the disease [41]. Exchange transfusion should be considered if phototherapy fails to decrease plasma bilirubin below toxic levels. This "rescue-treatment" however, is associated with a significant morbidity in sick newborns, and even mortality has been reported. These considerations have prompted investigators to develop alternative treatments for unconjugated hyperbilirubinemia [42]. Most of these treatments are still in an experimental phase. Nevertheless, it is highly conceivable that some of them will find their way into clinical practice in the foreseeable future.

83.7.1 Treatments that Decrease the Production of Bilirubin

Treatments that decrease the production of bilirubin could actually prevent unconjugated hyperbilirubinemia, which would be a more rational strategy compared with removing bilirubin that is already accumulated in the body (see Chapter 84). Bilirubin is produced in the macrophages of the reticuloendothelial system. These macophages contain two essential enzymes: heme oxygenase (HO) and biliverdin reductase. Heme oxygenase converts heme, the source of bilirubin, into blue-green biliverdin. Biliverdin reductase then converts biliverdin into bilirubin. Consequently, bilirubin production can be decreased by agents that inhibit HO, and/or biliverdin reductase (Fig. 83.1). Several agents have been developed to inhibit these enzymes such as the metalloporphyrins [43, 44]. Metalloporphyrins compete with heme for HO binding sites resulting in a competitive inhibition of HO and in a decreased conversion of heme into biliverdin. Currently, tin-mesoporphyrin is the most evaluated metalloporphyrin in humans. In the 8 clinical trials so far conducted, it was demonstrated that this agent mitigates unconjugated hyperbilirubinemia due to ABO incompatibility and prematurity. Also, the use of tin-mesoporhyrin replaced the need for phototherapy in glucose-6-phosphate dehydrogenase deficient newborns. Tin-mesoporphyrin thus seems a highly promising new treatment strategy for unconjugated hyperbilirubinemia. Currently, however, metalloporhyrins cannot be recommended for routine treatment of unconjugated hyperbilirubinemia due to insufficient evidence regarding the long-term safety of these agents.

D-penicillamine, a chelating agent that is used in the treatment of Wilson's disease, is another HO-inhibitor (Fig. 83.1) [43]. The use of this agent decreased the number of exchange transfusions in infants with ABO-hemolytic disease, but its efficacy has only been evaluated in a single clinical trial. Curiously, inhibitors of biliverdin reductase have never been explored, most likely because the accumulation of biliverdin in the blood would produce green babies.

83.7.2 Treatments that Increase the Hepatic Clearance of Biliribin

Almost all bilirubin is excreted via the bile, and many therapies aim to enhance this excretory pathway by targeting the hepatic clearance of the bilirubin. Newly produced bilirubin enters the microcirculation of the liver from where it is extracted by the hepatocytes. In the hepatocyte, bilirubin is firstly bound to cytosolic ligandin, which prevents its diffusion back into the blood. The enzyme UDP-glucuronosyltransferase 1A1 (UGT1A1), which resides in the endoplasmatic reticulum of the hepatocytes, subsequently conjugates bilirubin with one or two glucuronic acid groups.

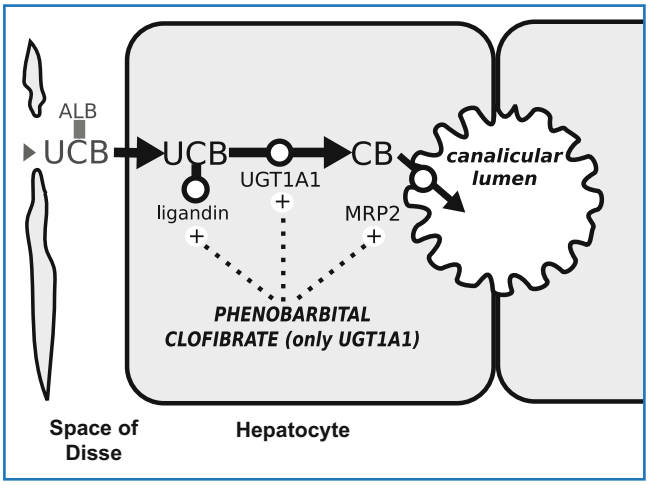

Fig. 83.2 Phenobarbital and clofibrate increase the hepatic clearance of bilirubin. *Alb* albumin, *UCB* unconjugated bilirubin, *UGT1A1* UDP-glucuronosyltransferase1A1. Reproduced from [43], with permission

This step increases the water solubility of the molecule and allows the now conjugated bilirubin to be excreted into the bile via the canalicular transporter MRP2. Several therapies target these 3 steps in bilirubin catabolism (Fig. 83.2). Clofibrate, a lipid-lowering drug, increases UGT1A1 activity (Fig. 83.2). This drug mitigated neonatal unconjugated hyperbilirubinemia in several clinical trials, and decreased the need for phototherapy if applied as add-on treatment. However, long-term clofibrate use is associated with an overall increase in non-cardiovascular mortality. Although short-term clofibrate treatment has not been shown to have serious adverse effects, its safety issues must be addressed before it could be considered for clinical use.

The most well-known agent that enhances hepatic bilirubin clearance is phenobarbital. This antiepileptic agent enhances ligandin, UGT1A1, and MRP2 activity (Fig. 83.2). Since the 1960s, phenobarbital has been used extensively in the treatment of neonatal jaundice. Numerous clinical trials have shown that administering phenobarbital to pregnant women or to newborns mitigates neonatal hyperbilirubinemia and decreases the number of exchange transfusions. Nevertheless, phenobarbital is currently not used as a routine treatment of neonatal jaundice. This is mainly because phototherapy is more effective, decline of TSB concentrations in infants treated with phenobarbital and phototherapy is not faster when compared to phototherapy alone, and because its therapeutic effect is not evident until a few days after administration, in contrast to some of the adverse effects (i.e., sedation) [43]. Phenobarbital is still applied in Crigler-Najjar type II patients, who have a 95% decrease in UDP-glucuronosyltransferase activity. In these patients phenobarbital is able to increase the residual enzyme activity, which effectively counteracts the development of severe unconjugated hyperbilirubinemia. Phenobarbital is not effective in the treatment of Crigler-Najjar type I, however, because these patients lack residual (e.g., inducible) UDP-glucuronosyltransferase activity.

The most effective treatment for Crigler-Najjar disease type I would be to repair or replace the defective UGT1A1 in the liver. Currently, this can only be achieved by a liver transplantation. In 1986 the first successful orthotopic liver transplantation (OLT) in a Crigler-Najjar patient was reported, and several other patients have undergone transplantation since.

Two types of transplantation have been used: OLT in which the patients' own liver is replaced by a donor liver, and auxiliary liver transplantation in which part of the own liver is left in situ and is supported by a donor graft. If successful, a liver transplant completely corrects the underlying metabolic defect, which dramatically improves the quality of life. Liver transplantation, however, remains a high-risk procedure, with a one-year survival between 85% and 90%. Infusion of hepatocytes with an unimpaired UGT1A1 activity into the liver of Crigler-Najjar patients would be an attractive alternative to a liver transplant. This procedure, which is known as hepatocyte transplantation, could partially restore enzyme activity without the many complications that are associated with a liver transplant. So far, 7 Crigler-Najjar type I patients have received this treatment, often with multiple infusions of hepatocytes (for example via the portal vein). Hepatocyte infusion, however, decreased plasma bilirubin levels only for a limited period of 5–6 months and did not eliminate the need for a liver transplant in these patients [45, 46]. Ultimately, gene therapy would be the most elegant method to repair or replace defective UGT1A1 within the hepatocytes of Crigler-Najjar type I patients. The results of gene therapy seem promising in animal models [47]. Currently, however, the results of ongoing clinical trials must be awaited before gene therapy can be applied in Crigler-Najjar patients.

83.7.3 Treatments that Decrease the Enterohepatic Circulation of Bilirubin

After conjugation, bilirubin enters the intestinal lumen via the bile. The intestinal conjugated bilirubin is subsequently mostly hydrolyzed to UCB, which can be reabsorbed into the enterohepatic circulation (Fig. 83.3a). The majority of this reabsorbed UCB, however, spills over into the systemic circulation due to the poor first pass extraction by the liver. Conditions that enhance this enterohepatic circulation contribute to the pathogenesis of unconjugated hyperbilirubinemia. For example, poor feeding in neonates is associated with increased plasma bilirubin levels most likely caused by a delayed gastrointestinal transit, which increases the amount of intestinal UCB available for reabsorption. Indeed, conditions that accelerate the gastrointestinal transit, such as early

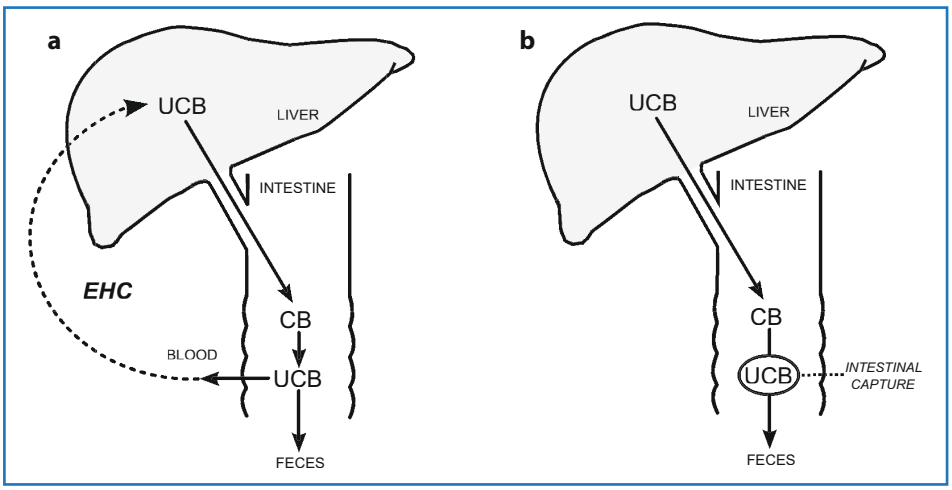

Fig. 83.3 **a** Normally, and especially in conditions that delay the intestinal transit, there is an enterohepatic circulation of unconjugated bilirubin which increases plasma bilirubin levels. **b** Binding unconjugated bilirubin to capture agents in the intestinal lumen may prevent this enterohepatic circulation and thus decrease plasma bilirubin levels. *UCB* unconjugated bilirubin *CB* conjugated bilirubin, *EHC* enterohepatic circulation. Reproduced from [43], with permission

and frequent feedings, seem to lower plasma bilirubin levels in newborn infants [48, 49]. Bilirubin reabsorption could also be prevented by agents that bind and capture the pigment within the intestinal lumen (Fig. 83.3b).

Several capturing strategies have so far been tested. Cholestyramine, a known binder of bile salts, and agar, a gelatinous substance derived form seaweed, decreased plasma bilirubin levels in hyperbilirubinemic rats, but was less effective in neonates. Treatment of neonates with activated charcoal effectively decreased plasma bilirubin levels, but only if it was administered within the first day of life. Charcoal, however, might also capture essential nutrients, which limits its clinical applicability [43]. Oral amorphous calcium phosphate did lower plasma bilirubin levels, but only in Crigler-Najjar type I patients. Calcium phosphate is currently used in a number of Dutch Crigler-Najjar type I patients as an adjunct to phototherapy if plasma unconjugated bilirubin levels become dangerously elevated. Orlistat, a lipase inhibitor, increases the intestinal fat content, which is hypothesized to capture the lipohilic unconjugated bilirubin. Orlistat has been shown to lower plasma bilirubin levels in a trial with Crigler-Najjar patients, but the decrease was considered clinically relevant (i.e., >10%) in only 7 of 16 patients. Zinc salts are also well-known binders of unconjugated bilirubin, and moderately decreased plasma bilirubin levels in patients with Gilbert's syndrome [43]. This inherited condition is characterized by a chronic, mild unconjugated hyperbilirubinemia related to diminished hepatic UGT1A1 expression. Administration of zinc salts, however, may lead to increased zinc levels in plasma, which may limit their clinical use.

83.8 Future Prospective

As indicated above, the molecular events leading to BIND are still partially undefined, as the criteria are not fully described to define BIND when the damage may be successfully treatable. It is therefore necessary to approach this increasingly present damage in a more translational way linking *in vitro* with *in vivo* models. This will hopefully provide hints on an effective prevention of the neurological damage in addition to the established phototherapy. To this end we need to better understand how unconjugated, free bilirubin may enter the cell and how the cells handle this potentially toxic substance. We know that MRP1 may extrude UCB from cells but data obtained *in vitro* suggest that the activity of this ABC transporter is not the only player in reducing UCB cytotoxicity. Intracellular oxidation of UCB may be an additional mechanism that needs to be assessed, as pharmacological inducers of oxidizing pathways are available. Also it is still unknown why UCB accumulates and damages only certain regions of the brain. Understanding this unexplained uneven distribution will unravel the background for regional sensitivity. Collectively these data will hopefully allow the definition of more effective treatments not only for the newborns but also for patients with Crigler-Najjar type I.

Treatment of Hyperbilirubinemia

M. Jeffrey Maisels and Jon F. Watchko

84.1 Introduction

The indications for the treatment of hyperbilirubinemia and the methods used for treatment vary according to the individual circumstances. Thus, treatment of hyperbilirubinemia can be prophylactic, when the purpose is to prevent further increase in the total serum bilirubin (TSB) level, or therapeutic, where the objective is to rapidly decrease a TSB level that is a threat to the infant. In some units, phototherapy is initiated soon after birth in all infants whose birth weight is <1000 g, irrespective of the TSB level. The TSB level can be lowered (or prevented from increasing further) in one of three ways: a) exchange transfusion, which removes bilirubin mechanically; b) phototherapy, which converts bilirubin to products that can bypass the liver's conjugating system and be excreted in the bile or the urine without further metabolism and c) pharmacologic agents that interfere with heme degradation and bilirubin production, accelerate the normal metabolic pathways for bilirubin clearance, or inhibit the enterohepatic circulation of bilirubin.

Table 84.1 Guidelines for the use of phototherapy and exchange transfusion in low birthweight infants based on birth weight

	Total bilirubin level *			
Birth weight	Phototherapy †		Exchange transfusion ‡	
(g)	mg/dL	μmol/L	mg/dL	μmol/L
<1500	5–8	85–140	13–16	220–275
1500–1999	8–12	140–200	16–18	275–300
2000–2499	11–14	190–240	18–20	300–340

Note that these guidelines reflect ranges used in neonatal intensive care units. They cannot take into account all possible situations. Lower bilirubin concentrations should be used for infants who are sick – for example, presence of sepsis, acidosis, hypoalbuminemia – or have hemolytic disease.

* Consider initiating treatment of these levels. Range allows discretion based on clinical conditions or other circumstances. Note that bilirubin levels refer to total serum bilirubin concentrations. Direct reacting or conjugated bilirubin levels should not be subtracted from the total.

† Used at these levels and in therapeutic doses, phototherapy should, with few exceptions, eliminate the need for exchange transfusions.

‡ Levels for exchange transfusion assume that bilirubin continues to rise or remains at these levels despite intensive phototherapy.
From [86], with permission.

84.2 Using Phototherapy and Exchange Transfusion to Prevent Kernicterus and/or Neurodevelopmental Impairment

A selection of recommendations and guidelines for the use of phototherapy and exchange transfusion in term, late preterm and preterm infants are provided in Tables 84.1–84.3 and Figs. 84.1 and 84.2. These recommendations vary, and are based, primarily, on the TSB levels, but also on gestation, birth

Table 84.2 Guidelines for use of phototherapy and exchange transfusion in preterm infants based on gestational age

	Total bilirubin level					
GA	Phototherapy		Exchange transfusion			
			Sick*		Well	
(weeks)	mg/dL	μmol/L	mg/dL	μmol/L	mg/dL	μmol/L

* Risk factors: Apgar < 3 at five minutes; PaO_2 < 40 mmHg ≥ 2 h; pH ≤ 7.15 ≥ 1h; birth weight < 1000g; hemolysis; clinical or central nervous system deterioration; total protein ≤ 4 g/dL or albumin ≤ 2.5 g/dL. B/A ratio, Bilirubin/albumin ratio. From [21], with permission.

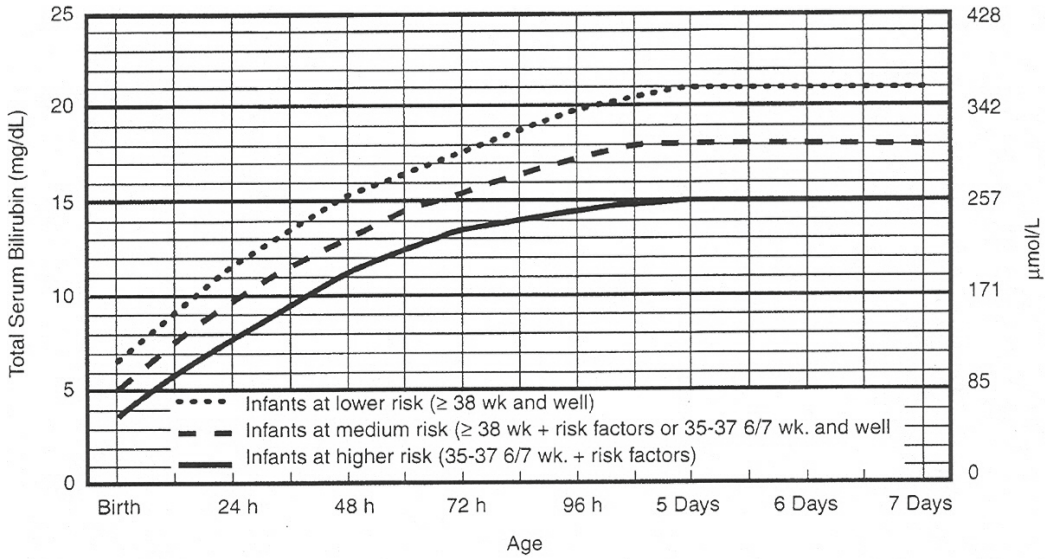

Fig. 84.1 Guidelines for phototherapy in hospitalized infants of 35 or more weeks' gestation. From [22], with permission.
– Use total bilirubin. Do not subtract direct reading or conjugated bilirubin.
– The lines for lower, medium and higher risk refer to risk for neurotoxicity.
– Risk factors for neurotoxicity – isoimmune hemolytic disease. G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis or albumin < 3.0 g/dL (if measured).
– For well infants 35–37 6/7 wk can adjust TSB levels for intervention around the medium risk line. It is an option to intervene at lower TSB levels for infants closer to 35 wks and at higher TSB levels for those closer to 37 6/7 wk.
– It is an option to provide conventional phototherapy in hospital or at home at TSB levels 2–3 mg/dL (35–50 mmol/L) below those shown but home phototherapy should not be used in any infant with risk factors.

These guidelines refer to the use of intensive phototherapy, which should be used when the TSB exceeds the line indicated for each category. Infants are designated as "higher risk" because of the potential negative effects of the conditions listed on albumin binding of bilirubin [24–26], the blood-brain barrier [82], and the susceptibility of the brain cells to damage by bilirubin [82].

Intensive phototherapy implies irradiance in the blue-green spectrum (wavelengths of approximately 430–490 nm) of at least 30 $\mu W/cm^2$ per nm (measured at the infant's skin directly below the center of the phototherapy unit) and delivered to as much of the infant's surface area as possible. Note that irradiance measured below the center of the light source is much greater than that measured at the periphery. Measurements should be made with a spectroradiometer specified by the manufacturer of the phototherapy system.

If the total serum bilirubin does not decrease or continues to rise in an infant who is receiving intensive phototherapy, this strongly suggests the presence of hemolysis. From [22], with permission.

weight, bilirubin/albumin ratios, and risk factors that increase the risk of bilirubin encephalopathy. Thus intervention at lower TSB levels is recommended in more premature infants and for those in whom risk factors for bilirubin-induced brain damage are present. It would be ideal if these guidelines were the product of evidence-based estimates of when the benefit of these interventions exceeded their risks and costs. Such estimates should come from randomized trials or high quality, systematic observational studies, but these studies are rare [1, 2]. Treatment guidelines must, therefore, rely on relatively

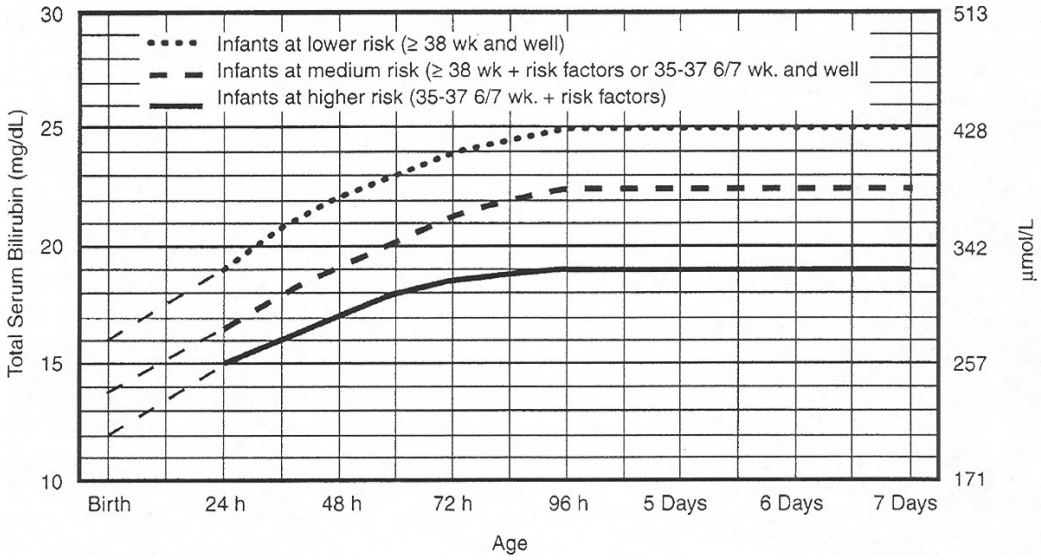

Fig. 84.2 Guidelines for exchange transfusion in infants 35 or more weeks' gestation. From [22], with permission.
- The dashed lines for the first 24 hours indicate uncertainty due to a wide range of clinical circumstances and a range of responses to phototherapy.
- Immediate exchange transfusion is recommended if infant shows signs of acute bilirubin encephalopathy (hypertonia, arching, retrocollis, opisthotonos, fever, high pitched cry) or if TSB is ≥ 5 mg/dL (85 μmol/L) above these lines.
- The lines for lower, medium, and higher risk refer to risk for neurotoxicity.
- Risk factors for neurotoxicity - isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis.
- Measure serum albumin and calculate B/A ratio (see legend).
- Use total bilirubin. Do not subtract direct reacting or conjugated bilirubin.
- If infant is well and 35–37 6/7 wk (median risk) can individualize TSB levels for exchange based on actual gestational age.

During birth hospitalization, exchange transfusion is recommended if the TSB rises to these levels despite intensive phototherapy. For readmitted infants, if the TSB level is above the exchange level, repeat TSB measurement every 2–3 hours and consider exchange if the TSB remains above the levels indicated after intensive phototherapy for 6 hours.

The following B/A ratios can be used together with but in not in lieu of the TSB level as an additional factor in determining the need for exchange transfusion. From [22], with permission.

Risk Category	B/A ratio at which exchange transfusion should be considered	
	TSB mg/dL/Alb, g/dL	TSB μmol/L/Alb, μmol/L
Infants ≥ 38 0/7 wk	8.0	0.94
Infants 35 0/7–36 6/7 wk and well or ≥ 38 0/7 wk if higher risk or isoimmune hemolytic disease or G6PD deficiency	7.2	0.84
Infants 35 0/7–37 6/7 wk if higher risk or isoimmune hemolytic disease or G6PD deficiency	6.8	0.80

If the TSB is at or approaching the exchange level, send blood for immediate type and crossmatch. Blood for exchange transfusion is modified whole blood (red cells and plasma) crossmatched against the mother and compatible with the infant [84].

uncertain estimates of risks and benefits as well as the recognition that using a single TSB to predict long-term behavioral and developmental outcomes is not reliable and will lead to conflicting results [1, 2].

Although kernicterus has been reported in term and near-term infants at levels below 25 mg/dL [1], such outcomes are rare, and, if TSB levels meeting or exceeding the American Academy of Pediatrics (AAP) exchange transfusion criteria (Fig. 84.2) are treated promptly, the outcomes are generally benign [3, 4]. Setting thresholds for intervention in the premature neonate is more challenging. Framing of guidelines for the use of phototherapy and exchange transfusion in preterm infants (Tables 84.1–84.3) has been a capricious exercise at best, and one for which no claim of an "evidence-base" can be made [5]. These guidelines are provided by different experts, none of whom would make any claim for the greater validity of one approach versus another [5]. A recent report from the United Kingdom showing a remarkably wide range of treatment thresholds for phototherapy and exchange transfusions in premature neonates, further underscores this uncertainty [6].

Phototherapy is effective in lowering the circulating bilirubin or preventing it from rising further. Its main demonstrated value is that it reduces the need for exchange transfusion although recent evidence suggests that it might also have a role in reducing neurodevelopmental impairment in infants of extremely low birth weight (ELBW, ≤1000 g) [7]. After this chapter went to press, two additional guidelines were published for the treatment of the jaundiced newborn [88, 89].

84.3 Assessing the Risk of Kernicterus and Neurodevelopmental Impairment in Preterm Infants

Although the concept of low bilirubin kernicterus in sick, low birth weight infants has long been recognized, kernicterus continues to be reported in preterm infants at low bilirubin levels and in the absence of acute neurologic signs [8–10]. Recently, kernicterus was documented in 2 preterm infants, 31 and 34 weeks of gestation, neither of whom were acutely ill and whose TSB levels were 13.1 mg/dL (224 μmol/L) and 14.7 mg/dL (251 μmol/L) respectively. These reports renew concerns about low-bilirubin kernicterus in the premature infant [8,9].

Until quite recently, there were no large studies of ELBW infants looking at the association between peak TSB levels and neurodevelopmental outcome. A follow-up of 2575 ELBW infants showed an association between peak serum bilirubin and (a) death or neurodevelopmental impairment (odds ratio [OR] 1.068: 95% CI 1.03–1.11): (b) psychomotor developmental index (PDI) < 70 (OR 1.057: 95% CI 1.00–1.12) and (c) hearing impairment (OR 1.138: 95% CI 1.00–1.30) [11]. Some ELBW neonates have also developed athetoid cerebral palsy, and hearing loss [7], features similar to term infants with kernicterus [9] as well as MRI findings characteristic of chronic bilirubin encephalopathy [9, 12, 13].

84.3.1 Unbound or Free Bilirubin

Recognition that a peak TSB level, by itself, is a rather poor predictor of the likelihood of poor neurodevelopmental outcome or kernicterus, raises the question of whether we should be using measurements of unbound or "free" bilirubin (B_f) or the ratio of bilirubin to albumin (B/A) to predict hyperbilirubinemia risk [14, 15]. Most bilirubin in the circulation is bound to albumin and a relatively small fraction remains unbound. The concentration of B_f is believed to dictate the biologic effects of bilirubin in jaundiced newborns, including its neurotoxicity. Elevations of B_f have been associated with kernicterus in sick, preterm infants [16, 17]. In addition, elevated B_f concentrations are more closely associated than TSB with transient abnormalities in the brainstem auditory evoked potential (BAEP) in both term [18] and preterm [19] infants. Although in one study a B_f level of > 1.0 μg/dL predicted the presence or absence of neurotoxicity in preterm neonates with high sensitivity and specificity [17], there is no agreement about what constitutes the neurotoxic B_f threshold [20] i.e., the threshold at which B_f produces changes in cellular function culminating in permanent cell injury and cell death. In addition, clinical laboratory measurement of B_f is not generally available.

The ratio of bilirubin (mg/dL) to albumin (g/dL) does correlate with measured B_f in newborns [21] and has been used as an approximate surrogate for the measurement of B_f [21] and the AAP has endorsed this approach [22]. A randomized controlled trial in the Netherlands (the BARTrial) is testing the use of the B/A ratio in conjunction with the TSB to determine when phototherapy and/or exchange transfusion should be used and will evaluate neurodevelopmental outcome at 18–24 months corrected age [23]. It must be recognized, however, that albumin binding capacity varies significantly between newborns [21, 24], is impaired in sick infants [25–27] and increases with increasing gestational age [25, 28] and postnatal age [26, 27]. A recent study of VLBW infants from one National Institute of Child Health and Human Development (NICHD) Neonatal Network institution confirmed that bilirubin-binding capacity was lower and B_f higher in unstable versus stable neonates but did not report on longer term neurodevelopmental outcomes [29]. Follow-up in the phototherapy trial of 224 infants born in 1974–1976 with birth weights < 2000 g and evaluated at age 6 years, showed no relation between measures of bilirubin-albumin binding and IQ scores [30]. It will be instructive to see how measures of B_f correlate with short- and long-term outcomes in the NICHD Neonatal Network ELBW cohort and how the bilirubin to albumin ratio correlates with neurodevelopmental outcome in the BARTrial [23].

Crucially important in the measurement of B_f is the bilirubin-albumin binding constant k, a term whose numeric value may actually vary considerably depending on conditions including among other factors, sample dilution, albumin concentration, and the presence of competing compounds [14, 15, 20]. Moreover, the risk of bilirubin encephalopathy is likely not simply a function of the B_f concentration alone or TSB level but a combination of both, i.e., the total amount of bilirubin available (the miscible pool of bilirubin) as well as the tendency of bilirubin to enter the tissue (the B_f concentration) [21].

An additional factor is the susceptibility of the cells of the central nervous system to damage by bilirubin [31, 32]. The B/A ratio can therefore be used together with, but not in lieu of, the TSB level as an additional factor in determining the need for exchange transfusion [21] (Table 84.3, Fig. 84.2). Clarifying and defining clinically germane B_f concentrations, bilirubin to albumin ratios, exposure conditions, and exposure durations, as well as improving, standardizing, and validating B_f measurements are important lines of clinical and translational research.

Table 84.4 Criteria for initiating phototherapy and exchange transfusions in the NICHD Neonatal Research Network Trial [7]

Birth weight	Aggressive management			Conservative management			
	Phototherapy begins	Exchange transfusion		Phototherapy begins		Exchange transfusion	
		mg/dL	μmol/L	mg/dL	μmol/L	mg/dL	μmol/L
501–750 g	ASAP after enrollment	≥13.0	≥222	≥8.0	≥137	≥13.0	≥257
751–1000 g	ASAP after enrollment	≥15.0	≥257	≥10.0	≥171	≥15.0	≥257

Enrollment is expected within the period 12–36 hours after birth, preferably between 12 and 24 hours.

84.3.2 Aggressive Versus Conservative Management of Infants with Birth Weights ≤1000 g

The NICHD Neonatal Research Network conducted a randomized controlled trial of "aggressive *vs* conservative" phototherapy in 1974 infants who were followed to age 18–20 months of corrected age [7]. The protocol for this study is shown in Table 84.4. Compared with conservative phototherapy, aggressive phototherapy did not reduce the primary outcome of death or neurodevelopmental impairment but, in surviving infants, did reduce the rates of (a) neurodevelopmental impairment (relative risk [RR] 0.86: 95% CI 0.74–0.99), (b) hearing loss (RR 0.32: 95% CI 0.15–0.68), mental development index score <70 (RR 0.83: 95% CI 0.71–0.98) and athetosis (RR 0.20: 95% CI 0.04–0.90). The reduction in neurodevelopmental impairment was attributable almost entirely to a decrease in infants with profound impairment in the aggressive phototherapy group (RR 0.68: 95% CI 0.52–0.89). The mean TSB levels were lower in the aggressive group (4.7 ± 1.1 mg/dL [80.4 ± 19 μmol/L]) than the conservative group (6.2 ± 1.5 mg/dL [106 ± 26 μmol/L]) and, although these differences were statistically significant ($p < 0.001$) it is surprising that this small difference was associated with a difference in outcome. On the other hand, the mean TSB levels in the surviving impaired and unimpaired infants were identical (5.4 mg/dL [92 μmol/L]) although the mean peak TSB was marginally higher in the impaired cohort (8.6 ± 2.3 mg/dL [147 ± 39 μmol/L] versus 8.3 ± 2.3 mg/dL [142 ± 39 μmol/L], $p = 0.02$).

It was noteworthy, however, that there was a 5% increase in mortality in infants with birth weights of 501–750 g who received aggressive phototherapy. This was not statistically significant, but a post-hoc Bayesian analysis estimated an 89% probability that aggressive phototherapy increased the rate of death in this subgroup. It is unclear why phototherapy might increase mortality in these tiny infants but it is likely that light penetrates more deeply through the thin, gelatinous skin, reaching the subcutaneous tissues and possibly producing oxidative injury to cell membranes [33].

What should neonatologists do with this information? In many units, phototherapy is initiated in ELBW neonates when their TSB reaches 5 mg/dL (86 μmol/L). As the TSB at the start of phototherapy in the aggressive group was 4.8 mg/dL (82 μmol/L), instituting phototherapy at a TSB of 5 mg/dL (86 μmol/L) will likely have a similar effect on TSB levels as does prophylactic phototherapy initiated in every infant soon after birth. When one combines these data with the previous observations from the NICHD Neonatal Research Network [11], it appears that modest elevations of TSB in these tiny babies are potentially harmful and, when used in a manner similar to that employed in this study, phototherapy could help to reduce long-term neurodevelopmental impairment. From the total population of 1974 infants only 5 (0.25%) required an exchange transfusion.

84.4 Phototherapy

Phototherapy uses visible light energy to change the shape and structure of bilirubin, converting it to molecules that can be excreted even when normal conjugation is deficient. Light provides an infusion of discrete photons of energy that correspond to the individual molecules of a drug in a conventional medication. Absorption of these photons by bilirubin molecules in the skin leads to a therapeutic effect in much the same way as binding of drug molecules to a receptor has a desired effect. Fig. 84.3 provides a detailed description of how phototherapy works. The relative contributions of the various reactions (Fig. 84.3) to the overall elimination of bilirubin are unknown, although *in vitro* and *in vivo* studies suggest that photoisomerization is more important than photodegradation [34]. Bilirubin elimination depends on the rates of formation as well as the rates of clearance of the photo products. Photoisomerization occurs rapidly during phototherapy, and isomers appear in the blood long before the level of plasma bilirubin begins to decline. The radiometric quantities used and the important factors that influence the dose and efficacy of phototherapy are listed in Tables 84.5 and 84.6 and illustrated in Fig. 84.4. A common misconception is that ultraviolet (UV) light (< 400 nm) is used for phototherapy. Phototherapy lights in current use do not emit significant erythemal UV radiation. In addition, the glass of the fluorescent tube, the plastic cover of the lamp and, in the case of preterm infants, the incubator, filter out UV light.

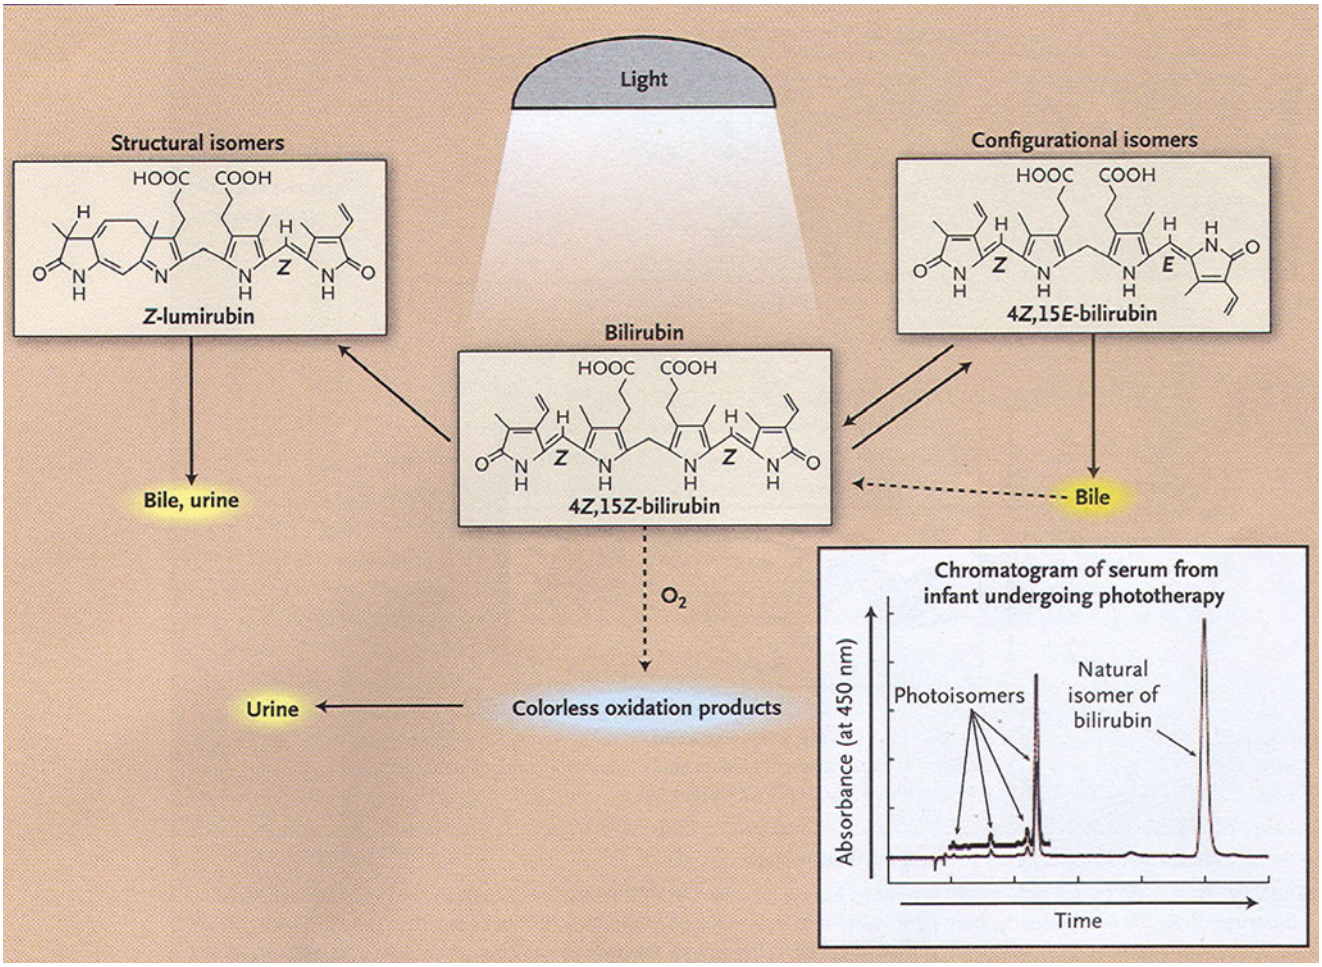

Fig. 84.3 Mechanism of phototherapy. The absorption of light by the normal form of bilirubin (4*Z*,15*Z*-bilirubin) generates fleeting transient excited-state bilirubin molecules. These fleeting intermediates can react with oxygen to produce colorless products of lower molecular weight, or they can undergo rearrangement to become structural isomers (lumirubins) or configurational isomers in which the configuration of at least one of the two *Z*-configuration double bonds has changed to an *E*-configuration. (*Z* and *E*, from the German *zusammen* (together) and *entgegen* (opposite), respectively, are prefixes used for designating the stereochemistry around a double bond. The prefixes 4 and 15 designate double-bond positions). Only the two principal photoisomers formed in humans are shown. The photoisomers are less lipophilic than the 4*Z*,15*Z* form of bilirubin and can be excreted unchanged in bile without undergoing glucuronidation. Lumirubin isomers can also be excreted in urine. Photooxidation products are excreted mainly in urine. Once in bile, configurational isomers revert spontaneously to the 4*Z*,15*Z* form of bilirubin. Configurational isomerization is reversible and much faster than structural isomerization, but the clearance of the 4*Z*,15*E* isomer is slow. Structural isomerization is irreversible and lumirubin is cleared more rapidly and makes the major contribution to overall bilirubin elimination. Both configurational and structural isomerization occur much more quickly than photooxidation. The graph, a high-performance liquid chromatogram of serum from an infant undergoing phototherapy, shows the presence of several photoisomers in addition to the 4*Z*,15*Z* isomer. Photoisomers are also detectable in the blood of healthy adults after sunbathing. From [85], with permission

84.4.1 Clinical Use and Efficacy of Phototherapy

The factors that influence the dose and efficacy of phototherapy are listed in Table 84.6 and illustrated in Fig. 84.4. There is a clear dose-response relationship between the irradiance (energy output of the phototherapy device) delivered to the infant and the rate of decline in the TSB [35] (Fig. 84.5). It is, therefore, important to perform regular measurements of the irradiance with a radiometer or spectroradiometer. Special blue fluorescent lamps or light-emitting diode (LED) lights have been found to be effective in clinical studies [36, 37] and will deliver 30–40 $\mu W/cm^2/nm$ in the 430–490 nm band.

Commonly used phototherapy units include those that contain daylight, white, or blue fluorescent tubes, halogen lamps, and light emitting diodes (LED). When the TSB approaches the range at which exchange transfusion is considered, intensive phototherapy is recommended [22]. The AAP defines intensive phototherapy as the use of high levels of

Table 84.5 Radiometric quantities used in phototherapy

Quantity	Dimensions	Usual units of measure
Irradiance (radiant power incident on a surface per unit area of the surface)	W/m^2	W/cm^2
Spectral irradiance (irradiance in a certain wavelength band)	W/m^2 per nm (or W/m^2)	$\mu W/cm^2$ per nm

From [74] with permission.

Table 84.6 Factors that affect the dose and efficacy of phototherapy

Factor	Technical terminology	Rationale	Clinical application
Type of light source	Spectrum of light (nm)	Blue-green spectrum is most effective at lowering total serum bilirubin (TSB); light at this wavelength penetrates skin well and is absorbed strongly by bilirubin	Use special blue fluorescent tubes or light-emitting diodes (LED) or another light source with output in blue-green spectrum for intensive phototherapy (PT)
Distance of light source from patient	Spectral irradiance (a function of both distance and light source) delivered to surface of infant	↑ irradiance leads to ↑ rate of decline in TSB. Standard PT units deliver 8–10 $\mu W/cm^2/nm$; intensive PT delivers ≥30 $\mu W/cm^2/nm$	If special blue fluorescent tubes are used, bring tubes as close as possible to infant to increase irradiance. (Do NOT do this with halogen lamps because of danger of burn.) Positioning special blue tubes 10–15 cm above infant will produce an irradiance of at least 35 $\mu W/cm^2/nm$
Surface area exposed	Spectral power (a function of spectral irradiance and surface area)	↑ surface area exposed leads to ↑ rate of decline in TSB	For intensive PT, expose maximum surface area of infant to PT. Place lights above and below* or around † the infant. For maximum exposure, line sides of bassinet, warmer bed, or incubator with aluminum foil
Cause of jaundice		Phototherapy (PT) is likely to be less effective if jaundice is caused by hemolysis or if cholestasis is present (direct bilirubin is increased)	When hemolysis is present, start PT at a lower TSB level and use intensive PT. Failure of PT suggests hemolysis is cause of the jaundice. When direct bilirubin is elevated, watch for bronze baby syndrome or blistering
TSB level at start of PT		The higher the TSB, the more rapid the decline in TSB with PT	Use intensive PT for higher TSB levels. Anticipate a more rapid decrease in TSB when TSB > 20 mg/dL

* Commercially available sources for light below include special blue fluorescent tubes available in the Olypmpic Bili-Bassinet (Natus Medical, San Carlos, CA) the BiliSoft Fiberoptic /LED mattress (GE Healthcare, Wauwatosa, WI), NeoBlue cozy mattress (Natus Medical Inc., San Carlos, CA).

† The Mediprema Cradle 360 (Mediprema, Tours Cedex, France) provides 360º exposure to special blue fluorescent light.

irradiance in the 430 to 490 nm band (usually 30 $\mu W/cm^2$ per nm or higher) delivered to as much of the infant's surface area as possible [22]. Thus, it is particularly important to use lamps that have an emission within the 430–490 nm band. Increasing the surface area of the infant exposed to light significantly increases the efficacy of phototherapy and can be achieved by placing additional sources of light below or around the infant (see Table 84.6 for details of some commercially available equipment) [38–40]. A simple method of increasing the area exposed is to place some reflecting material such as a white sheet or aluminum foil within or around the bassinette or incubator [40].

Because phototherapy acts on bilirubin that is present in the extra vascular space as well as in the superficial capillaries, it has become a common practice to turn the infant at intervals from supine to prone and back. Two randomized studies show that turning infants every few hours does not improve the efficacy of phototherapy [41, 42].

84.4.2 Phototherapy to Prevent an Exchange Transfusion

As the primary purpose of phototherapy is to prevent the need for an exchange transfusion, it is useful to know how many infants need to be treated with phototherapy in order to prevent one exchange transfusion.

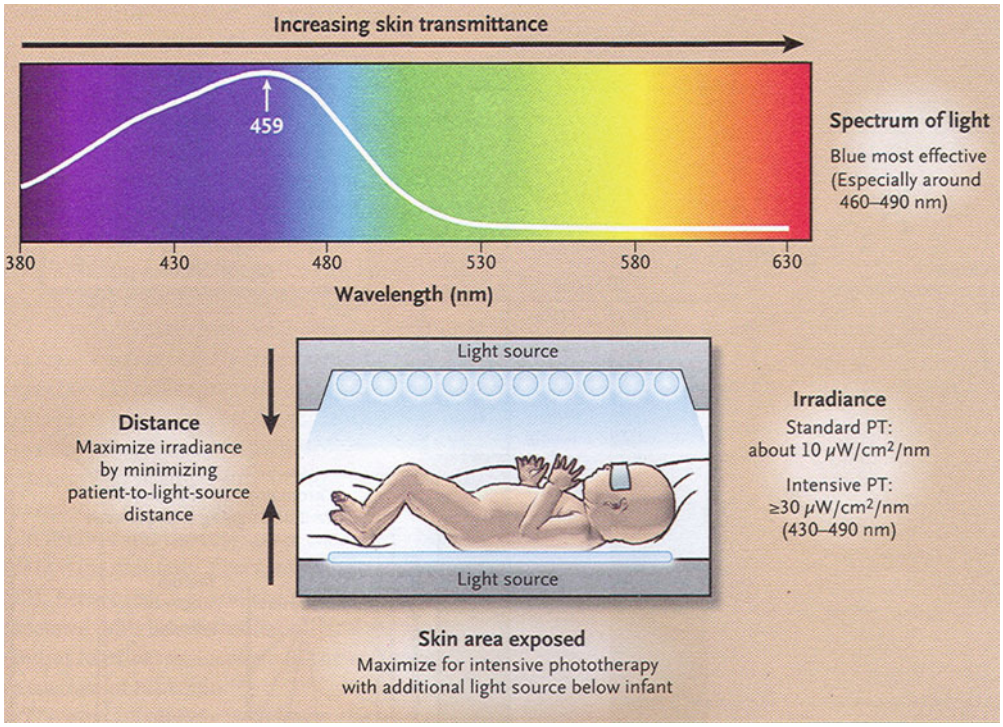

Fig. 84.4 Important factors in the efficacy of phototherapy. The absorbance spectrum of bilirubin bound to human serum albumin (white line) is shown superimposed on the spectrum of visible light. Clearly, blue light is most effective for phototherapy, but because the transmittance of skin increases with increasing wavelength, the best wavelengths to use are probably in the range 460–490 nm. Term and near-term infants should be treated in a bassinet, not an incubator, to allow the light source to be brought to within 10–15 cm of the infant (*except when halogen or tungsten lights are used*), increasing irradiance and efficacy. For intensive phototherapy, an auxiliary light source (fiber-optic pad, light-emitting diode [LED] mattress or pad, or special blue fluorescent tubes) can be placed below the infant or bassinet. Special blue fluorescent tubes can also be placed in a 360° configuration around the infant (see Table 84.6 for a list of some commercially available units). From [85], with permission

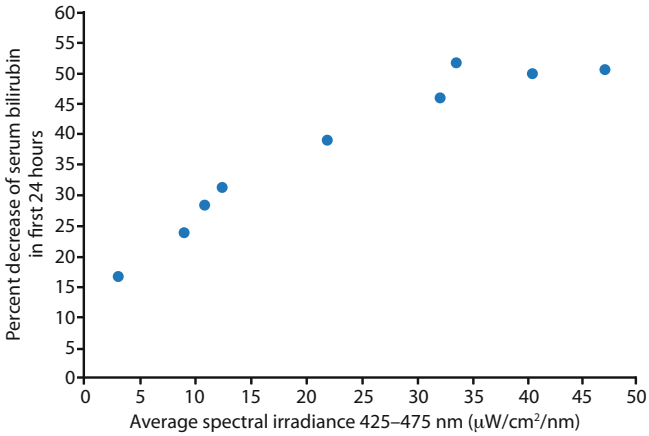

Fig. 84.5 Relationship between average spectral irradiance and decrease in serum bilirubin concentration. Term infants with nonhemolytic hyperbilirubinemia were exposed to special blue lights (Phillips TL 52/20W) of different intensities. Spectral irradiance was measured as the average of readings at the head, trunk, and knees. Drawn from the data of [35]. From [74], with permission

Previous randomized trials of phototherapy [43–45] found that, among infants without hemolysis, 6–10 infants needed to be treated with phototherapy to prevent one from developing a TSB level ≥20 mg/dL (343 μmol/L) [1]. These data, however, are not applicable to the current use of phototherapy because these studies included infants with lower TSB levels than those currently recommended for instituting phototherapy [22] and had as their end points lower TSB levels than those at which the AAP recommends exchange transfusions [22]. A recent analysis of infants ≥ 35 weeks of gestation evaluated the numbers needed to treat (NNT) with phototherapy in order to prevent one infant from reaching the exchange transfusion level according to the current AAP guidelines [46]. The NNT ranged from 10 (95% CI: 6–19) for < 24 hour old, 36 week gestation boys to 3041 (95% CI: 888–11,0096) for ≥ 3 day old 41 week girls [47]. If we need to treat 3000 infants with phototherapy to prevent one exchange transfusion, it is reasonable to ask whether, in many of these infants, phototherapy might have been avoided. In these infants, other interventions including lactation support, formula substitution or supplementation [45], or the use of home phototherapy should also be considered.

84.4.3 Adverse Effects

Reports of clinically significant toxicity from phototherapy are rare and there is no evidence, to date that the products of photodecomposition have any neurotoxic effects [48, 49].

Bronze Baby Syndrome In infants with cholestasis (direct hyperbilirubinemia), phototherapy can produce the bronze baby syndrome, in which the skin, serum, and urine develop a dark grayish-brown discoloration [50, 51]. The pathogenesis of this condition, which occurs only in infants with cholestasis, is not fully understood. When phototherapy is stopped and cholestasis resolves, the coloration disappears.

Skin Rare purpuric and bullous eruptions have been reported in infants with severe cholestatic jaundice who are receiving phototherapy [52, 53], probably as a result of sensitization by accumulating porphyrins. An erythematous rash has been reported in infants treated with tin-mesoporphyrin, who are subsequently exposed to sunlight or daylight fluorescent bulbs [54]. Congenital porphyria, a family history of porphyria, and concomitant use of photosensitizing drugs are absolute contraindications to phototherapy. Severe blistering and agitation during phototherapy could be a sign of congenital porphyria [55]. A recent study suggested that intensive phototherapy might increase the number of atypical melanocytic nevi identified at school age [56] although other research has not shown this association [57].

Insensible water loss and temperature control Conventional phototherapy can produce an acute change in the infant's thermal environment, leading to an increase in peripheral blood flow and insensible water loss [58, 59]. This question has not been studied with LED lights but, because of their relatively low heat output, they should be much less likely to cause insensible water loss. In term infants who are nursing or feeding adequately, additional intravenous fluids are usually not required.

Eye damage Because light can be toxic to the retina, the eyes of infants receiving phototherapy should be protected with appropriate eye patches [60].

Other effects Intensive phototherapy does not cause hemolysis [61]. Because bilirubin is a powerful antioxidant [62, 63], lowering the TSB, particularly in ELBW infants could have undesirable consequences [33] but none have yet been clearly identified although, as noted above, aggressive phototherapy was associated with a non-significant increase in mortality in infants with birth weight 501–750 g [7].

84.4.4 Expected Rate of Decline in Serum Bilirubin

The effectiveness of phototherapy depends not only on the dose of light but also on the cause and severity of the hyperbilirubinemia. During active hemolysis, the TSB may not decline or not decline as rapidly as it would in an infant without hemolysis. On the other hand, because phototherapy works on bilirubin present in the skin and superficial subcutaneous tissue, the more bilirubin present at those sites (i.e., the higher the TSB level) the more effective phototherapy will be [64]. In some infants with a TSB > 30 mg/dL (513 μmol/L), intensive phototherapy can result in a decline of as much as 10 mg/dL (171 μmol/L) within a few hours [65].

Hemolysis is more likely to be the cause of hyperbilirubinemia in infants who require phototherapy during the birth hospitalization than in those readmitted for such treatment [66–68] and phototherapy in infants treated during the birth hospitalization is almost always initiated at a lower serum bilirubin level. For both of these reasons, the level of TSB tends to fall relatively slowly in such infants.

84.4.5 Discontinuing Phototherapy

Although there are no firm standards for discontinuing treatment, phototherapy can be safely stopped in infants treated during the birth hospitalization if two consecutive TSB values fall below the level at which phototherapy was initiated. In infants readmitted for phototherapy, hemolysis is less often the cause for their hyperbilirubinemia [67, 68] and treatment is begun at higher initial TSB levels. In these patients, intensive phototherapy can result in a TSB decrement of 30-40% in the first 24 hours [67] with the most pronounced decline occurring in the first 4–6 hours. Phototherapy can be discontinued when the total serum bilirubin level has fallen below 13–14 mg/dL (222–239 μmol/L) [22].

84.4.6 Rebound After Phototherapy

A rebound in the TSB level of 1–2 mg/dL (17–34 μmol/L) [67], and occasionally more [68], can occur after phototherapy is discontinued. Infants at increased risk of a clinically significant rebound are those born at < 37 weeks' gestation, those with hemolytic disease, and those treated with phototherapy during the birth hospitalization [67, 68]. It is usually unnecessary to keep an infant in the hospital to check for rebound [67, 69] but for infants who require phototherapy during their birth hospitalization and for those with well-defined hemolytic disease, a follow-up bilirubin level should be obtained 24 hours after discharge.

84.4.7 Sunlight Exposure

Sunlight will lower the serum bilirubin level [70] but the practical difficulties involved in safely exposing a naked newborn to the sun either inside or outside (and avoiding sunburn) preclude the use of sunlight as a reliable therapeutic tool.

84.4.8 Home Phototherapy

The economic and social pressures for early discharge of infants from hospital after delivery have led to the widespread use of home phototherapy in the USA. When used appropriately and with adequate monitoring of the TSB, home phototherapy poses no obvious hazards to the infant and is certainly much cheaper than hospital treatment [71, 72]. The development of new LED mattresses and blankets has made it easier and more effective to administer phototherapy at home.

84.5 Exchange Transfusion

The prevention of Rh hemolytic disease with Rh immune globulin and the effective use of phototherapy has led to a dramatic decline in the number of exchange transfusions performed [74]. Of 1974 ELBW infants treated with phototherapy in the NICHD Neonatal Research Network study [7] only 5 required an exchange transfusion (0.25%). It is now possible for a pediatric resident to complete a 3-year training program without ever having performed or even witnessed an exchange transfusion. The indications for exchange transfusions in term and in preterm infants are provided in Tables 84.1–84.3 and in Fig. 84.2.

84.5.1 Exchange Transfusion Risks

The potential complications of exchange transfusions are listed in Table 84.7 and were recently reviewed [1]. The morbidity and mortality associated with exchange transfusions are significantly dependent on the clinical state of the infant before the exchange, being much higher in sick preterm infants and quite low in term and near-term infants who are relatively well [75]. It is interesting that when exchange transfusions were performed using both umbilical venous and arterial catheters, they were significantly more likely to be associated with adverse events than when performed through the umbilical vein alone or via other routes [75].

Table 84.7 Potential complications of exchange transfusion

Cardiovascular	Arrhythmias Cardiac arrest Volume overload Embolization with air or clots Thrombosis Vasospasm
Hematologic	Sickling (donor blood) Thrombocytopenia Bleeding (overheparinization of donor blood) Graft versus host disease Mechanical or thermal injury to donor cells
Gastrointestinal	Necrotizing enterocolitis
Biochemical	Hyperkalemia Hypernatremia Hypocalcemia Hypomagnesemia Acidosis Hypoglycemia
Infectious	Bacteremia Virus infection (hepatitis, CMV) Malaria
Miscellaneous	Hypothermia Perforation of umbilical vein Drug loss Apnea

84.6 Pharmacologic Treatment

Pharmacologic agents used in the management of hyperbilirubinemia can accelerate the normal metabolic pathways for bilirubin clearance, inhibit the enterohepatic circulation of bilirubin, and interfere with bilirubin formation by blocking the degradation of heme or inhibiting hemolysis. Currently the only drug in standard clinical use is intravenous immunoglobulin (IVIG). When administered to infants with isoimmune hemolytic disease IVIG will significantly reduce the need for exchange transfusion [76–78]. The usual dose is 500 mg/kg given over 2–3 hours and, if necessary, repeated in 12 hours. IVIG is recommended if the TSB is rising despite intensive phototherapy or the TSB level is within 2–3 mg/dL (34–51 μmol/L) of the exchange level [22] (Fig. 84.2).

84.6.1 Decreasing Bilirubin Production

The enzyme microsomal heme oxygenase is necessary for the conversion of heme to biliverden, one of the first steps in the formation of bilirubin from heme. Tin-mesoporphyrin (SnMP) is a potent inhibitor of heme oxygenase and is effective in reducing TSB levels and the requirements for phototherapy in term and preterm infants [79]. SnMP has also produced a temporary reduction in TSB levels [80] in patients with the Crigler-Najjar syndrome and has prevented the need for exchange transfusion in Jehovah's Witness' newborns with Rh hemolytic disease [81]. To date, more than 1000 newborns have received SnMP in controlled clinical trials but the drug is still awaiting FDA approval in the USA and currently is the subject of a randomized controlled trial.

Pathology and Treatment of Liver Diseases

Giuseppe Maggiore and Silvia Riva

Liver disease in the newborn usually presents with two principal and distinct syndromes: neonatal cholestasis and neonatal liver failure.

85.1 Neonatal Cholestasis

Cholestasis is related to a reduction of biliary flow, with accumulation in the liver and extrahepatic tissues of substances normally excreted in the bile, such as bilirubin, cholesterol and bile acids. In the newborn, bile acids are physiologically elevated in the serum due to a delayed maturation of biliary secretion. Cholestasis is a pathological condition of a prolonged or permanent disorder of biliary secretion, which is secondary to a wide range of possible causes, such as infections, inborn errors of metabolism, or genetic disorders of biliary transport.

In the neonate, cholestasis usually presents with prolonged jaundice or, less frequently, with a hemorrhagic syndrome related to late onset vitamin K deficiency. Cholestatic jaundice is associated with discolored stools and dark urines due to hyperbilirubinuria. More rarely, cholestasis can present with hypocalcemic seizures due to vitamin D malabsorption and deficiency. Hepatomegaly is a constant feature, while spleen enlargement is observed in about 50% of cases. Pruritus is absent in the neonatal period, but can occur from age 4 months onwards. Every newborn with jaundice that prolongs for more than 2 weeks should be considered a pathological case, and one that needs a precise diagnosis.

Cholestasis affects approximately 1 in every 2,500 infants. Its etiological spectrum is particularly wide, also including conditions with severe prognosis, such as biliary atresia, which is the single most frequent pathologic entity (Table 85.1). The diagnostic approach to prolonged jaundice is as follows:

- Determine its cholestatic nature by looking for an abnormal stool or urine color, and by measuring total and direct serum bilirubin;
- Prevent hemorrhagic complications related to vitamin K deficiency by administering a single 10 mg intramuscular dose of vitamin K1;
- Suspect biliary atresia early if the clinical picture is suggestive since a good outcome of surgery depends on early diagnosis;
- Early referal of the infant to a center experienced in the treatment of hepatobiliary disorders in childhood.

(See also Chapter 86)

85.2 Principal Causes of Cholestasis in the Newborn

85.2.1 Biliary Atresia

Biliary atresia (BA) is an obliterative cholangiopathy of unknown origin involving intra- and extrahepatic biliary structures. Its prevalence in Europe and the USA varies from 1:14,000 to 1:20,000 live born. BA spontaneously progresses to cirrhosis and liver failure in the first years of life. Its treatment is principally surgical and is based on two sequential procedures: the Kasai procedure or hepato-porto-enterostomy corresponding to a bilio-digestive anastomosis between the porta hepatis and an intestinal Roux loop. If this procedure fails, liver transplantation is perfomed [1].

BA seems to be a phenotype caused by several etiologies, including a perinatal insult that initiates an immune-mediated obliteration of the extra hepatic bile duct lumen and an embryonic or fetal defect in the normal morphogenesis of the biliary tree.

The success of the hepatoportoenterostomy depends mainly on the precocity of the diagnosis and surgery [2]. Unfortunately in the early phase of the disease, the newborn

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

Table 85.1 Neonatal cholestasis: the spectrum of etiology

Site of the lesion	Disease
Whole biliary tree	– Biliary atresia – Sclerosing cholangitis with neonatal onset – Sclerosing cholangitis and icthyosis due to claudin I defect
Intrahepatic biliary tree	• Infections – Prenatal: CMV, toxoplasmosis, syphilis, rubeola – Perinatal: disseminated bacterial infections – Postnatal: *E. coli* pyelonephritis • Genetic cholestasis – Progressive familial intrahepatic cholestasis (PFIC) – Benign recurrent intrahepatic cholestasis (BRIC) – alfa-1-antitrypsin deficiency – Cistic fibrosis – Familial cholestasis of native Americans (Quebec) – Niemann-Pick tipo II disease – Gaucher disease – Mucopolisaccaridosis type VI and VII – Mucolipidosis II – Peroxisomal disorders (Refsum disease, Zellweger disease) – Hepatocyte nuclear factor 1β HNF 1β) deficiency – Mithocondrial respiratory chain disorders – Citrin deficiency – Complex III assembly defect (GRACILE syndrome) – Inborn error of primary bile acids synthesis • Syndromic cholestasis – Alagille syndrome – Aagenas syndrome – Williams syndrome – Kabuchi syndrome – Hardikar syndrome – McCune-Albright syndrome – ARC (arthrogryposis, renal dysfunction, and cholestasis) syndrome – Donohue syndrome (Leprecaunism) – McCune-Albright syndrome • Benign intrahepatic colestasis • Other forms of intrahepatic cholestasis – Parenteral nutrition induced-cholestasis – Cholestasis secondary to congenital hypopituitarism – Cholestasis secondary to maternal hypothyroidism – Cholestasis secondary to hepatic hemangiomatosis – Cholestasis secondary to placentar chorioangioma – Cholestasis associated with congenital microvillous atrophy – Cholestasis secondary to fetal post-hemolytic (fetal erytroblastosis) cholestasis – Cryiptogenic intrahepatic cholestasis – Neonatal lupus
Extrahepatic biliary tree	– Choledocholithiasis – Spontaneous perforation of bile ducts – Congenital choledocal strenosis – Congenital choledocal dilatation (coledochal cyst)

appears healthy, meconium is rarely discolored, stools are only moderately discolored, and jaundice is mild. In regions with a high prevalence of BA, such as Taiwan (1:2,700), a strategy based on a universal screening using a stool color card has been successfully developed [3]. The outcome of the Kasai procedure depends on early surgery before the age of 6 weeks, and on the caseload of the center performing the primary surgery. Long-term results of the Kasai procedure show a 10-year survival rate in about 30% of patients, and a 20-year survival rate in about 25%. At present, sequential treatment for biliary atresia results in long-term survival, with a good quality of life in more than 90% of treated patients.

85.2.2 Genetic Cholestasis

Genetic cholestasis includes a heterogeneous group of rare disorders of hepatobiliary transport. This is sometimes restricted to specific geographic areas, such as the case of Aagenas syndrome (also known as Norwegian cholestasis), in which recurrent cholestasis with neonatal onset is associated with lymphedema, or native North American Indian childhood cirrhosis, a familial intrahepatic cholestasis described in Ojibway-Cree children from Quebec, typically presenting with transient neonatal jaundice in an otherwise healthy infant, but progressing to biliary cirrhosis. This disorder is associated with mutation of the FLJ14728 gene (also known as Cirhin), a protein preferentially expressed in the embryonic liver, and of still unknown function.

Bile salts take part in an efficient enterohepatic circulation in which most of the secreted bile salts are absorbed in the terminal ileum. Canalicular secretion is the driving force behind the enterohepatic cycling of bile salts, and most genetic diseases are caused by defects of canalicular secretion.

Progressive familial intrahepatic cholestasis (PFIC), once known as Byler disease, results from mutations in various genes that encode hepatobiliary transport proteins [4]. Mutations in the FIC1 gene (also known as ATP8B1) cause relapsing or permanent cholestasis. The relapsing type of cholestasis is called benign recurrent intrahepatic cholestasis (BRIC type 1), the permanent type of cholestasis is PFIC type 1. PFIC type 2 results from mutations in the bile salt export pump (BSEP) gene (also known as ABCB11). This condition is associated with permanent cholestasis from birth. Serum gamma-glutamyltransferase (γGT) activity is low to normal in PFIC and in BRIC types 1 and 2. PFIC type 3 is caused by mutations in the MDR3 gene (also known as ABCB4) coding for a phospholipid translocator in the canalicular membrane. Because of their inability to secrete phospholipids, patients with PFIC type 3 produce bile acid-rich toxic bile that damages the intrahepatic bile ducts. Serum γGT activity is elevated in these patients. Ursodeoxycholic acid therapy is useful for patients with a partial defect. Liver transplantation is a more definitive therapy for these patients.

Inborn errors of bile acid synthesis are rare genetic disorders that can present as neonatal cholestasis. These disorders are characterized by a failure to produce normal bile acids, with accumulation of unusual bile acids and/or bile acid intermediaries. Individuals with inborn errors of bile acid synthesis generally present with cholestasis and low or normal serum bile acid concentrations, normal γGT serum activity, and the absence of pruritus. Failure to diagnose any of these conditions can result in liver failure or progressive chronic liver disease. If recognized early, many patients have an excellent clinical response to oral bile acid therapy.

Cholesterol is converted to cholic acid and chenodeoxycholic acid through a series of reactions involving modifications of the steroid nucleus and oxidation of the side chain. Inborn errors have been shown for single enzymes involved in modification of the sterol nucleus, and in steps in modification of the side-chain. Unusual bile acids or bile alcohols can be identified using gas chromatography-mass spectrometry and fast atom bombardment mass spectrometry techniques. Two defects that influence the modifications of the steroid nucleus have been well characterized: the 3 beta-hydroxy-delta 5-C27-steroid dehydrogenase deficiency (the most frequent), and the 3-oxo-delta 4-steroid 5 beta-reductase deficiency. Diagnosis of the latter can be problematic because a similar pattern of metabolite excretion can occur as a result of liver damage caused by viruses or inborn errors of pathways unrelated to bile acid synthesis. The 3 beta-hydroxy-delta 5-C 27-steroid dehydrogenase catalyzes an early step in the synthesis of bile acids from cholesterol. Patients with autosomal recessive mutations in the encoding gene HSD3B7 fail to synthesize bile acids, and develop cholestatic jaundice and malabsorption of lipids [5]. Pathological findings may include intralobular cholestasis with giant cell transformation, and hepatic injury confined to the portal limiting plate where the smallest bile ductules may be injured, and where fibrosis typically develops. Interlobular bile ducts are usually spared. Ultrastructure of the liver reveals nonspecific change. Liver disease improves dramatically on treatment with chenodeoxycholic acid, which produces beneficial feedback inhibition of abnormal bile acid production and enhances choluresis.

Defective side chain oxidation in patients with cerebrotendinous xanthomatosis (CTX) leads to synthesis of bile alcohols, but patients with CTX do not have cholestatic liver disease. Their major problems (neurological disease, atherosclerosis and xanthomata) are caused by an accumulation of cholestanol and cholesterol in the tissues, while bile acid precursors are probably diverted into the synthesis of cholestanol. Chenodeoxycholic acid suppresses the production of abnormal metabolites from cholesterol (by inhibition of cholesterol 7 alpha-hydroxylase) and leads to improvement in the neurological condition. Defective side chain oxidation also occurs in peroxisomal disorders, leading to accumulation of such C27 bile acids as trihydroxycoprostanic acid (THCA).

Alagille syndrome (AGS) is an autosomal-dominant disorder with variable penetrance, and a prevalence of approximately 1 in 70,000 live births [6]. AGS may present in the neonatal period with cholestasis that may be severe enough to suggest biliary atresia. AGS is characterized by five principal features: chronic cholestasis resulting from paucity of interlobular bile ducts; peripheral pulmonary artery stenosis, butterfly-like vertebral arch defect, posterior embryotoxon, and a peculiar *facies* (Fig. 85.1). In the complete form of the syndrome, all five features are observed, though incomplete or partial forms exist. Other less frequent features include growth retardation, renal and bone abnormalities, ocular abnormalities – such as optic disc drusen, angulated retinal vessels, pigmentary retinopathy, and vascular intracranic abnormalities.

Fig. 85.1 Alagille syndrome: typical facies

Jagged1 (JAG1) has been identified as the gene responsible for coding for a cell surface protein that functions in an embryologically important signaling pathway, known as the Notch signaling pathway. Defects of the Notch pathway can impair angiogenesis. Mutations in JAG1 can be identified in at least 70% of AGS, though they are inherited in only 30% of cases. These JAG1 mutations include total gene deletions, as well as mutations (frameshift, missense, and nonsense) in almost all regions of the gene.

Therapy consists of nutritional supplementation with medium-chain triglycerides, essential fatty acids and fat-soluble vitamins. Liver transplantation has been used successfully to treat patients with liver failure, portal hypertension or severe pruritus and xanthomatosis (Fig. 85.2).

Alpha-1-antitrypsin deficiency (AATD) is a genetic disorder that can manifest as neonatal cholestasis or chronic liver disease in infancy and childhood, pulmonary emphysema in adulthood, and, more rarely, as skin panniculitis or membranoproliferative glomerulonephritis [7]. AATD is caused by mutations in the SERPINA1 gene encoding

Fig. 85.2 Alagille syndrome: diffuse xantomata

alpha-1-antitrypsin (AAT), and is inherited as an autosomal recessive trait. AATD is characterized by low serum levels of AAT, the main protease inhibitor (PI) in human serum. The prevalence in Western Europe and in the USA is estimated at approximately 1 in 2500/5000 newborns, most common amogst those of Scandinavian descent. The most common deficiency alleles in North Europe are PI Z and PI S, and the majority of individuals with severe AATD are PIZZ. The mutant Z protein product is synthesized in hepatocytes, and then accumulates intracellularly rather than being appropriately secreted, causing hepatocellular injury. Ten percent of PI-ZZ AATD infants present with cholestatic jaundice with an incidence of 1:10,000/20,000 newborns. However, only 5% develop a severe progressive cholestatic liver disease that requires early liver transplant. In the majority of cases, clinical jaundice disappears, but clinical and biochemical features of chronic liver disease may persist and progress to biliary cirrhosis in the pediatric age. The variable clinical presentations suggest an important contribution of genetic and environmental disease modifiers. In PIZZ homozygotes, specific globules, which are due to accumulation of a type of AAT, are seen in liver cells. Ursodeoxycholic acid therapy may significantly improve clinical status and liver test results in some children with liver disease associated with AATD. No beneficial effect of UDCA has been shown in children with the most severe liver involvement: these patients are candidates for liver transplantations.

85.3 Management of a Cholestatic Newborn

The main goal of management of an infant with cholestasis is to detect or at least to exclude biliary atresia within 45–60 days of age [8]. History and physical examination, together with simple laboratory tests and a liver ultrasound, will allow clinicians to achieve this in the majority of cases. Decolorized stools and a hard palpable liver strongly suggest BA, even though some infants with BA have pigmented stools at presentation.

There is no single laboratory test to confirm or exclude BA. However, biochemical evaluation will allow clinicians to [8]:

- Confirm the cholestatic nature of the jaundice by measuring total and direct bilirubin. A serum direct bilirubin value of >1.0 mg/dL (if the total bilirubin is <5 mg/dL), or a direct bilirubin of >20% of the total bilirubin (if the total bilirubin is >5 mg/dL), suggests cholestasis that can be confirmed by measuring the total serum bile acids levels. A non-cholestatic increase of direct bilirubin is present in Dubin-Johnson syndrome, an autosomal recessive inherited inborn error of bilirubin transport due to mutation of the MRP2 gene;
- Distinguish a cholestatic jaundice from a jaundice related to liver failure where a non-vitamin-K-dependent coagulopathy exists;
- Exclude other causes of cholestasis, such as alpha-1-antitrypsin deficiency, by examining the protein electrophoretic pattern or cystic fibrosis by a normal sweat test. A normal eye examination and a column x –ray showing absence of butterfly vertebrae are against a diagnosis of Alagille syndrome.

In BA, total bilirubin serum levels do not generally exceed 6–8 mg/dL, aminotransferase activity is generally increased, with a non-specific pattern, and alkaline phosphatase activity measurement is not helpful because of the high activity physiologically present in the newborn infant.

Gamma glutamyl transpeptidase (γGT) has been used in the past to distinguish biliary atresia from intrahepatic cholestasis, but wide variability in serum activity makes interpretation of test results difficult. The degree of elevation of γGT is not useful in discriminating the etiology of the cholestasis, even if a normal γGT level suggests genetic and metabolic causes of intracellular cholestasis [9].

Serum bile acids are, by definition, elevated in cholestasis. Light to moderate increase in cholestatic infants with low to normal γGT level suggests an inborn error of bile acids synthesis. Urinanalysis and culture are diagnostic in case of cholestasis secondary to an *E. coli* urinary infection.

Ultrasonography is recommended for the diagnostic evaluation of the infant with cholestasis. Ultrasound is operator dependent, and thus should be performed at a referral center by experienced personnel. Ultrasound is particularly useful in identifying anatomic abnormalities, such as abnormal dilatation of extrahepatic bile ducts. The finding of a small or absent gallbladder may suggest BA, but cannot be used to rule out this diagnosis. The presence of a visible gallbladder does not allow the exclusion of BA. The presence of features commonly associated with BA, such as poly/asplenia, preduodenal portal vein, complete situs inversus or cystic dilatation at porta hepatis, may suggest the diagnosis. Several reports on the high sensitivity and specificity of the triangular cord sign on ultrasound suggest that this test may be useful in the diagnosis of BA.

Hepatobiliary scintigraphy is time consuming, expensive, and generally adds little to the routine evaluation of the cholestatic infant because of its low specificity (a significant number of false-positive and false-negative results of the test).

Percutaneous liver biopsy can be performed safely in young infants and can provide disease-specific findings. Examples include PAS-positive granules in alpha-1-antitrypsin deficiency, ductal paucity in Alagille syndrome, necroinflammatory duct lesions in sclerosing cholangitis, and other findings that are relatively specific for metabolic and storage diseases. Liver biopsy has a very high sensitivity and specificity for the diagnosis of BA. However, because of the dynamic and progressive nature of extrahepatic biliary atresia, even this test can be misleading. Biopsy interpretation is pathologist-dependent, and requires expertise in pediatric liver disease [10].

85.4 Treatment of a Cholestatic Newborn Infant

Specific medical treatment of neonatal cholestasis is directed at the cause and may be associated with urinary tract infection, hypothyroidism, hypopitiutarism congenital toxoplasmosis or syphilis.

Ursodeoxycholic acid, particularly at a high dose (30 mg/kg/day) has been proven to be effective and safe in some cholestatic conditions of infancy, such as parenteral nutrition-associated cholestasis, progressive intrahepatic cholestasis of infancy (particularly of type 3), alpha-1-antitripsin deficiency, cystic fibrosis, biliary atresia after successful Kasai procedure, and post-hemolytic cholestasis.

If there is no specific therapy, treatment is supportive and consists primarily of nutritional therapy, including supplements of vitamins A, D, E, and K.

In infants with chronic cholestasis, replacement therapy of the fat-soluble vitamins may prove extremely difficult because of a low concentrations of intraluminal bile acids. Water-soluble forms of vitamin E, d-alpha-tocopheryl polyethylene glycol-1000 succinate, have enabled correction of vitamin E deficiency states in these patients. Exclusively breastfed infants are at particular risk of hypovitaminosis D, and at even greater risk in the absence of adequate exposure to sunlight or when the maternal diet is not sufficient to provide for vitamin D requirements.

Vitamin K prophylaxis at birth by oral or intramuscular administration of 1 mg of vitamin K effectively prevents vitamin K deficiency bleeding (VKDB), formerly known as hemorrhagic disease of the newborn. In exclusively breast-fed infants, a single intramuscular dose at birth effectively prevents late VKDB. Infants with cholestasis are not fully protected in this way and should be given supplements.

For formula-fed infants, a formula that is high in medium-chain triglycerides should be used because it is better absorbed in the presence of bile salt deficiency. Adequate calories and protein are required: infants may need more than 130 calories/kg day and 2–3 g of protein/day.

Infants with persistent cholestasis are at a high risk for essential fatty acid (EFA) deficiency, particularly of the omega-6 fatty acids linoleic and arachidonic acid. EFA deficiency appears to be related to fat malabsorption, hepatic EFA metabolism, enhanced lipid peroxidation and dietary intake. In case of severe itching, rifampin (10 mg/kg/day) can be administered.

85.5 Neonatal Acute Liver Failure

Neonatal acute liver failure (NALF) is a rare and challenging condition. NALF is a multietiologic syndrome that is difficult to recognize initially. As important as the recognition of causes that may indicate specific diet and medical therapy, is the selection of infants suitable for liver transplantation, given that mortality is high and only 25% of infants survive with their own liver. Management of NALF requires supporting the neonate until liver regeneration or liver transplantation takes place.

85.5.1 Definition

The definition of NALF is controversial. In adults, acute liver failure is defined by the onset of hepatic encephalopathy within 8 weeks of the first symptoms of illness, generally jaundice, in the absence of pre-existing liver disease. This definition is unsatisfactory in infancy because encephalopathy is a late event in the course of the disease. Furthermore, the duration of illness can be difficult to assess, particularly in infants who present with ALF in the first few weeks of life secondary to a condition that may be caused by unrecognized metabolic diseases. For these reasons, the Pediatric Acute Liver Failure Study Group has came to a consensus agreement, defining ALF in infancy as a coagulopathy due to liver dysfunction not corrected by vitamin K administration in a patient without a history of known chronic liver disease, and with an INR greater than 1.5 if the patient has encephalopathy, or greater than 2.0 if the patient does not have encephalopathy [11]. In the neonate, ALF can be defined by the presence of severe coagulopathy with a prothrombin time of >17 seconds and/or a factor V of < 50%, with an onset in the first 4 weeks of life, regardless of the presence of a clinical hepatic encephalopathy [12,13].

85.5.2 Etiology

NALF can be classified according to the timing of the onset of liver damage. if the onset is during fetal life, chronic liver damage develops with decompensation at birth. If there is

Table 85.2 Causes of neonatal acute liver failure

Fetal onset
- Neonatal hemochromatosis
- Hemophagocytic lymphohistiocytosis
- Mithocondrial respiratory chain disorders
  - Mithocondrial hepatopathy
  - Mithocondrial DNA depletion syndrome
  - Complex III/IV (cytochrome oxidase) assembly defect
- Inborn disorders of bile acids synthesis
  - Oxisterol 7α-hydroxylase deficiency
  - Di/trihydroxy-cholestanoic acidemia
  - Delta 4-3-Oxosteroid 5-β–reductase deficiency
- Neonatal lupus
- Neonatal veno-occlusive disease
- Neonatal leukemia

Perinatal onset
- Viral infections
  - Enterovirus
    - Echovirus 11
    - Echovirus 6 and 9, Coxackie
  - Herpes virus
    - Herpes simplex virus 1 and 2
    - HHV6
  - Parvovirus B19, Adenovirus, Paramixovirus
- Inborn metabolic disorders
  - Galattosaemia
  - Hereditary tyrosinaemia type 1
  - Hereditary fructose intolerance
  - Urea cycle disorders
- Bacterial infections
- Drug
- Ischemic (shock liver syndrome)
- Undeterminated

damage in the perinatal period, acute liver damage develops at birth without underlying liver disease. Table 85.2 lists most of the recognized causes of NALF. The most common etiologies are liver-based metabolic disorders and perinatally acquired infections [14].

85.5.2.1 Neonatal Hemochromatosis

Neonatal hemochromatosis (NH) is a rare and severe disorder associated with massive intrahepatic and extrahepatic (pancreas, heart, thyroid, salivary glands) abnormal iron storage (siderosis) that spares the reticuloendothelial system [15]. Liver injury has been identified as early as 28 weeks of gestation. The etiology of this condition is unclear, and probably an endpoint of different (viral, immununological) intrauterine insults of fetal liver. The recurrence within sibships at a rate higher than that predicted for simple Mendelian autosomal-recessive inheritance suggests a role for a maternal factor, and maternal alloimmunity has been hypothesized as a cause. Moreover, immunomodulation during at-risk pregnancy appears to lessen the severity of disease. Previous miscarriages are generally recorded and oligohydramnios or polyhydramnios can complicate the pregnancy. Neonates are often premature and/or small for dates. The usual presentation is of acute decompensation of end-stage liver disease in the first few days of life with hypoglycemia, coagulopathy, hyperammonemia, jaundice, irritability and/or drowsiness and ascitis.

The diagnosis of NH must be considered in any neonate with coagulopathy. Diagnosis is based on the exclusion of other causes of liver disease, such as neonatal lupus and hemophagocytic lymphohistiocytosis, and by evidence of iron overload with high serum ferritin, high trasferrin saturation (>95%), and by MR imaging of the liver and pancreas. When feasible, liver biopsy shows grade 3–4 siderosis in the hepatocyte. Biopsy of minor salivary gland is simpler for evidencing extrahepatic siderosis. The prognosis is poor. There have been some reports of spontaneous recovery, and of recovery with anti-oxidant therapy and iron chelation (Table 85.3) in those with a milder phenotype. Liver transplantation has been performed successfully to treat the disease.

Table 85.3 Etiology and diagnostic screening in case of neonatal liver failure

Etiology	Diagnostic screening
Infections	
Enterovirus	Viral culture and PCR detection in blood, urine, stools, CSF
HSV 1 and 2	
HHV6	Viral serology in mother and infant
Adenovirus	
Parvovirus B19	
Bacterial	Blood culture
Metabolic	
Galactosemia	Erytrhrocyte galactose-1-phosphate concentration. GALT activity
HFI	Mutations of HFI gene
HT1	Plasma tyrosine, phenylalanine, methionine and succinyl acetone in urine
MRCD	
IE bile acids	Total serum bile acids; FAB-MS and GC-MS urine analysis
Urea cycle disorders	Plasma aminoacids; urinary orotic acid
CDGS	Transferrin iso-electrofocusing
NH	Serum ferritin levels, saturation of transferrin; MRI
Infiltrative/storage	Bone marrow examination
HLH	
Leukemia	
Nieman Pick type II	
Others	Maternal autoantibodies of the Ro/La family
Neonatal lupus	
Drug	
Hypoxic/ischemic	

HSV herpes simplex virus, *HHV6* human herpes virus 6, *HFI* hereditary fructose intolerance, *HT1* hereditary tirosinemia type 1, *MRCD* mithocondrial respiratory chain disorders, *IE* bile salts: inborn errors of bile salt synthesis, *CDGS* congenital disorders of glycosylation syndrome, *NH* neonatal hemochromatosis, *HLH* hemophagocytic lymphohistiocytosis, *GALT* galactose-1-phosphate urydyl transferase, *FAB-MS* fast atom bombardement ionisation-mass spectrometry, *GC-MS* gas chromatography-mass spectrometry, *MR* magnetic resonance imaging, *CSF* cerebrospinal fluid.

85.5.2.2 Familial Hemophagocytic Lymphohistiocytosis

Familial hemophagocytic lymphohistiocytosis (FHLH) is a rare disorder, with autosomal recessive transmission involving inappropriate activation of macrophages. Clinical features include fever, marked liver and spleen enlargement and neurological abnormalities. Laboratory investigations show pancytopenia, hypertrigliceridemia, severe coagulopathy with hypofibrinogenemia, abnormal liver enzymes and cerebrospinal fluid pleiocytosis (in 50% of cases). The natural killer activity of the peripheral blood lymphocytes is severely depressed. The diagnosis is difficult because hemophagocytosis can be absent in bone marrow aspirate in the early phases of the disease. Initial management includes chemotherapy with dexamethasone, etoposide (VP 16) and cyclosporin, but the prognosis is poor, with a 5-year survival rate of 21%.

Long-term survival requires a bone marrow transplant with a matched sibling, a treatment with a 5-year survival rate of 68%. Liver transplantation is contra-indicated in this condition due to recurrence in the graft.

85.5.2.3 Mitochondrial Respiratory Chain Disorders

Most infants have an early onset with non-specific symptoms (lethargy, hypotonia, poor feeding) and/or extrahepatic features (neurological symptoms, myopathy, proximal renal tubular dysfunction, and hypertrophic cardiomyopathy, hematological and gastrointestinal disorders). A few patients with respiratory chain defects limited to the liver have been described. Thorough investigation is necessary to exclude significant extrahepatic involvement before OLT can be proposed. Liver dysfunction may precede neurologic involvement for weeks, months, or years. Laboratory tests supporting the diagnosis are increased lactate and ketone bodies, a 3-OH-butyrate: acetoacetate ratio >2, and the presence of 3-metylglutacoic aciduria.

85.5.2.4 Herpes Simplex Virus (HSV 1 and 2)

Neonatal herpes simplex virus (HSV 1 and 2) infection can be transmitted at delivery because of exposure to infected maternal genital secretions or lesions, although intrauterine or postnatal infection can also occur. The risk of transmission is highest in the case of primary infection in the mother, who is asymptomatic in most (60–80%) cases. The incidence is 1:3,500 to 1:20,000 live newborns, with a higher (70%) prevalence of HSV type 2. Delivery by cesarean section significantly reduces the risk of neonatal infection. Symptoms typically develop after day 5. ALF may occur within a disseminated disease involving skin, eyes, mucous membranes, brain, lung, adrenals and liver or as the only manifestation. Despite acyclovir therapy, the prognosis is poor, with a high mortality (50–70%) and morbidity (neurologic sequelae). Successful liver transplantation has been reported.

85.5.2.5 Hepatitis B Virus

Hepatitis B virus is vertically transmitted during delivery from a viremic mother. Infants at risk of developing ALF are those born to an HBeAg negative anti-HBe positive, but HBsAg positive mother. ALF usually develops after the neonatal period and within 12 weeks of life. Universal screening of HBsAg positive mothers and passive active immunizations by three or four doses of HBV vaccine in infancy and hepatitis B immunoglobulin within 24 hours of birth are effective in preventing HBV infection of the newborn babies independently of the HBe antigen status of the mother. In areas with a low prevalence of HBV infection or limited resources, three doses of HBV vaccine universally in infancy, instead of maternal screening, can also produce good protection.

85.5.2.6 Other Viruses

Human herpes virus 6 (HHV6) infection has been reported occasionally. Other viruses such as Adenovirus, Parvovirus B19, Paramyxovirus have also been associated with hepatic failure. Among enteroviruses, Echovirus, particularly serotype 11, is the most frequently identified. Severe infection with multi-organ involvement, including the liver, occurs almost exclusively in newborns, typically between days 4 and 7. Mortality is high, but antiviral treatment with an antiviral agent pleconaril, 15 mg/kg/d may improve the outcome.

85.5.2.7 Inborn Metabolic Disorders

Classic galactosemia is an autosomal recessive disorder because of a deficiency of the enzyme galactose-1-phosphate uridyl transferase. The onset usually occurs early in the neonatal period and complete elimination of dietary lactose/galactose results in the resolution of liver failure.

Hereditary fructose intolerance (HFI) is an autosomal recessive disorder caused by a deficiency of the enzyme fructose-1-phosphate aldolase. Symptoms develop only once fructose and sucrose have been introduced into the diet. Thus symptoms do not usually occur in neonates who are fed with fructose- and sucrose-free milk formulas, except for those given medications or rehydration formulas containing fructose, sucrose or sorbitol. Complete elimination of fructose, sucrose and sorbitol results in a dramatic improvement within 2 days.

Hereditary tyrosinaemia type 1 (HT1) is an autosomal recessive disorder caused by a deficiency of fumarylacetoacetate hydrolase, which results in accumulation of toxic metabolites responsible for liver failure, proximal renal tubular dysfunction, and porphyria-like crises. Infants most often present with a coagulopathy soon after birth. Clinical signs of liver failure become apparent usually between 1 and 6 months of age. Diagnosis is based on the finding of succynil

Table 85.4 Anti-oxidant cocktail used in management of neonatal hemochromatosis

– N-acetylcysteine (140 mg/kg orally, then 70 mg/kg 4 hour for 19 doses)
– Selenium (3 μg/kg/day) intravenously
– Prostaglandin E1 (0.5 μg/kg/h) intravenously
– Desferioxamine 30 mg/kg day intravenously over 8 hours until ferritin < 500 μg/L
– Alpha tocopheryl polyethylene glycol succinate (20–30 IU/kg/day)

acetone in the urine and by enzyme analysis of skin fibroblast. Management includes 2-(2 nitro-4-trifluoromethylbenzoyl)-1,3 cyclohexanedione diet (NTBC therapy) associated with a tyrosine- and phenylalanine-restricted diet, which has been proven curative in 90% of cases. Infants who do not respond to NTBC, or those with a suspicion of hepatocellular carcinoma are considered for liver transplant [16].

85.5.2.8 Inborn Error in Bile Acid Synthesis

The delta 4-3-oxosteroid 5beta-reductase deficiency is the principal defect recognized as a cause of hepatic failure. Early diagnosis is important because oral administration of chenodeoxycholic acid and/or cholic acid can be curative.

85.5.2.9 Ischemic Damage

Transient acute liver dysfunction in the neonate secondary to hemodynamic failure or shock liver syndrome is a well recognized complication of reduced hepatic blood flow in low cardiac output states. The peculiar pattern of liver blood flow in neonates characterized by a large intrahepatic shunt through the ductus venous and low arterial blood supply produces a symmetric response to ischemia, with a significant reduction of blood flow in the right lobe compared to left liver, which is supplied by the umbilical venous blood [17].

85.5.3 Clinical Presentation

The clinical presentation of acute liver failure (ALF) in the neonate depends on the etiology. Presentation at birth implies an intrauterine insult, such as congenital infection, NH or mitochondrial disorders. A later presentation may be related to bacterial or viral infection or a metabolic condition unveiled by the introduction of feeding (e.g. galactosemia, HFI, HT1). A detailed family history, including information on consanguinity, previous miscarriages, neonatal deaths, and liver disease in sibships is important to record. Neonatal ALF may be difficult to recognize initially. Non-specific symptoms such as vomiting, poor feeding, and lethargy are early signs. Jaundice is inconstant, especially when inborn metabolic diseases are involved. Encephalopathy can be a late feature, and is particularly difficult to diagnose in neonates. Irritability and reversal of day/night sleep patterns indicate hepatic encephalopathy. Convulsions may be caused by meningoencephalitic involvement or hypoglycemia. Hepatomegaly is most often present. Splenomegaly and ascites are usually noted in cases of severe diseases progressing to cirrhosis.

85.5.4 Management

Management of neonatal ALF requires intensive support and referral to a pediatric liver unit for early evaluation for liver transplantation. Enteral feeding should be preferred and recommenced as soon as possible, although temporary exclusively parenteral nutrition may be needed.

Galactose- and fructose-free diets should be used until the results of galactose-1-phosphate uridyl transferase and urine succinylacetone are available. Normoglycemia should be maintained by high glucose concentration infused through a central line. Coagulopathy, if severe, must be controlled with the infusion of fresh frozen plasma. Fluids should be restricted to 75% of maintenance to prevent cerebral edema. Ascites may respond to infusion of serum albumin associated with diuretic therapy. Gastrointestinal bleeding should be prevented with ranitidine or omeprazole.

Ventilatory support should be considered early in case of neurological as well as respiratory deterioration. Hepatic encephalopathy should be treated by protein intake restriction to 0.5 g/kg and enteral lactulose.

Wide spectrum antibiotics and fluconazole target on positive cultural findings should be administered even in absence of evidence of sepsis. Intravenous acyclovir should be continued until herpes virus infection has been excluded. Antioxidant cocktail (Table 85.4) may be useful in NH if begun within 48 hours of birth, and in milder cases.

The main causes of neonatal ALF that contraindicate orthotopic liver transplantation are familial hemophagocytic lymphohistiocytosis, neonatal leukemia, mitochondrial disorders with extrahepatic involvement, multi-organ failure and uncontrolled sepsis. Neonatal hemochromatosis and viral ALF are currently the most common indication for liver transplantation in neonatal ALF. Despite the introduction of surgical techniques, such as the split liver, which allow surgeons to use part of a donor liver, the mortality rate remains high for patients on the waiting list for surgery.

Neonatal Cholestasis-Conjugated Hyperbilirubinemia

Chad M. Best, Glenn R. Gourley and Vinod K. Bhutani

86.1 Introduction

Jaundice during the first few weeks of life is a common finding. Frequently, such jaundice is due to elevation of the unconjugated, or indirect bilirubin, and is often the result of a benign process. More concerning is jaundice due to elevation of the conjugated bilirubin fraction. Neonatal cholestasis is defined as an accumulation of biliary substances, such as bilirubin and bile acids because of impaired canalicular bile flow. Neonatal cholestasis manifests with a conjugated hyperbilirubinemia and must be differentiated from unconjugated hyperbilirubinemia, as it is more often associated with a specific disease process. The incidence of neonatal cholestasis has been estimated at 1 in 2500 live births [1].

86.2 Pathophysiology

The process of bile generation in the liver involves two key processes. The first process involves the uptake of bile acids from the blood into the hepatocyte. Uptake across the sinusoidal membrane of the hepatocyte is an active process and involves two receptors: the Na taurocholate cotransporting polypeptide (NTCP) and the organic anion transporting proteins (OATP). Besides transport of bile acids, these receptors also transport other anions, such as toxins and drugs, across the sinusoidal membrane. The secretion of bile acids across the biliary canalicular membrane involves the bile salt export pump (BSEP) and the multidrug resistant proteins (MRP2 and MDR3).

In neonates, there is structural, as well as functional, immaturity of the biliary system. Such immaturity increases susceptibility to cholestasis. The uptake of bile acids across the sinusoidal membrane can be affected a number of ways, as with down regulation of NTCP and OATP receptors, secondary to sepsis and hepatitis, resulting in cholestasis secondary to decreased bile production. Alteration in the canalicular membrane receptors can similarly result in cholestasis, such as that seen with mutation in the BSEP or MDR3 in the progressive familial intrahepatic cholestasis syndromes.

86.3 Classification of Neonatal Cholestasis

The differential diagnosis of neonatal cholestasis is extensive (Table 86.1). Neonatal cholestasis can be classified according to anatomy or etiology. Anatomically, causes of cholestasis can be classified as extrahepatic or intrahepatic. Examples of extrahepatic causes of cholestasis are choledochal cysts and biliary atresia, whereas idiopathic neonatal hepatitis, congenital infections, and α_1-antitrypsin (α_1-AT) deficiency are examples of intrahepatic causes. Etiologically, the causes of cholestasis can be categorized as infectious, metabolic, toxic, chromosomal, vascular disorders and bile duct anomalies.

86.4 Clinical Presentation

Infants with cholestasis usually present with the classic triad of prolonged jaundice, pale stools, and dark urine. Acholic stools warrant expedient evaluation. The spectrum of clinical presentation can vary from progressively poor feeding, failure to thrive, and hypoglycemia seen with metabolic disease to a picture of acute illness with lethargy, irritability, and poor feeding, in patients with such causes as bacterial sepsis, galactosemia and other metabolic syndromes. Bleeding may be present due to vitamin K deficiency secondary to malabsorption of fat soluble vitamins or from deficiency of clotting factors.

On physical examination, cholestatic infants will exhibit jaundice. Hepatomegaly is common, with splenomegaly a sign of advanced liver disease. A mass may be appreciated in

the right upper quadrant in the case of a choledochal cyst or a characteristic facies in Allagile's syndrome. Growth retardation can be seen with congenital infections, such as rubella and cytomegalovirus.

86.5 Evaluation

Neonatal cholestasis should be urgently evaluated in any infant who is jaundiced after 2 weeks of life [2]. Evaluation should commence with a detailed patient history, including family, pregnancy, antenatal, and postnatal histories, and physical examination. Important clues indicating a cholestatic etiology may be missed without a thorough history and examination. Fractionation of the total bilirubin level is crucial in the initial investigation of cholestasis.

Once cholestasis is established with an elevated conjugated bilirubin, further investigation should proceed in a logical, stepwise manner to ensure conditions requiring immediate intervention, such as galactosemia, sepsis, and hypothyroidism are not overlooked and are treated in a timely manner. Next, evaluation for biliary atresia is crucial as the successful surgical treatment of biliary atresia also depends on timely diagnosis [3]. After biliary atresia has been excluded, evaluation should be done to establish the cause of intrahepatic cholestasis. A suggested approach to the evaluation of infants with cholestatic jaundice is summarized in Fig. 86.1.

86.5.1 Laboratory Evaluations

The first step in diagnosing neonatal cholestasis is the fractionation of the total serum bilirubin. Conjugated hyperbilirubinemia is defined as a conjugated bilirubin greater than 1 mg/dL (17 μmol/L) or more than 20% of the total bilirubin level. Serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST) are sensitive indicators of hepatocellular injury but lack specificity or prognostic value. Elevation of alkaline phosphatase (ALP) can be seen in biliary obstruction, but also lacks specificity, as it is also found in bone and kidney. Thus, with ALP elevations, diseases in other organs, such as bone must be excluded. The enzyme gamma glutamyl transpeptidase (GGT) is located in biliary epithelium and elevations are highly sensitive for cholestatic disorders, such as biliary atresia, α_1-AT deficiency, and idiopathic neonatal hepatitis. One exception is seen in progressive familial intrahepatic cholestasis types 1 and 2 in which normal or low levels of GGT can be seen.

86.5.2 Radiographic Investigations

86.5.2.1 Abdominal Ultrasound

Abdominal ultrasonography is a simple, noninvasive procedure that is often used as the first step in the work-up of cholestatic infants. Ultrasound can provide useful information regarding size and appearance of the liver and gallbladder, visualization of gallstones and sludging of bile, and diagnosis of choledochal cysts [4]. The triangular cord sign, which represents a fibrous cone of tissue at the porta hepatis, has been reported to be highly specific and sensitive for biliary atresia, with a specificity of 100% and sensitivity ranging from 85–100% [5, 6]. Abdominal ultrasound can also be used as a screen for anomalies associated with biliary atresia, such as polysplenia and interruption of the inferior vena cava [4].

86.5.2.2 Hepatobiliary Scintigraphy

Hepatobiliary scintigraphy using technetium labeled iminodiacetic acid derivatives represents the only available method of imaging that can evaluate hepatobiliary physiology [7]. As the test can determine the patency of the biliary tract, it is highly sensitive for biliary atresia, but lacks specificity, estimated at 83–100% and 35–50%, respectively [6, 8]. Excretion of the isotope can also be delayed in forms of intrahepatic cholestasis. In biliary atresia, the uptake of the isotope occurs in a normal manner, but excretion into the biliary system and

Non-syndromic paucity of bile ducts

the intestines, is delayed or absent. In forms of intrahepatic cholestasis, such as in idiopathic neonatal hepatitis, the uptake of the isotope is delayed, but the isotope is ultimately excreted into the intestines. Pretreatment with phenobarbital, 5 mg/kg/day for 5 days, improves sensitivity for biliary atresia by stimulating bile acid-independent flow [1].

86.5.2.3 Magnetic Resonance Cholangiography

Magnetic resonance cholangiography is increasingly used to assess the biliary tract. In biliary atresia, there may be failure to visualize the common bile duct and the gallbladder is small. Sensitivity for detecting biliary atresia has been estimated at 95%, with a specificity of 88% [9]. Further research using this modality is needed to assess its reliability in the evaluation of neonatal cholestasis and excluding biliary atresia.

86.5.3 Duodenal Aspirate Analysis

Duodenal fluid can be obtained by either placement of a naso- or oroduodenal tube or using a string in the duodenum. Bilirubin concentration in the aspirate can then be assessed and a duodenal aspirate bilirubin concentration less than that in the serum is suggestive of biliary obstruction. Although sensitivity of duodenal aspirate analysis approaches that for scintigraphy, the test is more invasive.

86.5.4 Liver Biopsy

Percutaneous liver biopsy is the most definitive test in the evaluation of neonatal cholestasis and should be performed in most infants with undiagnosed cholestasis [2]. Biopsy is recommended prior to a surgical procedure for biliary atresia. If biopsy results are equivocal and the infant is less than 6 weeks of age, biopsy may need to be repeated. Histologic findings in biliary atresia include bile duct proliferation and bile plugs. These findings must be differentiated from idiopathic neonatal hepatitis, in which there is giant cell transformation and focal hepatocellular necrosis. Liver biopsy can also be useful to diagnose congenital viral infection, as viral inclusion bodies suggest cytomegalovirus or herpes infection. Lack of intrahepatic bile ducts in infants less than 1 year of age has been found to be an adverse prognostic factor independent of neonatal liver disease etiology [10].

86.6 Management of Cholestasis

The medical management of cholestasis is largely supportive because the underlying disease is often untreatable. Such treatment addresses complications of chronic cholestasis rather than the underlying cause (Table 86.2). These complications include pruritus, malabsorption, and nutritional deficiencies. See also Chapter 85.

86.6.1 Pruritus

The exact cause of pruritus is unknown but most agree that more than one factor is involved in the pathogenesis of cholestatic pruritus. It is not generally a problem in the care of the newborn. Its causes and treatment have been described in children and adults [11–13], when medical management of cholestatic pruritus is concentrated on decreasing the levels

Table 86.2 Medical and nutritional management of cholestasis

Drug	Dose	Side effects
Ursodeoxycholic acid	10–20 mg/kg/day	Diarrhea, hepatotoxicity
Rifampin	10 mg/kg/day	Hepatotoxicity, drug interactions
Phenobarbital	3–10 mg/kg/day	Sedative effects, behavioral changes
Cholestyramine	0.25–0.5 gm/kg/day	Constipation, steatorrhea; hyperchloremic metabolic acidosis
Vitamin A (Aquasol A)	5000–25,000 IU/day	Hepatotoxicity, hypercalcemia; pseudotumor cerebri
Vitamin D		
Cholecalciferol	2500–5000 IU/day	Hypercalcemia
25-OH cholecalciferol	3–5 mcg/kg/day	Nephrocalcinosis
Vitamin E		
Aquasol E	50–400 IU/day	Potentiation of vitamin K deficiency coagulopathy
TPGS (d-alpha tocopheryl polyethylene glycol-1000 succinate)	15–25 IU/kg/day	Diarrhea Hyperosmolality (with TPGS)
Vitamin K (Phytonadione)	2.5–5 mg every other day	
Water soluble vitamins	Twice the recommended daily allowance	

of circulating bile acids in the blood through a variety of mechanisms.

86.6.2 Nutritional Management

Nutritional management should start at the initial visit and growth parameters including height and weight for age and weight for height measurements closely followed. Decreased bile acid delivery to the intestines is the end result of cholestasis regardless of etiology, resulting in fat and fat-soluble vitamin malabsorption. Malabsorption occurs when the intraluminal bile acids concentration falls below the critical micellar concentration, resulting in decreased long-chain triglyceride lipolysis. Essential fatty acid (EFA) deficiency may occur secondary to malabsorption of long chain triglycerides and inadequate intake. Manifestations of EFA deficiency include growth impairment, dry scaly rash, thrombocytopenia, and impaired immune function [14].

Medium chain triglycerides (MCT) are more readily absorbed and are a better source of fat calories. Cholestatic infants should be started on an MCT-containing formula like Pregestimil or Alimentum, which contain 60% and 50% of fat calories as MCT oil, respectively. As a result of steatorrhea and increased energy expenditure, cholestatic infants should receive approximately 125% of recommended dietary allowance based on ideal body weight. Some infants may need additional calories for catch-up growth if significant malnutrition is present and use of nocturnal enteral feeds may be required if oral intake is not adequate.

The fat soluble vitamins A, D, E, and K require solubilization by bile acids into micelles to be absorbed across the intestines. Cholestatic infants are particularly susceptible to fat soluble vitamin deficiency as a consequence of malabsorption. Doses of at least two to four times the recommended daily allowance are given. Vitamin supplementation should continue at least 3 months after resolution of jaundice. Fat-soluble vitamin levels should be followed during treatment (Table 86.2).

86.7 Specific Diseases

86.7.1 Biliary Atresia

Biliary atresia is a progressive inflammatory cholangiopathy resulting in the obliteration of portions or the entire extrahepatic biliary tree. With time, progressive fibrosis and obliteration of the biliary tree results in biliary cirrhosis. Biliary atresia is the most common indication for pediatric liver transplantation and the etiology is unknown. The incidence of biliary atresia is estimated to be 1:8–15,000 [1]. There are two recognized clinical forms of biliary atresia. The perinatal form is most common, accounting for 80–90% of cases, and presents in the first few weeks of life with the cardinal features of jaundice, acholic stools, and hepatosplenomegaly. In the embryonic form of biliary atresia, infants present with early onset of disease, with jaundice at or shortly after birth. Infants with the embryonic form have associated anomalies that can include vascular anomalies of the splenic or portal veins, hepatic artery, or inferior vena cava. Situs inversus, annular lung disease, and congenital heart disease are additional associated anomalies [15].

The infant with biliary atresia is usually full-term, clinically normal at birth, and thrives without difficulty. With time, jaundice and hepatomegaly develop and stools become acholic. Failure to thrive ensues and pruritus, coagulopathy, and splenomegaly develop as the disease progresses.

86.7.1.1 Evaluation

Thorough history taking and physical exam coupled with a logical, systematic approach will help ensure a timely diagnosis of biliary atresia. After documentation of a conjugated hyperbilirubinemia with fractionation of the total bilirubin, further laboratory testing will show elevated transaminases, alkaline phosphatase levels, and gamma-glutamyl transferase levels. Prothrombin time may be elevated secondary to vitamin K deficiency resulting from fat malabsorption.

Abdominal ultrasound often shows a small or absent gallbladder. Care must be taken during interpretation of ultrasound findings because presence or absence of a gallbladder does not confirm or exclude biliary atresia. Observation of the triangular cord sign, by an experienced ultrasonographer, is highly sensitive and specific for biliary atresia. Splenic and vascular anomalies associated with the embryonic form of biliary atresia may also be seen. If findings on ultrasound are inconclusive for biliary atresia, hepatobiliary scintigraphy should be used to determine the extrahepatic biliary patency. Excretion of isotope into the intestines excludes biliary atresia although lack of excretion into the intestines is not specific for the disease and further evaluation is essential.

Liver biopsy can provide the diagnosis in up to 97% of cases when radiologic studies are inconclusive. In biliary atresia, classic histologic findings include bile duct proliferation, bile plugging, and portal tract edema with periportal fibrosis. As bile ductular inflammation and obliteration in biliary atresia is progressive, if liver biopsy is done early in the disease process, repeat biopsy may be necessary if results are initially equivocal [2, 16].

In the event that diagnosis is not possible after liver biopsy and radiologic evaluation, operative exploration and cholangiography is then recommended. α_1-AT deficiency, as well as other causes of intrahepatic cholestasis, presents similarly to biliary atresia and should be excluded prior to laparotomy, as these conditions can be worsened with portoenterostomy [17].

86.7.1.2 Management

After confirmation of biliary atresia with an intraoperative cholangiogram, the treatment of choice is the Kasai hepatoportoenterostomy. The surgery involves removal of the fibrous tissue at the porta hepatis and formation of a roux-en-Y anastomosis between the duodenum and the hilum of the liver. The two most important prognostic factors determining success of the Kasai procedure are age at operation and experience of the surgeon [18, 19]. The relationship of survival to age is not linear or stepwise and the rate of survival with native liver has been estimated at 90% for those with surgery by 100 days of age compared to 60% if the surgery is performed after 100 days of life [18]. Complications of the Kasai procedure include ascending cholangitis and portal hypertension. Ascending cholangitis is a common and frequently recurrent postoperative complication with affected patients presenting with fever, worsening jaundice, and elevated ESR. Cholangitis can worsen the prognosis in those who have had restoration of bile flow after portenterostomy. Recurrence of cholangitis is the single most significant variable pertaining to long-term prognosis [20]. After initial treatment with intravenous antibiotics, those with recurrent ascending cholangitis may benefit from prophylactic antibiotics, such as oral trimethoprim-sulfamethoxazole or neomycin [21].

Treatment with steroids after the Kasai procedure has been shown to lower postoperative bilirubin levels, but no improvement in terms of cholangitis attacks and early liver transplantation is seen [22]. Portal hypertension may develop in 40–80% of patients within 5 years after the Kasai procedure [15]. These patients have splenomegaly that may be complicated by ascites and variceal bleeding. 20% of the patients that have portal hypertension may be noted to have portal vein thrombosis, likely secondary to ongoing portal tract inflammation. Therapeutic endoscopy with either ligation or sclerotherapy can be used to treat acute variceal bleeding.

In addition to the surgical management, patients should also receive supportive care for cholestasis, including supplementation of fat-soluble vitamins and a high calorie diet. See also Chapter 85.

86.7.2 α_1-Antitrypsin Deficiency

Alpha$_1$-AT deficiency is the most common inherited cause of neonatal cholestasis, caused by mutations in the gene found on chromosome 14. α_1-AT is a glycoprotein with inhibitory activity against elastase, trypsin, and other proteolytic enzymes. More than 75 different variant α_1-AT mutants have been found but only a few are clinically relevant, with M being normal and Z being most deficient. Patients with PiZZ phenotype have greatly reduced amounts of α_1-AT, around 10%–15% of normal, with an incidence of 1 in 2000 live births in European and North American populations [23]. The PiZZ phenotype is associated with neonatal liver disease and adult emphysema.

Approximately 15 percent of PiZZ neonates develop clinical disease within 20 years and accumulation of the defective α_1-AT molecule in the liver is the cause of hepatic injury [24]. These infants have intrauterine growth restriction and are more likely to develop coagulopathy compounding the cholestasis. On biopsy, periodic acid-Schiff-positive diastase-resistant inclusions within hepatocytes represent the abnormal α_1-AT protein. Documenting low plasma α_1-AT levels and determining α_1-AT phenotype confirms the diagnosis.

As with idiopathic neonatal hepatitis, management of α_1-AT deficiency is mostly supportive and includes nutritional supplementation. Prognosis is related to the severity of the liver disease. In children with progressive liver disease, liver transplantation has shown good survival rates of 90 % at 1 year and 80% at 5 years [25].

86.7.3 Idiopathic Neonatal Hepatitis

Idiopathic neonatal hepatitis accounts for approximately 30% of neonatal cholestasis cases. A diagnosis of exclusion, idiopathic neonatal hepatitis is diagnosed by documentation of classic histologic findings on liver biopsy. Although occasional familial cases suggest a genetic association, most cases are sporadic.

Infants with idiopathic neonatal hepatitis are often low birth weight. Jaundice is present within the first few weeks of life and not immediately after birth. The liver may be enlarged on physical examination and serum bilirubin and hepatic transaminases mildly elevated. Low or normal GGT levels may signify more severe disease and a worse prognosis, especially if GGT levels do not increase over the course of the disease [26]. On liver biopsy, findings include lobular disarray with hepatocyte swelling, giant cell transformation, and increased extramedullary hematopoiesis.

In contrast to biliary atresia, management of idiopathic neonatal hepatitis is largely supportive. Prognosis is excellent with 90% resolution by 1 year of age in sporadic cases but worse in familial cases.

86.7.4 Progressive Familial Intrahepatic Cholestasis

Progressive familial intrahepatic cholestasis (PFIC) is a group of genetic disorders, with autosomal recessive inheritance, associated with progressive intrahepatic cholestasis. There are three forms that vary in presentation, diagnosis, and treatment.

PFIC-1, the original Byler disease described in an Amish family, is caused by a mutation in the FIC 1 gene. The FIC 1 gene mutation results in episodic cholestasis in the first month of life. With time, the jaundice resolves but the pruritus continues and end stage liver disease ensues. The FIC1 gene has a wide tissue distribution and besides the canalicular membrane, is also expressed in the pancreas, small bowel, stomach, bladder, heart, and kidney. Such wide tissue expression explains the diarrhea and pancreatitis with fat-soluble vitamin deficiency seen in affected patients. Importantly, serum GGT and transaminase levels are normal, with markedly elevated serum bile salts. Liver histology at biopsy shows bile duct paucity. Management is largely supportive. Surgical approaches that deplete the bile salt pool, such as partial biliary diversion and partial ileal bypass, may be effective. Cirrhosis is usually seen by the end of the 1st decade and liver transplantation for hepatic decompression by the 2nd decade.

PFIC-2 is caused by a defect in the canalicular bile salt excretory pump (BSEP). Clinical presentation is similar to PFIC 1, with the exception of lack of the extraintestinal manifestations. Liver biopsy usually shows more inflammation and management is supportive. Prognosis is worse for those requiring liver transplantation in the 1st decade of life.

PFIC 3 is caused by defective phospholipid flippase function of MDR3, the canalicular phospholipid transporter, resulting in bile characterized by significant concentrations of unmicellized bile salts. Clinical presentation, similar to PFIC 1, is often delayed until early adulthood. There is often a history of cholestasis of pregnancy in the mother. In contrast to PFIC 1 and 2, GGT is markedly elevated and bile analysis shows a high bile acid to phospholipid ratio. Liver biopsy may appear consistent with biliary atresia but the biliary tract will be patent on scintigraphy or cholangiography. The prognosis is variable and, as with the other forms of PFIC, management is supportive.

86.7.5 Cholestasis in Premature Infants

Cholestasis is common in very low birthweight infants, with a multifactorial etiology. The biliary system is immature in these infants resulting in an exaggerated physiologic cholestasis. Other factors can contribute to cholestasis in premature infants, including perinatal hypoxia, sepsis, parenteral nutrition (PN), and enteral feeding difficulties [27, 28].

Cholestasis is a frequent complication of PN. Although the exact etiology is unknown, immaturity of the enterohepatic circulation likely plays a role. Risk factors include early initiation and prolonged PN, lack of enteral feeds, sepsis, and prematurity. Conjugated hyperbilirubinemia with elevated transaminases is usually seen within 2 weeks of commencing PN. Management includes decreasing or cessation of PN and increasing enteral feeds. In those infants who cannot tolerate full enteral feeds, trophic feeds should be instituted to decrease enterohepatic circulation. In such infants, modifications in PN formulation should include limiting glucose intake to 15 gm/kg/day, limiting intralipid, cycling of PN to 12 hours daily, and reducing or eliminating manganese and copper, as these trace nutrients are primarily secreted via bile. Ursodeoxycholic acid can aid in stimulating bile acid excretion via mechanisms previously discussed.

Biliary atresia is rare in premature infants and liver biopsy and hepatobiliary scintigraphy should be delayed in these infants until corrected gestational age (CGA) is term and weight is greater than 2 kg. Liver biopsy should be performed if cholestasis persists past 2 months CGA, presence of acholic stools, and those without excretion on hepatobiliary scan.

86.7.6 Alagille Syndrome

Alagille syndrome is the most common cause of familial intrahepatic cholestasis. Characterized by paucity of intrahepatic bile ducts, Alagille syndrome is inherited in an autosomal dominant fashion, with variable penetrance, and is estimated to affect 1 in 100,000 live births. Mutation occurs in the Jagged 1 gene, on chromosome 20p12, that encodes a protein involved with cell differentiation [29].

Alagille syndrome manifests as chronic cholestasis associated with a characteristic facies and involvement of the skeletal, cardiac, and ocular systems. Infants have a saddle nose and broad forehead. Skeletal system involvement includes butterfly vertebrae, curved phalanges, and short ulna. Peripheral pulmonic stenosis, tetrology of Fallot, pulmonary atresia, and VSD are cardiac anomalies that may be seen. Posterior embryotoxon and optic nerve drusen constitute eye findings. Supernumerary digital flexion creases are seen in 1/3rd of cases [30]. Cutaneous xanthomas secondary to hyperlipidemia can also be seen.

Initially, infants with Alagille syndrome present with neonatal cholestasis, as seen in biliary atresia. Differentiation of the two disorders can be difficult because initial liver biopsies may show bile duct proliferation consistent with BA. Bile ducts are initially structurally normal and are then progressively lost. Characteristic facies may not be evident until 2 years of age.

Management is largely supportive, with nutritional support including fat-soluble vitamin supplementation. Of those who present with cholestasis in the newborn period, over 50% will require liver transplantation by 10 years of age secondary to cirrhosis.

Caution must be used in evaluation of family members as matched living donors, as there may be subclinical disease in such donors. Hepatocellular carcinoma has been reported in patients with Alagille syndrome.

Surgical Treatment of Biliary Tract Malformations

George Ekema and Pierluigi Pedersini

87.1 Biliary Atresia

Biliary atresia (BA) is a progressive necroinflammatory process involving the extrahepatic biliary tree, either partially or completely. The disease shows the onset during the first days of life and usually evolves into obliteration of the extrahepatic bile duct lumen with interruption of bile flow, resulting in cholestasis and chronic liver damage. If untreated, the disease leads to exitus within the first 2 years of life. Early diagnosis is mandatory to plan a timely surgery, preferably within 80 days of life.

Although Kasai portoenterostomy can achieve a good relief of cholestasis in about a half of cases, even children successfully treated show the consequences of liver derangement, namely hepatic fibrosis or cirrhosis with portal hypertension, so that the majority of BA patients need organ replacement later in life. Actually, BA is still the most common indication for pediatric liver transplantation worldwide, and the sequential use of Kasai's procedure and liver transplantation have dramatically increased the survival rate of these patients during the last few decades [2].

BA is the most common cause of cholestatic jaundice in the newborn and its prevalence is about 1:10,000–15,000 live births, meaning approximately 700 newborns affected every year in Europe, with a small female preponderance. Incidence of BA is highest in Asian and Pacific populations and familial cases have been reported [3].

Obliteration of bile ducts can involve any branch of the extrahepatic biliary tree, and the types of BA are classified according to the site of obstruction [4]: type I involves just the common bile duct; type II also involves the cystic and the hepatic ducts and type III, present in more than 95% of cases, involves all extrahepatic biliary ducts and represent the most severe form of BA.

P. Pedersini (✉)
Pediatric Surgery Unit, University of Brescia
Spedali Civili, Brescia, Italy

Two anatomical forms of BA have been identified: nonsyndromic BA (~90%), in which BA is an isolated anomaly; and syndromic BA (~10%), associated with various congenital anomalies such as polysplenia, asplenia, cardiac or intraabdominal defects (situs inversus, preduodenal portal vein, absence of retrohepatic inferior vena cava, intestinal malrotation) [5].

87.1.1 Etiology and Pathogenesis

The origin of BA still remains unclear. Some cases seem to be related to abnormal morphogenesis of bile ducts occurring early in pregnancy (embryonic or fetal BA), while many cases appear to arise from later damage to normally developing bile ducts (perinatal or acquired BA) [5].

Epidemiologic studies support a possible infectous etiology. An association with virus infections has been reported (CMV, RSV, EBV and HPV); in contrast, no association with hepatitis A, B and C viruses has been found [3]. The two viruses most commonly implicated are reovirus and rotavirus. In human neonates the association of Reovirus type 3 and BA has been suggested, but not confirmed otherwise. The role of Rotavirus type C in the etiology of BA in humans remains controversial. Thus, no study so far has managed to definitively prove the role of a specific virus as an etiologic agent of BA.

The role of immune dysfunction has been based on the assumption that the biliary epithelium may express inappropriate antigens on its surface that can be recognized by lymphocytes after viral or toxic damage; an immune cascade will produce inflammation and biliary fibrosis [6].

The progressive nature of liver injury in patients with BA, the presence of lymphocytes in the liver and the association with specific types of HLA, suggest a possible autoimmune, persistent attack against biliary epithelium [7].

Finally, several observations suggest that a genetic component plays a role in the pathogenesis of BA, although this is probably only one of multiple factors.

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

87.1.2 Clinical Aspects

The clinical signs are jaundice, acholic stools, dark urine and hepatomegaly. The liver gradually increases in size and consistency along with aging. Splenomegaly also follows hepatomegaly, suggesting portal hypertension. The general condition of the newborn is usually good with adequate weight growth; mild jaundice is often missed and the diagnosis is established later. When the patients are untreated, the majority of them will die of hepatic failure, esophageal variceal bleeding and infection [1].

87.1.3 Diagnosis

Antenatal diagnosis of BA remains exceptional. Since early diagnosis appears essential for successful surgical treatment, neonatal jaundice lasting more than two weeks should be investigated for BA

There are many causes of pathological jaundice in the neonatal period and the most likely to be confused with BA are neonatal hepatitis syndrome and interlobular biliary hypoplasia. When jaundiced infants show acholic stools, dark urine and hepatomegaly with hardening in consistence, BA should be strongly suspected [1].

Biochemical liver function tests show increased total bilirubin (TB) with predominance of direct bilirubin (DB) of more than 50% and high levels of γGT, ALT and AST (more than 2–3 times normal values). BA is very strongly suspected with the presence of TB greater than 4.5 mg/dL, DB more than 80% of TB and γGT greater than 500 UI/L [1].

Ultrasonography of the liver may identify a small, nondistended gallbladder and show the "triangular chord sign", representing the fibrous cone of bile duct remnant at porta hepatis [8]. This sign demonstrates high specificity and positive predictive value of 95% for the diagnosis of BA [9]. Ultrasonography also plays an important role in the assessment of splenomegaly or associated anomalies, such as polysplenia.

Hepatobiliary scintigraphy (e.g., Tc-99m DISIDA) shows a failure of escretion of the radioisotope into intestine, but this feature can also be observed in any severe neonatal cholestasis and therefore it is of limited value. The role of endoscopic retrograde cholangiopancreatography (ERCP) [10] and Magnetic Resonance Cholangiography (MRC) [11] in the diagnosis of BA have still been under discussion, because they may be performed in selected skilled centers only.

The definitive diagnosis is based on the fibrosing obstruction of the extrahepatic biliary tree during exploratory laparotomy with cholangiography and liver biopsy [1]. The main histological features suggestive of BA are bile plugs, ductular proliferation, inflammatory infiltration and portal fibrosis [12].

87.1.4 Therapy and Treatment

The current surgical management of BA provides two steps: Kasai operation in neonatal period, which aims to restore bile flow; and later liver transplantation, when the Kasai operation has failed [3].

The Kasai operation is a portoenterostomy, introduced by Kasay and Suzuky in 1959, in which biliary drainage is established by a 45 cm Roux-en-Y loop anastomosis to the hepatic hilum, after careful dissection to locate patent bile duct remnants in the porta hepatis [19]. An alternative laparoscopic approach was first reported in 2002 [13].

The best surgical results after Kasai operation are obtained in children operated within 60 days of life, with satisfactory biliary drainage in at least 70–80% of cases [5], resulting in increased pigmentation of stools and resolution of jaundice. Thus, the age at treatment is one of the most important factors determining surgical outcome, that can however be influenced by postoperative complications.

The most common complications following the Kasai operation are cholangitis and portal hypertension. Rare complications include hepatopulmonary syndrome, pulmonary hypertension, intrahepatic biliary cavities and malignancy [3].

Cholangitis occurs particularly in the first week or months after the operation in 40–60% of cases and is characterized clinically by fever, irritability, vomiting, jaundice, choluria and acholic stools; treatment requires IV antibiotics and corticosteroids [21]. Portal hypertension occurs in at least two-third of children after Kasai operation and the most common sites of varices include esophagus, stomach and Roux loop. Treatment requires variceal sclerotherapy or band ligation; severe hypersplenism may exceptionally require splenic embolization [3].

Factors shown to predict outcome after Kasai operation include: age at operation, experience of the surgeon, site of atresia of extrahepatic bile ducts and number and severity of episodes of cholangitis [5, 14].

87.1.5 Prognosis

Overall, Kasai operation is curative in approximately 20% of patients, while the other patients develop progressive hepatic failure that leads to liver transplantation [1, 2].

The choice of sequential treatment by Kasai operation and secondary liver transplantation is supported by the following reasons: firstly, performing liver transplantation in all children with BA would deprive some of these of the possibility to live with their own liver, while the long-term results of liver transplantation and prolonged immunosuppression are not entirely known; secondly, performing transplantation on all children with BA will dramatically increase the need of pediatric liver grafts at this time when the shortage of organs is as yet an

unsolved problem; lastly, liver transplantation at an older age reduces the period of immunosuppressive therapy.

The overall prognosis of BA has improved since the early days of pediatric liver transplantation. Currently, about 90% of children with BA, treated by Kasai operation and liver transplantation have an acceptable quality of life [3, 14].

87.2 Congenital Bile Duct Dilatation

Congenital bile duct dilatation (CBDD) is a relatively rare malformation of the pancreatobiliary system with an incidence between 1:130,000 and 1:2,000,000 and a female predominance (F:M = 3:1). For unknown reasons, it is much more common in Asians, with the majority of the reported cases in Japan. A maternally inherited condition, such as an X-linked dominant trait, has been suggested recently. Several cases of familial recurrence have been reported [15].

In 1977, Todani classified CBDD into 5 types:

- Type I: cystic dilatation of the common bile duct (80% of cases)
- Type II: diverticulum of the common bile duct (10%)
- Type III: choledochocele (4%)
- Type IV (11%)
  a. intra-extrahepatic bile ducts dilatation
  b. plurisegmental common bile duct dilatation and
- Type V: isolated intrahepatic bile ducts dilatation (<1%).

87.2.1 Etiology and Pathogenesis

The etiology of CBDD remains essentially unclear. An anomalous pancreatobiliary duct junction with a long common channel involving the common bile duct and the main pancreatic duct is often present and may be a responsible factor for CBDD, allowing pancreatic reflux into the biliary system and leading to duct wall destruction and dilatation. Distal common bile duct stenosis or obstruction may add to ductal dilatation. An autonomic dysfunction by diminished ganglion cells in the distal common bile duct causing partial obstruction and proximal dilatation has been suggested.

87.2.2 Pathology

Two histopathological types of CBDD that may be present concurrently or separately have been described: the "glandular" type, in which there are microscopic cavities in the mucosal layer with chronic inflammatory infiltrate; and the "fibrotic" type, in which the wall is composed mainly of fibrous tissue with interrupted elastic fibers, well-developed collagen fibers and lower inflammation.

87.2.3 Clinical Aspects

It is primarily a disease of older infants and young children and more than half of cases present in the first decade of life. The classic presentation of CBDD with jaundice, abdominal pain and a right hypocondrial mass is seen only in one third of children. Infants usually present with asymptomatic jaundice that may be mild and intermittent or progressive due to complete biliary obstruction. Late complications in cases with delayed or escaped diagnosis are represented by cholelithiasis, cirrhosis, portal hypertension, liver abscess, spontaneous rupture and biliary carcinoma [16].

87.2.4 Diagnosis

There are no specific laboratory tests, and the initial diagnosis is made by US. The findings of a dilated common bile duct with US is helpful for early diagnosis of CBDD. TC may show the cystic dilatation better than US, it does not however demonstrate ductal anatomy [17]. Because biliary duct imaging is essential, the diagnosis must be confirmed by MRC, especially when dealing with the fusiform type [18]. ERCP requires an experienced endoscopist and must be done in older infants or young children with caution, in order to avoid infection of the cyst or precipitate pancreatitis. In most cases, CBDD have been demonstrated in the developing fetus by antenatal maternal ultrasound.

87.2.5 Therapy and Treatment

In the past, internal drainage by cistoenterostomy was the accepted surgical treatment. Nevertheless, this procedure led to significant morbidity due to recurrent cholangitis, cholelitiasis, pancreatitis, anastomotic stricture and persistent risk of biliary carcinoma. The surgical procedure of choice today is cholecistectomy and total excision of the CBDD with a Roux-en-Y hepaticojejunostomy. Before intervention, a cholangiography through the gallbladder is performed to accurately demonstrate the anatomy of the cyst and the pancreatobiliary ductal system.

When the ductal dilatation extend into the main hepatic ducts, after excision of all involved ductal tissue, polyductal Roux-en-Y jejunostomy must be performed. In case of choledococele, which is located inaccessibly within the distal common bile duct, complete surgical excision is precluded. The approach should be transduodenally, and the presenting wall of choledococele is excised with marsupialization of choledococele into the duodenum.

The laparoscopic excision of CBDD is an alternative to standard surgical approaches and the first large pediatric series was published in 2004 [19]. This approach is technically feasible, safe and effective with a comparable outcome to the

open procedure. Additional benefits of laparoscopic approach, compared to laparotomy, are less postoperative pain with less pulmonary complications, a shortened period of ileus and less adhesion formation [20]. The increasing number of laparoscopic biliary reconstruction suggest that this procedure should be considered as a viable alternative to standard surgical approaches, nevertheless it is technically demanding and requires advanced skills; a long-term follow-up is still required to clearly demonstrate their benefits [20].

87.2.6 Prognosis

If the dilated bile duct is totally excised and surgery is performed prior to irreversible liver damage, the prognosis is excellent. Currently, the hepaticojejunostomy has a low surgical mortality and morbidity rate. Cholangitis, anastomotic stricture, and pancreatic duct injury are main postoperative complications.

87.3 Congenital Solitary Liver Cyst

Solitary liver cyst (SLC) is a benign lesion seen four times more often in females and it can be classified as simple solitary liver cyst and solitary intrahepatic biliary cyst [21]. The spectrum of potential pathologies causing congenital solitary liver cysts in children is wide [22].

87.3.1 Etiology and Pathogenesis

The etiology of simple congenital cysts is unknown. They are generally thought to develop from aberrant bile ducts or as a result of a vascular disruption during the fetal period [21].

87.3.2 Pathology

Simple cysts are typically unilocular, lined by cuboidal or columnar epithelium and underlined by loose connective tissue. The cystic fluid may be clear, brown or, occasionally, bilious [23]. They rarely communicate with the biliary tree and are not considered premalignant. They may be completely intrahepatic, partially extrahepatic, or pedunculated. The presence of septa is usually regarded as a pointer to other pathologies and the need for further investigations [22].

87.3.3 Clinical Aspects

Most solitary liver cysts are asymptomatic and identified incidentally or antenatally in the third trimester [21, 24]. Simple cysts rarely cause symptoms unless large. In such cases abdominal distension, feeding difficulties, respiratory distress and duodenal obstruction have been reported [25]. Infection, hemorrhage or rupture are other rare complications.

87.3.4 Diagnosis

US and TC are widely used for the diagnosis of SLC; US should demonstrate the cyst location, loculation, wall contour and characteristics, content and associated pathology. In the differential diagnosis, TC and MRI should be able to show a mesenchymal hamartoma [24]. In selected cases, functional hepatic scintigraphy may be useful in distinguishing a simple from choledochal cyst by the different radioisotope uptake [22].

The differential diagnosis of upper quadrant abdominal cysts and masses include hepatobiliary lesions such liver cysts, parasitic cysts, benign tumors (mesenchymal hamartoma, cystadenoma), malignant tumors (sarcoma), choledochal cyst and biliary atresia; other intra-abdominal cysts (ovarian, omental, mesenteric, adrenal or renal cysts) and different conditions such as dilated bowel loops, duodenum and gallbladder duplications [26].

87.3.5 Therapy and Treatment

Most unilocular cysts do not require intervention postnatally. They remain asymptomatic and may even decrease in size over time. Intervention is required among children who are symptomatic for a mass effect [24]. Percutaneous aspiration has been reported antenatally and postnatally and is a possible alternative to open surgery. The total excision or enucleation seems to be the treatment of choice, but will depend on the anatomical lesion. If this it not possible, partial excision with marsupialization of the cyst wall is recommended [21, 25].

During surgery, communication with the extrahepatic and intrahepatic biliary sistem has to be ruled out by cholangiography [21]. In the case of a biliary cyst, a Roux-en-Y cystoenterostomy or hepaticojejunostomy as described for CBDD, is recommended [23]. Radical liver resection should be avoided to minimize postoperative complications.

87.3.6 Prognosis

The postoperative course can be complicated by bile leakage, cholangitis, septicemia and recurrence of the cyst [21, 22]. Children who undergo partial excision must be followed up closely for recurrence.

88

Orofacial Malformations

Roberto Brusati and Giacomo Colletti

88.1 Embryology

During the 4th week of intrauterine life, a central depression forms at the front of the cephalic portion of the embryo, i.e., the primary stomodeum, around which are protuberances. The fronto-nasal protuberance is at the top (the future front part of the brain), the mandibular part of the 1st branchial arch is below, and the maxillary protuberances (also derived from 1st branchial arch) are on the sides. Two ectodermal thickenings (olfactory pits) form on the lower surface of the nasal-frontal protuberance: external and internal nasal processes. Meanwhile the maxillary processes grow forward and medially, meeting and fusing with the nasal processes and forming the upper lip and nostrils. Simultaneously within the floor of the primitive stomodeum, the tongue forms from the merging of five processes. The palatal processes form on the sides and a median laminar structure on the roof will become the septum.

At about the 5th week of gestation, the maxillary and mandibular processes merge, forming the ear, the temporo-mandibular joint and the muscles of mastication. The tragus, root of the helix and antihelical fold originate from the 1st branchial arch while the helix, antihelix, antitragus and lobe derive from the 2nd branchial arch.

At the 8th week of gestation, palatal processes (previously arranged vertically on the sides of the tongue) rise and become horizontal and then meet the septum in the midline to separate the oral from the nasal cavity.

88.2 Cleft Lip and Palate

Cleft lip and palate is one of the most frequent congenital malformations: frequency around 1 in 800 births. 20–30% of cases have a genetic basis while in others there is a teratogenic factor, e.g., a viral or bacterial infection, or the use of medications (e.g., cortisone, phenytoin, high doses of vitamin A), a hypovitaminosis (folic acid), alcohol or smoking. These factors have to act during the first two months of gestation for teratogenicity to occur and the genetic backgrounds on which these factors act is crucial for the teratogenic effect.

A cleft lip can be diagnosed from 12 weeks of intrauterine life by ultrasound while the cleft palate is better diagnosed by MRI. There are different anatomical types. The lesions may be:

a. unilateral or bilateral;
b. form where only the lip is affected, which are considered complete if the involvement goes from the nose floor to the vermilion, and incomplete if only the lower part of the lips is affected;

Fig. 88.1 Cleft of hard and soft palate (CP)

R. Brusati (✉)
Department of Maxillo-Facial Surgery, San Paolo Hospital
University of Milan, Milan, Italy

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

Fig. 88.2 Unilateral complete cleft lip and palate (CLP)

c. form affecting only the palate, involving only the soft or soft and hard parts or consisting of a failure of muscle fusion (submucous cleft) (Fig. 88.1);
d. form affecting the lip, alveolus, maxilla, hard and soft palate (complete cleft lip and palate) (Fig. 88.2).

At birth, children with cleft lip alone present only a cosmetic problem, whereas cleft lip and palate or isolated cleft palate are characterized by an impaired ability to suckle. Feeding is enabled by use of a nipple with an enlarged hole and a plastic bottle that can be gently squeezed (the ability to swallow is normally preserved) and even passage of milk from the nose is without serious consequence. A nasogastric tube should then be avoided. Treatment requires collaboration between different specialists: surgeon, orthodontist, otolaryngologist, pediatrician, psychologist and speech therapist.

In very wide clefts, when there is the interposition of the tongue between the stumps, a palatal plate is applied from the first days (Fig. 88.3). This can reduce the cleft size and facilitate feeding. In bilateral forms, where there is a very short columella, the insertion of a palatal plate with two intranasal prongs (Fig. 88.4) is associated with preoperative lengthening of the columella [1].

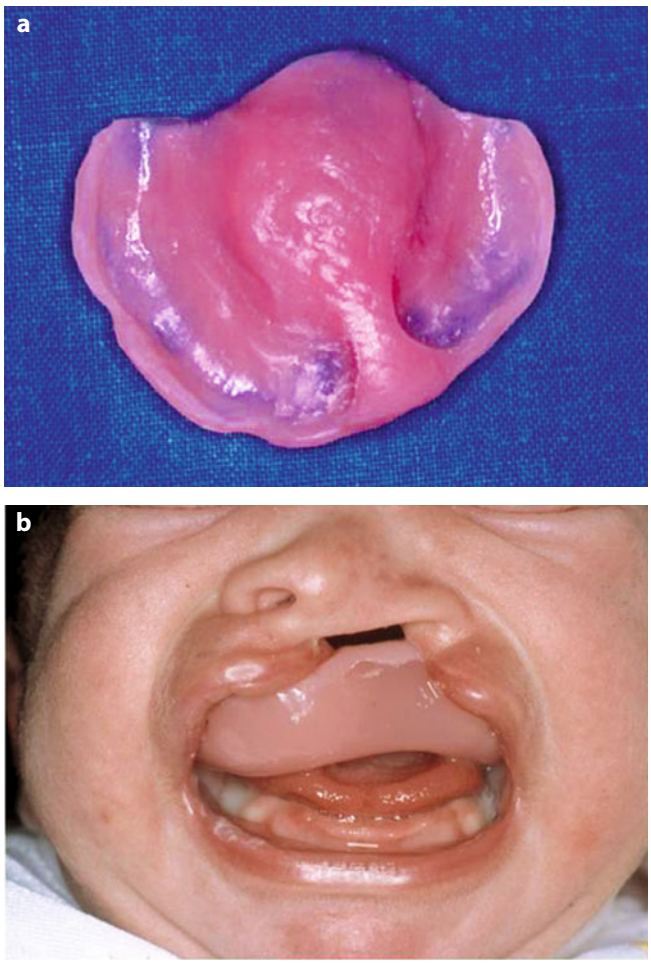

Fig. 88.3 Orthopaedic plate (**a**) in place (**b**)

There are various surgical approaches. At the maxillo-facial unit at University Hospital San Paolo, Milan, Italy, the soft palate is generally repaired at around 4–6 months [2–4] together with lip and nose. The hard palate and the alveolar region (gingivo-alveolo-plasty) are repaired between 18–36 months. In unilateral cases less than 10 mm in width, the lip, nose, and hard and soft palate are repaired in a single operation

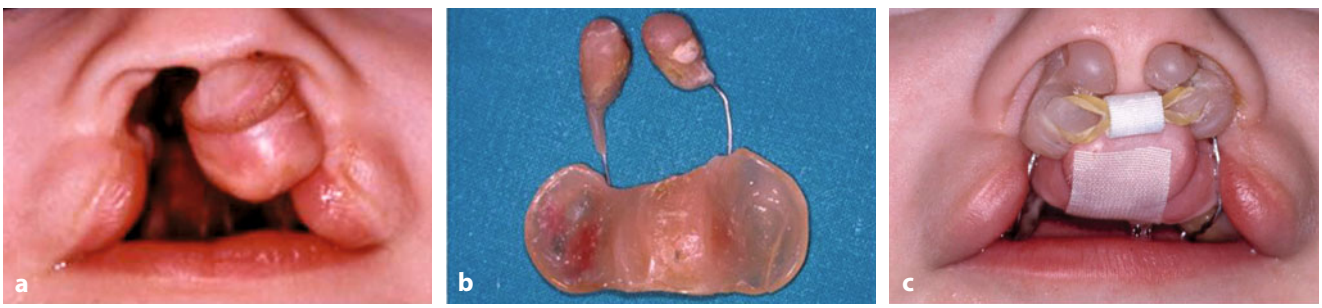

Fig. 88.4 **a** Bilateral CLP with a very short columella. **b** Orthopaedic plate to lengthen the columella. **c** The plate in place and the lengthened columella

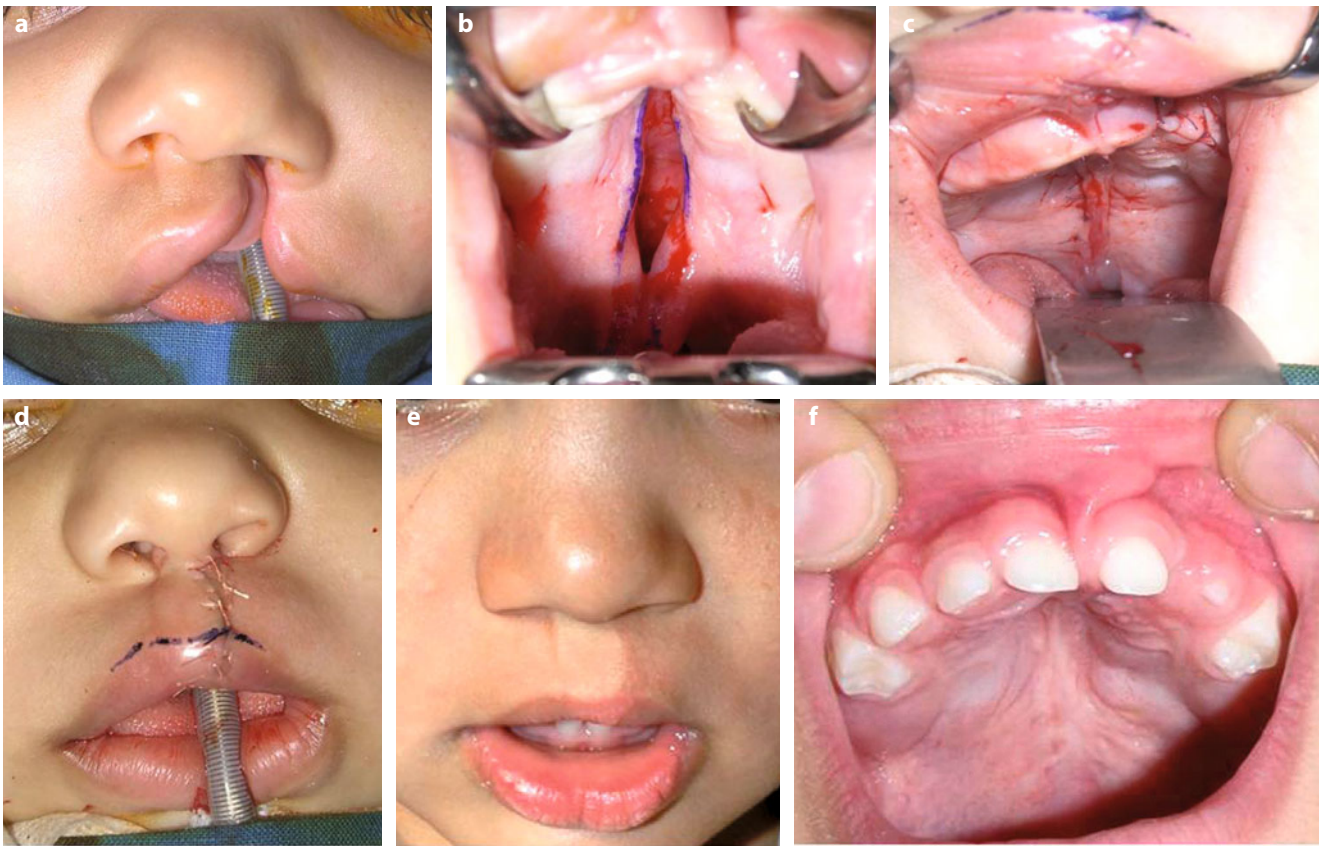

Fig. 88.5 Unilateral CLP operated "All in one"

(Fig. 88.5) [5]. When there is no early repair of the alveolar region, bone grafting is done at 6 years. These children are at high risk of developing ear infections because of altered function of the tensor palati muscle, which has its insertion at the auditory tube, and the otolaryngologist assesses the condition of the ears and the possibility of placing a trans-tympanic drain at the first procedure.

The orthodontist corrects malocclusions that are often present, generally not before the age of mixed dentition. The speech therapist evaluates phonation at 3 years. In a small number of cases, further work may be necessary to improve velopharyngeal competence. In some cases (20%), a maxillary osteotomy is required at the end of growth to optimize appearances and the occlusion with possible adjustments of residual nasal and labial anomalies.

88.3 Pierre Robin Sequence

Pierre Robin sequence is characterized by micrognathia, cleft palate, and glossoptosis. This sequence, which has a frequency between 1/10,000 and 1/20,000 newborns, is due to micrognathia that does not allow the tongue to go down to

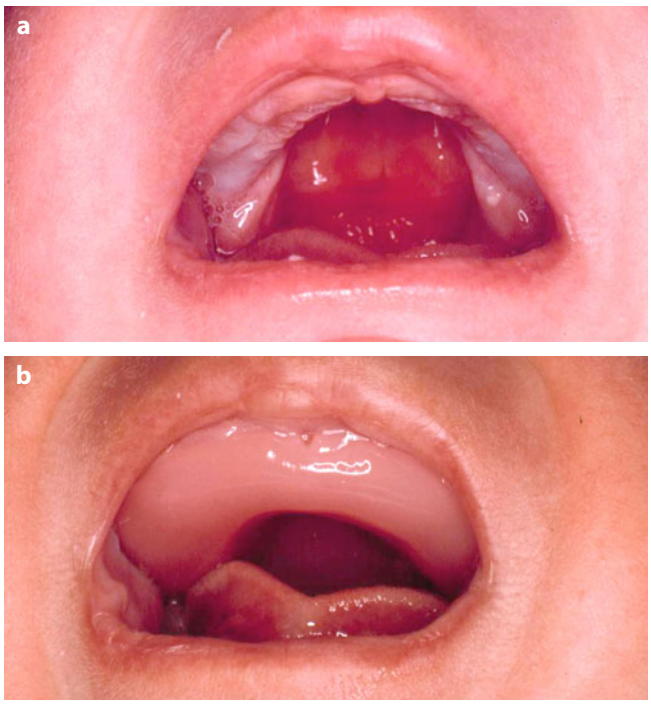

Fig. 88.6 Pierre Robin sequence: **a** typical extremely wide cleft palate; **b** orthopaedic plate in place

the floor of the mouth, remaining in the nasal cavity and preventing the palatine plates from rising and meeting and subsequently fusing in the midline. The result is a glossoptosis that may cause serious respiratory problems at birth. This may be associated with delayed neurological maturation and reduced tone of the muscles.

Treatment at birth ranges from simple positioning of the baby (lying on the side or prone) to the application of a palatal plate to prevent the tongue catching in the wide cleft palate (Fig. 88.6). A nasopharyngeal tube may be required for a few days since muscle tone often improves with the neurological maturation and problems related to glossoptosis resolve. If further intervention is required, the surgical procedure widely employed with success is the so-called tongue-lip adhesion (tip of the tongue to the internal surface of lower lip) (Fig. 88.7).

In severe cases, osteodistraction may be performed to stretch the microgenic jaw [6]; the tongue follows the chin forward with enlargement of the respiratory space and resolution of breathing difficulties.

88.4 Hemifacial Microsomias

In this chapter we will consider congenital malformations that arise with a common etiopathogenetic mechanism: a lesion of the 1st and 2nd branchial arch, including oto-mandibular dysostosis, Goldenhar syndrome and the Franceschetti syndrome.

88.4.1 Etiology and Epidemiology

Bleeding from the stapedia artery caused by teratogenic factors during the 30–40th day of gestation causes tissue disruption at the 1st and 2nd branchial arch. Oto-mandibular dysostosis, an autosomal dominant in a small percentage of cases (2%), affects one in every 5000 newborns. Franceschetti syndrome, a low penetrance autosomal condition with a negative family history in 50% of cases, affects one in every 50,000 babies.

88.4.2 Oto-Mandibular Dysostosis

There are different clinical types of oto-mandibular dysostosis. Microtia occurs in the most serious forms. There is absence of the pavilion (the cartiliginous part of the outer ear), meatus, middle ear, and temporo-mandibular joint; hypoplasia or absence of masticatory muscle; unilateral macrostomia, hypoplasia of the zygomatic arch, pre-auricular fibrocartilaginous appendices; and partial impairment of facial nerve. The consequence of those malformations is chin deviation toward the affected side and malocclusion. Incomplete forms may affect only the ear or the jaw and milder forms may slightly affect one or all of the components. When the jaw is involved, forms range from mild (where the condyle is hypoplastic and mandibular deviation is small [Type I]), to the most serious forms, where the condyle or the whole ramus are totally absent (Type III).

Surgical treatment varies according to the severity and the anatomical region involved. The pavilion may be reconstructed using autologous rib cartilage in two surgical operations carried out at intervals of 6 months at 10 years of age. The jaw is reconstructed (if absent) at around 5–6 years with a osteo-cartilagineous transplant from a rib that serves as a growth center. For defects of moderate severity, surgery can be performed at 5–6 years using osteodistraction. However, since a growth deficit is possible, a final correction is necessary after puberty [7].

88.4.3 Goldenhar Syndrome

The Goldenhar syndrome is basically similar to oto-mandibular dysostosis (with less mandibular involvement) with additional

ocular malformations (epibulbar cysts, lipomas, coloboma of the upper eyelid), vertebral and rib malformations. Malformations may be bilateral but asymmetric. The treatment is similar to that of oto-mandibular dysostosis but early treatment of eye malformations is required if they cause functional problems.

88.4.4 Franceschetti Syndrome

Franceschetti syndrome is characterized by bilateral and symmetrical malformations. There is a severe hypoplasia or aplasia of the cheekbone with the absence of the lateral floor of the orbit and of the corresponding orbital margin to the zygomatic process of the frontal bone and absence of the zygomatic arch. There may be a coloboma on the medial side of the lower lid with absent cilia. The mouth is wide and there may be involvement of the ear (the pavilion, the middle and inner ear). The mandible is severely hypoplastic with a receding chin. There may be other associated malformations such as cleft palate and vertebral anomalies.

Osteodistraction of the mandible can be performed during the first months of life if there are breathing problems. The correction of orbital problems (requiring an autologous bone graft) is performed at around 10 years and the jaws are repaired by bimaxillary osteotomies and genioplasty.

88.5 Craniostenosis and Craniofaciostenosis Malformations

Craniostenosis are related either to altered growth of the sutures or synchondrosis of anterior cranial base. The growth of sutures is influenced by an increase on the size of the skull contents. However, synchondrosis has an intrinsic growth potentiality and may therefore be considered as a real growth center. In this case recent molecular biology and genetics studies have shown inactivation of fibroblast growth factors receptors (FGFRs). The incidence of these malformations is 1/2000 for trigonocephaly, 1/10,000 for plagiocephaly and 1/65,000 for Apert's disease. They are most frequently sporadic, although there are some cases with autosomal dominant or recessive transmission. The following are the most frequent forms.

88.5.1 Trigonocephaly

The premature fusion of the metopic suture determines the characteristic shape of the forehead as a ship's prow. There is reduced transverse growth (with a short inter-temporal distance); there is usually also hypotelorism (reduced distance between the orbits). Surgical treatment is done at 3 months for more severe forms and between 6 and 12 months for moderate forms. Surgery consists of removal of a wide forehead bone flap and of the upper orbital frame, which is remodeled and reintegrated with resorbable fixation materials. The forehead flap is re-fashioned to restore normal facial appearances. The surgery is extradural and needs to be carried out by a collaboration between maxillofacial and neurosurgeons.

88.5.2 Plagiocephaly

This malformation is characterized by skull and face asymmetry and it is determined by the early fusion of half of the coronal suture. As with other cases of partial synostosis, there are no neurological sequelae due to intracranial hypertension. The face is characterized by backwards displacement of the superior orbit and frontal region on the affected side and hypoplasia of the cheekbone. The nose may be deviated towards the unaffected side and the ear of the affected side is in a forward position compared with that of the opposite side. Surgery may be performed in very severe cases at between 6 and 12 months: the upper frame of the orbit and the forehead are relocated to allow symmetric facial growth and an improved cosmetic result.

88.5.3 Scaphocephaly

There is premature fusion of the sagittal suture, resulting in compensatory growth of the coronal and lambdoid sutures and an elongated appearance of the skull. In less severe forms it is difficult to decide clinically if there is dolicocephaly or mild scaphocephaly. In the case of scaphocephaly, 3D CT shows a fused sagittal suture, and treatment, if indicated, is done at around 3 months. It comprises craniectomy (may be by endoscopy) with two paramedian craniectomies on the side of the sagittal suture, another parallel to the coronal suture and another at the level of the lambdoid suture (Fig. 88.8).

The intention is to free brain growth, expand the temporoparietal region and allow the forehead and occiput backwards and forward, respectively. If surgery is postponed it becomes more invasive and difficult and requires complete disassembly and reassembly of the skull.

88.5.4 Craniofaciostenosis

Includes Crouzon's and Apert disease. Coronal synostosis, syncondrosis and synostosis of the bones of the anterior cranial fossa are sometimes associated with lambdoid synostosis (particularly in Apert disease) and involve a serious alteration of facial growth. The reduced anteroposterior growth of the anterior cranial fossa and of the orbital frame together with maxillary underdevelopment lead to a reduced depth of the

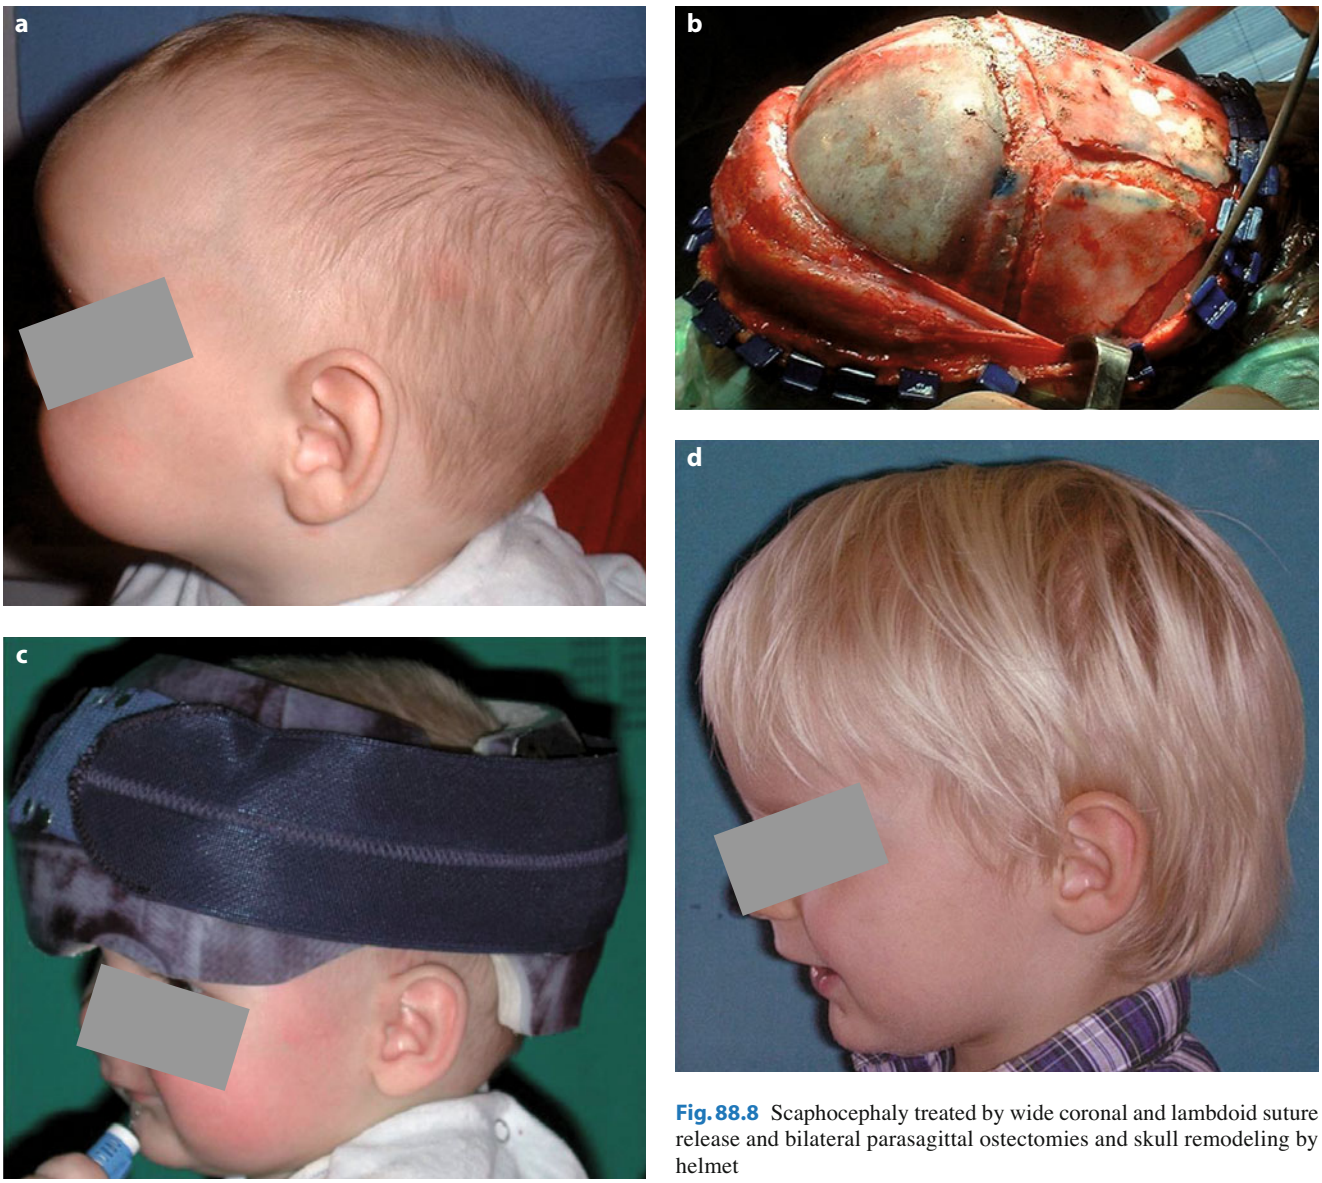

Fig. 88.8 Scaphocephaly treated by wide coronal and lambdoid suture release and bilateral parasagittal ostectomies and skull remodeling by helmet

orbit. This causes the most visible symptom of the disease, exorbitism (normal ocular volume in a small orbit). Besides the serious consequences of lack of growth on the brain, there may be ocular and respiratory problems. The range is from stasis of the papilla to corneal ulcers, causing severe eye infections and corneal lesions and diplopia. The respiratory problems include sleep apnea, which is secondary to upper jaw underdevelopment, and possible cardiopulmonary consequences. There is also an abnormal dental occlusion (open bite). In Apert's disease there is also cleft palate and syndactyly.

Treatment generally separates the neurosurgical from the facial stage. During the first months of life, the orbit and the forehead are brought forward. At 6 years, osteotomy (Le Fort type III) and distraction are performed. If exorbitism is associated with severe breathing problems, earlier treatment is indicated. This can be done in a single block (forehead, orbital frame, maxilla, zygomas) with distraction, a complex procedure [8].

88.6 Facial Clefts

The facial cleft is a rare facial disorder. Tessier [9] classified the condition considering the orbit as the center with axes radiating from it. Facial clefts occur along these lines. Thus there is considered to be a southern and a northern hemisphere around the orbit with 7 south axes corresponding to 7 north axes, giving a total of 14 axes. Clinically appearances are: hypertelorism, which is considered as a 0-14 cleft; the

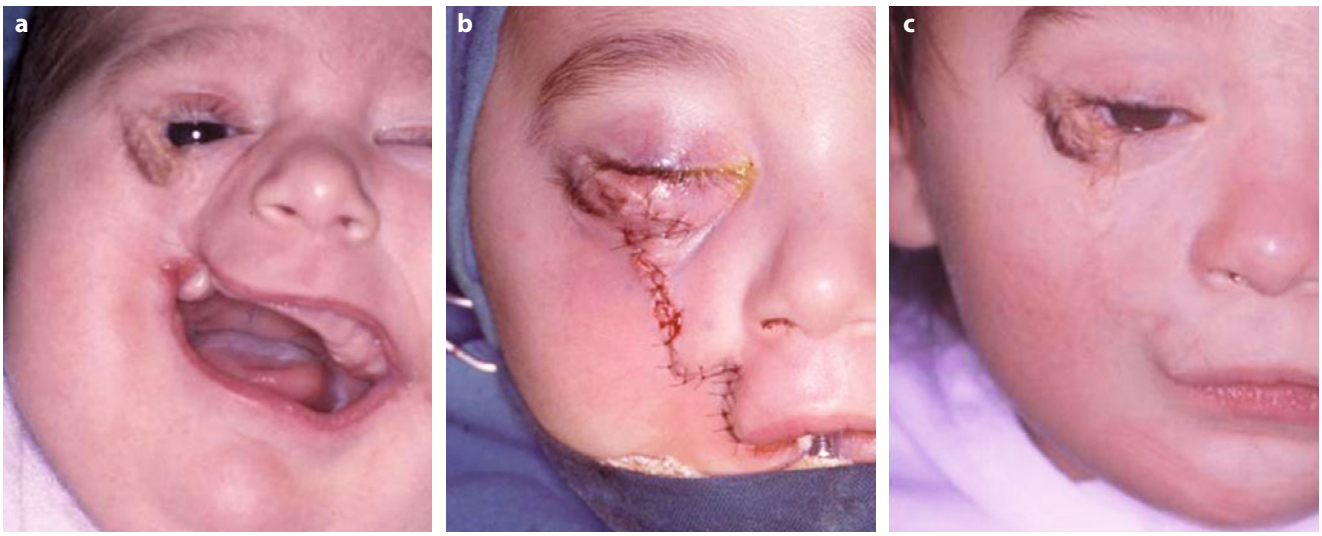

Fig. 88.9 Tessier's n°5 facial cleft treated with local flaps

typical facial cleft is considered as 5; a lateral dermoid cyst on the orbit (cleft 9); and upper or lower, medial or lateral eyelid colobomas.

Hypertelorism, is corrected by osteotomy during early life (4–6 years). This operation removes the bone excess between the orbits that are mobilized by osteotomies and medially transposed and the nasal process is rebuilt by bone graft. If hypertelorism is associated with craniofaciostenosis, it is possible to correct both by so-called facial bipartition to bring the two facial parts and the orbits closer to the midline. The facial clefts are corrected during the first months of life with restoration of bone, muscle and skin continuity of the involved regions, bearing in mind that muscles medially to the cleft may be atrophic or absent (Fig. 88.9).

In eyelid colobomas, restoring corneal protection by reconstructive procedures is necessary to avoid corneal ulceration. Local tissues are used for the reconstruction with good results both from aesthetic and functional perspectives (Fig. 88.10).

88.7 Cysts and Ranulas of the Oral Cavity

A ranula is a mucous cyst (mucocele) of the salivary glands in the floor of the oral cavity. The sublingual gland is most frequently responsible for the formation of ranula. The estimated incidence of congenital ranula is 0.74% with only 5 reported cases diagnosed prenatally. A simple ranula (Fig. 88.11), presenting as a mass in the oral cavity with a translucent azure-blue color, mobile and painless on palpation, can be distinguished from a ranula in the neck, which may threaten airways patency [10]. The most common treatment consists of ranula and sublingual gland excision. Marsupialization only has a significant failure rate.

Mucoceles are the equivalent of ranulas but in different locations, arising from the lower lip (80%) or more rarely the mucosa of cheek, palate or upper lip. They clinically manifest as soft translucent blue or bluish, mobile painless swellings. Treatment is surgical.

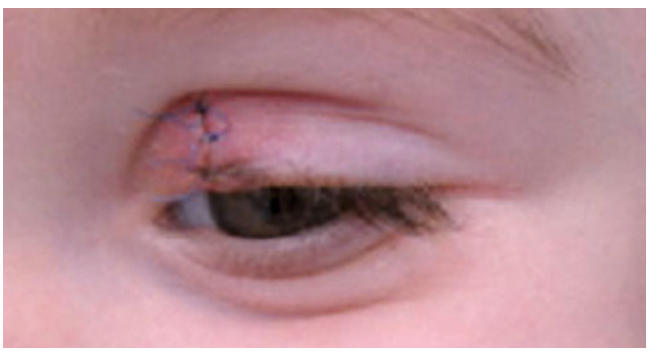

Fig. 88.10 Upper lid coloboma treated with local flaps

Fig. 88.11 Ranula of the floor of the mouth

88.8 Other Cysts of the Oral Cavity

Other types of congenital cysts may occur at the oral cavity [11], though more rarely. They are divided into epidermoid, dermoid, teratogenic and lympho-epithelial cysts. The distinction is based on histological appearance: epidermoid cysts are surrounded only by simple squamous epithelium; dermoid cysts are from squamous epithelium and skin adnexae such as hair follicles or sebaceous glands; teratogenic cysts consist of stratified squamous and often respiratory epithelium and within the cyst there may be skin adnexae and structures derived from mesoderm, ectoderm and endoderm; lympho-epithelial cysts consist of a stratified squamous epithelium surrounded by clusters of lymphoid tissue. The location of these cysts within the oral cavity is rare. Clinical presentation is similar for each type and is as an elastic mass, which is asymptomatic and presents early. Most often the cyst is located on the floor of the mouth and may be located above or below the mylohyoideus muscle. Treatment is by simple excision using an intraoral approach.

88.9 Tongue Malformations

The most relevant tongue malformations are divided into: ankyloglossia, lingual fissures, macroglossia, microglossia and aglossia.

88.9.1 Ankyloglossia (Tongue Tie)

The ankyloglossia is a common condition affecting approximately 2–5% of newborns [12]. It is caused by a short or fibrous lingual frenum or fusion of the ventral surface of the tongue with the floor of the oral cavity (complete ankyloglossia) (Fig. 88.12). The diagnosis is based on clinical signs by assessing the impossibility of reaching the palate with the tongue or protruding the tip beyond the lower teeth. Ankyloglossia can present a serious problem for the young patient during the first months of life if the child cannot suck normally.

Fig. 88.12 High grade ankyloglossia

Treatment is surgical and involves removal of the frenum, not by a simple cut but by excision that includes the upper bundle of the genioglossus muscle. In the case of fusion of the tongue with the oral floor, grafting may be indicated.

88.9.2 Macroglossia

A congenitally large tongue, or macroglossia, may be due to true hypertrophy of the tongue or occur as an epiphenomenon of a space occupying mass inside the tongue or in the oral floor. True macroglossia may occur with Beckwith-Wiedemann syndrome and Down syndrome [13, 14]. However, true isolated congenital macroglossia is rare condition with a range of clinical manifestations from dental malpositions at the least serious end of the spectrum to excessive mandibular growth and open bite causing speech difficulties. A particularly large macroglossia can cause respiratory disorders. Treatment consists of surgical reduction with a wedge excision at the tip to decrease the length and with a central excision to reduce the width (Fig. 88.13).

88.9.3 Tongue Fissures

Relatively frequent (0.5–5%) and sometimes genetic, they have no clinical significance apart from Melkersson-Rosenthal syndrome where the most important problem is facial nerve impairment.

88.9.4 Microglossia and Aglossia

Lingual agenesis is very rare and related to particular syndromes (e.g., Hanart syndrome). The main clinical effects of microglossia are dental crowding, impaired swallowing and phonation. Therapy consists of ensuring adequate nutritional support. Surgical treatment is difficult and grafting can only be done in less severe forms with functional improvement.

88.10 Congenital Muscular Tortocollis

Congenital muscular torticollis is relatively common with an estimated incidence of 0.3–2%. The etiology is uncertain and there are many etiological theories related to a possible vascular or postural cause. The clinical presentation is with flexion of the neck and head to the affected side with contralateral rotation of the face. There are three subgroups of myogenic

Fig. 88.13 Macroglossia in Beckwith-Wiedemann syndrome treated by resection and remodeling

torticollis: group 1, where a mass is palpable in the sternocleidomastoid muscle; group 2, where there is muscle rigidity and group 3, where the torticollis is not associated with any other symptoms. An association between congenital myogenic torticollis and congenital hip dysplasia has been described [15]. Newborns with hip dysplasia have a doubled risk of developing congenital torticollis compared with the general population. Congenital torticollis should be differentiated from other serious diseases with similar clinical features. Involvement by neurologists, ophthalmologists and otolaryngologists is recommended because 18% of torticollis cases are not myogenic and are caused by brain or spinal tumors, nervous system malformations etc.

After excluding non-myogenic torticollis, therapy for early myogenic torticollis should be started within 4–6 months of age [16, 17]. Conventional treatment consists of frequent physiotherapy sessions of passive stretching. The therapy needs active cooperation of relatives who need to perform traction exercises at home. Botulinum toxin has been used to facilitate stretching if physical therapy alone is not successful. Ninety per cent of cases improve with conservative treatment. The rare non-responders may require surgically correction to prevent secondary craniofacial deformities.

88.11 Ankylosis of Temporo-Mandibular Joint

The temporomandibular joint (TMJ) connects the mandibular condyle to the base of the skull with the interposition of a fibro-cartilaginous disc. It is a complex diarticular joint, meaning that it has two components, allowing both rotation and translation (sliding). Normal anatomy and hence function of the TMJ is essential for mouth opening.

TMJ ankylosis is present when the two articular tips do not move normally or do not move at all. False ankylosis occurs when normal joint mobility is impeded by extra-articular problems, e.g., when there is coronoid process hypertrophy

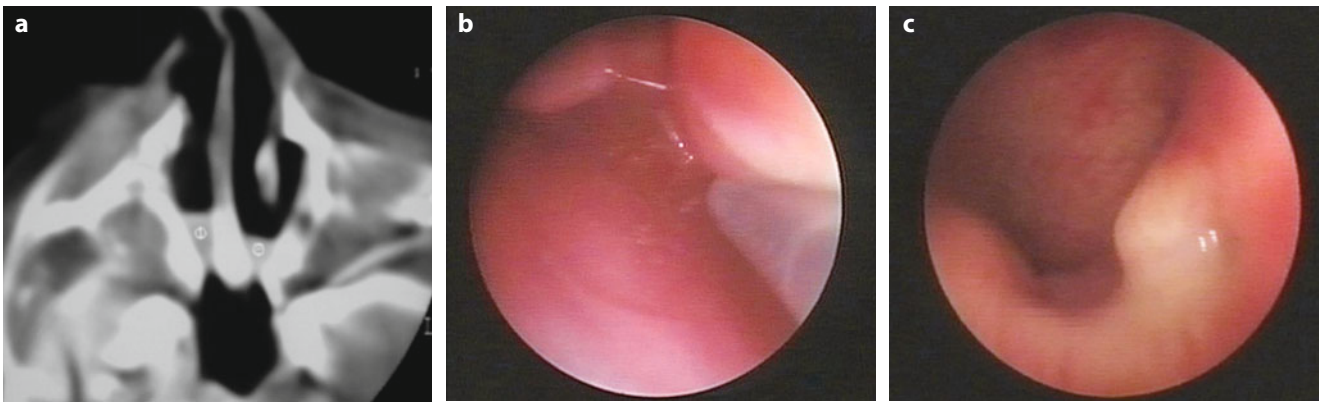

Fig. 88.14 Choanal atresia before and after endoscopic treatment (Case treated by Prof. G. Felisati)

or temporalis muscle fibrosis [18]. True ankylosis is when there is fusion and immobility of the TMJ. Classification is based on the nature of the tissue involved (bone, fibrous or fibro-osseous) and on severity (complete, incomplete) [19].

True congenital ankylosis is extremely rare with an unknown etiology [20]. Few cases have been reported, generally due to the expression of embryogenic errors in association with other malformations. Congenital TMJ ankylosis is more often the consequence of joint damage, which may be infective or iatrogenic (by forceps). The diagnosis is often not made immediately because TMJ has some mobility at birth. True congenital unilateral ankylosis is characterized by an inability to open the mouth associated with facial deformity and chin deviation toward the affected side. In bilateral forms there is symmetrical mandibular hypoplasia with a so-called bird's face. Diagnostic suspicion is confirmed by CT and MR imaging, which can assess the type of ankylosis (fibrous or bony), joint anatomy and mandibular deformity.

Treatment is surgical with resection of the ankylotic bone block and reconstruction of the growth center using a rib bone-cartilaginous transplant. However, early intervention before 5–6 years is characterized by a high relapse rate because of the need for patient cooperation to mobilize the joint.

88.12 Choanal Atresia

Congenital choanal atresia is an anatomic malformation that affects about 1 in 8000–10,000 newborns. It affects girls twice as often as boys. It is more often unilateral than bilateral. In approximately 20–50% of cases, there are other associated malformations.

The etiology is uncertain. Suggestions include a failure of the oro-nasal membrane to perforate, persistence of the oropharyngeal membrane, impaired migration of neural crest or mesoderm cells, or overgrowth of the vertical and horizontal processes of the palatine bone. Atresia consists of a bony-membranous fusion in about 70% of cases and of a complete bony fusion in about 30% of cases.

Congenital choanal atresia, especially when bilateral, may constitute a clinical emergency because newborns are obligate nasal breathers. The presentation is variable, ranging from respiratory embarrassment during feeding to complete postnatal asphyxia with cyanosis. The diagnosis should be suspected in cases where extubation of the infant is impossible. Treatment is to maintain ventilation by oro-tracheal intubation. Correction of the atresia is performed during the first weeks, avoiding the risks associated with tracheotomy.

Several methods have been described for the surgical correction of atresia [21, 22]. The approach may be transnasal

Fig. 88.15 Total arhinia and Franceschetti syndrome

or transpalatine. The latter has a higher complication rate, particularly related to maxillary growth and is therefore reserved for failures of transnasal corrections. A transnasal endoscopic technique provides for perforation with or without resection of the imperforate region and the placement of stents, which need to be in place for at least three months to prevent relapse (Fig. 88.14). Exceptionally a complete arhinia (no external and internal nose) can be observed (Fig. 88.15) and a staged reconstruction can be performed at 5-6 years of age or later.

88.13 Congenital Facial Palsy

Moebius first described congenital facial paralysis in 1888. Congenital facial paralysis is rare. Moebius syndrome is characterized by the presence of paralysis of the V, VI, VII and XII cranial nerves as well as malformations of the eyelids, lacrimal apparatus, palate, and various bony structures, mental retardation, epilepsy and anosmia. Today the term Moebius syndrome is used to describe cases with congenital facial and abducens nerve palsy associated with skeletal malformations. The most frequent causes of congenital facial paralysis are: Bell's palsy (acute dysfunction of cranial nerve VII [the facial nerve] of unknown cause), intrauterine infections and intrapartum trauma. Rarely the cause is an isolated error of embryogenesis.

Clinically, facial paresis may only be diagnosed several months after birth [23]. When bilateral, as in Moebius syndrome, the lack of facial movements is complete. Facial paralysis presents functional problems, the most important of which is corneal exposure due to a failure of eyelid occlusion. This can result in keratitis and corneal ulceration. Associated malformations should be sought.

Treatment of congenital facial paralysis depends on the cause [24–26]. A large proportion of newborns with congenital facial paralysis due to infection or trauma recover facial function spontaneously. Good results have been reported for surgery for facial paralysis that does not resolve spontaneously. The following techniques have been used: muscle rotation to allow movement of the eyelids (temporal muscle), and muscle (gracilis, latissimus dorsi) transfer using microsurgery and reinnervation with a nerve graft from the unaffected side, or, if bilateral paralysis, from the adjacent motor nerves (masseter nerve, a branch of the trigeminal nerve).

Esophageal Atresia

Alfredo Garzi and Mario Messina

Esophageal atresia includes a group of congenital anomalies characterized as interruption of the continuity of the esophagus combined with or without a persistent communication with the trachea [1]. These congenital malformations occur in 1:2500–3000 live births. The overwhelming majority of cases of esophageal atresia are sporadic/non-syndromic, although a small number within this non-familial group are associated with chromosomal abnormalities [1]. Familial/syndromic cases of esophageal atresia are extremely rare, representing less than 1% of the total. Esophageal atresia is 2–3 times more common in twins [2].

The etiology of esophageal atresia is likely multifactorial and remains unknown [3, 4].

89.1 Embryology

The mechanism that causes tracheoesophageal malformations are still unclear, however, the development of reproducible animal models of these anomalies has allowed detailed analysis of the various stages of faulty organogenesis [4]. By contrasting these stages with normal development, it has been possible to identify key developmental processes that may be disturbed during embryogenesis [5].

It is generally accepted that the respiratory primordium appears as a ventral evagination on the floor of the postpharyngeal foregut at the beginning of the fourth week of gestation and that the primitive lung buds are located at the caudal end of this evagination. During a period of rapid growth, the ventrally placed trachea becomes separated from the dorsally placed esophagus [5, 6].

The presence of associated malformations could provide clues as to the possible etiology of esophageal atresia [1, 4, 7].

Such malformations are present in 50% of cases and can occur in distinct patterns. These are non-random associations rather than syndromes because the presence of anomalies in one system makes it more likely that defects exist in another. One of the best-described associations is the VACTERL association, which comprises vertebral, anorectal, cardiac, tracheo-esophageal, renal and limb abnormalities. The pattern of these associations is likely to be dictated by the timing of a possible insult that affects multiple morphogenetic events [1, 7, 8].

89.1.1 Classification

In 1976 Kluth [9] published an extensive *Atlas of Esophageal Atresia* which comprised 10 major types, each with numerous subtypes which is based on the original Vogt classification. It would appear to be more valuable to describe the anatomical anomaly rather than assign a label, which may not be widely recognizable (Fig. 89.1) [10, 11].

89.1.1.1 Esophageal Atresia with Distal Tracheoesophageal Fistula (86%, Vogt IIIb, Gross C)

This is the most common variety in which the proximal esophagus, which is dilated, and the muscular wall thickened ends blindly in the superior mediastinum at about the level of the third or fourth thoracic vertebra. The distal esophagus, which is thinner and narrower, enters the posterior wall of the trachea at the carina or more commonly one to two centimeters more proximally in the trachea. The distance between the blind proximal esophagus and the distal tracheoesophageal fistula varies from overlapping segments to a wide-gap. Very rarely the distal fistula may be occluded or obliterated leading to the misdiagnosis preoperatively of an isolated atresia [10, 11].

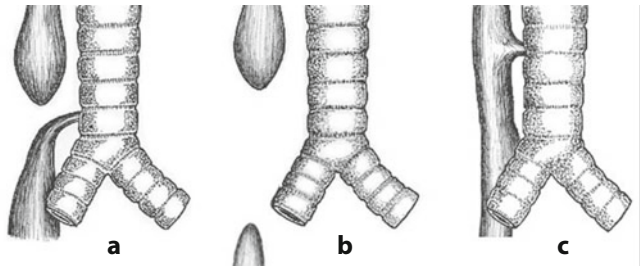

Fig. 89.1 Common anatomical types of esophageal atresia. **a** Esophageal atresia with distal tracheoesophageal fistula (86%). **b** Isolated esophageal atresia without tracheoesophageal fistula (7%). **c** H-type tracheoesophageal fistula (4%)

89.1.1.2 Isolated Esophageal Atresia without Fistula (7%, Vogt II, Gross A)

The proximal and distal esophagus end blindly without any connection to the trachea. The proximal esophageal segment is dilated and thick-walled and usually ends higher in the posterior mediastinum at around the second thoracic vertebra. The distal esophagus is short and ends a variable distance above the diaphragm. The distance between the two ends will determine whether a primary repair is feasible (rarely) or a whether a delayed primary anastomosis or an esophageal replacement should be performed. It is important to exclude a proximal tracheoesophageal fistula in these cases [10, 11].

89.1.1.3 Tracheoesophageal Fistula without Atresia (4%, Gross E)

There is a fistulous connection between an anatomically intact esophagus and trachea. The fistulous tract may be very narrow or 3–5 mm in diameter and is commonly located in the lower cervical region. They are usually single but two and even three fistulas have been described [10, 11].

89.1.1.4 Esophageal Atresia with Proximal Tracheoesophageal Fistula (2%, Vogt III and Gross B)

This rare anomaly needs to be distinguished from the isolated variety. The fistula is not at the distal end of the upper pouch but is sited 1–2 cm above the end on the anterior wall of the esophagus [10, 11].

89.1.1.5 Esophageal Atresia with Proximal and Distal Tracheoesophageal Fistula (<1%, Vogt IIIa, Gross D)

In many of these infants the anomaly was misdiagnosed and managed as proximal atresia and distal fistula. As a result of recurrent respiratory infections, investigations carried out revealed a tracheoesophageal fistula, previously mistaken for a recurrent fistula. With the increasing use of preoperative endoscopy (bronchoscopy and/or esophagoscopy) early recognition of the double fistula is made and total repair performed at the initial procedure.

If the proximal fistula is not identified preoperatively, the diagnosis should be suspected by a large gas leak emanating from the upper pouch during the fashioning of the anastomosis [10, 11].

89.2 Pathophysiology

The motility of the esophagus is always affected in esophageal atresia. The disordered peristalsis more commonly involves the distal esophageal segment. Whether the motility disorder is primarily due to abnormal innervation as evidenced by an abnormality in neuropeptide distribution or secondary to vagal nerve damage occurring during the surgical repair remains uncertain. The resting pressure in the whole esophagus is significantly higher than in normal patients and the closing pressure of the lower esophageal sphincter is reduced. The trachea is also abnormal in esophageal atresia. The abnormality consists of an absolute deficiency of tracheal cartilage and an increase in the length of the transverse muscle in the posterior tracheal wall. When severe, these abnormalities result in tracheomalacia with collapse of the trachea over a 1–2 cm segment in the vicinity of the fistula [12, 13].

89.3 Associated Anomalies

Over 50% of infants with esophageal atresia have one or more additional anomalies. The systems affected are as follows:

- Cardiovascular 29%
- Anorectal anomalies 14%
- Genitourinary 14%
- Gastrointestinal 13%
- Vertebral/skeletal 10%
- Respiratory 6%
- Genetic 4%
- Other 11%.

There is an increased incidence of associated anomalies in pure atresia (65%) and a lower incidence in H-type fistula (10%).

The VATER association first described by Quan and Smith in 1973 [14] consists of a combination of anomalies including vertebral, anorectal, tracheoesophageal and renal or radial abnormalities. This association was later expanded as the VACTERL association to include cardiac and limb defects [1, 7].

Other associations, which may include esophageal atresia are the CHARGE association (coloboma, heart defects, atresia

choanal, retarded growth and development, genital hypoplasia and ear deformities), Potter's syndrome (renal agenesis, pulmonary hypoplasia, typical dysmorphic facies) and Schisis association (omphalocoele, cleft lip and/or palate, genital hypoplasia). Genetic defects associated with esophageal atresia include Trisomy 21 and 18, and 13q deletion. Of the cardiac anomalies, the most common are ventricular septal defect and tetralogy of Fallot. Major cardiac malformations are one of the main causes of mortality in infants with esophageal atresia [1, 7, 15].

The vertebralanomalies in esophageal atresia are mainly confined to the thoracic region and are responsible for later development of scoliosis. The claim that the presence of 13 ribs is associated with long-gap atresia has not been substantiated. Of the gastrointestinal anomalies, the most frequently encountered are duodenal atresia and malrotation, while there is an increased incidence of pyloric stenosis. Miscellaneous anomalies include cleft lip and palate, omphalocoele, lung abnormalities, choanal atresia and hypospadias [15, 16].

89.4 Genetic Counseling

The majority of cases of esophageal atresia are sporadic/non-syndromic, although a small number within this non-familial group are associated with chromosomal abnormalities. Familial/syndromic cases of esophageal atresia are extremely rare. Esophageal atresia is 2–3 times more common in twins. The overall risk of esophageal atresia recurrence in a sibling of an affected child is about 1% [6, 7].

89.5 Clinical Description and Diagnosis

The diagnosis of esophageal atresia may be suspected prenatally by the finding of a small or absent fetal stomach bubble on ultrasound scan performed after the 18th week of gestation. Overall the sensitivity of ultrasonography is 42% but in combination with polyhydraminos the positive predictive value is 56% [17, 18].

Available methods of improving the prenatal diagnostic rate include ultrasound examination of the fetal neck to view the blind-ending upper pouch and to observe fetal swallowing and magnetic resonance imaging [19–21].

The newborn infant of a mother with polyhydramnios should always have a nasogastric tube passed soon after delivery to exclude esophageal atresia. Infants with esophageal atresia are unable to swallow saliva and are noted to have excessive salivation requiring repeated suctioning. A plain X-ray of the chest and abdomen will show the tip of the catheter arrested in the superior mediastinum (T 2–4) while gas in the stomach and intestine signifies the presence of a distal tracheoesophageal fistula (Fig. 89.2). The absence of gastrointestinal gas is indicative of an isolated atresia. A fine bore catheter may curl up in the upper pouch giving the false impression of an intact esophagus or rarely it may pass through the trachea and proceed distally into the esophagus through the fistula [17, 19].

Fig. 89.2 Plain X-ray of the chest and abdomen showing the radioopaque tube in the blind upper esophageal pouch. Air in the stomach indicates the presence of a distal tracheoesophageal fistula

89.6 Management

89.6.1 Preoperative

Once the diagnosis of esophageal atresia has been established, the infant will need to be transferred to a pediatric surgical centre. A suction catheter, preferably of the double lumen type, is placed in the upper esophageal pouch to suction secretions and prevent aspiration. The infant is placed on its side in the

portable incubator while monitoring the usual vital signs. Vascular access should be provided as a precautionary measure but intravenous fluid administration is not usually necessary [16].

The preterm infant with respiratory distress requires special attention. Clearly there is a need for endotracheal intubation and mechanical ventilation. In addition, there is the added risk of gastric over-distension and rupture of the stomach due to escape of respiratory gases down through the distal fistula into the stomach due to the increased pulmonary resistance. This sequence of events can be minimized by positioning the end of the endotracheal tube distal to entry of the tracheoesophageal fistula and by applying gentle low pressure ventilation [13, 16, 17].

All infants with esophageal atresia should have an echocardiogram prior to surgery. The ECHO and/or MR will define any structural anomaly of the heart or great blood vessels and occasionally may indicate a right-sided aortic arch, which occurs in 2.5% of cases. These diagnostic tests determine the side of approach for the operative repair [15].

89.6.2 Risk Categorization and Prognosis (Outcome)

In 1962, Waterston proposed a classification of infants born with esophageal atresia into three groups "with different chances of survival". The classification based on birth weight, associated anomalies and pneumonia comprised:

- Group A Over 5 ½ lb (2500 g) birth weight and well.
- Group B
  1. Birth weight 4–5 ½ lb (1800–2500 g) and well
  2. Higher birthweight, moderate pneumonia and congenital anomaly
- Group C
  1. Birth weight under 4 lb (1800 g).
  2. Higher birth weight and severe pneumonia and severe congenital anomaly.

Over the last 40 years there has been a steady improvement in the overall survival rate due to early diagnosis and prompt referral, improvements in preoperative care and diagnosis and treatment of associated anomalies, advances in anesthetic techniques and sophisticated neonatal intensive care [11].

The Spitz classification for survival in esophageal atresia is:

- Group I Birth weight over 1500 g with no major cardiac anomaly.
- Group II Birth weight less than 1500 g or major cardiac anomaly.
- Group III Birth weight less than 1500 g PLUS major cardiac anomaly.

Major cardiac anomaly was defined as either cyanotic congenital heart disease that required palliative or corrective surgery or non-cyanotic heart anomaly that required medical or surgical treatment for cardiac failure [12].

89.6.3 Selection for Non-Treatment

Infants with Potter's syndrome (bilateral renal agenesis) and trisomy 18 which is fatal in the first year of life in over 90% of affected infants should be offered the option of no active treatment. Similarly, infants with totally uncorrectable major cardiac defects or with Grade IV intraventricular hemorrhage should be considered for non-operative management [11, 12].

89.6.4 Emergency Ligation of the Distal Tracheoesophageal Fistula

Generally, the operative correction of an esophageal atresia is not regarded as an emergency procedure. The one exception is the preterm infant with severe respiratory distress syndrome requiring ventilatory support. Ventilatory gases escaping down the distal fistula result in gastric distension, which further impedes respiratory function. With progressively increasing gastric distension, the stomach may eventually rupture causing a tension pneumoperitoneum, which renders ventilatory support even more difficult [12, 16, 17].

Many maneuvers have been advocated to alleviate the problem including positioning of the endotracheal tube distal to the fistula. However, if the fistula is sited at the level of the carina, this maneuver is impossible to achieve. Others have advocated blocking of the fistula by a Fogarty catheter passed at bronchoscopy. The affected infants are usually preterm and in critical respiratory status. The smallest caliber bronchoscope will not permit ventilation while maneuvering a Fogarty catheter into the distal esophagus in a cyanotic infant will aggravate the condition and further exacerbate the hypoxia [21, 22].

89.6.5 Operative Approach

The operation is performed under general endotracheal anesthesia with dependable vascular access and employing gentle ventilatory pressure so as not to produce gastric distension (Fig. 89.3) [22, 23].

Intraoperative endoscopy Preliminary bronchoscopy may be carried out to define the site of entry of the distal tracheoesophageal fistula and to assess the presence of tracheomalacia. An alternative is to carry out an esophagoscopy to define the length of the upper esophagus and to exclude an upper pouch fistula, which is more common with isolated esophageal atresia [24–26].

Position The infant is placed on the left side with the right arm across the front of the chest for a right posterolateral thoracotomy.

Incision A curved incision centred 1 cm below the inferior angle of the scapula approximately 5–6 cm long is made. The muscle of the chest wall may either be split or divided with

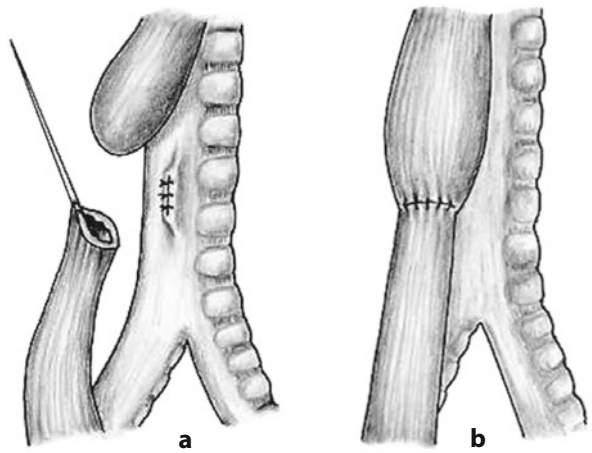

Fig. 89.3 The operative repair of an esophageal atresia and distal tracheoesophageal fistula. **a** Ligature of the fistula. **b** Anastomosis

electrocautery taking care to preserve the long thoracic nerve to serratus anterior. The thorax is opened through the 4th or 5th intercostal space by dividing the intercostal muscles or by entry through the bed of the unresected rib.

Extrapleural Approach Has the advantage of conferring protection of the pleural space in the event of an anastomotic leak. Commencing posteriorly, the pleura is gently freed off the chest wall using blunt dissection. The dissection proceeds into the mediastinum to provide good access to the esophagus. The extrapleural approach is slightly more time-consuming and has theoretically advantages over the transpleural approach still used by many surgeons [21, 27].

Exposure of the esophageal segments The azygos vein is the first structure encountered on entering the mediastinum. The azygos vein is gently mobilized and divided between ligatures to expose the esophagus. The distal esophagus usually lies directly deep to the azygos vein and is identified by the vagus nerve coursing over its anterior aspect [28–30].

Repair of the anomaly The distal esophagus is mobilized. A marking seromuscular suture is placed in the lateral wall of the distal esophagus to assist with orientation. The distal esophagus is dissected to the level of the fistula and the upper and lower extent of the fistula is marked with fine non-absorbable sutures before dividing the esophagus just distal to the fistula. The tracheal side of the fistula is closed with interrupted 5.0 sutures to achieve an air-tight closure. The tracheal closure may be tested by instilling warm saline over the suture line while the anesthesiologist expands the lungs. An end-to-end anastomosis between the proximal and distal esophagus is fashioned using interrupted full-thickness fine sutures. If there is a wide gap, the distal esophagus can be mobilized safely well down towards the diaphragm. Just prior to the final suture being tied a transanastomotic fine-calibre nasogastric tube may be passed. This allows gastric decompression in the early postoperative course and provides a route for early enteral feeding [22, 24, 31].

Methods to overcome a wide gap Various maneuvers have been proposed to overcome a wide gap but in our experience a very tense anastomosis can be achieved in most cases and if the infant is subsequently electively paralyzed and mechanically ventilated for approximately 5 days postoperatively, the anastomosis will heal without leakage. Others have proposed tubularization of the upper pouch after creating a flap, circular myotomy of the upper pouch or abandoning any attempt at initial primary anastomosis awaiting delayed primary anastomosis 6–12 weeks later [32, 33].

The thoracotomy incision is now closed with or preferably without intercostal drainage especially if the procedure has been totally extrapleural and a technically satisfactory anastomosis has been performed. The procedure can be carried out thoracoscopically but this requires advanced skills in minimal invasive surgery [23, 34, 35].

89.6.6 Postoperative Management

In all other instances, regular pharyngeal suction is necessary for the first few postoperative days. The suction catheter should be clearly marked to prevent the tube being passed to the site of the anastomosis and causing damage. Transanastomotic nasogastric feeds may be commenced on the second or third postoperative day and when the infant is swallowing saliva, oral feeds may be started. It is not regularly perform a follow-up contrast study but if there is any doubt as to the integrity of the anastomosis a water-soluble contrast study is carried out [22].

89.6.7 Complications and Outcomes

89.6.7.1 Anastomotic Leaks

These occur in 15–20% of patients but in only one-third or less is there a major disruption. Major leaks occur in the early postoperative period (<48 hours) and present with life-threatening tension pneumothorax. Minor leaks may be detected on the routine contrast study usually performed on the 5–7th day postoperatively [12, 21].

89.6.7.2 Anastomotic Strictures

These develop in 30–40% of cases most of which will respond to one or two dilatations. Risk factors that have been implicated in stricture formation include anastomotic tension, anastomotic leakage and gastroesophageal reflux. Endoscopic dilatation of the stricture can be carried out either at rigid esophagoscopy using semi-rigid bougies (Savary-Gillard) of progressively larger calibre or by balloon dilatation introduced either at fluoroscopy or during flexible

endoscopy. At the end of the procedure, contrast is introduced into the esophagus to ensure that there has been no perforation and to establish the effectiveness of the dilatation [33]. Only rarely is it necessary to resort to resection of an intractable anastomotic stricture.

89.6.7.3 Recurrent Tracheoesophageal Fistula

The incidence of recurrent tracheoesophageal fistula is between 5–14%. A recurrent fistula should be suspected if the infant manifests respiratory symptoms (coughing during feeds, apneic or cyanotic episodes) or has recurrent respiratory infections after "successful" repair of the esophageal atresia [12, 17, 32]. The diagnosis may be suspected on the plain chest radiograph, which shows an air esophagogram.

Bronchoscopic examination will reveal the recurrent fistula at the site of the original tracheoesophageal fistula. It is essential to pass a fine ureteric catheter across the fistula into the esophagus and to view the catheter in the esophagus at endoscopy [22].

89.6.7.4 Gastroesophageal Reflux (GOR)

GOR is common in all infants following repair of esophageal atresia – significant reflux occurs in around 40% of cases, about half of whom will require surgical management. GOR is more common following anastomosis under tension and after delayed primary repair. Incompetence of the lower esophageal sphincter mechanism may be due to a primary neurogenic disturbance inherent in the development of the esophageal atresia or to technical factors involved in the repair or it may be due to shortening of the intra-abdominal esophagus and/or abolishment of the gastroesophageal angle of His [36–38].

Symptoms of GOR are similar to those of recurrent fistula with acute or chronic respiratory problems but also include recurrent vomiting and stricture formation. The diagnosis can be established on contrast swallow, pH monitoring and endoscopy and biopsy of the distal esophagus. Anti-reflux medication including gastric acid suppression is only successful in about half the cases. Surgical treatment is problematic given the inherent dysmotility present in the distal esophagus. A fundoplication may in itself produce a functional obstruction at the gastroesophageal junction. The failure rate of fundoplication carried out in the first three months of life is excessively high. With regard to the nature of the wrap, there are advocates for partial (Thal) as well as for a short, floppy wrap (Toupet or Nissen type) [35, 36].

89.6.7.5 Tracheomalacia

Tracheomalacia may be defined as a structural and function weakness of the trachea resulting in partial and occasionally complete respiratory obstruction. The structural abnormality comprises a deficiency in the cartilage in the tracheal rings and an increase in the length of the transverse muscle. The result is that the airway collapses during expiration causing expiratory stridor, which varies in severity from a hoarse barking cough, to recurrent respiratory infection to acute life-threatening episodes of cyanosis or apnea. The incidence of tracheomalacia is around 10% and about half will require surgical correction [29].

The definitive treatment consists of aortopexy in which the ascending and arch of the aorta are elevated anteriorly towards the sternum. The result is usually dramatic with immediate resolution of the obstruction to the air passages.

89.6.7.6 Dysmotility

This affects the distal esophagus particularly in relation to abnormal coordination of contractions, which in fact can be seen on contrast studies of the esophagus. The dysmotility is a major factor in the long-term swallowing problems encountered in these children [28].

89.6.7.7 Respiratory Function

During infancy and for the first three years of life, patients with esophageal atresia suffer increased frequency of respiratory infections. The tendency to respiratory infections has variously been attributed to esophageal dysmotility and/or gastroesophageal reflux with recurrent aspiration or to a primary respiratory abnormality [16, 17].

89.6.7.8 Congenital Esophageal Stenosis

Congenital esophageal stenosis due to tracheobronchial remnants in the distal esophagus in an infant with esophageal atresia is a rare but well documented phenomenon. It is thought to arise as a result of defective separation of the trachea from the esophagus. It may be recognized at the time of the initial repair of the esophageal atresia when passage of a catheter into the stomach is impeded. Alternatively, symptoms develop quite early with dysphagia and regurgitation of solid food [33, 35].

89.7 Esophageal Replacement

The need to replace the esophagus in esophageal atresia is extremely rare and should only be considered in very long-gap situations or where repeated attempts at retaining the host esophagus have failed and the infant's survival is at risk. There are basically three methods of esophageal replacement currently being practiced in children – gastric transposition, colonic interposition and jejunal interposition [12, 38, 39].

Gastrointestinal Malformations

Remigio Dòmini and Marcello Dòmini

90.1 Anorectal Malformations

Anorectal malformation (ARM) is a generic term referring to a group of congenital anomalies of the anus and the rectum, ranging from simple "anal stenosis" to complex "cloacal persistence syndrome". It includes a wide spectrum of presentations, of which anorectal agenesis is the most frequent. ARMs are challenging both from diagnostic and surgical points of view. Even prompt and appropriate treatment is likely to result in lifelong disability due, for example, to incontinence and constipation.

ARMs affect 1 every 4000 births. "High" and "intermediate" forms (anorectal agenesis) are more common in boys (M:F rate = 3:1), whereas "low" forms are more common in girls (M:F = 1:3) (see classification below) [1].

90.1.1 Embryogenesis

The anus and its controlling sphincter muscle complex originate from an ectodermal introflexion that joins the anorectal canal (the end of the primitive gut) and has endodermal origins. Damage at these stages results in an anorectal malformation (ARM) due to incomplete embryological evolution of the primitive "cloaca". At the 4th week of development, the cloaca divides from the cloacal membrane in two parts. The urethra and rectum combine to form the external cloaca. The allantois, the primitive gut and mesonephric ducts form the internal cloaca, which is later divided by a uro-rectal septum into an anterior "uro-genital sinus" and posterior "anorectal sinus" [1]. The "cloacal membrane" then develops into the ventral genital tubercle, the lateral genital folds and the posterior anal tubercles.

M. Domini (✉)
Pediatric Surgery Unit, 'Alma Mater Studiorum' University
S. Orsola-Malpighi Hospital, Bologna, Italy

The reasons for interruption of this developmental process are incompletely understood. They give rise to different forms of anorectal anomalies, from a simple "imperforate anus" to multiple forms of "anorectal agenesis", where the rectum ends as a fistula in the neighbouring organs (bladder or urethra in the male, vagina in the female), and the extremely rare "rectal atresia", where the anal orifice is apparently normal but the anal canal ends blindly after few centimetres, and the rectum is atretic.

The "rectal" group of the ARM arises from defects of the internal cloaca, whereas the "anal" group is due to defects of the external cloaca (perineum, genital folds, and proctodeum).

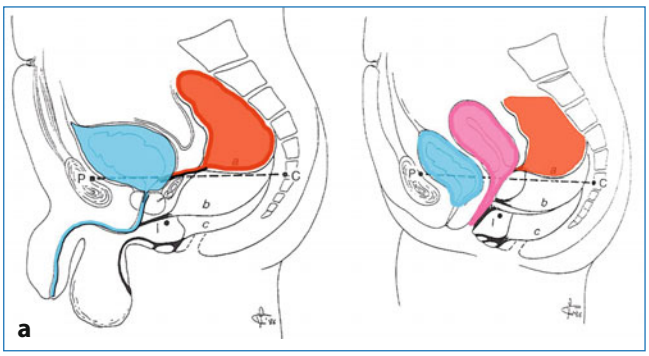
90.1.2 Classification

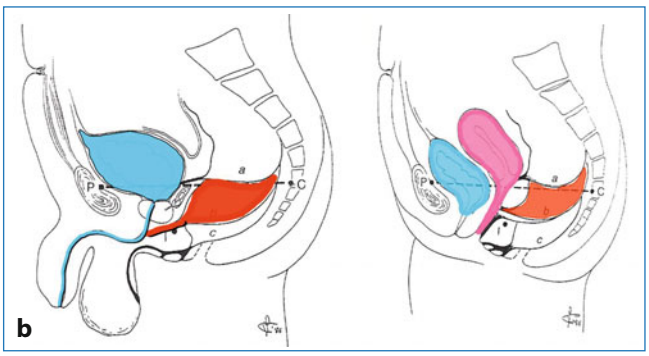
The Melbourne Classification (1970), modified by Wingspread (1984), is used to classify the different forms of ARM. These are based on radiological assessment of the level of the ARM: an abdominal X-ray 24 hours after birth images the position of intestinal gas relative to the rectal pouch by using a radiopaque spot painted in the perineal area to mark where the anal orifice should be [2]. A line is then drawn on a lateral radiograph from the middle of the pubic bone to the sacrococcygeal joint at the level of the "ischiatic point" ("the pubococcygeal [p-c] line"). The classification is based on the level of the rectal pouch in relation to this line.

- "High ARM" is when the intestinal air of the rectal pouch stops above the pubo-coccygeal (p-c) line (Fig. 90.1a).
- "Intermediate ARM" is when the intestinal air stops between the p-c line and the ischiatic point (Fig. 90.1b).
- "Low ARM"is when the intestinal air stops below the p-c line and the ischiatic point, close to the perineal skin (Fig. 90.1c)

In the past these X-rays were taken with the baby held by the legs and the head down (so called "invertography"), but this has been shown to be useless and a simple plain X-ray is sufficient.

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.





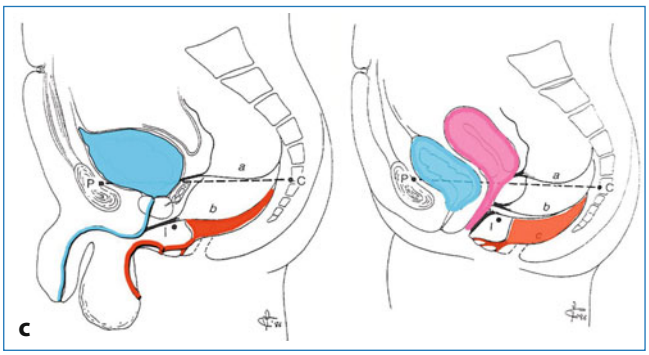


Fig. 90.1 **a** Classification of "high" forms of ARM in males and females. Note: rectal agenesis above the pubo-coccygeal line and its relationship to genital or urinary organs. **b** Classification of "intermediate" forms of ARM. Note: rectal agenesis is below the pubo-coccygeal line and there is a fistula. **c** Classification of "low" forms of ARM. The anal canal is incomplete but very far from the perineal skin. Mostly it presents with a cutaneous fistula

In the Wingspread classification, the cloaca is considered as a separate form ("the clover syndrome"), also subdivided into three forms: high, intermediate and low, according to the length of the common canal into which the outputs of the rectum, urethra and vagina flow. Recently Peña proposed a new classification system. It is purely descriptive with therapeutic and diagnostic implications for males and females. It does not define ARM as "high", "intermediate" or "low" but relies on clinical features and the presence or absence of a fistula [2].

90.1.3 Associated Anomalies

Associated anomalies are frequent, probably due to cloacal subdivision occurring between the 4th and the 6th week, i.e., at the start of organogenesis. The incidence of associated anomalies is 50–60% and varies with the form of ARM. In the "rectal" forms (high and intermediate ARM), the incidence and severity of associated malformations is almost twice that of the "anal" forms (low ARM). In decreasing order of frequency, they involve the uro-genital, skeletal, digestive, cardiac, nervous, pulmonary systems.

Uro-genital system The most frequent anomalies (20–30% with low ARM, 50–70% with high/intermediate ARM). Vesico-ureteral reflux (VUR) is the most frequent anomaly in the female. Obstructive uropathies and neurological bladder are extremely common in association with sacral agenesis.

Skeleton Vertebral anomalies are common (40% with "rectal" ARM, 17% with "anal" ARM). Most are localized to the sacrum or coccyx (sacral agenesis or hemisacrum). Because these anomalies affect almost half of high forms, imaging (radiography, CT and MR) is required to identify a "tethered cord", i.e., caudal traction on the medullar cone causing abnormal neurological signs in the legs or a neuropathic bladder. Neurosurgical referral is indicated if there is a tethered cord.

Intestinal system Incidence is about 10% (15% with "rectal", 7% with "anal" ARMs). Esophageal atresia affects 10%, duodenal atresia 2%, and Hirschsprung's disease 3-5%.

Cardiovascular system Cardiovascular anomalies are present in 9% of cases, regardless of the form of ARM.

Other Other associated anomalies may also occur (cleft lip, hydrocephalus, rachischisis).

VATER association An association of anomalies due to: Vertebral anomalies (V), Anorectal agenesis (A), Tracheo-esophageal fistula (TE) with or without esophageal atresia, Renal dysplasia (R). The association may be more complex (VACTER, VACTERL) if a cardiac defect (C) and/or limb hypoplasia (L) are present.

90.1.4 Symptoms

ARMs usually present immediately after birth at clinical examination of the perineal area. If the diagnosis is missed, the clinical features are those of intestinal obstruction: abdominal distension, a failure to pass meconium, bile-stained vomiting. If there is a perineal fistula, meconium may be passed normally with normal growth during infancy but chronic constipation and sub-acute intestinal obstruction.

90.1.5 Diagnosis

ARM is not usually diagnosed prenatally. Sometimes there is colonic dilatation without polyhydramnios. The condition may be suspected when a skeletal defect is identified (radial or sacral aplasia), particularly in the presence of an associated uropathy or cardiomyopathy. Simple examination of the perineal area after birth is usually sufficient to make the diagnosis. In low forms, meconium is sometimes passed from a cutaneous fistula in the perineum. In males, this orifice can be observed ventrally along the raphe line anywhere from the anus to the tip of the penis. In females, the orifice can be in the anterior perineal region, at the vaginal vestibule or vulva.

In high or intermediate forms, there may be an internal rectal fistula (recto-urethral fistula in males; recto-vaginal fistula in females) and meconium may be passed from the urethra or vagina. In patients with persistence of the cloaca, meconium and urine may be passed from a single orifice, the common channel.

Further examination (e.g., sacral radiography, cardiac ultrasound, urinary ultrasound, CT or MR, cysto-urethrography and urodynamics) should exclude associated abnormalities, such as vesico-ureteral reflux, a neurological bladder or "tethered cord". Vaginoscopy may be useful to distinguish a duplex from a septate vagina and to identify any fistula, which is most common on the right. In cloacal forms, visualisation of the common channel by endoscopy is required to measure its length. When a temporary colostomy has been fashioned, distal colonography is useful to determine the position of the fistula.

90.1.6 Therapy

The management of low forms is different to high or intermediate variants.

In low ARM, complete surgical correction is done within 24–48 hours after birth. The rectum is normally positioned in the "pubo-rectal sling" and a new functioning anal orifice is established in its natural anatomic site by identifying the middle of the external sphincter using a muscle electro-stimulator (Fig. 90.2).

In high or intermediate forms, a temporary colostomy is performed before definitive surgical correction. The most usual surgical technique is the "Posterior Sagittal Ano-Recto-Plasty" described by Peña-De Vries (1982) [3]. The baby is placed prone and a sagittal posterior skin incision is made through the intergluteal line, separating the muscle structures "like a book" until the rectal pouch is reached. The fistula is identified, sutured and divided. The rectal pouch is opened and separated from the urethra (in males) or vagina (in females), then positioned in its appropriate anatomic site inside the "muscle complex", which is identified by the electro-stimulator.

A similar technique is used to correct the cloacal malformation, bringing the three separate orifices out on the skin of the perineum.

Fig. 90.2 Low ARM. The electrostimulator allows for the identification of the point at which to create the new anus. The rectum has been identified a few millimetres from the perineal skin

Results obtained by Peña's technique are better from a functional (fecal continence) and an esthetic viewpoint than previous surgical techniques that favored an abdomino-perineal approach (Stephens 1953; Rehbein 1965; Swenson 1967; Kiesewetter 1967). The advantages of Peña's technique can be summarized as follows: 1) precise identification of each perineal muscle; 2) optimal surgical visualization; 3) correction at a single operation of each type of ARM (including persistence of the cloaca); 4) optimal siting of the neo-anus (and other orifices in cloacal forms); 5) a good functional result in respect of urinary and fecal continence.

In 1997, Bianchi proposed a technique ("Trans-Ano Proctoplasty TAP") [4] that combined an abdominal with a perineal approach for correcting high and intermediate forms of ARM in males. This technique gained interest because it allowed the malformation to be corrected without splitting the muscle complex. In 2000, Georgeson introduced the "Laparoscopic Assisted Ano-Recto-Plasty" (LAARP), a new mini-invasive technique that developed Bianchi's approach further by using laparoscopy [5]. The fistula is identified, sutured and divided using a three-trocar laparoscopic approach. In Siena, Italy, it is considered the treatment of choice for high forms of ARM, although specific laparoscopic skills are needed.

A video-assisted surgical technique for ARM in females has been proposed by Marcela Bailez [6].

There have been concerns about the lack of data relating to complications and follow-up studies are needed.

90.1.7 Postoperative Treatment

The postoperative care of these children is important. Every child must have repeated postoperative anal dilatations (for 3–6 months) to progressively dilate the muscle complex to achieve an "elastic" anal canal. The colostomy closure should be delayed for at least three months. The patient should be followed for the first 2–3 years during toilet training, and enemas or laxative therapy should be used until there is regular intestinal motility. Continence is graded by a four-point system: 1) clean; 2) stained; 3) sporadic fecal soiling; 4) constant fecal soiling.

90.1.8 Outcomes

Deaths in patients with ARM are confined to those with serious associated life-threatening anomalies. High and intermediate forms are associated with 30–40% disability (e.g., fecal incontinence, neurologic bladder).

90.2 Intestinal Malrotations

This abnormality occurs during the rotation and fixation phases of intestinal development and there is malposition of the ascending colon, which is under the stomach instead of on the right flank. The peritoneum that covers the colon and fixes it to the posterior abdominal wall has to pass in front of the duodenum, and the resulting compression may cause an obstruction. Because the large intestine is mobile, there is also an increased risk of intestinal volvulus. About 1 in 10,000 births show abnormal clinical features, but the incidence at autopsy is 1 in 2–300. These findings underline the fact that anorectal malformations are generally well tolerated and that only 1 in every 500 patients experiences complications. Boys are affected twice as frequently as girls.

90.2.1 Classification

The rotation-fixation process is complex and interruption at any stage results in different forms of malrotation (Table 90.1).

The most frequent forms are [7]:

- Type I A: Lack of rotation also called "mesenterium commune", where the small bowel is in the right hemi-abdomen while the colon is in the left.
- Type IIIA: There is incomplete rotation: the small bowel remains in the right hemi-abdomen and the cecum and ascending colon are in the epigastrium. In this form, parietal adhesions (Ladd's band) between the abdominal wall and colon may cause obstruction by external compression of the 3rd part of the duodenum.

"Volvulus neonatorum" occurs most frequently in types IA and III.

Table 90.1 Types of intestinal malrotation and possible consequences

Type	Anatomy	Clinical aspects
IA	No rotation	Volvulus of the midgut
IIA	No duodenal rotation; normal colonic rotation	Duodenal obstruction; Ladd's bands
IIB	Inverse duodenal rotation; Normal colonic rotation	Intestinal obstruction
IIIA	Normal duodenal rotation; Absent colonic rotation	Duodenal obstruction; Ladd's Bands; Intestinal volvulus
IIIB	Incomplete rotation and fixation	Duodenal obstruction; Ladd's Bands
IIIC	Incomplete fixation of the cecum	Volvulus of the caecum
IIID	Internal Hernias	Obstruction or sub-acute obstruction

90.2.2 Embryogenesis

There are no genetic or familial causes for ARM. The primitive gut completes the anticlockwise rotation between the 4th and the 10th week of gestation and fixes to the posterior abdominal wall when it reaches its definitive position (the ascending colon on the right, the descending colon on the left). Failure of this developmental process constitutes intestinal malrotation [8].

90.2.3 Associated Anomalies

Intestinal malrotation invariably complicates Bochdalek's diaphragmatic hernia, omphalocoele or gastroschisis. Malrotation also occurs with intestinal atresias.

90.2.4 Symptoms and Diagnosis

Antenatal ultrasound does not assist the diagnosis of intestinal malrotation.

Clinical features are those of intestinal obstruction. It may be present as a duodenal obstruction, a volvulus or an internal hernia. Half of infants with ARM show abnormal physical signs during the first weeks of life. The other 50% usually show some evidence of malrotation within the first six months. Later, the presentation is variable [9].

90.2.4.1 Duodenal Obstruction

In neonates and toddlers, the presentation is acute because of "Ladd's bands" that obstruct the third part of the duodenum, giving rise to bile-stained vomiting. Infants and pre-school children may present with cramp-like abdominal pain

90.2.4.2 Intestinal Volvulus

Usually clockwise, constituting a diagnostic and surgical emergency. In about 50% of affected patients, volvolus occurs during the first two weeks of life ("volvulus neonatorum"), with bile-stained vomiting and progressive painful abdominal distension. There may be bloody stool. This is followed by a rapid clinical deterioration and the development of shock, which, if not treated promptly, may be followed by death within hours. In infancy or adolescence, symptoms may be subtle and varied, usually comprising cramp-like pain and vomiting, which may be bile-stained.

Acute appendicitis may be difficult to diagnose when there is a malrotation because, instead of being in the right lower abdominal quadrant, the cecum may be in the left iliac fossa, hypogastrium or elsewhere in the abdomen and acute appendicitis may only be diagnosed at laparotomy or by laparoscopy. There may be malabsorption because of intermittent torsion of the intestinal loops with twisting of lymphatic vessels causing mesenteric lymphoadenomegaly.

May be very difficult but early diagnosis results in a better outcome.

The first investigation for "volvulus neonatorum" is a straight abdominal X-ray [9]. However, this may not be diagnostic because air-fluid levels are generally absent. Volvulus should be suspected when there is no intestinal air and massive abdominal opacification due to a peritoneal transudate. If there is sufficient time, a contrast enema will show the colon on the left side of the abdominal cavity. A contrast medium radiograph of the abdomen may also help. Prompt diagnosis and treatment results in preservation of the intestine, avoiding the serious complication of short bowel syndrome (SBS) because of removal of a large section of necrotic bowel.

90.2.5 Therapy

Surgery is indicated for all types of malrotation.

For types II and III, the operation consists of resection of the Ladd's bands, followed by the identification and treatment of associated volvulus or internal hernia, and repositioning the bowel with the small bowel to the right and the large bowel to the left. A prophylactic appendicectomy should always be performed [10].

In cases of "volvulus neonatorum", surgery should be performed as soon as possible. Following a supraumbilical skin incision, the volvulus is reduced by anti-clockwise rotation of the cyanotic bowel. It is useful to wait about ten minutes to observe return of blood to the gut. Ladd's bands must be carefully resected and the bowel repositioned in the abdomen. If bowel loops appear to be necrotic with no apparent recovery after correction of the torsion, the recommendation is not to resect the intestine immediately but to suture the abdomen with the gut inside, planning for a repeat laparotomy after 24 hours. This conservative approach may allow the necrotic area to become defined allowing a shorter resection. Alternatively, an ileostomy of the healthy bowel may be performed. Recurrence of volvulus is extremely rare.

In the last decade, laparoscopy has also been used to treat symptomatic intestinal malrotation or to identify by imaging patients with possible intestinal malrotation as a group that is prone to volvulus (and therefore requiring treatment) and a group that is not [11]. Laparoscopy can be used to perform an identical procedure to conventional surgery.

90.2.6 Prognosis

Intestinal malrotation uncomplicated by volvulus has a very good prognosis. By contrast, the prognosis for "volvulus neonatorum" is very poor (death and/or SBS in 10–30% of patients). Patients with SBS may survive with lifelong total parenteral nutrition (TPN), but this has a high complication rate (sepsis and liver failure). If there is only 20–30 cm of small bowel but preservation of the ileo-caecal valve a good quality of life is achievable and TPN may be combined with some enteral nutrition. Combined liver and intestinal transplantation carries a poor prognosis.

90.3 Duplications of Alimentary Tract

Intestinal duplications are spherical or tubular structures, which may occur anywhere from esophagus to anus. Tubular duplications may be joined to, and sometimes communicate with, normal bowel.

The incidence is low, representing only 0.1–0.3% of all congenital malformations of the alimentary canal. Table 90.1 shows the regional incidence along the enteric canal. There is no sex prevalence if considered as a single group, but gastric duplications are more likely in girls while boys are more likely to have thoracic duplications.

90.3.1 Embryopathogenesis

Since the morphology varies, it is difficult to establish a single embryological origin [12]. Three different theories have been proposed.

90.3.1.1 Diverticular Theory

In 1905 Kaible observed that in the 4–8 week human embryo there are microdiverticular structures inside the enteric tract. He proposed that persistence and growth of these diverticular structures, which normally disappear, is the basis of the development of duplications. This may explain the origin of spherical but not tubular duplications.

90.3.1.2 Theory of Abnormal Enteric Recanalization

In 1944 Bremer proposed that abnormal recanalization of the intestinal lumen after the solid stage of development of the primitive gut during the 6th–7th week of gestation may result in duplications. However, it has since been shown that the solid stage of human embryo gut development does not usually extend beyond the duodenum.

90.3.1.3 Notochord Split Syndrome

The most satisfactory theory of the origin of gastrointestinal duplications relates to the development of the neuroenteric canal. Saunders (1943) and subsequently Bentley-Smith (1960) established a "split notochord theory", hypothesising that these malformations are dependent on the incorrect separation of the notochordal plate during the presomitic stage. According to these authors, if the notochordal plate fails to migrate as a result of adhesions to the endodermal lining, the spinal canal cannot close ventrally and a tract resembling a diverticulum is established with the primitive gut. This tract may remain open leaving a fistula between the gut and the spinal canal. However in the majority of cases it disappears completely leaving only duplication of the gastrointestinal tract. This theory explains thoracic and caudal duplications, but does not really explain other alimentary duplications and underlines the impossibility of creating a unified model.

90.3.2 Pathology

Duplications are hollow structures with a muscle and a mucosal layer that may contain a small area of heterotopic lining (usually gastric mucosa but sometimes also pancreatic or respiratory mucosa). They often share a common muscular wall and blood supply with the adjacent normal bowel and may communicate with its lumen (more common in the case of tubular duplications which are usually on the antimesenteric border). More frequently there is no communication (cystic duplications are generally on the mesenteric edge).

90.3.2.1 Cystic Duplications

These represent about 90% of cases. Most are located in the small bowel (60%) and do not communicate with the normal intestinal lumen. Must be differentiated from other cystic masses in the abdominal cavity that lack an intestinal mucosal lining.

90.3.2.2 Tubular Duplications

These represent about 10% of cases and are long structures adherent to the normal lumen with which they communicate. Usually located on the antimesenteric border, their length varies from a few centimetres to one meter or more. The duplication may extend the length of the small bowel or the colon. Sometimes abdominal forms may extend to the thorax, causing rare thoraco-abdominal duplications (usually gastroesophageal duplications).

90.3.3 Associated Anomalies

Rare, principally consisting of:

- malformations of the intestinal tract, e.g., esophageal atresia, intestinal atresia;
- vertebral malformations;
- lumbar myelomeningocele or complex genito-urinary malformations in the case of rectal or colonic duplications.

90.3.4 Symptoms and Diagnosis

70% of cases present during the first six months of life. The remaining 30% present during the next eighteen months. Clinical presentation at an older age is exceptional.

When an antenatal ultrasound scan shows an intra-abdominal cyst, cystic duplication should be considered. Tubular duplications are usually not diagnosed antenatally.

The clinical picture depends on the level of the duplication in the alimentary tract, on its morphology (cystic or tubular), and on the mucosal lining. Cystic forms often cause obstruction because of a "mass effect" due to increasing volume because of internal secretions. Sometimes there is volvulus or intussusception with intestinal obstruction.

Tubular forms that are lined with gastric mucosa usually present with intestinal bleeding or perforation.

Clinical features depend on which region of the intestine is affected:

- esophagus: dysphagia, respiratory distress, cardiac disturbances;
- gastrointestinal tract: mass effect, vomiting, obstruction, intestinal bleeding;
- colorectal tract: mass effect, constipation, bleeding.

Diagnosis is by abdominal ultrasound, contrast medium radiography of the abdomen, MRI or CT and scintiscan with 99Tc pertecnectatum to identify tubular forms with gastric mucosa if there is bleeding.

The video-capsule has become a useful diagnostic tool for recognition of the inner orifice of a tubular duplication of the small bowel [13]. Colonoscopy remains the gold-standard for colonic duplications.

90.3.5 Therapy and Prognosis

Cystic duplications must always be excised even if asymptomatic because of the risk of malignancy. For cystic duplications,

intestinal resection with an end-to-end anastomosis is usually performed. For tubular duplications (e.g., esophageal) the mucosal layer may be stripped away. Sometimes colonic duplications may be treated by forming a distal communication between normal and duplicated colon [12]. Rectal forms should be approached by a posterior sagittal incision, for example, Peña's procedure. An alternative approach is by a combined perineal and abdominal approach. A temporary colostomy may be needed. The prognosis is usually good but depends on the form and level of the duplication.

90.4 Persistance of the Omphalo-(mes)enteric Duct

The pathology of the omphalo-enteric duct (incorrectly called "omphalo-mesenteric") consists of a wide range of congenital anomalies all due to missed or partial involution.

90.4.1 Classification

Five different presentations can be recognized, in decreasing order of frequency [14].

- Meckel's Diverticulum.
- Omphalo-enteric fistula, where there is communication between ileum and umbilicus.
- Fibrous cord (obliterated omphalo-mesenteric duct, extending from ileum to umbilicus).
- Umbilical sinus or polyp (remnant of intestinal mucosa at the umbilicus).
- Cyst of the vitelline duct (as a fibrous cord).

90.4.2 Meckel's Diverticulum (MD)

MD is the most frequent, with an incidence of about 82–96%, fibrous cord about 10% and omphalo-enteric fistula between 2 and 6%. Described in 1809 by J.F.Meckel, a German anatomist who defined its embryological origin from the vitelline duct [14]. The MD is a "true" ileal diverticulum. Its wall contains all three layers of the intestinal wall, in communication with the ileal lumen and about 20–60 cm from the ileocaecal valve (Fig. 90.3). It is located on the antimesenteric border of terminal ileum. In 75% of cases MD is not connected to the internal abdominal wall; in the remaining 25% its tip is joined to the umbilicus. Usually MD has its own vascular pedicle deriving from the vitelline arteries. In 25% of cases it is lined with heterotopic tissues (islets of gastric mucosa or, more rarely, pancreatic parenchyma). MD with heterotopic tissues is three times more likely to cause symptoms than the other forms of MD.

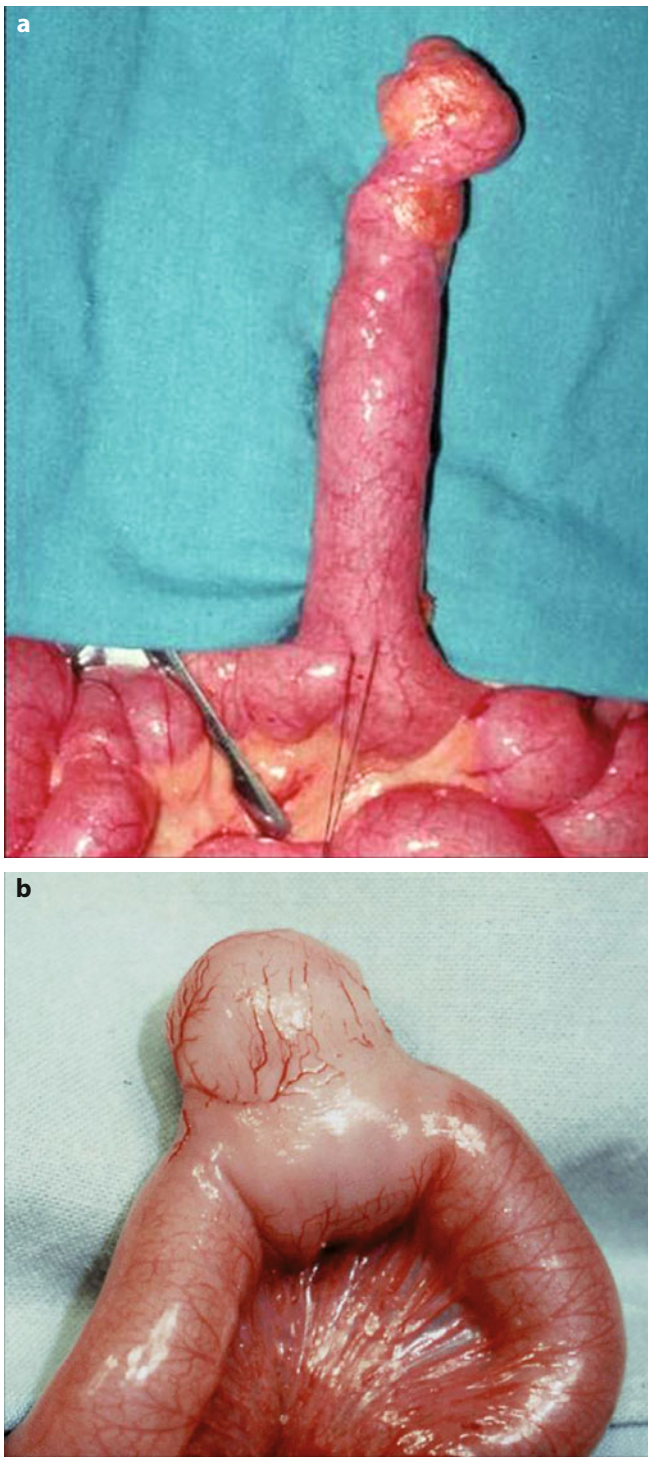

Fig. 90.3 **a**, **b** Meckel's diverticula, please note the wide spectrum of presentation

In a postmortem study, MD was identified in 2% of people. The male:female ratio is 3:1 in symptomatic cases, but was 1:1 when identified at autopsy. Eighty percent of complicated MD present below 10 years of age, 60% younger than 2 years.

90.4.2.1 Embryopathogenesis

MD is the embryonal remnant of the omphalo-mesenteric duct (or vitelline duct), which connects the primitive gut with the yolk sac. It is a consequence of its persistence because of incomplete obliteration, which normally occurs during the 5th–7th week of gestational age [15].

90.4.2.2 Associated Anomalies

MD is frequently associated with other intestinal malformations: omphalocoele (24%), anorectal malformations (11.4%), duodenal or jejunal atresia (12.7%) and esophageal atresia (5%). MD must be looked for at abdominal surgical exploration (either by laparoscopy or laparotomy).

90.4.2.3 Symptoms

Only 4–6% of people with MD will develop symptoms. The incidence of clinical presentation is inversely proportional to age and is most common in males. Complications can be subdivided into five groups:

- intestinal bleeding (31–35%)
- intestinal obstruction (27–30%)
- diverticulitis (22–25%)
- enteric fistula or omphalitis (4–10%)
- other (1–10%).

Usually symptoms manifest within 2 years after birth, particularly with intestinal obstruction or bleeding (in older patients, the main presentations are bleeding or diverticulitis).

Intestinal obstruction may be due to intussusception of the MD or volvulus. Intussusception causes recurrent abdominal pain, vomiting, rectal bleeding and a palpable lower quadrant abdominal mass. Volvulus may occur because intestinal loops twist around the fibrous remnant of the vitelline duct, which is joined to the abdominal wall, causing intestinal ischemia and necrosis.

Bleeding is a consequence of peptic ulceration due to hydrochloric acid secreted by the islets of heterotopic gastric mucosa lining the inner mucosa of the MD. Peak incidence is during the first 2–3 years of life.

90.4.2.4 Diagnosis

When intestinal bleeding is seen, MD should be considered. An abdominal scintiscan with Tc-99 pertecnectatum (Fig. 90.4) [16] is used to confirm the presence of heterotopic gastric mucosa. Introduced by Jewett in 1970, it is based on the preferential uptake of the radioisotope by gastric mucosa. Sensitivity can be increased to about 80% by the administration of pentagastrin or cimetidine. When bleeding stops, the diagnosis can be also be made by video-capsule to identify the orifice of MD [17]. If the diagnosis remains uncertain, videolaparoscopy has been used.

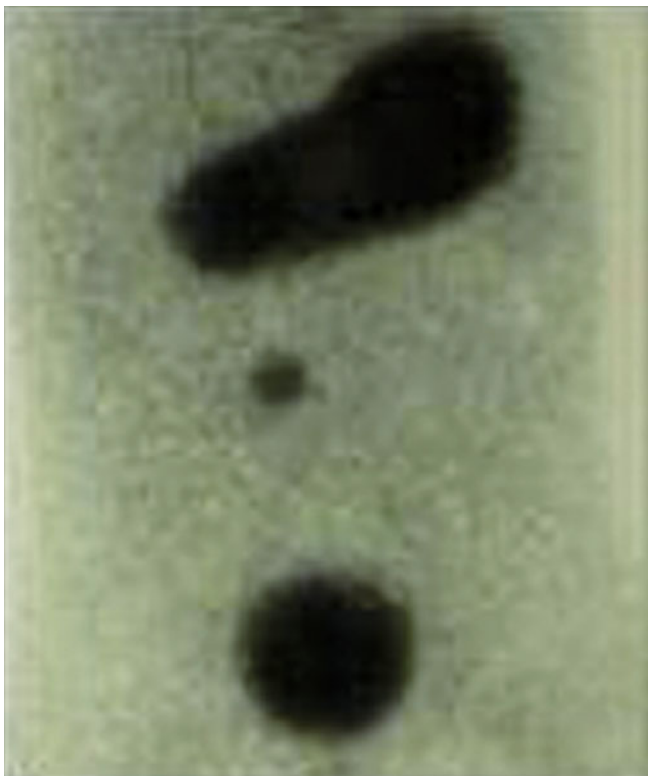

Fig. 90.4 Scintiscan with Tc99. At the top you see the gastric accumulation of radionuclide; at the bottom there is the bladder filled with radioactive urine and among them there is a little accumulation in correspondence of an isle of gastric mucosa inside the MD

90.4.2.5 Therapy and Prognosis

Treatment is by resection of the MD or of the intestinal loop that contains the MD and subsequent ileal anastomosis, either at laparotomy or by laparoscopy [17]. When a MD is found by chance during laparotomy or laparoscopy for other indications, the surgeon should ask parents for permission for prophylactic ablation. The prognosis of MD is good after excision.

90.5 Intestinal Obstructions

Intestinal congenital obstructions are caused by atresias and functional disorders of the gut:

- jejunal atresia
- ileal atresia
- colonic atresia
- meconium ileus.

90.5.1 Jejunal and Ileal Atresia

Represent 95% of congenital intestinal intrinsic obstructions. The remaining 5% are due to intestinal stenosis.

The most common sites are:
- proximal jejunum (31%)
- distal jejunum (20%)
- proximal ileum (13%)
- distal ileum (36%).

Incidence varies from 1 in 1500–2000 births and therefore rather more common than duodenal atresia. Usually these babies are low weight at birth.

90.5.1.1 Classification

Five different types [18]:
- Type I: No apparent external interruption to the bowel at the level of the atretic loop, but dilatation above the endoluminal mucous web.
- Type II: The atretic bowel is joined to the subsequent segment by a thin fibrous cord with intact mesentery.
- Type IIIa: The atretic segments are completely separated with a "V"-shaped defect of the mesentery.
- Type IIIb: There is an "apple peel" (sometimes known as "Christmas Tree") defect of the mesentery (Fig. 90.5).
- Type IV: Multiple atresias.

The most frequent is the type IIIa. The most serious types are IIIb and IV.

90.5.1.2 Embryogenesis

In contrast to other intestinal atresias (esophageal, duodenal, rectal) that have their origins during early development (embryopathies), jejunal and ileal atresias develop later (fetopathies). For this reason they are rarely associated with other anomalies and usually are only apparent after the fifth month of gestation. Two theories that have been proposed to explain the genesis of this malformation:
- Louw-Barnard theory (1955): This states that atresias are the consequence of ischemic bowel damage that may have another cause (e.g., volvulus, internal hernia, vascular disturbance), resulting in necrosis of the intestinal segment with consequent reabsorption and creation of an atretic pouch. This theory seems more likely than the alternative theory.
- Tandler theory (1902): This proposes an error during the phase of recanalization that follows the solid phase of intestinal development causing atresia.

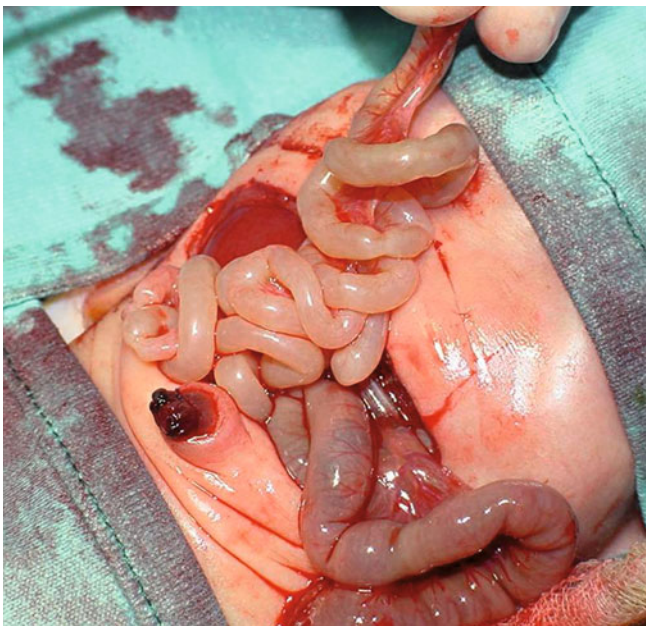

Fig. 90.5 "Apple peel" ileal atresia

90.5.1.3 Associated Anomalies

Intestinal atresias are usually isolated anomalies. Sometimes associated with other malformations (e.g., gastroschisis, omphalocele, meconium peritonitis) and probably secondary to ischemic damage of the bowel caused by these conditions.

A familial pattern of multiple atresias affecting the stomach, duodenum, small bowel and colon has been described in individuals of French-Canadian background, probably representing a rare autosomal recessive gene.

90.5.1.4 Antenatal Diagnosis

Antenatal diagnosis is possible after the 20th week of gestational age. Often there is associated polyhydramnios, usually more pronounced the higher the position of the atresia in the intestinal tract. Antenatal ultrasound shows multiple "bubbles" representing intestinal loops filled with amniotic fluid and secretions and apparent after the 24th week of development.

These findings are not pathognomonic of intestinal atresia and can also be found with other conditions, e.g., meconium ileus, total colonic atresia, Hirschsprung's disease, small left colon syndrome, meconium plug syndrome.

90.5.1.5 Symptoms and Diagnosis

In the absence of an antenatal diagnosis, the newborn will have progressively severe abdominal distension, followed by bile-stained vomiting.

A plain abdominal X-ray shows multiple air-fluid levels and no gas beyond the atresia (Fig. 90.6). The more distal the atresia, the greater the abdominal distension and the greater the number of distended intestinal loops and air-fluid levels. The abdominal radiograph should also be carefully examined for signs of intra-abdominal calcification, which is pathognomonic of meconium peritonitis.

A contrast enema with gastrographin should be done to investigate a possible colonic atresia. It may suggest Hirschsprung's disease. It may also be therapeutic if there is a meconium ileus or meconium plug syndrome and about

Fig. 90.6 Abdominal X-ray showing the ileal distension and no gas in the large bowel

Fig. 90.7 Contrast enema showing the microcolon and the "soap bubbles" image typical of Meconium ileus

50% of patients with uncomplicated meconium ileus respond to such non-operative therapy (Fig. 90.7).

Meconium ileus and 10% of ileal atresias may be consequent to cystic fibrosis and these infants should have sweat tests before hospital discharge.

90.5.1.6 Therapy

These are not surgical emergencies and surgery can be delayed until the 2nd or 3rd day of life, after placing a nasogastric tube and starting total parenteral nutrition. The standard surgical approach is by a transverse supraumbilical laparotomy. However, these days a video-assisted approach is used and laparoscopy using a transumbilical approach allows for exteriorisation of the atretic loop through the umbilical incision (which can be enlarged laterally by 1–2 cm).

- In types I, II and IIIa, a primary end-to-end anastomosis is performed.
- In type IIIb a primary anastomosis is usually performed or, a temporary ileostomy can be fashioned with the anastomosis being delayed for several months.
- In type IV, primary anastomosis is done.

Total parenteral nutrition is continued until there are bowel movements and the gastric stasis ceases.

90.5.1.7 Prognosis

There is a good outcome in 90–95% of babies if other malformations are absent. Type IIIb has a poorer recovery rate due to a poorer gut blood supply.

"Short bowel syndrome" (SBS) may complicate type IIIb or IV atresias where a large section of bowel has to be removed. This is a serious complication, which may have dire consequences in terms of poor nutrition. However, some techniques have been developed to attempt to elongate the residual bowel to increase the absorptive surface of bowel (particularly, Bianchi's technique). The outcome is good for babies who have 25–30 cm of functioning small intestine and a preserved the ileo-caecal valve [19].

90.5.2 Colonic Atresia

Extremely rare. Above the splenic flexure in more than 50% of cases. When below and at the level of the sigmoid, may be confused with rectal atresia.

Incidence varies from 1 in every 10,000–20,000 births [20]. Only pyloric atresia is rarer than colonic atresia.

90.5.2.1 Classification

Similar to the classification used for the small bowel atresias:

- Type I: Endoluminal mucous web (complete or partial).

- Type II: A thin fibrous cord, with intact mesentery joining the two segments.
- Type III: The atretic segments are completely separated with a "V"-shaped defect of the mesentery.

90.5.2.2 Embryogenesis

Similar theories as for small bowel atresias.

90.5.2.3 Associated Anomalies

Skeletal malformations (syndactylism, polydactylism, radial agenesis) are fairly frequent, as are cardiac and ocular anomalies. Sometimes seen in patients with an omphalocoele or gastroschisis, and probably a consequence of ischemic damage due to the pathology itself.

90.5.2.4 Symptoms and Diagnosis

Colonic atresia is very difficult to recognize by antenatal ultrasound. Mostly there is a normal liquor volume and the presence of dilated bowel loops is not pathognomonic.If no antenatal diagnosis has been made, there will be abdominal distension without the passage of meconium, followed by bile-stained vomiting.

A plain abdominal X-ray shows multiple air-fluid levels either in small or large intestine and no gas beyond that point.

A gastrographin contrast enema will show a micro-colon and allow for the recognition of colonic atresia, or raises the suspicion of Hirschsprung's disease and may be therapeutic if there is meconium ileus or meconium plug syndrome.

90.5.2.5 Therapy and Prognosis

Not a surgical emergency, as for small bowel atresias. An umbilical incision and video assisted approach allows the dilated colon to be exteriorised and primary colo-colonic anastomosis. If the proximal colon is very dilated, a temporary colostomy is indicated, delaying the definitive colo-colonic anastomosis for weeks or even months. Colonic biopsies must be taken for the histological identification of neuronal cells and to exclude Hirschsprung's disease.

There is a good outcome in more than 90% of babies if no other malformations.

90.5.3 Meconium Ileus

A congenital neonatal intestinal obstruction due to thickened and tenacious meconium that cannot pass along the intestinal lumen and accumulates within it. Due to an autosomal recessive disease, cystic fibrosis (CF), which is characterized by various clinical manifestations of which meconium ileus (MI) is an early and serious one.

Between 1 in 1500–2000 births in white population. Rare in African-Caribbean babies (1/17,000) and extremely rare in those of Asian origin (1/100,000) [21]. A family history of CF is present in 10%–33% of patients with MI.

90.5.3.1 Embryogenesis

The defect of CF is an exocrine gland dysfunction, particularly of mucus secreting and sweat glands. Two pathological events in meconium ileus lead to the intraluminal accumulation of tenacious meconium: the development of a pancreatic exocrine enzyme deficiency and the secretion of hyperviscous mucus by pathologically abnormal intestinal glands

90.5.3.2 Antenatal Diagnosis

Family history, amniocentesis and antenatal ultrasound allow for the prediction of which infants are at risk of developing MI (almost 20% of CF population) [21].

90.5.3.3 Differential Diagnosis

The major differential diagnosis is with other causes of neonatal intestinal obstruction, in particular:

- ileal atresia
- meconium plug syndrome
- neonatal small left colon
- Hirschsprung's disease.

90.5.3.4 Symptoms and Diagnosis

MI presents during the newborn period in two forms:

- uncomplicated or simple MI
- complicated MI (meconium peritonitis).

Uncomplicated MI presents at birth and abdominal distension is the main symptom. There is then bile-stained vomiting and failure to pass stool. The clinical picture is similar to that of intestinal atresia.

Complicated MI is often recognized in utero by the observation of intra-abdominal calcification due to intestinal perforation following intestinal obstruction. Sometimes a cystic mass is palpable at birth.

The radiological picture shows an absence of air-fluid levels since the gas cannot form above the inspissated meconium, and a granular "soap bubble" appearance due to air bubbles intermixed within the sticky meconium (Fig. 90.7). In complicated MI, abdominal calcifications can be observed.

A contrast enema shows a microcolon.

The diagnosis is by a sweat test, which measures the amount of sodium and chloride in the sweat. A sweat chloride

concentration above 60 mEq/L is diagnostic of CF [18]. The definitive diagnosis is by genetic studies.

MI may occur in the absence of CF in term or preterm infants with pancreatic insufficiency due to other causes.

90.5.3.5 Therapy and Prognosis

Non-surgical treatment consists of trying to dissolve the inspissated intraluminal meconium with solubilizing agents either taken by mouth or by enema (Noblett technique) [22]. Gastrografin enema is the standard non-operative treatment. It is a hyperosmolar, water-soluble, radiopaque solution that draws fluid into the intestinal lumen helping to release intestinal meconium. Surgery remains the mainstay of treatment of MI. The initial procedure is laparotomy with an enterostomy with irrigation and ileal emptying of meconium. An alternative procedure is the formation of a temporary ileostomy to relieve the obstruction.

Survival is now 100% either with non-operative treatment or surgery. This should be compared with results in the 1960s when survival was 33% for the first 6 months. The prognosis depends on the course of CF and its complications.

90.6 Duodenal Obstructions

Duodenal obstruction can be "intrinsic" or "extrinsic".

Intrinsic obstructions are more frequent and comprise, in decreasing order of frequency:

- duodenal atresia
- duodenal web
- endoluminal diverticulum.

The extrinsic forms are rare and include, in decreasing order of frequency:

- annular pancreas
- congenital Ladd's bands (in intestinal malrotation)
- duodenal duplication
- preduodenal portal vein.

The clinical features are similar for intrinsic and extrinsic forms. Incidence varies from 1 in 3000–5000 births.

90.6.1 Duodenal Atresia

In 90% of cases it is located in the first or second portion of the duodenum near the papilla of Vater, usually (75-85%) beyond the outflow of Oddi's sphincter.

There are three different types [23]:

- 1st type: complete duodenal web, with mucosal and submucosal layer.
- 2nd type: two blind pouches joined by a thin, short fibrous cord with intact mesentery.
- 3rd type: the two duodenal pouches are separate and there is a mesenteric "V-shaped" defect.

90.6.2 Partial Intrinsic Obstruction

- Incomplete mucous web: there is a diaphragm with a central hole that can be primary (created at the same time as the web) or secondary (consequent to a perforation of the web due to the increased pressure).
- Endoluminal diverticulum: a membranous fold that extends inside the lumen as a "windsock". It may be initially only partly obstructive, but either duodenal or biliary tree obstruction increases progressively. If it goes beyond the Vater papilla, there may be biliary stagnation with the formation of gall stones.

90.6.3 Partial Extrinsic Obstruction

- Annular pancreas: partially or totally obstructive. It is an embryologic consequence of a persistent primitive ventral pancreas that normally rotates around the duodenum to form the head of the pancreas (Fig. 90.8) [23].
- Ladd's bands: found in patients with intestinal malrotation where the caecum is in the epigastric region. These bands connect the caecum and the right abdominal wall compressing the descending part of the duodenum.
- Preduodenal portal vein: unusual and due to the anomalous persistence of the anterior vitelline veins.

90.6.4 Embryogenesis

Thought to depend on a defect in the vacuolization process of the primitive gut between the eighth and the tenth week of gestation.

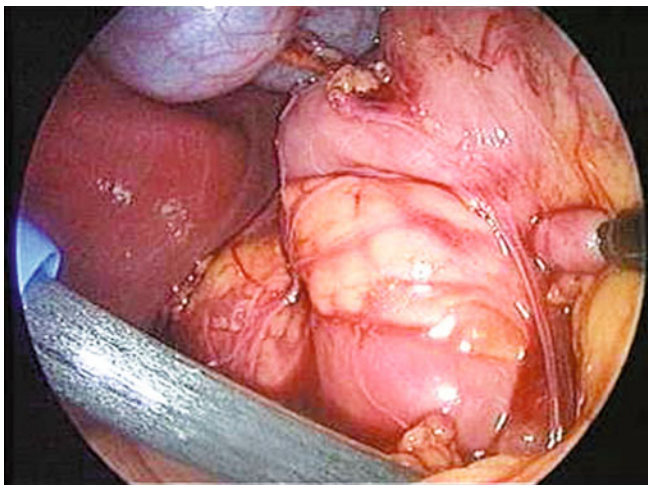

Fig. 90.8 Laparoscopic view of an annular pancreas

90.6.5 Associated Anomalies

Frequently associated with other congenital anomalies. The most frequent are skeletal (ribs, vertebrae, sacrum, radius) (36%), and intestinal (26%) (esophageal atresia, anorectal malformations, Hirschsprung's disease, malrotations). In 20% of cases, there is a cardiopathy. Urinary anomalies are present in 8% of cases.

Down syndrome is particularly frequent in subjects with duodenal atresia (30%) and if duodenal atresia is suspected on antenatal ultrasound, fetal karyotyping is recommended.

90.6.6 Symptoms and Diagnosis

It is possible to make an antenatal diagnosis after the 20th week. The ultrasound observation of polyhydramnios with a "double bubble" is diagnostic (except in the extremely rare case of coexisting type I esophageal atresia). If there has been no antenatal diagnosis, the main symptom is bile-stained vomiting in 80% of cases (due to the subvaterian atresia).

Plain abdominal radiography shows a diagnostic "double bubble" sign. If there is doubt about the diagnosis, a contrast medium will reveal the atresia or partial duodenal obstruction.

90.6.7 Therapy and Prognosis

Not a surgical emergency. The operation can be delayed for 24–72 hrs, allowing for pre-operative assessment, which should include studies of cardiac function.

After a nasogastric tube is passed, enteral feeding is replaced by total parenteral nutrition (TPN) and surgery for very low birth weight babies can be delayed until they have achieved an adequate weight.

- If there is a web, a duodenotomy is performed and the duodenal web is excised with careful attention to the Vater papilla.
- If there is atresia, a duodeno-duodenotomy is performed. The anastomosis is done using the Kimura technique where a "diamond-shaped" suture is used with a horizontal incision on the upper pouch and sagittal incision on the lower pouch (Fig. 90.9a,b) [24]. If the upper duodenum is dilated, "tapering" can be performed.

No gastrostomy is required. Oral feeding can be started when gastric aspirates are no longer bile-stained and bowel movements have started. This may take ten days or more.

The same operation is performed for an annular pancreas with particular attention to the choledocal and pancreatic ducts.

Laparoscopy has recently been used for duodenal atresia or stenosis [25]. Since this is a very difficult operation with limited workspace in the newborn abdominal cavity, a video-assisted approach allows for the identification of the two duodenal pouches, which are exteriorized through the umbilical incision and surgery is completed by traditional means.

Fig. 90.9 The "diamond-shaped" Kimura's anastomosis

There is a 5% mortality due to associated malformations (mainly cardiac). Such operations should be performed a level III Centre with a neonatal ICU.

90.7 Pylorus

90.7.1 Pyloric Atresia, Aplasia

These malformations are very rare (1/100,000 births) without sex prevalence. There are fewer than 200 cases in the literature. These are often babies with more than one malformation, i.e., associated esophageal atresia, cardiac malformations.

The diagnosis can be made by antenatal ultrasound scanning after the 3rd–4th month of development when a single gastric bubble and polyhydramnios is seen. The neonate presents with gastric vomiting (i.e., no bile-staining) and epigastric distension. If there is an incomplete pyloric web, clinical features of obstruction occur later and it can be confused with hypertrophic pyloric stenosis [26]. The diagnosis is made by imaging using ultrasound and contrast medium radiography of the stomach.

Surgical resection of the obstruction is required, except when there is a membranous pyloric web that may be treated by endoscopic resection. In the last decade, a transumbilical skin incision with or without laparoscopy has become the surgical approach of choice for many procedures in neonates including pyloric pathologies.

90.7.2 Hypertrophic Pyloric Stenosis

Hypertrophic pyloric stenosis most frequent cause of gastrointestinal obstruction in children of all ages with an incidence

of about 0.2% and much more common in boys (male:female ratio 5:1).

No clear causative factors have been identified. Both genetic (ethnic variability, male preponderance and positive family history with first-born infant prevalence) and environmental (breastfeeding, seasonal variability with spring/autumn prevalence) factors seem to play a role. Histologically, there is marked hypertrophy of the circular muscle layer with complete reduction of the pyloric lumen. The pylorus is enlarged and elongated with a pale firm mass (pyloric "olive") measuring 2–2.5 cm in length and 1–1.5 cm in diameter.

90.7.2.1 Symptoms and Diagnosis

The onset of symptoms is at 2–8 weeks of age. They consist of non-bilious projectile vomiting (sometimes with blood), becoming progressively more severe and causing a hypochloraemic hypokalaemic alkalosis [27]. A delay in the diagnosis leads to serious dehydration.

In the past, the diagnosis was made by the clinical picture and palpation of the pyloric "olive" on the right side of the abdomen. Nowadays, ultrasound imaging frequently enables an accurate diagnosis (pyloric muscle thickness more than 3.5 mm, pyloric channel length more than 16 mm) [2]. If there is uncertainty, upper gastric contrast radiography enables a definitive diagnosis.

90.7.2.2 Therapy and Prognosis

Preoperative preparation includes stopping enteral feeds, passing a naso-gastric tube and intravenous fluids for correction of dehydration and electrolyte disturbances.

Surgical treatment is by Fredet-Ramstedt pyloromyotomy. The traditional approach was by a small right upper quadrant transverse incision, but in recent years a supraumbilical skin incision (Bianchi's technique) with the upper division of the midline fascia (Fig. 90.10) has been used [28].

After exteriorisation of the pyloric mass, a longitudinal sero-muscular incision of the pylorus is made. The muscle is split and separated till the mucosa bulges through the incision. In some centre this procedure is performed by laparoscopy [29]. Feeding may be restarted 6 hours after the operation, first with a glucose solution and then with increasing volumes of milk, reaching full feeds after 15–20 hours. Babies are discharged on the 3rd postoperative day.

Prognosis is excellent. Recurrences are unusual.

90.8 Defects of the Abdominal Wall

Defects of the anterior abdominal wall have a wide spectrum of presentation. They may extend to the thorax (Ectopia cordis) or present as an infraumbilical defect (exstrophy of the bladder). However, they are mostly limited to the umbilical region as an omphalocoele or gastroschisis.

90.8.1 Omphalocele

An omphalocele is central defect of the abdominal wall in the umbilical region, through which viscera may herniate. The defect is covered by a sac formed by the amniotic membrane on the outside and the peritoneum on the inside. The umbilical cord is always attached at the top of the sac (Fig. 90.11).

The size of the defect may vary from 4 to 8–10 cm. When the defect is wide, the sac may contain liver, small and large intestine and sometimes stomach, bladder and internal genitalia (uterus ovaries and adnexa in females; intra-abdominal testes in males). The larger the defect, the less well developed the abdominal cavity.

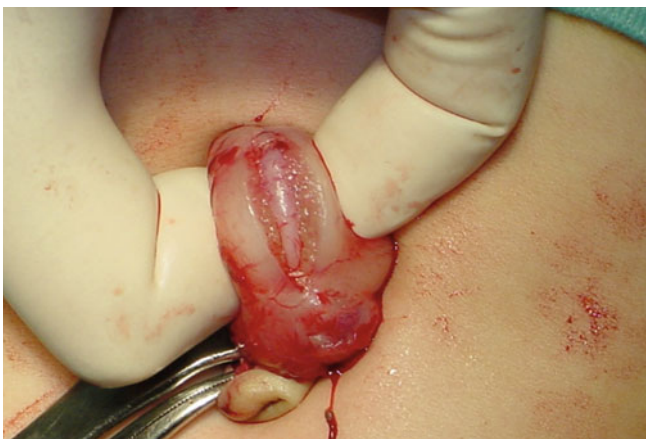

Fig. 90.10 Transumbilical pyloromyotomy. The muscle has been divided and split and it is possible to observe the bulging of the mucosa

Fig. 90.11 Giant omphalocele. The liver and the intestinal loops are seen inside the translucent sac. Please note the cord insertion

The overall incidence is about 1 in 5000 live births with a slight male preponderance.

90.8.1.1 Embryology

During embryological development of the abdominal cavity, at about 5 weeks, the gut develops within the umbilical celom outside the abdominal wall and returns to the peritoneal cavity five weeks later. This is followed by rotation and fixation. Failure of this process causes a defect in the abdominal wall [30]. Since the gut is normally outside the peritoneal cavity until the 10th week of gestation, an omphalocoele cannot be diagnosed until the 12th week.

90.8.1.2 Associated Anomalies

About 50% of patients with omphalocele present with other associated anomalies. Most are cardiac anomalies (Tetralogy of Fallot, ventricular and atrial defects, ectopia cordis, and coarctation of the aorta). Chromosomal anomalies such as Down syndrome are more frequent in patients without herniation of the liver and have been reported in 15–20% of cases. The most frequent is the Beckwith-Wiedemann syndrome (7%), presenting as macroglossia, gigantism, visceromegaly, hypoglycemia and subsequent tumor formation, such as Wilms' tumor, hepatoblastoma, rabdomyosarcoma, neuroblastoma. Rarely the Beckwith-Wiedemann syndrome may be familial.

Omphalocole always presents with an intestinal malrotation due to incomplete intestinal rotation and fixation, and there is an increased incidence of volvulus.

90.8.1.3 Diagnosis

Antenatal diagnosis is possible after the 12th week of gestation, when the bowel returns to the peritoneal cavity. The ultrasound visualization of viscera outside the abdomen and contained by an amniotic sac with the umbilical cord at the top of the sac allows differentiation from gastroschisis.

90.8.1.4 Therapy Prognosis

Consider delivery at a level 3 perinatal center. After birth, the baby's abdominal wall should be covered with a tepid, moist gauze and wrapped in a plastic bag to avoid dehydration. A nasogastric tube is passed to drain the stomach and this may reveal an esophageal atresia. The herniated viscera is returned to the abdominal cavity and defect is closed, preferably at a single operation (primary closure).

For small omphaloceles, primary closure is almost always achieved. The sac is excised and the bowel reinserted in the abdomen. Often "stretching" the abdominal muscular wall is required to close the defect without increasing intra-abdominal pressure to such an extent that the cardiopulmonary system is compromised by reducing venous return [31].

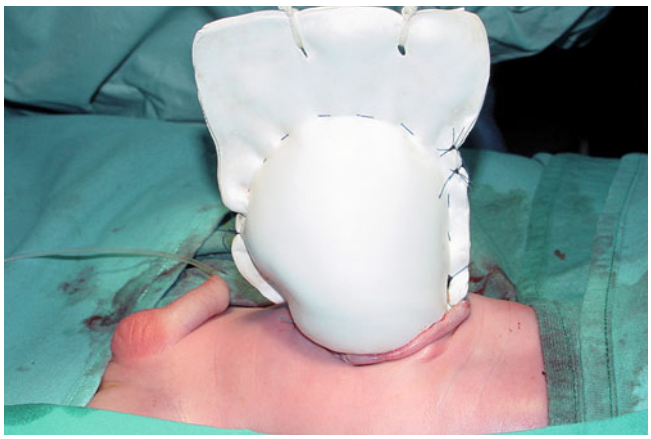

Fig. 90.12 Giant omphalocele. A silastic prosthesis has been sutured to the abdominal wall according to the Schuster's technique. It will be progressively reduced in the following days

If the omphalocele is so large that primary closure is not possible, a staged reduction of the intestinal contents using a silastic prosthesis (Schuster's technique) is used (Fig. 90.12) [32]. The viscera are placed in a silo and are gradually squeezed back into the abdomen until complete closure of the abdominal wall is achieved after a couple of weeks.

Dependent on associated conditions, in particular the presence of cardiac malformations, and on abdominal complications related to the intervention and to the use of the prosthesis, e.g., infections, intestinal adhesions and intestinal obstruction. Survival rate is 75–80%.

90.8.2 Gastroschisis

A small (2–4 cm) defect of the abdominal wall to the right of the abdominal insertion of the umbilical cord, through which intestinal loops herniate uncovered by any sac or membrane (Fig. 90.13). The liver is always inside the abdomen. The bowel may be thickened and edematous because of the chemical action of amniotic fluid and kinking of the mesenteric vessels; less frequently, the bowel appearances are normal without any sign of inflammation.

The overall incidence is about 1 in 10,000 live births with a slight male preponderance. The incidence is highest in Northern Europe [30].

90.8.2.1 Embryology

A likely consequence of intrauterine regression of the right umbilical vein, determining the development of a site of least resistance through which the bowel protrudes before complete fixation.

Fig. 90.13 Gastroschisis. The defect of the abdominal wall is on the right of the umbilical cord insertion

90.8.2.2 Associated Anomalies

Since gastroschisis occurs late during development, the incidence of associated anomalies is low. Intestinal malrotation is almost always present. In 10–15% of cases, there is intestinal atresia or stenosis, probably because of ischemic bowel injury. Cardiac anomalies complicate 1% of cases. Chromosome anomalies are rare. These babies are often small for date because of excessive protein loss into the amniotic fluid.

90.8.2.3 Diagnosis

Antenatal diagnosis is possible after the 12th week of pregnancy. Ultrasound is used to visualize intestinal loops outside the abdomen, uncovered by an amniotic sac with normal insertion of the umbilical cord. There is often polyhydramnios. Delivery should be by cesarean section.

90.8.2.4 Therapy and Prognosis

The herniated bowel is covered by tepid, moist sterile gauze and wrapped in a plastic bag to prevent dehydration. A nasogastric tube is passed to deflate the stomach.

The first attempt at closure is by Bianchi's "minimal invasive management" (Fig. 90.14) [33]. This is not an operative procedure but consists of patient, slow manual reduction

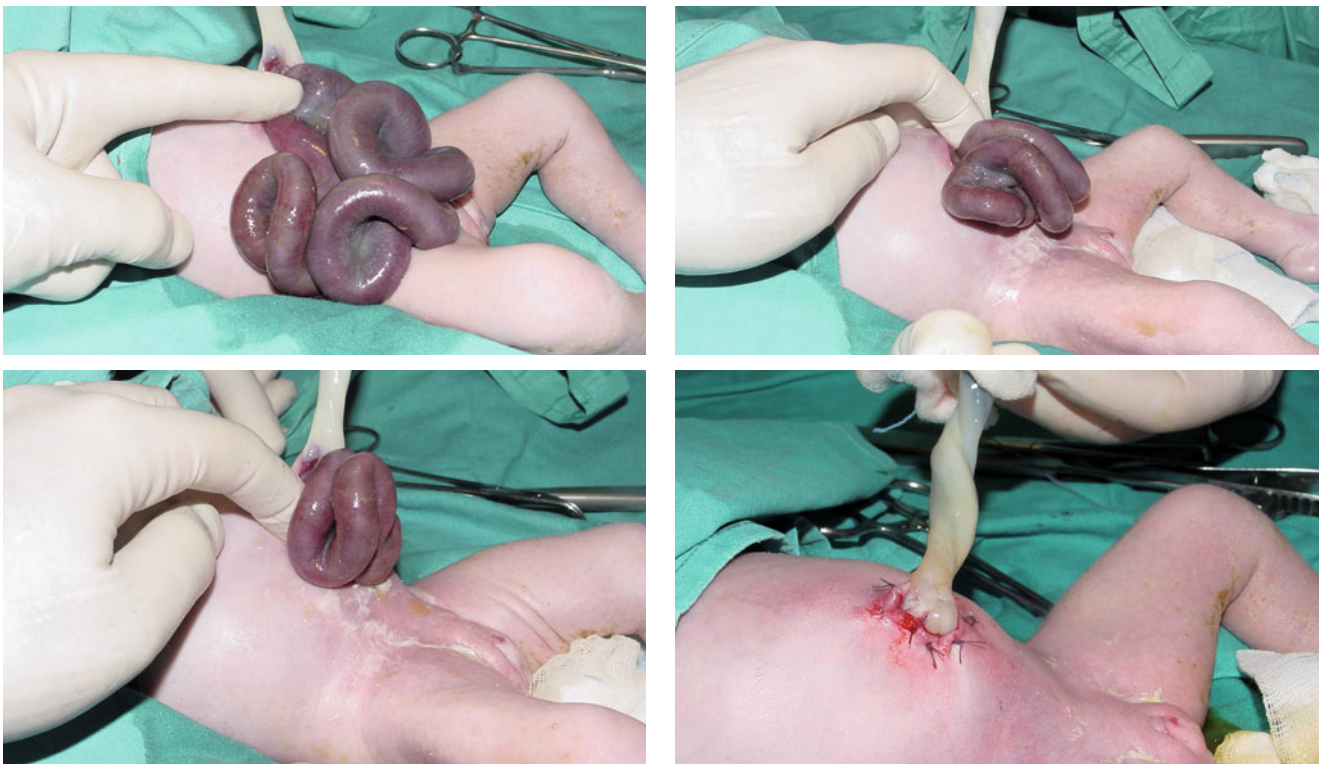

Fig. 90.14 Gastroschisis. Bianchi's "minimal invasive management"

of the herniated intestinal loops through the original hole. The maneuver is done with the baby asleep in his crib without general anesthesia and can be completed in 3–4 hours, leaving the bowel to adapt within the peritoneal cavity. This approach may be followed by prolonged absence of bowel motility and parenteral nutrition must therefore be started.

When reduction using this approach fails, usually because of serious thickening of the bowel wall, a traditional surgical operation is used where the defect is enlarged cranially and caudally by a few centimetres and the gut is re-introduced into the abdomen, sometimes using the "stretching" manoeuvre [34]. If reduction remains impossible, the staged Schuster's (silo) technique is used [32].

Survival rate is high, about 85–90%. Mortality is principally due to the low birth weight and associated intestinal conditions, e.g., atresia, stenosis, bowel perforation.

Rare Surgical Emergencies

Mario Messina, Francesco Molinaro and Alfredo Garzi

91.1 Background

Over the past decade, multiple factors have changed the pattern of neonatal surgical emergencies. An increase in prenatal screenings and the development of neonatal tertiary care centers have changed the clinical approach to these kinds of emergencies. In fact, most conditions, leading to gastrointestinal (GI) emergencies, are uncommon and treatment in specialist centers enables concentration of appropriate resources and expertise. Co-morbidity is common, particularly in the preterm or low birth weight infant [1].

Symptoms of GI emergencies may be subtle, including irritability or feeding intolerance, or they may be more apparent, with vomiting (bilious or nonbilious), abdominal distention, and shock. Vomiting in the neonatal period should always prompt the consideration of a pathologic process. It may be difficult to differentiate a life-threatening cause from a mild viral gastroenteritis or even severe gastroesophageal reflux. The initial symptoms may be nonspecific and the history may not be helpful in a neonate who has not developed a normal pattern. Early diagnosis, availability of diagnostic service and prompt surgical intervention with optimal pre- and post-operative care are necessary to increase survival of newborns with such problems [2]. In this chapter we only explain the pathologies causing GI emergencies in newborns with a rare prevalence. Table 91.1 reports a list of the principal causes of neonatal surgical emergencies of the GI tract performed according to the current literature.

91.2 Incidence, Etiology and Pathophysiology

The principal causes of neonatal surgical emergencies of the GI tract can be divided into common and uncommon ones and can cause an occlusive or a perforative clinical pattern (Table 91.1).

91.2.1 Obstruction

Intestinal obstruction is the most common surgical emergency of the newborn. The incidence of neonatal intestinal obstruction is approximately 1 case per every 500–1000 live births. Approximately 50% of these neonates will have intestinal atresia or stenosis. Duodenal atresia and jejunal atresia occur in approximately equal numbers, although some authors report that jejunoileal atresia is the more common [3]. Congenital pyloric atresia (CPA) is a very rare condition that was first described by James Calder in 1734 [4]. Commonly, CPA occurs as an isolated lesion, which has an excellent prognosis, but it can also be seen in association with other malformations, which can have a negative impact on the final outcome [5]. Colon atresia is an extremely rare condition [6].

Intestinal duplications are rare congenital malformations that could cause intestinal obstruction as mass effect or causing volvulus. Duplications of the alimentary tract occur in 1 of 4500 births Gastric duplications constitute 8% of these or roughly 17 of every 1,000,000 births. A bowel volvulus caused by the presence of a cystic intestinal duplication can lead to an intestinal perforation. The different locations and sizes of these duplications require a specific diagnostic and surgical approach. Early diagnosis and treatment of uncomplicated intestinal duplications by means of prenatal sonographic screening and laparoscopic-assisted resection, respectively, are desirable in this congenital malformation, in order to prevent the risk of occlusion/perforation [7].

91.2.1.1 Pathophysiology

Proximal intestinal obstruction as in cases of duodenal or pyloric atresia leads to fluid loss that has a high concentration of hydrogen, potassium and chloride ions. Hypochloremic

Table 91.1 Neonatal surgical emergencies of GI tract. The tables shows the principal causes of neonatal emergencies, specifying the common and uncommon ones

Occlusion	
Common	*Uncommon*
– Malrotation (duodenal obstruction, volvulus, internal hernia)	– Gastric duplications and acute stomach volvulus
– Duodenal atresia, stenosis or annular pancreas	– Congenital pyloric atresia or web
– Jejunal atresia or stenosis	– Duodenal duplication
– Ileal atresia or stenosis	– Preduodenal portal vein
– Simple meconium ileus	– Cystic duplication of the bowel with volvulus
– Meconium ileus with perforation	– Colon atresia
– Meconium plug syndrome	– Colon duplication with volvulus
– Hirschsprung's disease	– Functional intestinal obstruction
– Drug-induced ileus	– Intestinal psuedo-obstruction
– Hypertrophic pyloric stenos	– Neuronal intestinal dysplasia
– Meckel's diverticulum	
Perforation	
Common	*Uncommon*
– Necrotising enterocolitis	– Spontaneous intestinal perforation
– Meckel's diverticulum	
Miscellaneus	
Common	*Uncommon*
– Hemangiomas, lymphangiomas and vascular malformations of GI	– Neonatal appendicitis
	– Littre's hernia

alkalosis can develop if fluid losses are not replaced. Distal intestinal obstructions lead to fluid and electrolyte loss from both emesis as well as from fluid sequestered into the lumen of dilated bowel loops. Fluid shifts and intravascular volume depletion may lead to severe dehydration, oliguria, metabolic acidosis, and inadequate peripheral perfusion. Prolonged intestinal obstruction leads to alterations in intestinal motility, accumulation of gas and fluid, and bacterial overgrowth. Severe abdominal distention in the neonate can easily impair diaphragmatic function causing respiratory acidosis. As plasma volume loss increases, alterations in blood flow may result in bowel ischemia and necrosis [3].

91.3 Perforation

Gastrointestinal perforation is a catastrophic condition in neonates, especially in premature neonates.

Spontaneous perforations of the gastrointestinal tract occur in the stomach, duodenum, small intestine or colon. The problem is encountered only infrequently; so, the exact incidence is unknown. Male infants are affected more often than females (approx. 4:1). Although neonatal gastric perforation is a well-recognized entity, other spontaneous GI perforations are much rarer and often incorrectly attributed to other disease processes (i.e., necrotizing enterocolitis) [8].

Gastric perforation among neonates is a rare but frequently fatal condition of uncertain etiology. It is associated with high mortality, particularly in premature infants. There is also a trend towards higher mortality in lower-birth-weight infants [9].

91.3.1 Pathophysiology

Almost all spontaneous perforations of the GI tract are considered to be the result of ischemic necrosis. The perforation is the end result of "selective circulatory ischemia," a defense mechanism of the neonate to hypoxia, physiologic stress, and shock. Microembolic phenomena may also play a role. In response to physiologic stress (hypoxia, hypovolemia, etc.), blood is selectively shunted away from mesenteric vessels to the more vital heart and brain. Local mesenteric ischemia can progress to microvascular thrombosis and subsequent gastrointestinal wall necrosis and perforation. Although ischemia is likely the underlying problem, other factors including bacterial colonization, hyperosmolar feeds, and an immature neonatal immune system may also contribute. Indomethacin may also play a causal role in spontaneous GI perforations particularly in preterm infants as it does in the etiology of necrotizing enterocolitis. Risk factors for neonatal gastrointestinal perforation include all causes of severe fetal distress (abruption, emergent c-section, etc.) [8].

Specifically, in the gastric tract, gastric wall ischemia, hypothalamic mechanisms, excessive gastric acid-pepsin ulceration and congenital muscular wall defects could account for spontaneous gastric perforation, even if many authors believe

that this spontaneous rupture is due to an acute rise in the intragastric pressure at the time of parturition [9].

91.4 Miscellaneous

Acute neonatal appendicitis is a rare condition associated with significant morbidity and mortality. The severity of this disease is caused by its tendency to occur more frequently in premature infants, an increased perforation rate with rapid progression to peritonitis, and delay in diagnosis and intervention. Although appendicitis in the perinatal period may occur as an isolated event, in many cases it occurs in association with other pathologic states, including prematurity, inguinal hernia, and others. The presentation of neonatal appendicitis can be identical to necrotizing enterocolitis, leading to misdiagnosis [10].

Littre's Hernia was originally defined by Rinke in 1841 as "the presence of a Meckel's diverticulum in any hernial sac". It is generally difficult to differentiate from other types of hernia, until complications arise. It is a rare and accidental finding at any age, but absolutely exceptional in neonates. The potential surgical risk is linked to the presence of a Meckel's diverticulum [11].

91.5 Clinical Findings

91.5.1 Occlusion

Prenatal ultrasonography can readily identify proximal obstructing lesions that can produce proximal bowel dilation with hyperperistalsis and the classic "double bubble" appearance of duodenal atresia. Distal intestinal obstructions are less likely to cause polyhydramnios but on occasion dilated loops of bowel may be identified as anechoic masses.

Over the maternal polyhydramnios, four clinical findings suggest intestinal obstruction in the neonate: excessive gastric aspirant, abdominal distention, bilious vomiting, and failure to pass meconium. The presence or absence of each of these clinical findings depends largely upon the level of gastrointestinal obstruction. Early recognition of intestinal obstruction is imperative if the complications of respiratory compromise and sepsis are to be avoided [2].

91.5.1.1 Excessive Gastric Output

Passage of a nasogastric or orogastric tube is often performed in premature infants and infants with a maternal history of polyhydramnios. If the initial volume of gastric aspirant is large (> 50 cc) or is bilious then gastrointestinal obstruction should be considered.

91.5.1.2 Abdominal Distention

Abdominal distension may not be apparent at birth but develops over time as ingested air accumulates proximal to an obstruction. The time of onset, degree and characteristic appearance of the distention may suggest the level of obstruction. Gastric distention within a few hours may cause the epigastrium to protrude indicating an obstruction of the stomach or duodenum. Gradual overall abdominal distension occurring over a 12–24 hour period suggests a distal gastrointestinal tract obstruction.

91.5.1.3 Bilious Emesis

It is usual for healthy newborns to spit-up postprandially but bilious emesis in a term newborn is distinctly abnormal. Premature infants (< 35 weeks) occasionally have bilious emesis secondary to an immature or poorly functioning pyloric sphincter but proximal gastrointestinal obstruction must still be considered. Sepsis with an associated paralytic ileus may also result in bilious emesis. Vomiting begins soon after delivery if the lesion is proximal or complete, but may be delayed in cases of distal or incomplete obstruction.

91.5.1.4 Failure to Pass Meconium

A normal newborn is expected to pass a large amount of thick, dark green, shiny meconium usually within the first twelve hours of life and almost always by 24 hours. Failed or delayed passage of meconium suggests obstruction, but neonates with proximal obstructing lesions may pass a normal amount of meconium. Because neonates with ileal atresia or distal small bowel obstruction may pass several meconium stools on the first day of life, passage of meconium does not exclude the possibility of obstruction. Preterm infants commonly have delayed passage of meconium. Approximately 20% will not pass stool during the first 48 hours following birth.

Additional physical findings that suggest obstruction are the presence of intestinal patterning and peristalsis that is visible through the intestinal wall. Distended loops of bowel may be palpable as ill-defined tubular masses. The rectum may feel tight on exam if small and unused as in cases of distal bowel obstruction. Lethargy and hypotonia are late signs of intestinal obstruction and the resultant sepsis. Abdominal wall discoloration and ecchymosis suggest perforation and/or necrosis [3].

91.6 Perforation

Most infants can immediately present signs of perforation. In fact, in cases of spontaneous gastrointestinal perforation

infants present within the first week of life (usually 4–5 days) with an abrupt onset of abdominal distention and associated tachycardia, hypovolemia, and poor systemic perfusion. With severe pneumoperitoneum, respiratory function is compromised requiring urgent intubation. Typically, the abdomen is markedly distended and tympanitic to percussion. Pneumoperitoneum is usually present in these infants. The clinical course of neonates with spontaneous gastrointestinal perforation may mimic those of NEC or other diseases associated with perforation [8].

91.7 Diagnosis

In cases of rare disease causing emergencies, the diagnosis can be difficult, but it is possible to research clinical grounds of intestinal obstruction or perforation.

In case of occlusion, flat and upright abdominal radiographs are obtained to confirm the diagnosis. Swallowed air serves as the contrast media to help delineate the level of obstruction. A normal neonate swallows air from birth and has air within the proximal small bowel within 30 minutes. Air usually reaches the colon by 3–4 hours and can be identified in the rectum by 6–8 hours. There should be no air-fluid levels in an upright film of a normal newborn [12].

When a complete obstruction exists the air pattern may stop abruptly leaving the remainder of the bowel airless. Bowel loops proximal to complete obstruction are dilated. Multiple dilated loops of bowel with "stepladder" air fluid levels on the upright film is the pattern most often seen with distal intestinal obstruction. However, air-fluid levels are not characteristic of the distal intestinal obstruction due to meconium ileus. Partial obstructions as in stenosis may allow small amounts of air to pass beyond the level of obstruction, but the paucity of bowel gas in the bowel distal to dilated bowel segments can easily be identified as abnormal. The abdominal films should always be inspected for peritoneal and/or scrotal calcifications which may signify an intrauterine perforation with meconium peritonitis.

Barium or gastrografin contrast enema examination may be useful to distinguish between causes of distal bowel obstruction (ileal atresia, meconium ileus, Hirschsprung's, meconium plug, etc.) and in cases of meconium ileus or plug may also be therapeutic. Upper gastrointestinal barium studies are generally not as useful unless one is seeking patterns of abnormal bowel rotation. UGI contrast studies are reserved for cases of partial obstruction that cannot be confirmed by plain radiographs [13].

Under the suspicion of perforation the contrast study is strictly not recommended and the diagnosis is confirmed by plain abdominal X-rays (flat and decubitus views) that demonstrate free intraperitoneal air. Serial abdominal films are to be obtained if perforation cannot be demonstrated initially but remains highly suspected [8].

Additional laboratory evaluation includes blood cultures, blood leukocyte and platelet counts, arterial blood gases, and serum pH, especially in case of appendicitis.

91.8 Treatment

The specific management strategies and surgical considerations for the various conditions causing intestinal obstruction in the neonate are not described in this chapter. However, the initial treatment of any suspected neonatal obstruction includes placement of a nasogastric tube to decompress the stomach and to prevent vomiting/aspiration. Fluid and electrolyte replacement should be quickly undertaken to resuscitate the infant and restore circulating blood volume in anticipation of the potential need for surgical intervention. Most obstructive lesions in neonates will require surgical therapy and surgery should not be delayed once volume resuscitation is adequate. If an intestinal anastamosis is anticipated perioperative antibiotics are indicated [3].

In the presence of clinical and radiological signs of perforation, treatment commences as soon as possible, simultaneous to the diagnostic workup. Rapid deterioration is anticipated and prevented with aggressive fluid resuscitation, intravenous antibiotics, correction of acid-base disturbances, and nasogastric decompression. Intubation and ventilatory support is required in infants with respiratory distress. Aspiration of the massively distended pneumoperitoneum can be helpful in infants with severe life-threatening respiratory compromise. Surgical exploration is indicated. The site of perforation is identified although in up to 10% of cases the perforation site has sealed spontaneously and cannot be identified. Surgical treatment is dictated by the infants physiologic condition and the findings at laparotomy (i.e., site of perforation, tissue condition, soilage, etc) and include primary repair, resection with external diversion, resection with anastamosis, drainage, etc. Obstruction distal to the site of perforation is excluded whenever possible [14].

91.9 Outcomes

A multi-disciplinary team of surgeons, anesthetists, neonatologists, radiologists, cardiologists, obstetricians, nurses, physiotherapists and other health professionals experienced in dealing with extremely small infants will provide the best outcome.

The outcomes from neonatal intestinal obstruction or perforation vary with the etiology of the disease. Overall survival is generally good but often is influenced by the associated anomalies of each condition [2].

The prognosis is adversely affected by prematurity, the presence of other anomalies, and a delay in diagnosis [14].

Meconium Plug Syndrome

Mario Messina and Francesco Molinaro

92.1 Definition

Meconium plug syndrome, also described as functional immaturity of the colon, is a transient disorder of the newborn colon characterized by the delayed passage (>24–48 h) of meconium associated with intestinal dilatation. The retained meconium shows up on contrast enema as a filling defect or plug producing a double-contrast effect. Small left colon syndrome is a subset of the meconium plug syndrome where an enema demonstrates an apparent transition zone between dilated distal colon and colon of normal or decreased calibre at the splenic flexure [1].

Fig. 92.1 Inspissated meconium causing colonic obstruction

92.2 Background

Meconium is the material found in the intestine in a newborn. It consists of succus entericus, which is made up of bile salts, bile acids, and debris shed from the intestinal mucosa during intrauterine life. It is normally evacuated within 6 hours after birth or in utero as a vagal response to perinatal stress [2]. The terms small left-colon syndrome, colon immaturity, and functional colonic obstruction are synonymous. All refer to functional immaturity of the ganglion cells of the colon, which manifests as failure to pass the first stool. The problem is probably more common than generally realized and, in most cases, the symptoms are so mild and transient that they pass unnoticed. However, if significant obstruction develops, symptoms become more serious and there may even be perforation [3].

The term meconium plug syndrome was first reported by Clatworthy in 1956 to describe colonic obstruction due to inspissated meconium (Fig. 92.1). Initial reports described a 13% incidence of Hirschsprung's disease with meconium plug syndrome and no association with cystic fibrosis [4]. However, the literature over the last 40 years has reported Hirschsprung's disease in as many as 38% and cystic fibrosis in as many as 43% of patients with meconium plug syndrome [1].

In a review, Keckler et al found that when meconium plug syndrome was identified as pellets only in the colon, cystic fibrosis was rare and the incidence of Hirschsprung's disease was around 13% [5].

There are three associated gastrointestinal (GI) conditions: meconium ileus, meconium peritonitis and ileus–equivalent syndrome.

92.3 Meconium Ileus

Meconium ileus occurs when meconium becomes inspissated and obstructs the distal ileum. The condition is usually a manifestation of cystic fibrosis and about 20% of infants with cystic fibrosis present with meconium ileus at birth.

Meconium ileus is generally the earliest manifestation of cystic fibrosis until proven otherwise. Meconium ileus

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

may occasionally occur in association with pancreatic atresia or stenosis of the pancreatic duct. Meconium ileus also rarely occurs in the absence of any apparent abnormality of the pancreas and these infants have a favorable outcome after decompression because they do not have cystic fibrosis. The problem is more likely related to gut immaturity with decreased intestinal motility and impaired passage of meconium.

In meconium ileus, low or distal intestinal obstruction results from the impaction of thick, tenacious meconium in the distal small bowel. There may be additional complications, such as ileal atresia or stenosis, ileal perforation, meconium peritonitis and volvulus with or without pseudocyst formation [1].

92.4 Meconium Peritonitis

Meconium peritonitis usually results from intrauterine GI perforation. It may occur as early as the second trimester. It is initially a sterile chemical peritonitis, but if perforation of the GI tract persists after birth, complicating bacterial infection may supervene and the prognosis worsens. Perforation and subsequent meconium peritonitis have multiple causes, but most often are due to obstruction and/or volvulus associated with meconium ileus (and cystic fibrosis). In other instances, perforation is due to other causes of neonatal bowel obstruction (such as intestinal atresia) [1].

92.5 Meconium Ileus–Equivalent Syndrome

Meconium ileus–equivalent syndrome is a misnomer that is applied to a partial bowel obstruction in older patients known to have cystic fibrosis. Many prefer to call this the distal intestinal obstruction syndrome (DIOS). DIOS has nothing to do with meconium (as meconium is seen only in the newborn bowel), but on occasion the appearance of feces on the abdominal radiograph have been likened to that of meconium. In 15% of adolescents and adults with cystic fibrosis, abnormally viscid bowel contents become impacted in the distal small bowel.

It is estimated that 37% of patients with cystic fibrosis experience meconium ileus–equivalent syndrome or DIOS at some time [6].

92.6 Age

Although meconium plug syndrome is found mostly in term infants, Mees et al reported that three of their four patients were premature [4].

92.7 Clinical Details

92.7.1 Clinical Signs of Meconium Plug Syndrome

Meconium plug syndrome is common in infants of diabetic mothers (incidence 40%–50%), but also occurs in infants with neurological depression at birth or who are hypotonic for other reasons and hypermagnesemia has been implicated as a cause. Sepsis can also lead to diminished bowel motility (paralytic ileus), mimicking meconium plug syndrome. Most infants with this form of colonic obstruction present during the first 24–36 hours of life. Findings include abdominal distension, bile-stained vomiting, and failure to pass meconium.

The clinical presentations of meconium plug syndrome and meconium ileus are similar, although the source of meconium obstruction is different: ileal obstruction with proximal small bowel dilatation and microcolon in meconium ileus, while the meconium is located in the colon in meconium plug syndrome.

Hirschsprung's disease is also a cause of meconium plugging. The initial clinical and radiologic findings may be similar, but during an enema, abnormal contractions with bowel wall irregularity may be seen in the narrowed, aganglionic bowel of Hirschsprung's disease. The bowel wall typically has a smooth contour when there is an uncomplicated meconium plug [7].

92.7.2 Clinical Signs of Meconium Ileus

Infants with meconium ileus present with vomiting (usually bile stained), abdominal distension and a failure to pass meconium. Pulmonary abnormalities due to cystic fibrosis do not usually present at birth. Although meconium ileus in the absence of cystic fibrosis is considered rare, it occurred in 21.6% of newborns in one series and these infants had no laboratory or clinical evidence of cystic fibrosis [8].

92.7.3 Clinical Signs of Meconium Peritonitis

Meconium peritonitis may be incidentally detected on abdominal radiographs. Clinically, patients may present because of bowel obstruction caused by fibro-adhesive bands, which are the result of the inflammatory peritoneal reaction. The bowel may be intact with the perforation having healed, but there may be associated bowel atresias. If the processus vaginalis is patent when the perforation occurs, calcification or hernias may involve the scrotum. Ascites may also be present [9].

92.8 Preferred Examination

The preferred initial imaging modality is a plain film, which includes supine and horizontal beam views (left lateral decubitus or cross-table lateral) of the abdomen. Plain images are nonspecific and usually show findings of a low small-bowel obstruction. If an erect abdominal radiograph is done (seldom necessary in the newborn), there is a paucity of air-fluid levels, and, in most cases, no gas in the colon. If air is introduced into the rectum from below (e.g., by rectal examination), rectal gas may be visualized. In this situation, meconium in the rectum can erroneously suggest a small presacral mass. However, if air entirely surrounds the meconium mass, it will outline the contour of the mass and suggests the correct diagnosis.

If peristalsis forces gas from the small bowel into the colon, it mixes with meconium and there may be a granular or bubbly appearance, mimicking the findings of pneumatosis cystoides intestinalis and necrotizing enterocolitis (NEC). If a bubbly pattern is seen during the first 12 hours of life, meconium plug syndrome should be considered, but if it arises after 12-18 hours, NEC is more likely. NEC typically affects preterm infants.

Individual assessment is most important. A contrast enema shows a characteristic appearance of the colon, with contrast material outlining the solid column of inspissated meconium and the wall of the colon, giving a double-contrast effect.

Water-soluble contrast enemas can be curative, causing passage of the meconium. After the meconium has been passed, the part of the colon from which it was evacuated may appear narrowed, and a transition zone mimicking that seen in Hirschsprung's disease may be seen. The small, contracted portion of the descending colon in these infants has led to the term, neonatal small left-colon syndrome [7].

92.9 Management

The treatment of meconium plug or small left-colon syndrome is conservative. It consists of stimulation of the rectum or colon. In most cases, simple finger examination of the rectum or insertion of a rectal thermometer produces enough stimulation to induce peristalsis and promote evacuation of the meconium. In other cases, a water-soluble contrast enema examination may induce meconium passage. If this or saline enemas fail, water-soluble contrast agents, should be used. Examinations with such contrast materials require careful attention to the patient's fluid and electrolyte balance [10]. With conservative treatment, complete decompression usually occurs within hours. However, in some infants, the process may take up to 2–3 days.

92.10 Contrast Enema Technique

- Use blankets and lamps to keep the baby warm and the contrast medium should be warmed to body temperature.
- Advance a small-caliber soft, rubber catheter (10–14F) into the rectum using minimal lubricant. Hold the catheter in place by taping the patient's buttocks tightly together.
- Some radiologists deploy a small Foley balloon (5 mL) to aid contrast retention. The balloon should not be inflated until after a preliminary injection of a small amount of contrast under fluoroscopy demonstrates adequate caliber of the rectum. This initial injection without an inflated balloon also allows assessment for a possible low-transition zone in patients with Hirschsprung's disease.
- Because the internal volume of the colon may be low, at the author's institution contrast is injected by hand using a syringe under careful and almost continuous fluoroscopic monitoring. Others use a low-capacity reservoir, such as an intravenous bag, and infuse via gravity drip.
- The entire colon should be opacified to maximize the therapeutic effect of the enema and to identify the position of the caecum (Fig. 92.2).
- This should be followed by carefully enabling reflux of the contrast medium into the distal ileum in patients who may have meconium ileus.
- After the colon has been filled and appropriate films obtained, the catheter is removed without attempting to drain the colon. Allowing the patient to expel the contrast may dislodge the meconium plug [11].

Fig. 92.2 The entire colon should be opacified both to maximize the therapeutic effect of the enema and to identify the position of the caecum

Response to the enema is often dramatic and curative, with immediate passage of meconium and resolution of intestinal dilatation. In some patients, clinical findings persist and a second therapeutic enema may be required. However, since the plug is a symptom in this disorder rather than its cause, multiple repeat procedures are not generally justified [12].

About half of neonates with meconium ileus cannot be treated adequately with irrigations and/or additionally have an intestinal obstruction complicated by neonatal intestinal perforation or ileal atresia secondary to intrauterine perforation. Such cases always require a surgical procedure such as resection of the dilated meconium-filled ileum and ileal anastomosis. Complicated cases of meconium ileus are seen in newborns with an extreme difference in diameters of the proximal and distal ileum, and a significant microcolon. If there is an atresia, the atretic segment should be resected and thick meconium from the proximal part and the grey stool pellets from the distal part evacuated by repeated irrigations with warm saline through a 5–8 Ch feeding tube with gentle manual forward and backward manipulation [13].

A variety of surgical techniques have been developed, comprising resection of the enlarged bowel segment and temporary decompression by distal or proximal enterostomy. The simplest form is a double-barreled ileostomy, described by Mikulicz, with the two loops brought out side-to-side. This is quick and avoids an intra-abdominal anastomosis. Alternative approaches have been described: a distal ileostomy with end-to-side ileal anastomosis (Bishop-Koop), known as a "distal chimney enterostomy". This procedure consists of a Roux-en-Y anastomosis between the end of the proximal segment and the side of the distal segment at least 3 to 5 cm from the open end. The open limb of the distal segment is used as an ileostomy. A variation of this technique requires an angulating proximal segment that is obliquely anastomosed with the distal stump.

Proximal chimney enterostomy, the so-called Santulli procedure, consists of a proximal ileostomy with end-to-side ileal anastomosis. The end of the distal limb is anastomosed to the side of the proximal limb, the end of which is used as the enterostomy. This technique should facilitate irrigation as well as decompression of the proximal small bowel. The enterostomies can be closed by an end-to-end anastomosis when through passage of the intestinal contents is established, usually after 7–12 days [14].

Hirschsprung's Disease

Vincenzo Jasonni and Alessio Pini Prato

93.1 Introduction

Although sporadic reports of patients with suggestive clinical features date back to the seventeenth century, the first telling and concise description of the disease is that of Sir Harald Hirschsprung, a Danish pediatrician who reported the details of his series of two patients at the Society of Pediatrics in Berlin in 1886.

Hirschsprung's disease (HSCR) is one of the most common causes of intestinal obstruction in the newborn. The disease occurs as a consequence of abnormal migration/differentiation of neural crest derived neuroblasts into the developing gut that determines absence of intestinal intramural ganglia. Synonyms of HSCR are Congenital Megacolon and Intestinal Aganglionosis that indicate severe bowel loops distension and absence of intramural ganglia, respectively. Most patients present in infancy and early diagnosis is important to avoid complications. Overall prognosis is good. In fact, with proper treatment most patients live normal adult lives [1].

93.2 Etiology and Pathogenesis

The disease is caused by the failure of neural crest derived neuroblasts to migrate cranio-caudally during weeks 5–12 of gestation. This abnormal migration determines congenital absence of intestinal intramural ganglia within the enteric nervous system (myenteric and submucosal plexuses) with variable distal bowel involvement. This intrinsic innervation is named "gut mini brain" or enteric nervous system (ENS) and coordinates movements, immune functions, and secretion of the gut. Subsequently its abnormality determines functional bowel obstruction and facilitates the onset of severe infections known as Hirschsprung associated enterocolitis (HAEC), which represent the most severe complication of the disease.

The diseased bowel begins at the pectinate line (anal canal shows physiologic aganglionosis) and extends proximally with variable distal bowel involvement. Aganglionosis extending up to the splenic flexure of the colon is named classic HSCR (most frequent, accounts for up to 80% of cases), that extending beyond (confined within the large bowel) is named long HSCR (10%), whereas that involving the whole large bowel (usually extending to at least 5–7 cm of terminal ileum) is defined Total Colonic Aganglionosis (TCSA) or ultralong HSCR (10%). Total bowel involvement is extremely rare and is nearly incompatible with life [1–3].

This is a complex genetic disease as suggested by the high proportion of sporadic cases, variable expressivity, incomplete sex-dependent penetrance, and variable risk of sibling recurrence. In 1994, mutations affecting the RET proto-oncogene on chromosome 10q11.2 were identified in HSCR patients, the same being also involved in different diseases such as multiple endocrine neoplasia type 2A and 2B and sporadic and familial medullary thyroid carcinoma. Since then, loss-of-function of RET tyrosine-kinase has been demonstrated in approximately 50% of familial and 10–15% of sporadic HSCR cases [4–6]. Eight other HSCR susceptibility genes have been identified to date namely GDNF, EDN3, EDNRB, NRTN, ECE1, PHOX2B, SOX10, and ZFHX1B. Amongst these, GDNF belongs to the Ret signaling pathway.

Strong genetic background is also confirmed by the frequent presence of associated anomalies that can basically involve all systems and organs. Association can be either syndromic or not. Down syndrome (trisomy 21) is the most common chromosomal abnormality associated with the disease, accounting for approximately 10 percent of patients. Other syndromic associations are those with congenital central hypoventilation (Ondine's course), Waardenburg-Shah, Bardet-Biedl, Mowat-Wilson, Goldberg-Shprintzen, and others. Non-syndromic association are those involving neurologic, cardiovascular, urogenital, gastrointestinal, and skeletal

systems, metabolism or pigmentation. Anomalies that have been encountered in HSCR patients include congenital deafness, hydrocephalus, bladder diverticulum, Meckel's diverticulum, imperforate anus, ventricular septal defect, renal agenesis, cryptorchidism, and neuroblastomas. Recent evidence suggested that the incidence of associated anomalies is somehow underestimated with true isolated HSCR being relatively rare [7–9].

93.3 Clinical Aspects

HSCR is a congenital disease, which can be familial or sporadic. It occurs in roughly 1 in 5000 live births but its incidence varies significantly among ethnic groups (1.5, 2.1, and 2.8 per 10,000 live births in Caucasians, African-Americans, and Asians, respectively). There is a strong male preponderance, with a male to female ratio of roughly 4:1. Familial cases are not infrequent. Approximately 3–5% of male siblings and 1% of female siblings of children with classic HSCR also have the disease. However, the risk is substantially higher (12.4–33%) in siblings of children with TCSA.

Symptoms range from neonatal intestinal obstruction to chronic progressive constipation in older children (Table 93.1). Although meconium delay has long been considered a characteristic feature of HSCR patients, in a recent review of more than one hundred patients, we demonstrated that "only" 64% percent of infants with Hirschsprung's disease fail to pass meconium in the first 24 hours of life [10]. More than 90% of HSCR patients had symptom onset before one year of age with difficult bowel movements, poor feeding, and progressive abdominal distention. Explosive bowel movements caused by functional colonic obstruction and hyperperistalsis are common in infants with Hirschsprung's disease. In fact, rectal examination may demonstrate a tight anal sphincter and explosive discharge of stool and gas. A small percentage of patients may not have symptoms until later in life. Common symptoms in older children include chronic progressive constipation, recurrent fecal impaction, failure to thrive, and malnutrition. One third of patients with Hirschsprung's disease present with the so-called Hirschsprung associated enterocolitis (HAEC) rather than constipation. This severe and frightening complication is characterized by explosive smelly diarrhea, abdominal distension and signs of impending septic or hypovolemic shock. HAEC still carries a significant morbidity (need for enterostomy) and up to 10% mortality [11–14].

Though clinical features do not strictly correlate to length of aganglionosis, long HSCR and TCSA tend to have worse clinical features and outcome. Total bowel aganglionosis is extremely rare and is nearly incompatible with life [14, 15].

Based on typical clinical findings, HSCR can be suspected if the child is younger than 12 months at onset, complains of meconium delay, fails to thrive, does not experience overflow incontinence or soiling, and has a tight anal sphincter with empty rectum at physical examination. Symptoms may recur after previously resolving with enemas, laxatives, or feeding changes. Conditions that can mimic HSCR in the neonatal period include cystic fibrosis, meconium plug syndrome, small left colon syndrome, hindgut atresia, anorectal malformations, ENS immaturity of the preterm, hypothyroidism, Intestinal Neuronal Dysplasia (IND) and chronic intestinal pseudo-obstruction [11, 16].

Table 93.1 Clinical features of patients with Hirschsprung's disease and incidence of symptoms

Symptoms of Hirschsprung's disease (series of 112 patients) [10]	Incidence (%)
Newborns and infants	
Abdominal distension	94
Difficult bowel movements	92
Failure to pass meconium	63
Intestinal obstruction	61
Failure to thrive	42
Enterocolitis	35
Older children

93.4 Diagnosis

The gold standard for the diagnosis of HSCR is rectal suction biopsy (RSB) [17]. This is a safe and painless procedure that can be accomplished in an outpatient setting. The harvested specimens must be taken 1, 3 and 5 cm above the pectinate line and should contain enough submucosa to properly assess the ENS. It should be processed with histochemical staining techniques including acetylcholinesterase, alpha-naftylesterase, NADPH-diaphorase and lactate dehydrogenase for innervative assessment, and toluidine blue or hematoxylin and eosin for gross histology. The diagnostic features include absence of ganglia and thick parasympathetic nerve trunks in the submucosa and increased achetycholinesterase activity in the lamina propria. The diagnostic accuracy of RSB is close to 100% after one month of age but must be taken with care in the newborn or preterm who can only partially express all diagnostic features. In order to improve the diagnosis of HSCR we implemented an innovative instrument to perform safe RSB at the bedside of both newborn and adult patients, which was named Solo-RBT. We reported a series of 389 biopsies performed with the instrument Solo-RBT with an incidence of complications (bleeding, perforation) lower than 1% [18, 20]. Imaging can help diagnose Hirschsprung's disease. A plain abdominal radiograph may show a dilated small bowel or proximal colon. Contrast

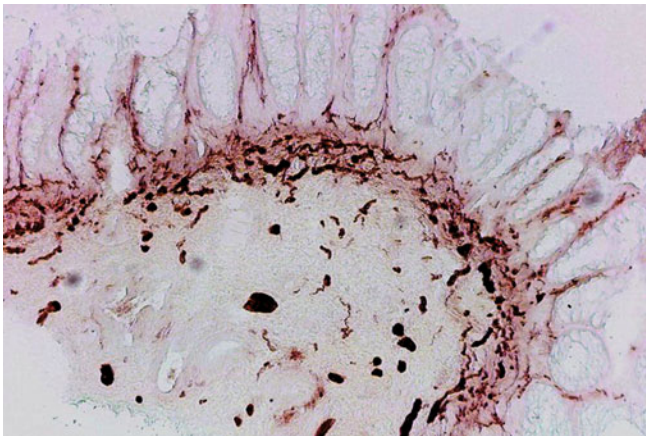

Fig. 93.1 Rectal suction biopsy of a neonatal Hirschsprung's disease. Acetylcholinesterase staining showing absence of ganglia, thick nerve trunks in the submucosal and increased acetylhcolinesterase activity in the lamina propria

enema radiographs of the colon are commonly normal for the first few months of life and indefinitely in patients with total colonic disease. After the dilation process begins, the diseased portion of the colon will appear normal and the more proximal colon will be dilated. A "transition zone" (passage from aganglionic to normoganglionic bowel) may be visible on a contrast enema radiograph. However, the aganglionic colon will extend beyond this point in about 10 percent of patients [12]. Fig. 93.1 shows contrast enema radiographs of an infant with Hirschsprung's disease. Anal manometry (balloon distention of the rectum) demonstrates the absence of internal anal sphincter relaxation upon rectal distention. Contrast enema and anal manometry are similar in sensitivity and specificity and can only be used as adjunctive diagnostic tools with the diagnosis only being confirmed by histochemistry with a RSB (Fig. 93.2). The usefulness of barium enema relies in the possibility of predicting the length of aganglionosis and therefore plan surgical treatment accordingly.

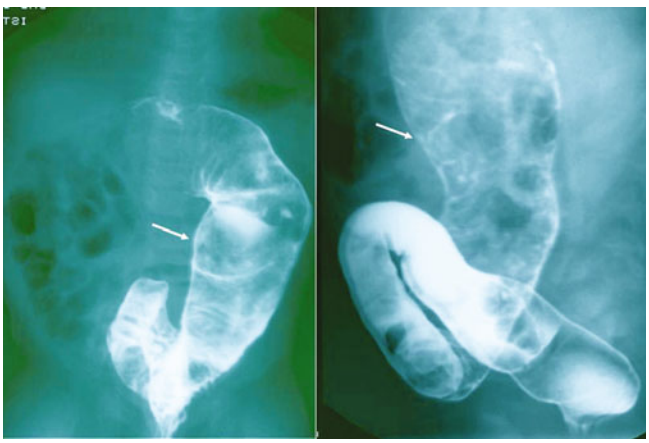

Fig. 93.2 Barium enema of a 2 month old baby showing dilated descending colon (*white arrows*). These slides do not clarify the site extent of aganglionosis and the site of normoganglionic colon

93.5 Treatment

After HSCR is diagnosed, surgery is mandatory. Serial rectal irrigation helps decompress the bowel and prevent enterocolitis in the preoperative period. This treatment is essentially a temporary non-invasive colostomy to decompress the dilated colon. In otherwise healthy newborns with undistended colons and classic HSCR, radical surgery can be attempted primarily. If the child has HAEC, TCSA, or a significantly dilated colon, a decompressive enterostomy (either a colostomy or a ileostomy) can be placed for several months while the child recovers. There are several alternative surgical procedures to treat HSCR. All work well provided certain considerations are taken into account: 1) aganglionic bowel must be removed radically, including the rectum down to the sphincters, 2) the normoganglionic bowel must be identified with intraoperative seromuscular biopsies stained with histochemistry avoiding gross anatomical considerations and blind pull-through, 3) an experienced pathologist is required for intraoperative assessment in order to correctly identify the correct site of anastomosis as well as the possible presence of associated hypoganglionosis or intestinal neuronal dysplasia and 4) surgeons must be well experienced to achieve better results and reduce the incidence of complications. The radical resection of the aganglionic bowel can be performed either with an endorectal, retrorectal, or perirectal approach (Soave, Duhamel, or Swenson procedure, respectively) depending on the surgeon's attitude. We have operated on more than 150 HSCR patients younger than 6 months of age since 1991 and we adopted either endorectal, retrorectal or perirectal approaches with similar results [10]. Recently, minimally invasive approaches have gained popularity and HSCR treatment changed accordingly [21, 22, 23]. The most frequently employed technique is, at present, the so-called Soave-Georgeson technique, which embraces the advantages of the endorectal pull-through and those of the minimally invasive surgery (Figs. 93.3–93.5) [23].

We reviewed the results of a series of patients who underwent the Soave-Georgeson procedure and compared them with those of a matched series of patients who underwent a Soave-Boley procedure (conventional laparotomic procedure). We observed similar results (complications, functional outcome, fecal continence, etc.) but shorter hospitalization and better cosmetic scores.

Basing on these considerations, we concluded that laparoscopic assisted endorectal pull-through (Soave-Georgeson technique) is the procedure of choice both in newborns and infants with HSCR.

93.6 Prognosis

Mortality rate for HSCR is relatively low, being more frequent in the preoperative period as a result of severe HAEC occurrences. Although mortality involves mainly newborns or young children, some reports described adult deaths due to septic complications secondary to severe enterocolitis. Postoperative results of the surgical treatment of HSCR appear to be satisfactory. However, despite good overall outcome, some authors showed a higher than expected incidence of problems in the long-term follow-up. Enterocolitis, constipation, failure to thrive, fecal soiling and incontinence are the most frequent complaints regardless of the surgical technique adopted [10, 14, 21]. In particular, various reports demonstrated that soiling and incontinence have an important impact on psychosocial functioning and parental criticism, and therefore on quality of life [10, 14, 15]. Outcome of classic (rectosigmoid) HSCR can be hardly compared to that of ultralong HSCR (total colonic aganglionosis) as it is well known that the latter implies a significantly worse prognosis. Nonetheless, various reports demonstrated that overall outcome of HSCR improves with time and that this occurs during the whole childhood up to adolescence or adulthood.

We recently presented the results of a series of 112 patients with HSCR [10]. We observed a 15% incidence of complications (residual achalasia, stricture, adhesions, leakage,

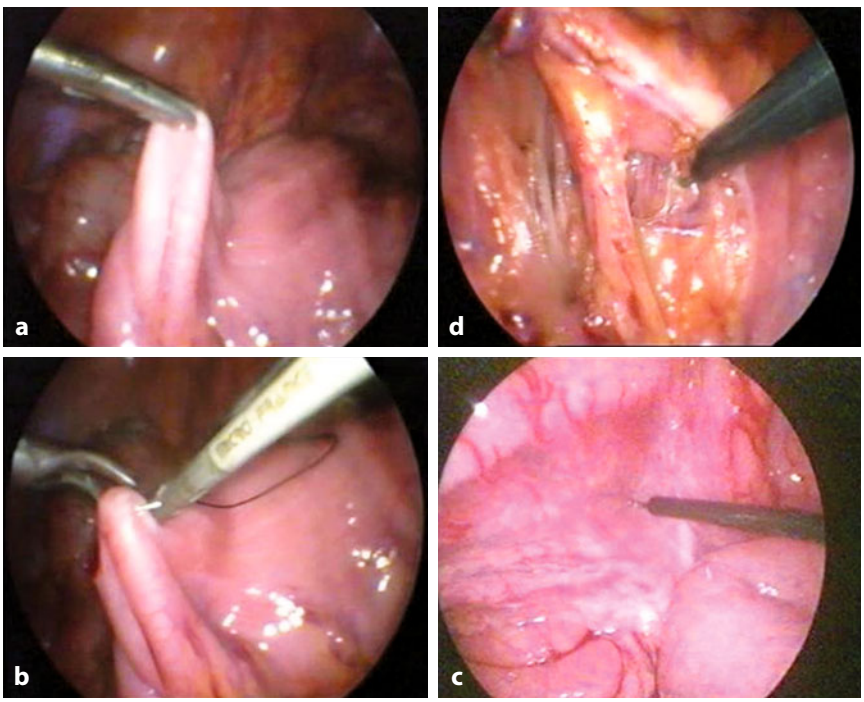

Fig. 93.3 Laparoscopic pictures of the intracorporeal steps of Soave-Georgeson technique. Anticlockwise: **a** Identification of the distended and hypertrophic colon, site of the seromuscular biopsy, **b** seromuscular biopsy to identify normoganglionic bowel, **c** commencing the preparation of the aganglionic rectum (newborn patients with virtually transparent mesentery), **d** nearly completed preparation of the mesentery before the perianal step of the procedure

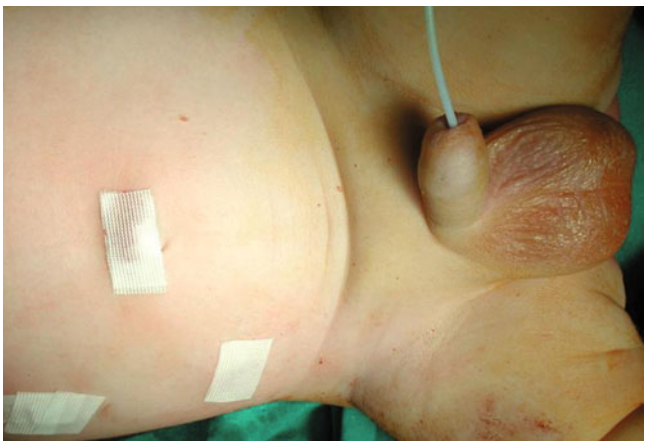

Fig. 93.5 Soave-Georgeson technique: final cosmetic appearance of the baby's belly

postoperative constipation and enterocolitis) in the classic HSCR group and roughly 60% in the TCSA group. This confirmed that outcome is significantly interfered by extent of aganglionosis. With regard to long-term outcome we observed overall good functional results. In particular, we observed 85% of excellent to good continence in the classic HSCR group of patients and 69% in the TCSA group. Psychological self-acceptance scored good to fair in 80% of classic HSCR and 55% of TCSA. Patients' perspectives were excellent to good in 98% and 100% of patients, respectively. Cosmetic results were excellent to good in 75% of classic HSCR and 18% of TCSA patients. Overall good expectations are reasonable but a number of patients with persistent issues can occur [10].

In the case of a redo operation we can expect similar long-term results and outcome provided experienced surgeons and pathologists cooperate in the radical treatment. Our series of 70 patients who underwent a redo pull-through for various reasons experienced results that do not significantly differ from those of a single pull-through. This allows optimistic expectations but suggests centralization of care in order to achieve the best for patients.

Gastroenteritis and Intractable Diarrhea

Assunta Braito

94.1 Introduction

The term gastroenteritis (GE) is applied to diarrhea and vomiting caused by infectious agents involving the upper small bowel and/or colon. Diarrheal diseases are the leading cause of morbidity and mortality in infants and children under 5 years. Ten million children under 5 years die each year worldwide and 19% of these deaths are attributable to infectious diarrhea. There are an estimated 25 million neonates with gastroenteritis with a case/fatality rate of 0.6% [1].

In developed countries, a low exposure to enteropathogens and protection by breastfeeding seem to reduce the risk of newborns to acute gastroenteritis (AGE). Outbreak of the disease in hospitals is likely to be a consequence of a failure to take appropriate preventative measures.

Neonatal GE is common in the poorest areas of the world, where low levels of education, sanitation, hygiene and medical care increase the early risk of exposure to enteropathogens. Malnutrition, intrauterine growth restriction and low birth weight increase the risk of new diarrheal episodes, predisposing to chronic diarrhea, which may have a significant impact on nutritional status and on the psychomotor and cognitive development of young infants.

Recurrent or protracted diarrhea of infectious origin should be differentiated from early onset severe protracted diarrhea (SPD) or chronic diarrhea primarily due to intrinsic enterocyte defects or to immunoinflammatory enteropathies.

This chapter discusses the etiopathogenesis, transmission, clinical aspects and prevention of GE caused by those microorganisms most frequently identified as causative agents of diarrheal diseases.

94.2 Etiology

Causative agents of GE during neonatal period include viruses, bacteria and protozoa most commonly isolated from the stools during diarrheal disease in older children and adults [2].

94.2.1 Enteric Viruses

These viruses infect the intestinal mucosa and cause GE. They should be differentiated from *Enterovirus*, which are generally associated with systemic illness. The significance of *Enterovirus* detection in the stools of infants with diarrhea is uncertain.

94.2.2 Rotavirus

Rotaviruses are by far the most common causative agents of diarrhea in children and infants worldwide. Based on common group antigens, three different *Rotavirus* groups have been identified in humans (A, B, C). Group A strains are associated with more than 95% of rotavirus infections. The subclassification into serotypes is based on epitopes VP4 and VP7, which stimulate neutralizing antibody production. Some uncommon strains seem to be endemic in neonatal units [3, 4].

Rotavirus penetrates and disrupts mature columnar enterocytes located on the brush border of the small intestine. The transfer of *Rotavirus* into the cells is probably mediated by lactase as enterocytes lacking this enzyme are not susceptible to infection.

Diarrhea results from the decrease of intestinal surface area, disruption in epithelial integrity, transient lactase deficiency and altered water and electrolyte absorption. The pathogenic role of enteric types of *adenovirus*, frequently associated with diarrhea in older children, is less common during the first weeks of life.

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

94.2.3 Norovirus

Noroviruses, belonging to the *Caliciviridae*, are the leading cause of viral gastroenteritis worldwide and the commonest agent of severe pediatric AGE, especially where the antirotavirus vaccines are widely used. They are responsible for nosocomial outbreaks of diarrhea in neonatal nurseries and in adults [5, 6].

94.2.4 Bocavirus

Bocavirus, related to human *Parvovirus*, are mainly associated with acute upper respiratory infections in infants. During the course of the disease an increased rate of gastrointestinal symptoms has been observed. Its role as a causative agent of diarrhea is being investigated [7].

94.2.5 Escherichia coli

E. coli are the predominant aerobic enteric flora in humans. Coliform bacilli colonize the lower intestinal tract of the newborn during the first days of life. There are at least six pathotypes of diarrhea-producing *E. coli* with different entero- pathogenicity. Enterotoxic *E. coli* (ETEC) produces two types of toxins, one causing an immediate and reversible secretory response (ST) the other activating adenylate-cyclase (LT). The raised cAMP levels that result from stimulation of enterocytes by LT causes over-secretion of salts and water and inhibition of their absorption. ETEC has been uncommonly associated with neonatal diarrhea in areas of the world where sanitation is good. By contrast, it is frequently isolated from infants with acute watery diarrhea in less developed countries, where 16–26% of diarrheal disease in neonates is attributed to ETEC [8].

Enteroinvasive *E. coli* (EIEC) invade the intestinal epithelium causing inflammatory diarrhea. The ability to invade cells by EIEC is based on the presence of a virulence-plasmid. Little is known about its association with neonatal diarrhea.

Some strains of *E. coli* (0 55, 0111) are strongly associated with epidemic and sporadic infantile diarrhea and known as enteropathogenic *E. coli* (EPEC). EPEC are among the most important causes of bacterial diarrhea occurring during the first months of life. They have been implicated in nursery outbreaks both through vertical transmission from a contaminated birth canal and through horizontal transmission from asymptomatic adult carriers. The mechanism by which EPEC causes diarrhea involves plasmid-related pathogenicity and chromosomally encoded traits. Two virulence factors have been identified: one is the locus of enterocyte effacement, encoded by the LEE chromosomal pathogenicity locus. A second virulence plasmid factor probably mediates the aggregation of bacteria to enterocytes, facilitating mucosal colonization [9].

Enterohemorrhagic *E. coli* (EHEC) is rarely reported as a cause of neonatal diarrhea. Experimental data suggest that receptors for the Shiga toxin, produced from these strains, may not be developed at this age, decreasing the risk of EHEC infection for neonates [8].

Several outbreaks of enteroaggregative *E. coli* (EAEC) in nurseries have been described in developing countries. EAEC seems to be of increasing importance in industrialized countries, although rarely observed in neonates [8].

94.2.6 Salmonella spp.

Salmonella spp. is serologically divided into groups A to E according to the O antigen. More than 2000 serotypes have been identified as causes of human diseases; some of them are frequently associated with neonatal and infantile diarrhea.

The invasiveness of *Salmonella* strains is related to certain serotypes: *S. typhi*, *S. paratyphi A* and *B*, *S. typhimurium*, *S. choleraesuis*, *S. enteritidis* and *S. dublin* are particularly invasive. The invasiveness may be mediated by invasion-plasmid, a mechanism similar to *E. coli* and *Shigellae*.

Laboratory investigations have shown several strain-related differences in inducing secretory diarrhea, in invading intestinal mucosa and submucosa and in generating disseminated infection. Invasion of the submucosa is probably favoured by the production of citotoxins which penetrate and damage the epithelial cells [2].

Neonatal infection by *Salmonella* spp. is relatively common (75 cases per 100,000 infants during the first month of life). Most infections are acquired in nurseries [8].

94.2.7 Campylobacter

Campylobacter is increasingly recognized as a cause of diarrhea. *Campylobacter fetus* causes prenatal and neonatal infections, resulting in abortion, stillbirth, prematurity and systemic disease [8].

94.2.8 Shigella

Although the peak incidence of *Shigella* disease occurs during the first four years of life, symptomatic infection is rarely seen during the newborn period. The relative resistance of newborns to *Shigella* infection is not known.

94.2.9 Other Microorganisms

Other microorganisms, as *Clostridium difficile*, *Vibrio cholerae*, *Yersinia enterocolitica* and *Aeromonas hydrophila* have sometimes been associated with AGE in the newborn. Their significance as a cause of diarrhea in nurseries has not been systematically investigated.

94.2.10 Parasites

Intestinal parasites as *Giardia intestinalis*, *Entameba hystolitica* and *Cryptosporidium parvum* are rare causes of neonatal diarrhea. The occurrence of the infection is associated with high endemicity, inadequate delivery care and poor hygienic conditions.

94.3 Transmission

Microbial agents responsible for GE are almost exclusively transmitted by the fecal-oral route. The human intestine is the main reservoir of infection, although some species of *Salmonella* and *Campylobacter* are well adapted to some animal hosts. Food and water contaminated with enteropathogenic microorganisms are the commonest source of infection.

Some bacterial species (*Salmonella*, *Shigella*, EPEC), which require a low inoculum dose to cause diarrhea, can also spread from person to person or through contaminated objects. Contact with an infected person or a contaminated source is the most important means of transmission during the neonatal period. Human and formula milk have been implicated in transmission of *Salmonella* spp. to newborns [8].

Two different epidemiological patterns are described, depending on the place of delivery. In developing countries, where most infants are born at home, household contacts and overcrowding communities are the main source of AGE in the newborns. Poor hygiene and sanitation are responsible for a high attack rate and high mortality [10].

Infants born in hospital are at risk of nosocomial infection. In the nurseries, the prevalence increases directly with the length of hospital stay. Newborn babies can acquire bacterial diarrhea during the first days of life from their mother's birth canal through fecal contamination. Infection may then spread from the infected newborn to others as a result of inadequate hygiene by personnel. Other common sources of infection have been identified in fomites such as rectal thermometers, soap dispensers and oropharyngeal suction devices [11].

Rotavirus infection may also be transmitted by aerosol droplets from the upper respiratory tract. Although this view has been based on isolation of the virus from respiratory secretions and a high rate of transmission in closed communities, the evidence for airborne transmission of *Rotavirus* has not been established [8].

94.4 Clinical Aspects

The clinical consequences of acute gastrointestinal tract infection range from asymptomatic infection to severe, life threatening gastroenteritis. The degree of exposure, the virulence of the strains and the microorganism load needed to cause infection correlates with outcome.

Host-related risk factors for severe disease are the relative hypochlorydria of the newborn during the first days of life, prematurity, low birth weight, malnutrition, underlying diseases, congenital anomalies and previous gastrointestinal infections.

Colonization without illness is probably the most common outcome of infection in the newborn. It can only be detected by laboratory investigation of stool specimens when there is an outbreak of diarrhea in a nursery. Some newborn babies exposed to enteropathogenic microorganisms develop mild, self-limiting diarrhea.

A clinical definition of diarrhea during the neonatal period is not simple, as newborns have frequent relatively loose stools. It is possible that mild diarrheal episodes caused by enteropathogens are diagnosed as normal evacuations or vice versa. The clinical assessment should therefore include a history of the preceding bowel habit (the frequency and consistence of stools). The incubation period, usually calculated during outbreaks in nurseries where the index case can easily be identified, ranges from a few hours to several days (mean 3–4 days). The onset of diarrhea can be abrupt or insidious, characterized by remarkable variability, with watery, mucus-containing or bloody stools; gross bloody stools and hematochezia are rare in the newborn. Fever and vomit can be additional signs of infections, however they are inconstant and cannot be considered as key symptoms.

Severe diarrhea is infrequent in the neonatal period. The clinical presentation includes fever, vomiting, abdominal distension, dehydration, convulsions and lethargy. Chronic or recurrent diarrhea may occur as a consequence of functional damage to the mucosa of the small intestine induced by enteropathogens, leading to secondary intolerance to disaccharides or a combination of disaccharides and cow's milk proteins.

Colonic perforation, pseudomembranous colitis, megacolon and peritonitis are rare complications of *Shigella dysenteriae* type 1 diarrhea, more frequent in newborns than in older children and adults [8].

There are little data about the extraintestinal manifestations of viral diarrhea. The relationship between *Rotavirus* gastroenteritis, Reye syndrome and aseptic meningitis is controversial.

Some species of bacteria causing diarrhea give rise to extraintestinal manifestations. The clinical picture and frequency are reported in Table 94.1. The risk of extraintestinal complication is considerable with *Salmonella* spp. infection.

94.5 Prognosis

The outcome of uncomplicated diarrhea is mostly good. Clinical manifestations usually last less than 7 days.

Table 94.1 Extraintestinal manifestations of infectious diarrhea caused by entheropathogenic bacteria

Disaccharidase deficiency	Acquired immunodeficiency syndrome
Cystic fibrosis	Wiskott-Aldrich syndrome
Hartnup's disease	Thymic dysplasia
Hirschsprung's disease	
Intestinal lymphangectasia	
Acrodermatitis enteropatica	

Dehydration is the most important and frequent complication of gastrointestinal tract infection and generally reflects the severity of the disease rather than its etiology. The degree of dehydration is considerably less with *Shigella* infection than with diarrhea due to other pathogens, although the frequency of stool passage may be very high.

It is estimated that loss of water and electrolytes due to *Rotavirus* AGE causes at least 150,000 annual deaths in infants before 30 days of life, mostly in newborns who were malnourished or already infected by other enteropathogens. The regions most affected are South-East Asia and Sub-Saharan Africa.

Signs of poor prognosis include weight loss, prolonged capillary refill time, poor skin turgor, sunken eyes, reduced urine output and lethargy. Severe hypovolemic shock and renal failure are the commonest causes of death.

During the neonatal period, acute diarrhea may be the first manifestation of viral or bacterial sepsis. Babies with mild or severe acute diarrhea should be monitored carefully until the diagnosis and the clinical outcome are established.

AGE or protracted post-infectious diarrhea should be differentiated from a wide range of non-infectious diseases causing acute or protracted diarrhea in the newborn (Table 94.2).

94.6 Diagnosis

The diagnosis of AGE is based on clinical recognition, on evaluation of its severity by assessing the degree of dehydration and identification of its etiology by appropriate laboratory investigations.

Clinically determining the etiology of diarrhea can be useful to promptly start antibiotic treatment if necessary. A presumptive clinical diagnosis is required in developing countries where laboratory facilities are not available. The focus should be on the identification of invasive pathogens causing inflammatory diarrhea from those causing a non-inflammatory process (Fig. 94.1).

The definitive diagnosis of gastroenteritis depends on the identification of enteropathogenic agents in the stools [2]. Pathogenic strains of *E. coli* cannot be detected by routine culture methods as they are indistinguishable from normal intestinal flora. EPEC organisms can be identified by agglutination on slides with specific antisera. Blood cultures should be routinely obtained in neonates with suspected or confirmed *Salmonella* infection. Cerebrospinal fluid examination should be considered if the newborn appears to be severely ill or when *Salmonella* or other bacteria species are identified in the blood.

Various methods have been used for the detection of viruses in the stools. Elisa and Latex agglutination are most widely used for detecting *Rotavirus* and enteric *Adenovirus* in clinical samples. In many cases a causative agent is not identified by laboratory investigations; such cases are generally assumed to be of viral etiology.

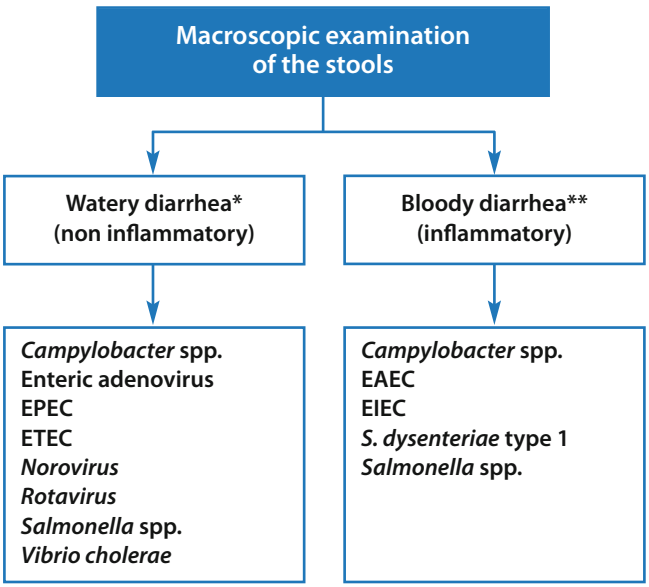

Fig. 94.1 Algorithm for clinical diagnosis of diarrhea. * Limited to small intestine tract; copious fluid stools. ** Colorectal mucosal infection. Microscopic examination for fecal leukocytes and red blood cells can be an useful indicator of inflammatory diarrhea

94.7 Treatment

The principles of management of AGE include rehydration and antimicrobial therapy if indicated. As infants are very susceptible to dehydration because of their high basal fluid and electrolyte requirements, correction of fluids and electrolytes is the mainstay of treatment of any diarrheal disease (see Chapter 95).

The degree of dehydration should be carefully assessed and rapidly corrected. Most neonates have a relatively mild disease with minimal or absent dehydration and can be treated with oral rehydration solutions (ORS). ORSs are available worldwide in several commercial forms, varying in osmolality, glucose and salt composition. Lower osmolality solutions are preferable in the newborn to decrease the stool output and shorten the duration of the disease.

Severe dehydration may require intravenous fluid replacement. Those most at risk are the youngest babies, those with profuse fluid loss with watery stools or persistent vomiting, poor urine output, and depressed level of consciousness.

Most AGE cases are self-limited and antimicrobial therapy is not routinely indicated. The use of antibiotics is confined to newborns who are severely ill or present with inflammatory diarrhea and fever due to enteroinvasive bacteria (Table 94.3). As enteropathogenic bacteria are frequently resistant to antibiotics, antibiotic sensitivity testing should be performed routinely. Although the use of antibiotics in *Salmonella* infection may induce a carrier status, antimicrobial treatment for infants under 3 months is recommended because of the substantial risk of systemic complications. Duration of therapy is between 3 and 5 days, with the exception of sepsis or meningitis when treatment should be continued at least 10 days and 2–3 weeks respectively.

Breastfeeding should be continued during an episode of AGE. Undiluted regular formula milk should be reintroduced as soon as possible, as enteral feeding during diarrhea assists recovery.

Therapy with probiotics for diarrhea in the newborn has not been proven.

Antimotility agents such as loperamide and atropine- like drugs to reduce intestinal motility should be avoided.

Racecadotril, an enkephalinase inhibitor, can reduce stool output in older children. Its effect in neonatal AGE is unknown.

Table 94.3 Antibiotic therapy in newborn diarrhea

Etiology	Antibiotic therapy
Viruses	Not indicated
E. coli	
– EAEC	Controversial*
– EIEC	Controversial*
– EPEC	Neomycin sulfate 100 mg/day**
– ETEC	Controversial**
Campylobacter spp.	Erythromycin within the first 4 days of disease
Salmonella spp.	3rd generation cephalosporins***
Shigella spp.	id

* Rarely observed in the newborn, may be useful in severely ill patients.
** Oral administration. 2nd choice drugs: colistine or polymixyne. The treatment is indicated in moderately to severely ill infants.
*** May be responsible for cholestasis.

94.8 Prevention

Currently, the best strategy for the prevention of neonatal diarrhea consists of prolonged exclusive breastfeeding.

When AGE in the newborn occurs in nursery outbreaks in developed countries, infants born to mothers with diarrhea should be isolated until the results of maternal and infant stool cultures are available. Hand washing before and after contact with each baby is the single most efficacious and least expensive measure for preventing the spread of infection from an infant or a caretaker to others [8, 11].

A wide range of strategies should be undertaken in resource-poor countries to reduce morbidity and mortality from diarrhea affecting the newborn. These include improved standards of hygiene and education, environmental sanitation, safe water supply, implementation of primary health care activities and political commitment.

Rotavirus vaccine, recommended for older children to consistently reduce the burden of AGE and its severity, is of minimal value in the neonatal period [8, 12].

94.9 Intractable Diarrhea

Severe protracted diarrhea (SPD) is a chronic condition starting soon after birth due to congenital anomalies of gastrointestinal function, leading to dependence on total parenteral nutrition (TPN). The causes of SPD are listed in Table 94.4.

SPD is a rare condition, requiring the support of specialized centers where intestinal mucosal biopsy and adequate management can be performed. Intrinsic enterocyte defects are characterized by a high degree of consanguinity in the affected families and autosomal recessive transmission has been suggested. TPN or intestinal transplantation are the only therapeutic options when ultrastructural abnormalities of enterocytes have been demonstrated.

X-linked, autoimmune enteropathy is characterized by a family history of autoimmune diseases. It is frequently associated with extraintestinal symptoms. Treatment consists of administration of immunosuppressive drugs.

Table 94.4 Causes of severe protracted diarrhea in the newborn [13–19]

Primary epithelial abnormalities
Transport and absorption systems
Absorption of carbohydrates, proteins and fats
Reabsorption of bile acids
Electrolyte secretion and absorption
Primary enterocyte abnormalities
Microvillous inclusion disease
Tufting enteropathy
Congenital deficiency of α6β4 integrin
Kindler syndrome
Primary immunological abnormalities
Autoimmune enteropathy
Severe congenital immunodeficiencies
Neutrophil granule deficiency

Rehydration after Diarrhea

Carlo Bellieni

95.1 Introduction

Babies with diarrhea undergo huge fluid loss; the main problems a physician faces are choosing the fluids for rehydration and deciding on the best way to administer them. Fluids should be rapidly absorbed from the intestinal lumen: this effect is maximized with a composition of salts and other components. The combined use of an oral rehydrating solution (ORS) and an appropriate regimen of refeeding is called oral rehydrating treatment (ORT). Fluid absorption can be promoted by the enteral administration of properly designed fluids, even in the presence of ongoing losses. Water passively follows the osmotic gradient generated by the transcellular transport of electrolytes and nutrients. This is why water alone cannot be usefully employed for oral rehydration. Nevertheless, with appropriate ORS, most dehydrated children can be rehydrated successfully without resorting to parenteral intravenous (or intraosseous, when necessary) therapy; here we will see when and how, and in which cases intravenous (iv) rehydration is suggested.

95.2 Mechanism of Enteral Rehydration

The main mechanism by which ORS is effective is the coupled transport of sodium and glucose molecules at the intestinal brush border. This process is known as co-transport: the absorption of a molecule of an organic substrate promotes the absorption of an ion of sodium from the small intestine which, in turn, provokes the rapid absorption of a molecule of water. Co-transport across the luminal membrane is facilitated by the protein sodium glucose co-transporter 1 (SGLT1); once in the enterocyte, the transport of glucose into the blood is facilitated by glucose transporter type 2 (GLUT2) in the basolateral membrane, through the gradient promoted by the Na^+/K^+ ATPase [1]. This mechanism remains intact, even in patients with severe diarrhea [2]. That is why an ORS should basically contain water, sodium and glucose or another co-transporter, in well-determined proportions.

95.3 Types of Enteral Rehydration Solutions

Glucose is the most used co-transporter, though different types of co-transporters of sodium (e.g., aminoacids or cereals) have been proposed [3, 4]. The composition of some ORS is detailed in Table 95.1. A high concentration of co-transporters increases the osmolarity of the solutions, and may decrease rather than improve sodium and water transport into the bloodstream [5]. Solutions of lower osmolarity, but that maintain the 1:1 or 2:1 glucose to sodium ratio [6], perform optimally as oral solutions for diarrhea management.

ORS often contain 20 mEq/L of potassium and 10–30 mEq/L of base in the form of citrate or bicarbonate (Table 95.1) [7]. In May 2004, the WHO and the United Nations Children's Fund (UNICEF) released a joint statement to decrease diarrhea deaths among the world's most vulnerable children [8]. This statement recommended two simple and inexpensive changes from previous formulations for ORS: the switch to a new lower osmolarity formulation that reduces the need for intravenous fluids and shortens the duration of the episode [9]; and the introduction of zinc supplementation for 10–14 days, to decrease the duration and severity of the episode and the likelihood of subsequent infections in the 2–3 months following treatment [10, 11]. It is estimated that more than three quarters of all diarrhea deaths could be prevented with full coverage and utilization of zinc and ORS [12, 13]. Despite the evidence of benefit, there has been little progress on the widespread introduction of low osmolarity ORS and zinc for diarrhea treatment [13].

The WHO originally developed an ORS solution composed of glucose 111, sodium 90, potassium 20, chloride 80

Table 95.1 Composition of WHO ORS and of some ORS products [17, 19, 20]

Solution	Osmolarity osm/L	Glucose mmol/L	Sodium mmol/L	Chloride mmol/L	Potassium mmol/L	Base mmol/L
WHO (1975)	311	111	90	80	20	30 (bicarbonate)
ESPGAN guidelines (1977)	200-250	74-111	60	60	20	10 (citrate)
WHO (2002)	245	75	75	65	20	10 (citrate)
Dicodral (Dicofarm)	205	104	30	41	20	10 (bicarbonate)
Dicodral 60 (Dicofarm)	221	90	60	37	20	14 (citrate)
Dioralyte (Sanofi-Aventis)	240	90	60	60	20	10 (citrate)
Electrolade (Thomson & Ross)	251	111	50	40	20	30 (bicarbonate)
Pedialyte (Abbott)	250	139	45	35	20	10 (citrate)
Rapolyte (KoGEN)	250	110	60	50	20	10 (citrate)

and bicarbonate 30, all in mmol/L [7]. However, as in developed countries, viral gastroenteritis is the usual cause of diarrhea and is associated with less severe salt losses, so the sodium content of the original WHO ORS solution was considered excessive, because higher osmolarity decreased rather than increased intestinal sodium and water absorption, and hypernatremia was reported with its use [14]. In 2002, the WHO proposed a new ORS solution, composed of glucose 75, sodium 75, potassium 20, chloride 65 and citrate 10, all in mmol/L [15]; this preserves the 1:1 molar ratio of sodium/glucose that is critical for efficient co-transport of sodium. It has a reduced osmolarity (245 mOsm/L) compared with the previous formulation (311 mOsm/L).

ORS with complex carbohydrates (derived from rice or carrots) should be given to infants only when they have already been eating solid food, and therefore should not be given to infants who are less than 4 months old [16].

95.4 Assessing Dehydration to Decide the Type of Fluid Therapy

One of the main concerns when dealing with infantile diarrhea is the mode of fluid administration. To this aim, dehydration was formerly divided into mild, moderate and severe, according with the amount of fluid loss calculated through a series of clinical signs; iv fluids were reserved for the last category (dehydration > 10%). As the boundaries between the three degrees were difficult to assess, more recently only two degrees of dehydration (some dehydration and severe dehydration) have been proposed [17].

The British Guideline Development Group (GDG) proposed a new and easy clinical assessment scheme (Table 95.2) that divides patients into no clinically detectable dehydration, clinical dehydration and clinical shock [17, 18], the last group requiring specific emergency management with administration of iv fluid boluses. When the patient has been assigned to one of the three groups, an easy flow-chart helps to decide the type of rehydration needed (Fig. 95.1). The GDG classification is useful because a small infant with gastroenteritis might experience sudden severe fluid loss at the onset of gastroenteritis sufficient to cause hypovolemic shock, needing iv therapy, before any signs of dehydration (for example, dry mucous membranes or reduced skin turgor) were present. Nevertheless, some signs can be common to different classes of dehydration: both dehydration and shock might be associated with a change in conscious state, though to different extents. The GDG concluded that when there was uncertainty the safe approach would be to treat as though shock were present [17]. Red flag signs (altered responsiveness, sunken eyes, tachycardia, tachypnea, reduced skin turgor) should alert the clinician to a risk of progression to shock (Table 95.2). Children with such red flag signs require especially careful consideration and close monitoring. For instance, tachycardia (a red flag sign) would be of even greater concern if it worsened over time, pointing to a serious risk of clinical deterioration and shock.

Babies with dehydration will usually be treated with oral fluid rehydration, those with red flag symptoms and/or evidence of deterioration will require careful management, probably in a hospital setting, while those with suspected or definite shock will require emergency iv treatment in hospital (Fig. 95.1). The GDG considered that recognition of the symptoms and signs of dehydration and shock needs considerable expertise. Clinicians therefore require training and experience in order to ensure competence in assessing children with gastroenteritis.

95.5 Modes of Alimentation

Newborns who cannot drink can be offered ORS through a nasogastric tube. If babies vomit ORS persistently, continuous infusion through a nasogastric tube may improve tolerance. The GDG [17] counsels treating suspected or confirmed shock with a rapid intravenous infusion of 20 mL/kg of 0.9%

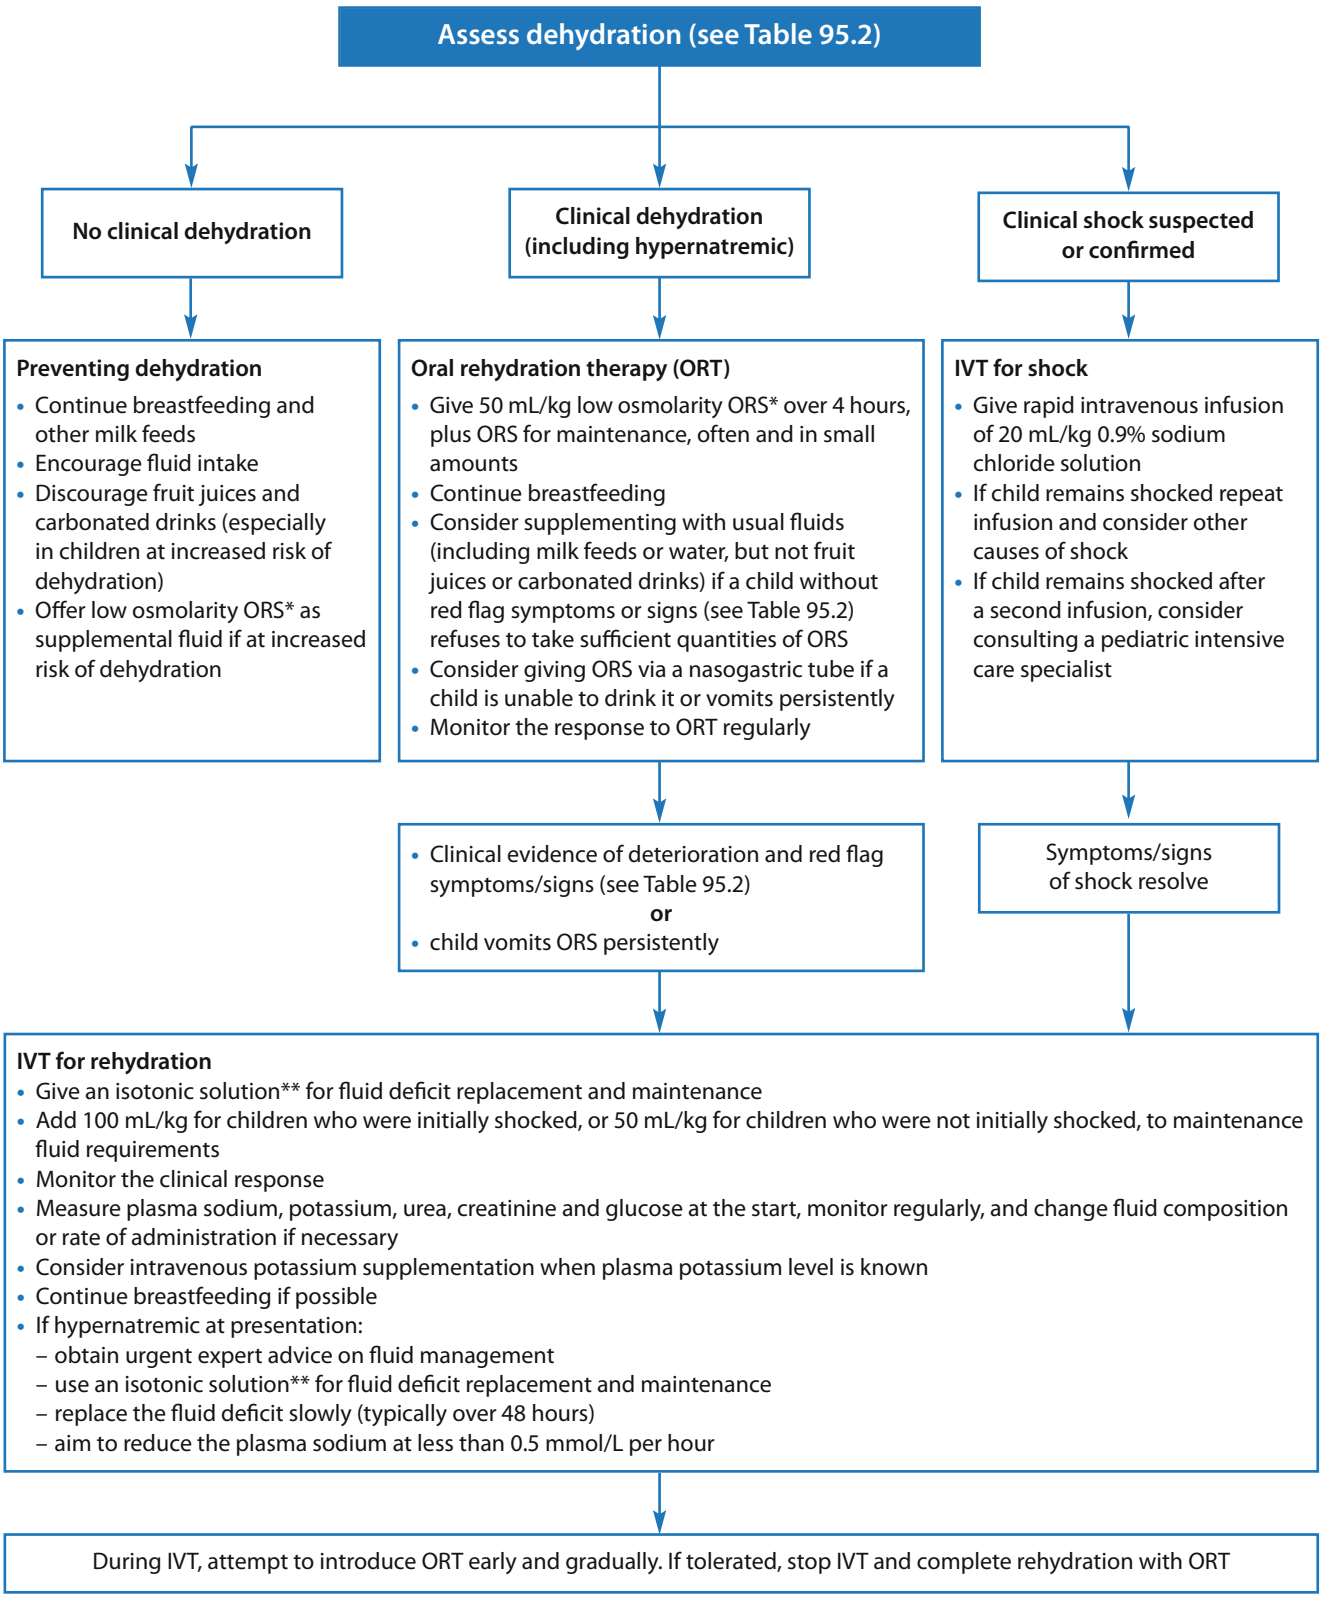
Table 95.2 Assessment of dehydrated patients. From [17]

	Increasing severity of dehydration →		
	No clinically detectable dehydration	Clinical dehydration	Clinical shock
Symptoms (remote and face-to-face assessments)	Appears well	Appears to be unwell or deteriorating	–
	Alert and responsive	Altered responsiveness (for example, irritable, lethargic)	Decreased level of consciousness
	Normal urine output	Decreased urine output	–
	Skin color unchanged	Skin color unchanged	Pale or mottled skin
	Warm extremities	Warm extremities	Cold extremities
Signs (face-to-face assessments)	Alert and responsive	Altered responsiveness (for example, irritable, lethargic)	Decreased level of consciousness
	Skin color unchanged	Skin color unchanged	Pale or mottled skin
	Warm extremities	Warm extremities	Cold extremities
	Eyes not sunken	Sunken eyes	–
	Moist mucous membranes (except after a drink)	Dry mucous membranes (except for "mouth breather")	–
	Normal heart rate	Tachycardia	Tachycardia
	Normal breathing pattern	Tachypnea	Tachypnea
	Normal peripheral pulses	Normal peripheral pulses	Weak peripheral pulses
	Normal capillary refill time	Normal capillary refill time	Prolonged capillary refill time
	Normal skin turgor	Reduced skin turgor	–
	Normal blood pressure	Normal blood pressure	Hypotension (decompensated shock)

sodium chloride solution. A second rapid intravenous infusion of 20 mL/kg of 0.9% sodium chloride solution should be administered if a child remains shocked after the first infusion, and possible causes of shock other than dehydration must be considered. If the rapid intravenous infusions resolve the symptoms/signs of shock, rehydration with intravenous fluid therapy should be started. For fluid deficit replacement and maintenance (if the baby is not hypernatremic at presentation), an isotonic solution such as 0.9% sodium chloride, or 0.9% sodium chloride with 5% glucose should be used. For those who require initial rapid intravenous fluid boluses for suspected or confirmed shock, 100 mL/kg for fluid deficit replacement should be added to maintenance fluid requirements, and the clinical response should be monitored; for those who are not shocked at presentation, 50 mL/kg for fluid deficit replacement should be added to maintenance fluid requirements, and the clinical response monitored; plasma sodium, potassium, urea, creatinine and glucose at the outset should be measured, and fluid composition and rate of administration should be monitored regularly and altered. If necessary, provision of intravenous potassium supplementation should be considered once the plasma potassium level is known.

If intravenous fluid therapy is required in a newborn presenting with hypernatremic dehydration:

- use an isotonic solution such as 0.9% sodium chloride, or 0.9% sodium chloride with 5% glucose, for fluid deficit replacement and maintenance
- replace the fluid deficit slowly, typically over 48 hours
- monitor the plasma sodium frequently, aiming to reduce it at a rate of less than 0.5 mmol/L per hour [17].



* 240–250 mOsm/L (Table 95.1)
** Such as 0.9% sodium chloride, or 0.9% sodium chloride with 5% glucose

Necrotizing Enterocolitis

Elvira Parravicini and Federica Fromm

96.1 Historical Prospective and Epidemiology

The very first time Necrotizing Enterocolitis (NEC) appeared in medical literature was 1952, when two articles published in Z. Kinderheikd described a particularly severe form of enteritis, which the authors called *Enterocolitis Ulcerosa Necroticans*. Schmid described the pathology [1] and Quaiser the clinical aspect [2] of the diseases. The year after, the same authors named this condition Necrotizing Enterocolitis (NEC) [3]. It was only in 1964 that Berdon from the New York Babies Hospital described the clinical and radiological findings of the disease [4]. Since the first description of NEC, multiple etiologic factors have been identified, however many questions related to pathogenesis, early diagnosis, treatment and prevention, remain unanswered.

Although the incidence of NEC widely varies by year, by country and by institution, prematurity and low birth weight remain the most significant risk factors. In fact, the overall incidence is 1–5 per 1000 live births, but dramatically increases to 100 per 1000 in very low birth weight (VLBW) and to 200 per 1000 in extremely low birth weight infants (ELBW). In 2008 the Vermont Oxford network reported 2.4 and 9.9% as the 25th and 75th percentiles of NEC rate respectively in VLBW infants. Typically NEC affects preterm infants at about 3–4 weeks of life and often occurs in clusters, suggesting an infectious etiology. The disease is relatively more common in black infants, but both males and females can be affected. In full term infants NEC is a rare event, occurs within the first few days of life, and is associated with pre-existing conditions such as perinatal asphyxia, congenital heart defects, and polycythemia. The mortality rate associated with NEC is highest for the smaller infants and those requiring surgery and ranges from 10–50% [5].

96.2 Pathogenesis

The pathogenesis of NEC is multifactorial and, regardless of the triggering mechanisms, the resultant outcome is significant inflammation of the intestinal tissues, release of inflammatory mediators, and down-regulation of cellular growth factors, all of which lead to variable degrees of intestinal damage. Given that NEC mainly occurs in premature infants, its pathogenesis definitively correlates with developmental immaturity of the GI tract. Other significant risk factors include intestinal ischemia, sepsis and enteral feedings.

96.2.1 Intestinal Underdevelopment

Premature infants are at high risk for NEC because of their gastrointestinal immaturity. Although enteral feedings can enhance its maturation, motility is quite underdeveloped before the third trimester in both animal models and extremely premature infants and can be impaired in neonates who experience asphyxia [6]. Impaired digestion and absorption of nutrients can contribute to intestinal injury. An animal model of NEC was established in piglets by creating intestinal loops provoking dysmotility and by administration of intraluminal injection of acidified casein, which mimics enteral feeds [7]. Other animal data suggest that overproduction and/or accumulation of small chain fatty acids in the intestinal lumen can induce concentration-dependent injury to the intestinal mucosa [8]. Another point of weakness of the GI tract of premature infants is the immaturity of the epithelial barrier in both its structural and biochemical components. Epithelial cells lining the intestinal tract are charged with major tasks related to the protection of the mucosa. These mechanisms include the enhancement of salt and water secretion to flush pathogens and toxins, the production of intestinal mucins by goblet cells and the secretion of antimicrobial molecules by Paneth cells [9]. These defense mechanisms can be severely

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

underdeveloped in premature infants with consequent overgrowth of pathogens and increased susceptibility to injury.

96.2.2 Intestinal Ischemia

The histological findings of NEC, including hemorrhagic lesions, subserosal collection of gas and gangrenous necrosis, have suggested that ischemia contributes to the pathogenesis of NEC. It is most likely that the first event begins within the intramural microcirculation and the submucosal arteriolar plexus, as these represent the principal sites of resistance regulation in the intestin. Bowel ischemic injury can be induced by decreased perfusion secondary to hypotension, decreased cardiac output or by stealing phenomenon via a patent ductus arteriosus or by diving reflex, where blood flow is diverted from the intestine towards heart and brain. Ischemia can also be secondary to mucosal surface inflammation, leading to villous arterioles and submucosal vessel damage, which may play a critical role in disease extension. Regulation of vascular resistance in neonatal intestine is mainly determined by a balance between the endothelial production of two molecules, the vasoconstrictor peptide endothelin-1 (ET-1) and the vasodilator free radical nitric oxide (NO). Under normal conditions high blood flow is maintained as the balance favors NO-induced vasodilation. However, in the transition from fetal to newborn life, especially in premature infants, a reduced endothelial production of NO can predispose to ischemic injury. Moreover, the ET-1:NO balance can be altered with prevalence of vasoconstriction by factors that disrupt endothelial cell function, including ischemia-reperfusion, sustained low-flow perfusion, or production of proinflammatory mediators. Eventually the interaction of ET-1 and NO might facilitate rapid extension of ischemia into larger portions of the intestine [10].

Although hypoxia and ischemia contribute to NEC pathogenesis, several studies suggest a stronger association with abnormal bacterial colonization, sepsis and enteral feedings [11].

96.2.3 Sepsis

Although many infants affected by NEC have negative culture findings, several organisms have been associated with outbreaks of NEC, including *Klebsiella pneumoniae*, *Escherichia coli*, *Staphylococcus epidermidis*, and bacteria belonging to the *Clostridia* family. However it is unclear whether these organisms are at the origin or consequential to the event.

Premature infants are often colonized by pathogenic species, with a reduced degree of colonization by normal microbial flora such as *Bifidobacterium* and *Lactobacillus* species, which are found in healthy full term and breast-fed infants [12].

Colonization by pathogenic bacteria or a paucity of commensal bacterial flora may contribute to the pathogenesis of NEC. Rat pups colonized with *Staphylococcus aureus* and *Escherichia coli* demonstrated increased incidence and severity of NEC compared with those whose intestines were populated with various bacterial species [13]. On the contrary, it is known that animal models devoid of bacteria fail to develop intestinal inflammation [14]. Moreover, many preterm infants receive frequent exposure to broad-spectrum antibacterial agents, further altering the intestinal bacterial environment. Outbreaks of NEC have been associated with *Enterobacter sakazakii*, a known contaminant of powdered milk formula, also implicated in episodes of sepsis and meningitis [15]. The presence of this bacteria in the intestine is strongly associated with development of NEC, as demonstrated in animal models, where oral feeding contaminated with *Enterobacter sakazakii* induced NEC [16].

96.2.4 Enteral Feedings

NEC occurs mainly in infants who have been fed, although there is no evidence that delaying introduction of enteral feeds decreases the incidence of the disease. Rather it has been demonstrated that NEC occurs more often when high volumes of enteral feeds are achieved [17] and that a prolonged use of trophic feeds is protective compared with quick increments in the first 10 days of life [18]. Promotion of breastfeeding reduces the incidence of NEC by three to ten-fold [19] although there is no agreement whether donor milk has the same protection as mother's milk [20].

96.2.5 Abnormal Inflammatory Response

An abnormal inflammatory response has been advocated as the final pathway after exposure to risk factors associated with NEC, such as intestinal underdevelopment, ischemia, abnormal bacterial colonization, sepsis and formula feeding. Laboratory and human investigations suggest that these risk factors may activate the production of several pro- and anti-inflammatory cytokines in an unbalanced fashion that ultimately leads to bowel injury and necrosis. Although premature infants are capable of mounting both pro- and anti-inflammatory responses, there is evidence that the pro-inflammatory pathway is favored. Toll-like receptors (TLRs) are able to recognize molecules found on microbes and are present on various cells, especially inflammatory cells. Following activation of TLRs a complex cascade of signals occurs, culminating in the translocation of the pro-inflammatory transcription factor NF-kB (nuclear factor kappa-light-chain-enhancer of activated B-cells) to the nucleus and release of inflammatory cytokines. There is experimental evidence that intestinal epithelial cells

normally express a low level of TLRs, maintaining a status of hypo-responsiveness of intestinal epithelial cells to commensal bacteria. This process is developmentally regulated, and perturbations of this response could lead to intestinal inflammation and necrotic injury [21].

In animal models it has been demonstrated that in mother fed animals, there is a decrease in TLR4 expression in intestinal epithelium, while in formula-fed and asphyxia-stressed animals, TLR4 expression increases [22]. Moreover, it has recently been shown that TLR4 wild-type mice exposed to hypoxia and fed with formula have increased incidence of NEC when compared with TLR4 mutant mice. There is a suggestion that the increase in NEC is secondary to increased apoptosis and decreased capacity for intestinal repair [23]. Alterations in downstream signaling after TLR activation may also influence the balance of the inflammatory response. The most likely molecules involved include Tumor Necrosis Factor-Alpha (TNF-α), Platelet Activating Factor (PAF), interleukins (IL-1, IL-6, IL-8, IL-10, IL-12 and IL-18), nitric oxide and oxygen free radicals, as documented by studies on animal models and newborns affected with NEC.

Intestinal inducible nitric oxide synthase (iNOS) mRNA expression in animals exposed to hypoxia and/or formula feeding was increased when compared with the expression of maternally fed pups [24]. A study on human newborns compared the presence of iNOS mRNA by immunofluorescence in pathology specimens of infants who underwent intestinal surgical resections. All the specimens from a group of 15 infants affected with NEC were positive. On the contrary, only 2 out of 6 pathology specimens obtained from infants who underwent surgery for indications other than NEC, were positive for iNOS expression [25]. Data on a population of infants affected with NEC showed that both pro-inflammatory IL-8 and anti-inflammatory IL-1 and IL-10 were elevated in the most severely affected infants compared with those less severely affected [26]. Although these data demonstrate that both systemic anti-inflammatory and pro-inflammatory signaling is active in neonates, premature infants can be vulnerable at this level because of inappropriate regulation of their inflammatory response.

96.2.6 NEC and Blood Transfusion

There have been anedoctal reports linking cases of NEC to blood transfusions. McGrady et al observed an odds ratio for developing NEC of 15.5, during an outbreak of NEC, if a baby had received at least one blood transfusion. However, neither temporal association, nor pathophysiological mechanisms were identified [27]. Mally et al published the results of a retrospective chart review of a population of 908 premature infants who received 751 PRBC transfusions. They identified a sub group of 7 stable premature infants who developed severe NEC following elective blood transfusion for anemia of prematurity [28]. The invoked pathophysiologic mechanisms include regional alterations in oxygen delivery caused by the altered oxygen carrying characteristics of stored blood, or by transient polycythemia and hyperviscosity with local variation in blood flow in the mesenteric circulation [29]. Blood flow variation can cause endothelial dysfunction producing ischemia via nitric oxide production [30]. Finally, transfusion of blood products may cause reactions, as there are reports of Thomsen-Friedenreich cryptantigen activation (TCA), which exposes neonates with NEC to the risk of hemolysis after transfusion of blood products [31].

Although neonatal exchange transfusion [32] and intrauterine transfusion [33] have been shown to be associated with an increased incidence of NEC, there is no current evidence for an association of NEC with blood transfusion.

96.3 Clinical Presentation

NEC presents with signs of gastrointestinal dysfunction such as bilious gastric residuals, emesis, abdominal distension, hematochezia and/or signs of systemic illness characterized by apnea and respiratory distress, lethargy, temperature instability, hypotension and poor perfusion. Very often early signs are not specific, as feeding intolerance is extremely common in premature infants.

The clinical progression can vary from a slowly evolving and relatively benign course to a sudden fulminant onset rapidly progressing to massive intestinal necrosis. The most severe cases are often complicated with perforation and peritonitis, and their clinical course is characterized by cardio-respiratory compromise, metabolic acidosis, shock and multi-organ failure, requiring vigorous resuscitation and sometimes leading to death.

The age of presentation varies with gestational age, with peak occurrence within the first week of life for full term and 3rd–4th week of life for very low birth weight infants [34]. The clinical course varies as well with the infant's gestational age. A prospective observational study on a population of newborns with gestational age (GA) of 23–42 weeks identified 202 infants who developed NEC. The most common sign of NEC among infants with GA of 23–26 weeks was ileus (77%), followed by abdominal distention, emesis, pneumoperitoneum, fixed intestinal loop, gasless abdomen and bloody stools. Pneumatosis intestinalis was detected in 100% of full-term infants, but only in 29% of infants with GA 23–26 weeks ($P<0.0001$) [35].

The physical exam can be characterized by minimal findings such as mild hypotonia, little spontaneous movements, moderately distended abdomen and/or distended loops with decreased bowel sounds. In the most severe cases the infant is lethargic, unresponsive, skin is pale and poorly perfused, the abdomen can be severely distended, markedly erythematous or discolored to inspection, tender and firm to palpation.

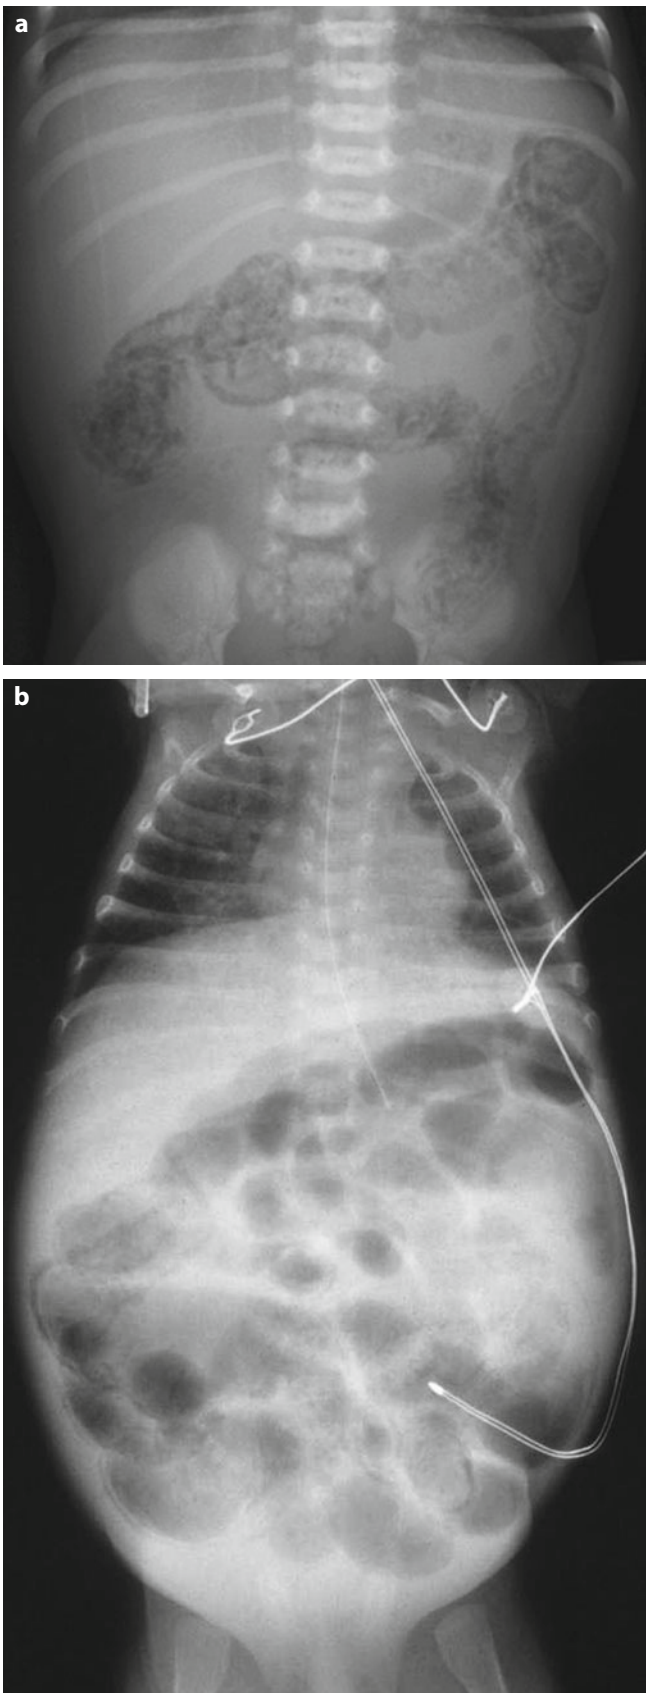

Fig. 96.1 Radiographic appearance of pneumatosis intestinalis with bubbly gas pattern (**a**) and linear gas collections in the bowel wall (**b**)

Regardless of the clinical presentation, diagnosis is established with radiologic imaging by the presence of pneumatosis intestinalis (Fig. 96.1). Other associated radiological findings include portal venous gas (Fig. 96.2), and pneumoperitoneum (Fig. 96.3).

Pneumatosis intestinalis or presence of air bubbles in the bowel wall is the result of fermentation and hydrogen production in the intestinal wall by invading bacteria, while intramural air absorbed into the mesenteric venous circulation leads to portal venous gas. Pneumoperitoneum in the absence of pneumatosis may be suggestive of spontaneous intestinal perforation, currently recognized as a disease distinct from NEC. Finally, the finding of a fixed loop that remains unchanged for 24–48 h is often associated with transmural necrosis.

Diagnostic supportive laboratory tests include a white blood cell count that can be depressed or elevated, thrombocytopenia, metabolic acidosis, electrolyte imbalance and increase of serum BUN and creatinine, markers of acute renal impairment. Culture of body fluids may grow bacteria.

A method of clinical staging was proposed by Bell in 1978 [36] and subsequently modified [37]. These criteria combine signs obtained by physical exam, signs of systemic illness and radiological findings and suggest appropriate treatment (Table 96.1).

Fig. 96.2 Radiographic appearance of portal vein gas with linear dark streaks within the liver

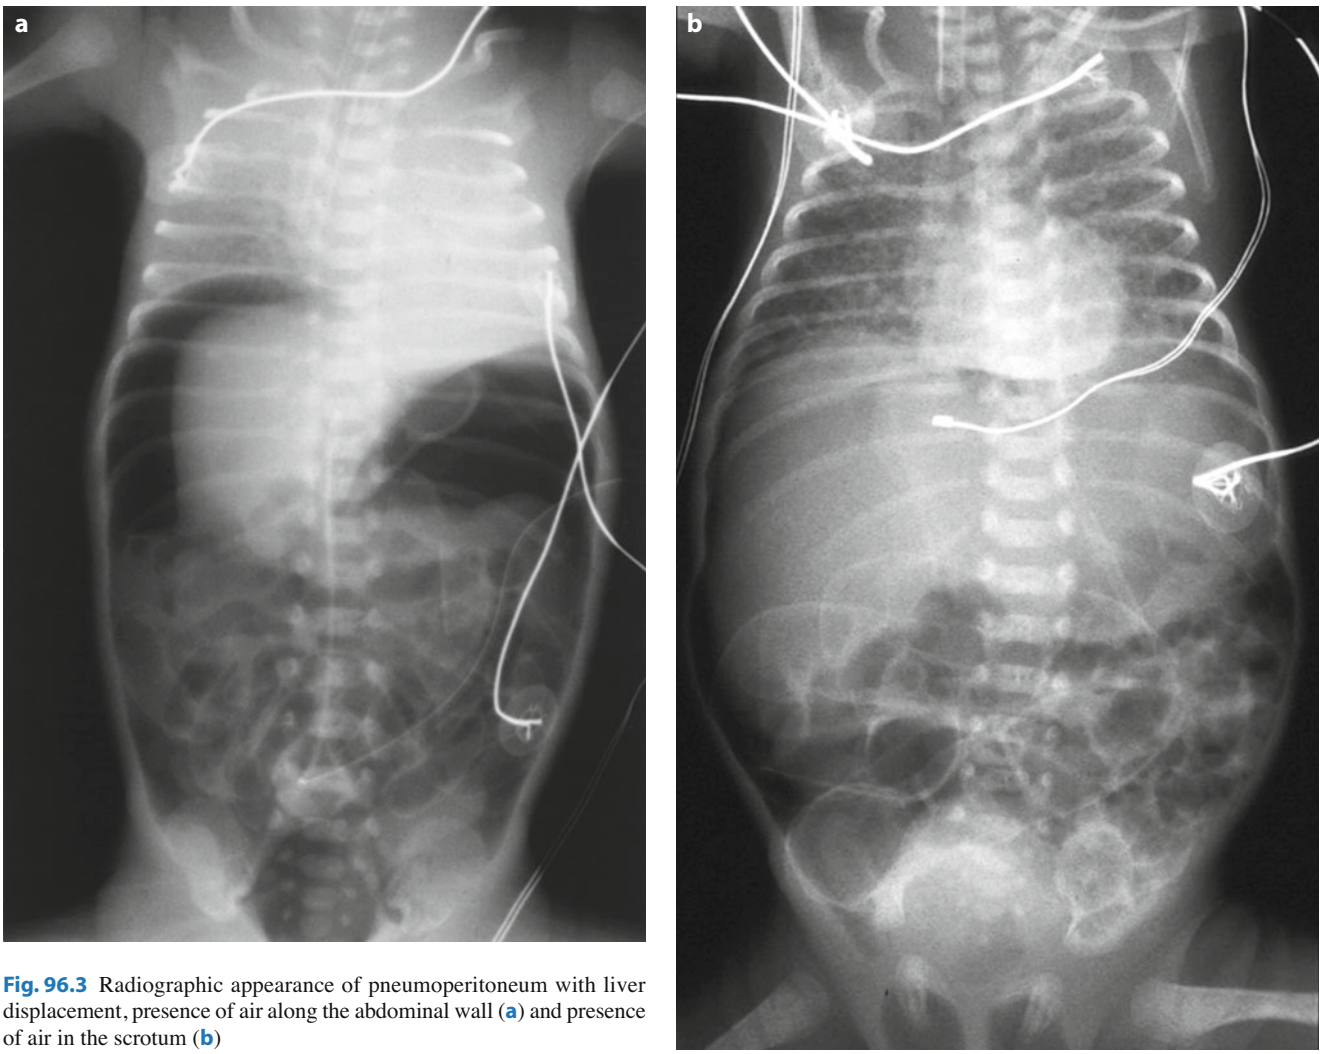

Fig. 96.3 Radiographic appearance of pneumoperitoneum with liver displacement, presence of air along the abdominal wall (**a**) and presence of air in the scrotum (**b**)

96.4 Treatment

The medical management of NEC should focus on 3 aspects: aggressive support in case of cardio-respiratory compromise, antibiotic coverage and optimal nutritional support. Intubation and ventilatory support should be initiated in infants developing apnea or respiratory compromise secondary to abdominal distension and upward displacement of the diaphragm. Hypotension is treated with fluid boluses, volume expanders and inotropic agents. Broad-spectrum antibiotic therapy should be started after body fluids have been obtained for culture. Anaerobic coverage should be added in case of bowel perforation.

Enteral nutrition is discontinued for 10–14 days and the stomach should be decompressed with an oro-gastric suctioning catheter. Nutritional support is provided via parenteral nutrition, often through a central line, provided that the infant is not bacteremic. Secondary to third space fluid losses these infants may require large volumes of fluid, especially within the first 48–72 hours.

In the acute phase of the disease radiological imaging should be repeated every 6–8 hours to assess presence of pneumatosis intestinalis and progression to pneumoperitoneum.

In case of failure of medical treatment documented by persistent metabolic acidosis, worsening respiratory distress, and shock or in presence of signs of intestinal perforation, surgery is indicated.

96.5 Prevention

Potential preventive strategies are based on prevention of the risk factors, including prematurity, infections, and hypoxic-ischemic episodes. NEC incidence can be reduced by adopting adequate feeding practices, such as early trophic feeds and preferential use of breast milk, although no conclusive study

Table 96.1 Modified Bell's staging criteria for necrotizing enterocolitis

Stage	Systemic signs	Abdominal signs	Radiographic signs	Treatment
IA Suspected	Temperature instability, apnea, bradycardia, lethargy	Gastric retention, abdominal distention, emesis, heme-positive stool	Normal or intestinal dilation, mild ileus	NPO, antibiotics × 3 days
IB Suspected	As above	Grossly bloody stool	As above	Same as IA
IIA Definite, mildly ill	As above	As above, plus absent bowel sounds with or without abdominal tenderness	Intestinal dilation, ileus, pneumatosis intestinalis	NPO, antibiotics × 7 to 10 days
IIB Definite, moderately ill	As above, plus mild metabolic acidosis and thrombocytopenia	As above, plus absent bowel sounds, definite tenderness, with or without abdominal cellulitis or right lower quadrant mass	As for IIA, plus ascites	NPO, antibiotics × 14 days
IIIA Advanced, severely ill, intact bowel	As for IIB, plus hypotension, bradycardia, severe apnea, combined respiratory and metabolic acidosis, DIC, and neutropenia	As above, plus signs of peritonitis, marked tenderness, and abdominal distention	As for IIA, plus ascites	NPO, antibiotics × 14 days, fluid resuscitation, inotropic support, ventilator therapy, paracentesis
IIIB Advanced, severely ill, perforated bowel	As for IIIA	As for IIIA	As above, plus pneumoperitoneum	As for IIA, plus surgery

DIC disseminated intravascular coagulation, *NPO* "nil per os" or nothing by mouth. Modified from [41], with permission by the AAP.

can clearly define the best feeding strategy. The use of a probiotics supplement has been shown as a promising preventive intervention by laboratory evidence and clinical studies.

Commensal bacteria, acquired at birth, have an important role in the maintenance of intestinal homeostasis, by inhibiting inflammatory pathways. However, premature infants are prone to pathogen colonization because of their exposure to nosocomial flora and treatments with wide spectrum antibiotics. It has been suggested that the prevalence of abnormal colonization induces a pro-inflammatory response [38]. Breast milk seems to be protective against NEC. In fact the predominance of bifidobacteria, typical of healthy individuals, is enhanced by the presence of oligofructose, a component of human milk, in the intestinal lumen. Infants who receive formula feedings without oligofructose have a predominance of clostridial organisms.

Experimental data from NEC-induced animal models show that exogenous administration of *Bifidobacterium infantis* decreases the incidence of NEC and lowers plasma levels of toxins in treated rats [39].

A recently published meta-analysis systematically reviewed several randomized clinical trials searching to demonstrate the benefit of probiotic administration in populations of premature infants. Although the risk of sepsis was not different between groups of infants treated with probiotics and controls, the risk of developing NEC and the risk of death was significantly lower in the treated population. The conclusion of this systematic review is that probiotics might reduce the risk of necrotizing enterocolitis in preterm neonates with gestational age less than 33 weeks. Several questions related to dose, duration, and type of probiotic agents still remain open [40].

Surgical Treatment of Necrotizing Enterocolitis

Nigel J. Hall and Agostino Pierro

97.1 Introduction

Whilst many infants with NEC respond to intensive medical treatment, up to 50% develop more severe NEC requiring surgical intervention [1]. This group of infants represents a major challenge for pediatric surgeons and there is little consensus as to the most appropriate timing and nature of surgery. In addition to surgery in the acute phase, a number of infants develop late complications of NEC, either following medical or previous surgical treatment, and these complications require surgical intervention.

There is great controversy surrounding the indications for surgery in infants with NEC. Table 97.1 summarizes the indications reported in the literature. In a survey of pediatric surgeons from the United Kingdom, the indications for operation in neonates with NEC included pneumoperitoneum in 45%, clinical deterioration in 37% and intestinal obstruction in 18% [2]. The most widely accepted indication for surgery is the presence of pneumoperitoneum but this is not always demonstrable even in neonates with intestinal perforation. Other absolute indications for surgery in acute NEC include the continued deterioration of an infant that is refractory to maximal medical treatment, persisting inotrope requirement and an abdominal mass or abscess secondary to intestinal perforation.

In similarity to the lack of consensus regarding indications for surgical intervention, there is a lack of consensus concerning the ideal surgical management of infants with NEC. Whilst a number of factors may be considered in determining the type of surgical intervention including the weight and clinical status of the infant, even very low birth weight infants appear to tolerate surgery well [3]. Surgical options for the infant with NEC include primary peritoneal drainage (PPD) or laparotomy. At laparotomy, the principal surgical objectives are to control sepsis, remove gangrenous bowel and to preserve as much bowel length as possible [4–6]. Within these objectives a number of surgical options exist (Table 97.2) depending primarily on the extent of intestinal disease and the clinical stability of the infant. At laparotomy, the extent of the disease can be classified as focal when it is limited to a single intestinal segment; multifocal if it includes two or more intestinal segments with more than 50% of the small intestine viable and panintestinal when the majority of the small and large bowel are involved with less than 25% viable bowel remaining [5].

Table 97.1 Indications for surgery in infants with NEC

Absolute indications
– Pneumoperitoneum
– Clinical deterioration despite maximal medical treatment
– Abdominal mass with persistent intestinal obstruction or sepsis
– Intestinal stricture
Relative indications
– Abdominal mass
– Increased abdominal tenderness, distension and/or discoloration
– Intestinal perforation associated with persistent signs of intestinal obstruction and/or sepsis
– Portal vein gas

Table 97.2 Surgical options for advanced NEC

Primary peritoneal drainage
Laparotomy
– Resection with enterostomy
– Resection with primary anastomosis
– Proximal diverting jejunostomy
– "Clip and drop" technique

97.2 Primary Peritoneal Drainage

The use of peritoneal drainage before laparotomy, as a method of stabilizing and improving the systemic status of extremely

Table 97.3 RCTs comparing laparotomy with primary peritoneal drainage in infants with perforated necrotising enterocolitis

Study	Included infants	Number	Main outcomes	Authors conclusion
Moss et al, 2006 [9]	<1500 g	PPD 55 Lap 62	No difference in mortality or dependence on PN at 90 days or length of hospital admission	No effect of procedure on outcome
Rees et al, 2008 [10]	<1000 g	PPD 35 Lap 34	No difference in survival, ventilator or PN dependence at 1 or 6 months or length of hospital admission 74% of infants undergoing PPD required delayed rescue laparotomy	Recommend early laparotomy

PPD primary peritoneal drain, *Lap* laparotomy, *PN* parenteral nutrition.

low birth weight premature infants with intestinal perforation secondary to NEC was first proposed by Marshall and Ein in the 1970s [7, 8]. Initially, it was hoped that the drainage of air and stools from an infant too unstable for a laparotomy would relieve symptoms of abdominal compartment syndrome and infection, and subsequently improve tolerance of a laparotomy. Subsequent reports, predominantly of infants weighing <1500 g, have proposed that peritoneal drainage may be used as a definitive treatment without the need for subsequent laparotomy. In fact some reports have claimed that this method of treatment may in fact be superior to laparotomy. Recently, 2 randomised controlled trials (RCTs) have addressed the issue of whether primary peritoneal drainage (PPD) or laparotomy is superior in the smallest infants with NEC [9, 10]. These are summarized in Table 97.3.

Interestingly neither trial found a significant difference in primary outcome measures between infants treated with PPD or laparotomy. However, the authors of one of the trials advocate the use of a primary laparotomy as a definitive treatment on the basis of no significant difference in outcome between the groups and a need for delayed/rescue laparotomy in 74% in infants who initially had PPD [10].

97.3 Resection of Affected Bowel and Enterostomy Formation

Resection of necrotic bowel in neonates with NEC has the theoretical advantage of reducing bacterial translocation and correcting the septic state of the patients. Following intestinal resection, the conventional view is that it is safer to exteriorize the bowel ends as the presence of peritonitis, inflammation of the bowel wall and the reduced intestinal blood supply in patients with NEC are unfavorable factors for the healing of an anastomosis [11]. Furthermore, the stoma allows adequate healing and rests the distal bowel prior to subsequent re-anastomosis [5]. There are, however, a number of potential disadvantages to this approach. It is often difficult to re-establish sufficient enteral feeding for adequate weight gain. High output stomas, in particular, carry a risk of dehydration and electrolyte imbalance, and the importance of early closure to avoid chronic salt and water loss has been highlighted. Enterostomies have also been associated with significant morbidity whilst present, including stenosis, prolapse and excoriation of the surrounding skin. Stoma closure involves a second anesthesia and is usually performed once the infant is thriving and fully recovered from the acute stage of the illness. Metabolic or physical problems, however, may demand earlier surgery. In one series, the incidence of complications in infants with enterostomies for NEC was 68% [12]. This high rate has prompted the search for alternative strategies that may avoid the need for repetitive surgery and complications associated with stomas, whilst ensuring that the underlying surgical principles of treating NEC by means of laparotomy are adhered to. Thus in many centers a primary anastomosis is preferred following intestinal resection whenever deemed safe to do so.

97.4 Resection and Primary Anastomosis

The attractiveness of primary anastomosis following intestinal resection is that a second surgical procedure can be avoided. However consideration must be given to the potential complications of intestinal anastomoses, particularly leakage and in the longer term, stricture formation. Once considered a hazardous surgical option because of the very risk of anastomotic leakage due to poor intraperitoneal healing in the presence of peritonitis, inflammation of the bowel wall and compromised intestinal blood supply, this approach has gained popularity. A number of centers have published retrospective reviews of infants treated with intestinal resection and primary anastomosis with results comparable with or in some cases favorable to those obtained with stoma formation. Furthermore, whilst resection and primary anastomosis was initially described in selected patients with focal disease and in good general condition, it is also now gaining acceptance as a valid treatment option for severe NEC, in very low birth weight infants [13] and even for multifocal disease [6].

Despite a number of reports there remains no good quality evidence to suggest whether stoma formation or primary anastomosis confers an advantage over the other approach following intestinal resection for NEC.

97.5 Operations for Panintestinal Disease

The techniques described thus far are of particular use for the infant with one or more short segments of NEC. Multiple resections and primary anastomoses may be appropriate for some infants with more widespread disease, provided careful attention is paid to the viability of resection margins. Infants with NEC affecting a large proportion of the gastrointestinal tract pose a particularly difficult problem, and treatment of this group remains particularly controversial. The surgical principles in these children are difficult if not impossible to fulfill. Due to the length of bowel involved, it is often not possible to fully remove all gangrenous intestine whilst salvaging adequate length for sustainable life. It is for these reasons that in the infant with panintestinal NEC who is unstable and critically ill, some surgeons would forego further treatment. However, when there is doubt, a number of techniques have recently been reported with the aim of allowing time for stabilization of the infants' general condition and the possibility of some healing of the gastrointestinal tract to occur. Due to the severity of the disease, the mortality with these strategies remains high.

97.5.1 Proximal Jejunostomy

Initially proposed by Martin and Neblett [14], surgical creation of a high jejunostomy in the presence of panintestinal disease has been reported in one series of 10 infants [15]. This technique allows decompression and defunctioning of the diseased intestine but does not remove gangrenous segments and may permit continued bacterial translocation. A second-look laparotomy and intestinal reconstructive surgery are performed after 6–8 weeks and the aim is once again to preserve as much bowel length as possible. This procedure may be useful in neonates with NEC affecting the majority of the intestine, but the high morbidity and mortality rate should be carefully considered.

97.5.2 "Clip and Drop" Technique

This method complies with surgical principles and also avoids stoma formation. For the infant with extensive bowel necrosis, Vaughan et al [16] advocated the resection of all segments of grossly nonviable or perforated bowel, irrigation and aspiration of peritoneal contamination, clipping the ends of remaining bowel and returning them to the abdomen. This is followed by a second-look laparotomy with delayed anastomosis 48–72 h later. In their small series, all three infants with NEC survived [16], and in a subsequent report of four infants in whom this technique was employed, one died and the remaining three required stoma formation at the second look [17].

97.6 Authors' Preferred Surgical Strategy

The authors' preferred approach to the operative management of infants with NEC is illustrated in Fig. 97.1. In infants with focal disease involving a small length of small or large bowel, a resection and primary anastomosis is usually performed, with the exception of patients unstable during the operation who are managed with a stoma at the level of the affected bowel.

In infants with multifocal disease (> 50% of the bowel assumed to be viable), various surgical options are available. Resection and one or more intestinal anastomoses (preferably not more than two) are performed when it is possible to ascertain the viability of the bowel distal to NEC without causing significant bleeding. Stoma (with or without intestinal resection),

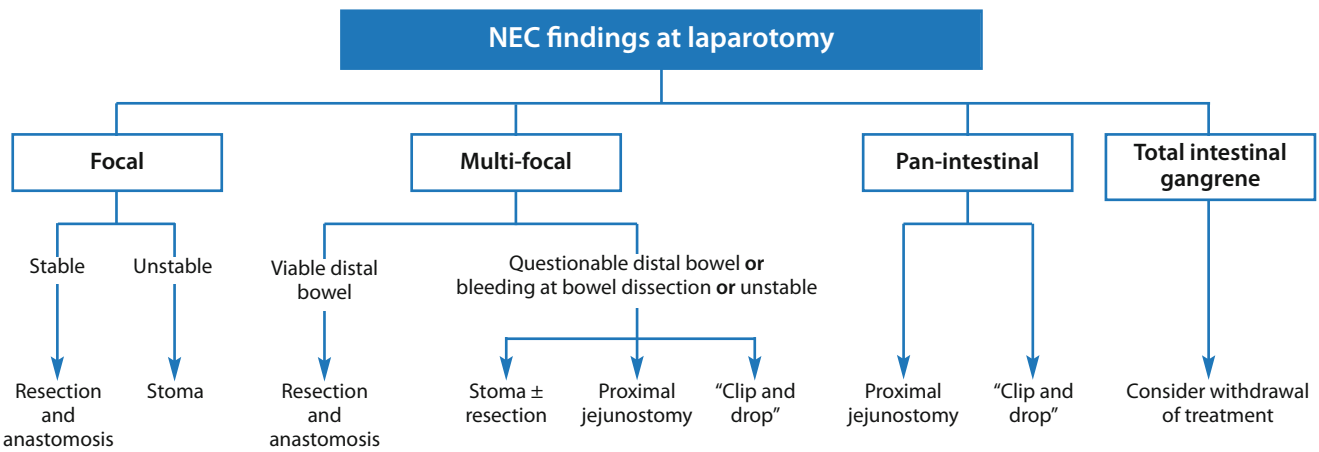

Fig. 97.1 Authors' preferred operative management of NEC. Adapted from [21]

proximal enterostomy or clip and drop technique are performed when: (a) it is not possible to ascertain the status of the bowel distal to the NEC; (b) the distal bowel is of dubious viability; (c) attempts to dissect the distal bowel cause significant bleeding and (d) the patient is unstable peri-operatively. In these circumstances, a stoma with or without intestinal resection(s) is the preferred surgical option. However, if this would lead to massive intestinal resection, the "clip and drop" technique described earlier will be adopted in an attempt to salvage as much intestinal length as possible. If the mobilization of the bowel loops affected by NEC causes significant bleeding, a high diverting jejunostomy is preferred.

In patients with panintestinal disease (>75% of small and large bowel involved), two options are considered: (a) proximal diverting jejunostomy when the intestinal resection would cause significant bleeding or loss of the majority of the small bowel and (b) "clip and drop" technique in the attempt to salvage some of the affected bowel and avoid a short bowel syndrome. In neonates with total intestinal gangrene, closure of the abdomen and treatment withdrawal are considered.

97.7 Outcome of Surgical Intervention

Central to the decision to operate on an infant with NEC and in determining the most appropriate operation to perform is the effect of any surgical intervention on outcome. Mortality from NEC is related to severity of disease, degree of prematurity and associated anomalies. In a study of 83 neonates who required a laparotomy for advanced NEC [5], the overall mortality rate was 30%. Causes of death included multisystem organ failure (n = 10), sepsis (n = 14) and congenital cardiac abnormality (n = 1). The mortality rate was higher (67%) in infants with panintestinal involvement compared with infants with focal (12%) or multifocal disease (30%). Whilst mortality is clearly the most important outcome to be considered, morbidity in survivors of NEC is often significant. In addition to the "surgical" complications related to intestinal anastomoses and stomas, other medium- and long-term complications include short bowel syndrome (affecting up to 23% of survivors of NEC) [18], hepatic cholestasis related to long-term parenteral nutrition dependency, and malabsorption. Importantly it is being increasingly recognized that infants who develop NEC are at increased risk of adverse neurodevelopmental outcome compared with preterm infants who do not develop NEC. Infants with NEC who require surgery appear to be more severely affected than those who respond to medical treatment alone [19, 20].

Clearly knowledge of these outcomes is important in counseling parents and in assessing effectiveness of treatments. As we now progress to critically determine whether a particular surgical approach is more effective than another in the setting of randomized controlled trials it is imperative that we consider these morbidities and in particular neurodevelopmental outcome in addition to mortality as part of our evaluation.

Hematology and Immunology: Overview

Robert D. Christensen

98.1 The Reference Range Concept

"Normal ranges" for hematologic values of neonates are generally not available. This is because blood is not drawn on healthy normal neonates to establish such ranges, as is done with the consent of healthy adult volunteers. Instead, neonatal hematology generally utilizes "reference ranges". These ranges consist of 5th to 95th percentile values compiled from laboratory tests that were performed on neonates thought to have minimal pathology relevant to the laboratory test, or with pathology unlikely to significantly affect the test results. The premise on which the reference range concept is based is that these values approximate normal ranges, although they were admittedly obtained for a clinical reason and not from healthy volunteers.

Defining reference ranges in neonatal hematology is complicated by the fact that ranges obtained from term infants generally do not apply to preterm infants, and ranges obtained from low-birth-weight preterm infants can be very different from ranges obtained from extremely-low-birth-weight infants. As an example, a venous hematocrit of 38% would be within the reference range for a 2-hour-old neonate born at 24 weeks gestation, but would be low for a term infant.

Another problem encountered in defining reference ranges in neonatal hematology is that unstable, sick neonates might have values within the reference range, yet those values might not be optimal for patient care. As an example, for a neonate born at 24 weeks gestation, now 4 weeks old, a venous hematocrit of 24% would be within the reference range. However, if such a patient develops a nosocomial infection, becomes hypoxemic and tachycardic, and is placed on a ventilator, the hematocrit of 24% might be too low for optimal patient care. A higher hematocrit might facilitate better tissue oxygenation, diminish the heart rate, and permit better caloric utilization for growth. Therefore, just because a value falls within the reference range does not assure that it is optimal for the clinical circumstance.

Making a determination about whether a specific hematologic value is normal or abnormal often requires cognizance of the gestational age of the neonate, the age (hours after delivery) when the sample was obtained, any specific illnesses involved, the level of intensive care support given, and the anatomical site of the blood sampling (venous, arterial, capillary). Sometimes knowledge of other factors is pertinent, such as whether "stripping" of the umbilical cord was performed after delivery; and whether a capillary sample was obtained from a warmed or an unwarmed, mottled extremity. This chapter describes the reference ranges that have been assembled for use in neonatology and provides information needed to avoid pitfalls in interpreting these values. Ranges are given for erythrocytes, leukocytes, platelets, and bone marrow differential cell counts.

98.2 Erythrocytes

98.2.1 Hemoglobin Concentration

The concentration of hemoglobin in the blood and the hematocrit are among the most commonly performed of all clinical laboratory tests. The hemoglobin can be quantified by manual or automated techniques. The standard assay for hemoglobin determination, approved by the World Health Organization, is simple but highly reproducible [1]. It involves the conversion of the several forms of hemoglobin in the blood, including oxyhemoglobin, carboxyhemoglobin, and the minor quantities of other hemoglobin species present, to a single compound, hemoglobincyanide, which is then determined spectrophotometrically. The hemoglobin concentration and the hematocrit are for the most part different measurements of the same biologic variable. However, because the hemoglobin concentration is a direct measurement but the hematocrit is usually

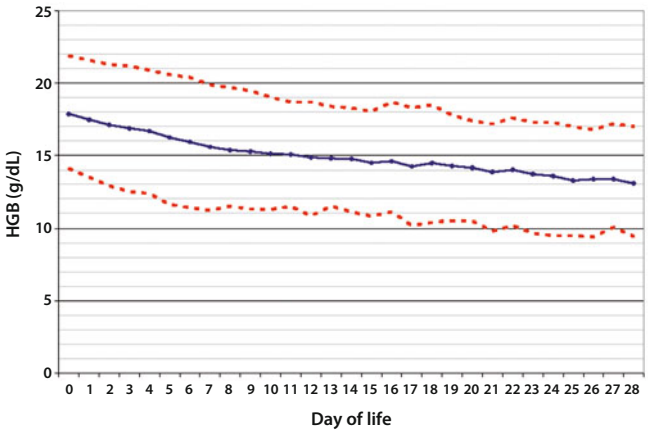

Fig. 98.2 Reference range for blood hemoglobin concentration during the 28 days after birth for neonates 35–42 weeks' gestation. The solid line shows the mean value and the dashed lines show the 5% and 95% reference range. Reproduced from [2], with permission

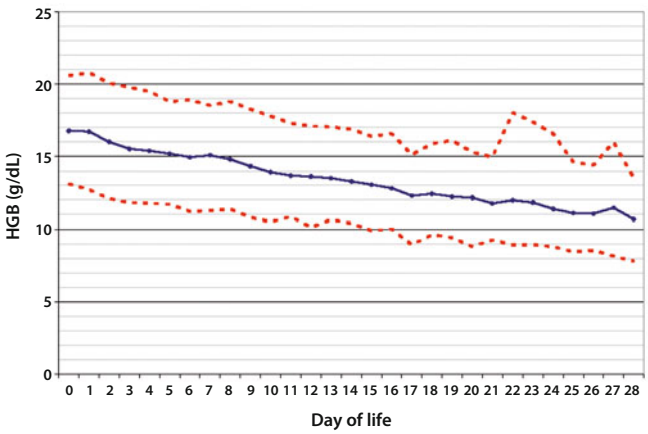

Fig. 98.3 Reference range for blood hemoglobin concentration during the 28 days after birth for neonates 29 to 34 weeks' gestation. The solid line shows the mean value and the dashed lines show the 5% and 95% reference range. Reproduced from [2], with permission

calculated, as explained later, the hemoglobin concentration has sometimes been a slightly preferred method.

Reference ranges for hemoglobin values of newborn infants 22–42 weeks' gestation [2] are shown in Fig. 98.1. In keeping with the reference range concept, values were not included in the figure if the mother had a diagnosis of placenta previa, abruptio placenta, or any antenatal hemorrhage, or if the patient had a diagnosis of hemorrhage at birth. No differences occur on the basis of gender. Postmature infants do not have higher hemoglobin concentrations than those delivered at term, unless chronic hypoxemia has occurred.

Reference ranges for hemoglobin over the first 28 days after birth are shown in Fig. 98.2 for patients 35–42 weeks' gestation at birth, and in Fig. 98.3 for patients 29–34 weeks' gestation. Hemoglobin values for patients < 29 weeks were not included in the report because virtually all had repeated phlebotomy and erythrocyte transfusions, thus confounding the slope of the hemoglobin reference range.

98.2.2 Hematocrit

In 1929, Dr. Maxwell M. Wintrobe described a clinical laboratory test that he called the volume of packed red blood cells (VPRC) [3]. The test was performed by centrifuging blood in a specifically designed glass tube called a hematocrit. Originally, "hematocrit" was the name of the tube used in the measurement, not the measurement itself. However, usage subsequently changed, and the term hematocrit now typically indicates the measurement, and the term VPRC is rarely used.

The hematocrit measurement is the proportion of the blood sample occupied by erythrocytes. The units for hematocrit are usually given as either a percentage or a decimal fraction (liters of red blood cells/liter of blood). Because neonates and young children do not have a liter of blood in their entire circulation, children's hospital laboratories sometimes choose to express the hematocrit as a percentage, not as liters per liter.

Originally, the result of the hematocrit test was read directly from the tube, after a standardized centrifugation, as the proportion of the height of the total column of blood occupied by red cells. Although an extremely simple concept, this test constituted a significant advance in clinical medicine. It was highly successful and became widely used, probably because the results were very reproducible and useful in patient care and because the test could be performed without complicated or expensive instrumentation. Subsequent modifications of the hematocrit test to permit the use of small blood samples led to its applicability to neonates. Ten years after it was described for testing adults, Waugh and colleagues reported that the hematocrit of normal infants, averaging 51.3%, was higher than that of normal adults [4].

Most hospital laboratories no longer use centrifugation methods for hematocrit determinations; instead, aperture-impedance instruments calculate the hematocrit. This is done by

electronically measuring the mean red blood cell volume and multiplying this number by the erythrocyte concentration, also measured electronically. The mean volume of the erythrocytes multiplied by their number per microliter yields the volume of red blood cells per microliter, or the hematocrit. Other types of cell counters calculate the hematocrit using laser optics, correlating the magnitude of a light pulse generated by passing a red blood cell through a laser with the cell's volume.

Many neonatologists have noticed that when manual and electronic methods for hematocrit determination are used on an individual neonate, a consistent difference occurs between the two, a difference usually not seen in testing older children and adults. Neonates tend to have a slightly higher spun hematocrit than automated hematocrit. The reason for this involves the phenomenon of trapped plasma in the spun hematocrit determinations. When blood is centrifuged in a hematocrit tube, a small amount of plasma is always "trapped" between the erythrocytes, slightly elevating the spun hematocrit value. The amount of trapped plasma is insignificant in most cases, usually in the range of 1 to 3% of the plasma volume, as determined by radioiodinated serum albumin labeling experiments [5]. However, in samples with a very high hematocrit, more plasma becomes trapped when the cells are centrifuged. Because term neonates have considerably higher hematocrits than adults, this additional plasma trapping tends to make the spun hematocrit a higher value than the automated, calculated value (which is not subject to the plasma trapping pitfall). Few spun hematocrits are used in modern neonatology, but in any NICUs doing so, this difference between spun and automated hematocrit values should be recognized.

Reference ranges for hematocrits of newborn infants 22–42 weeks' gestation [2] are shown in Fig. 98.4. As with hemoglobin values, no differences occur on the basis of gender. Reference ranges for hematocrit over the first 28 days after birth are shown in Fig. 98.5 for patients 35–42 weeks' gestation at birth, and in Fig. 98.6 for patients 29–34 weeks' gestation.

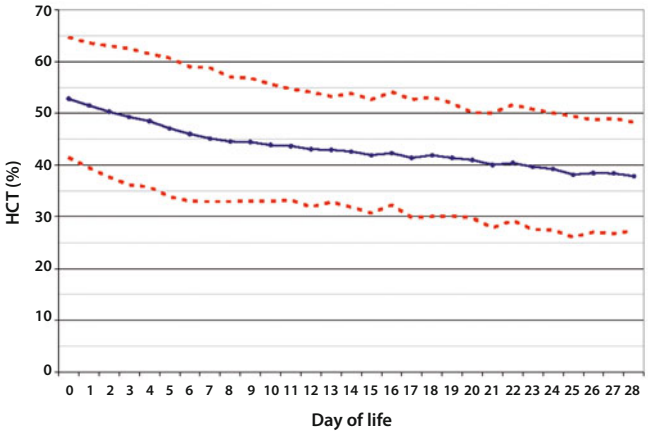

Fig. 98.5 Reference range for hematocrit during the 28 days after birth for neonates 35–42 weeks' gestation. The solid line shows the mean value and the dashed lines show the 5% and 95% reference range. Reproduced from [2], with permission

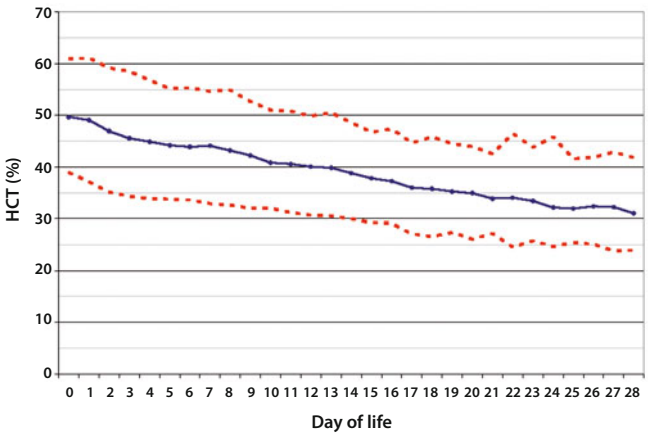

Fig. 98.6 Reference range for hematocrit during the 28 days after birth for neonates 29–34 weeks' gestation. The solid line shows the mean value and the dashed lines show the 5% and 95% reference range. Reproduced from [2], with permission

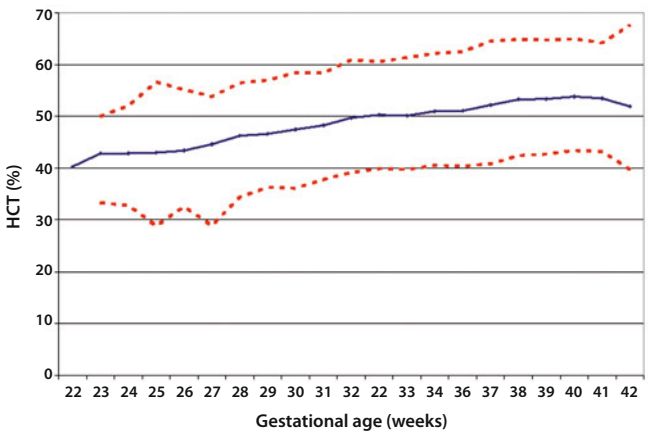

Fig. 98.4 Reference range for hematocrit on the day of birth (n = 25,464 patients) at 22–42 weeks' gestation. The solid line shows the mean value and the dashed lines show the 5% and 95% reference range. Reproduced from [2], with permission

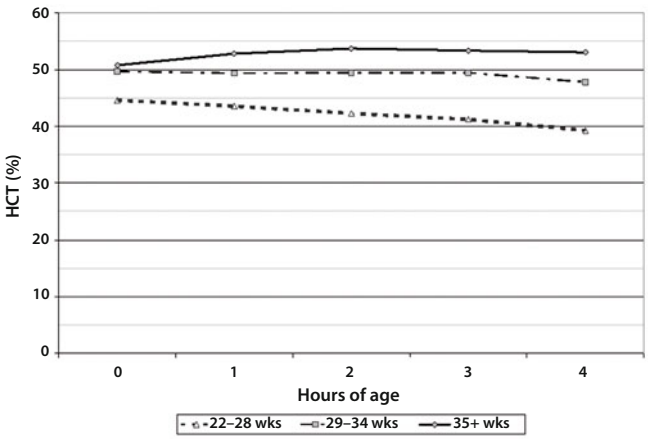

Fig. 98.7 Reference range for hematocrit over the four hours period following birth (n = 23,534 patients). Three groups are shown based on gestational age. Reproduced from [2], with permission

The hematocrit, like the hemoglobin concentration and the erythrocyte count, normally increases during the first four hours after birth. The increase, as shown in Fig. 98.7, might not occur in preterm infants. Gairdner et al [6] first reported this consistent postnatal increase in hematocrit during the hours following birth, and speculated that it was the result of intravascular concentration of blood received by placental transfusion. Its absence in preterm infants might be due to early phlebotomy losses for laboratory studies, lack of a placental transfusion (because of the desire to rapidly hand the patient to the neonatology team), or other reasons.

98.2.3 Erythrocyte Count

The erythrocyte count is the number of erythrocytes in a volume of blood, usually expressed as cells per microliter, or cells per liter. Older methods for determining the erythrocyte count used a counting chamber viewed from a microscope, but modern methods use an electronic particle counter, sampling many logs more cells than the previous methods.

98.2.4 Erythrocyte Indices

In addition to devising the hematocrit, Dr. Wintrobe introduced the concept of erythocyte indices and described methods for their calculation. Virtually every CBC includes a report of these indices. The original manual methods for making the measurements with which the erythrocyte indices were calculated have been replaced by automated instruments, which provide measurements that are more precise and reproducible. Although sometimes overlooked, these indices can provide the neonatologist with valuable information not otherwise available.

The mean corpuscular volume (MCV) is a measure of the average size of circulating erythrocytes, expressed in femtoliters (fL, 10^{-15} L). Most modern automated cell counters, using laser optics or aperture-impedance, measure the MCV of erythrocytes directly. However, as originally described, the MCV was calculated after measuring the hematocrit and the erythrocyte count by the formula:

$$\text{MCV (fL)} = \frac{\text{Hematocrit (L/L)} \times 1000}{\text{Erythrocyte count } (\times 10^{12}\text{ / L})}$$

The mean corpuscular hemoglobin (MCH) is a measure of the amount of hemoglobin in an average circulating erythrocyte. It is expressed in picograms of hemoglobin (pg, 10^{-12} gram) and is given by the formula:

$$\text{MCH (pg)} = \frac{\text{Hemoglobin (g/L)}}{\text{Erythrocyte count } (\times 10^{12}\text{ / L})}$$

The mean corpuscular hemoglobin concentration (MCHC) is a measure of the concentration of hemoglobin in an average circulating erythrocyte, and is expressed as units of grams of hemoglobin per deciliter of packed red blood cells (g/dL):

$$\text{MCHC (g/dL)} = \frac{\text{Hemoglobin (g/dL)}}{\text{Hematocrit (L / L)}}$$

Reference ranges for MCV and MCH [7] from 22–42 weeks' gestation, are shown in Fig. 98.8. A fetus at 22–24 weeks' gestation, and similarly an extremely preterm neonate at 22–24 weeks' gestation, has erythrocytes that are exceeding large, by comparison to those of adults. The MCV and MCH fall immediately when a preterm neonate receives an erythrocyte transfusion, because the MCV and MCH of the blood donor will be much lower. By 3–4 months after birth the MCV and MCH of a neonate have diminished gradually to that of the level of a normal adult (88 ± 8 fL). Thereafter, the MCV continues to decline, reaching nadir levels during the 4–6 months and then slowly increasing to adult values after the first year. When a newborn infant has an MCV of less than 94 fL, α-thalassemia trait or iron deficiency should be considered. Erythrocyte indices of Central African neonates do not differ

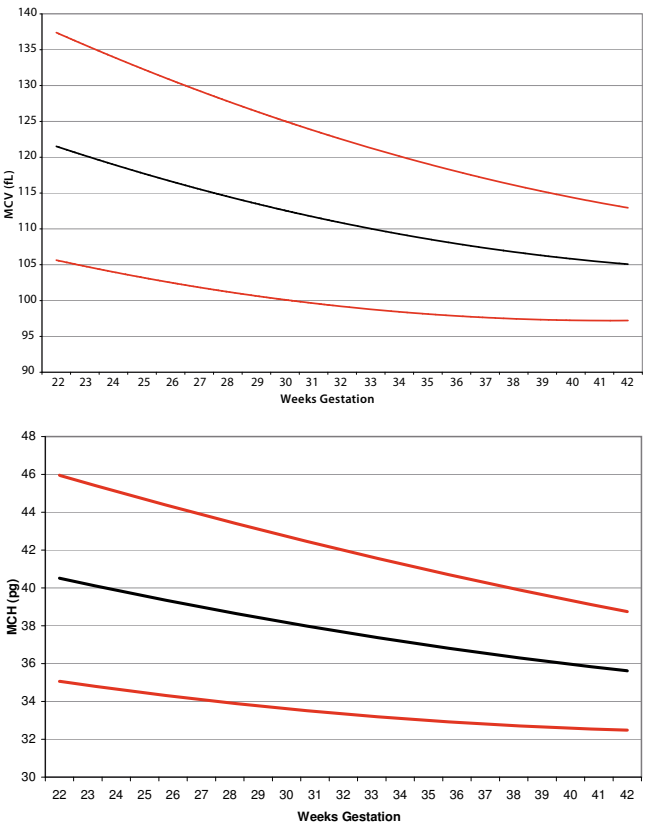

Fig. 98.8 Reference range for mean corpuscular volume (MCV) and mean corpuscular hemoglobin (MCH) for neonates on the first day after birth for neonates 22–42 weeks' gestation. The lower line shows the 5th percentile values, the middle line shows the mean values and the upper lines shows the 95th percentile values. Reproduced from [7]

Table 98.1 An elevated mean corpuscular hemoglobin concentration (MCHC) in a neonate can suggest the possibility of hereditary spherocytosis. Values are shown as mean and 95% confidence intervals or mean ± SD (when too few values were present to calculate confidence intervals)

	N	MCHC (g/dL)
Non-transfused neonates <12 hrs since birth	17,624	34.0 (33.0–35.1)
Neonates with Coombs (–) jaundice	1592	34.4 (33.2–35.5)
Neonates with Coombs (+) jaundice	363	34.7 (33.3–36.0)
Neonates with hereditary spherocytosis	15	36.9 ± 0.7
P Coombs (+) vs *Coombs(–) neonates*		<0.001
P Hereditary Spherocytosis vs *Coombs (–) neonates*		<0.001
P Hereditary Spherocytosis vs *Coombs (+) neonates*		<0.001

from those of neonates from other parts of the world, although the hematocrits of these neonates are somewhat lower [8].

Unlike the MCV and MCH, the MCHC does not change, either during gestation or after delivery. A reference range for MCHC of 34±1 g/dL is appropriate to all ages [6]. An high MCHC can be useful screen for hereditary spherocytosis. Michaels and associates compared automated MCHC measurements from 112 children with hereditary spherocytosis who had not undergone splenectomy with 112 matched healthy children [9] and observed that the MCHC of the group with hereditary spherocytosis was 35.9 g/dL, significantly higher than the controls (34.3 g/dL, $P < 0.001$). Similarly, newborn infants with hereditary spherocytosis have a higher MCHC than neonates with a similar peak serum bilirubin concentration who do not have hereditary spherocytosis (Table 98.1).

In addition to the erythrocyte indices, the RDW and the hemoglobin distribution width (HDW) are commonly reported on automated CBCs. The RDW is a measure of the homogeneity of red blood cell size, and the HDW is a measure of the homogeneity of red blood cell hemoglobin. The RDW is expressed as a percentage, meaning the percent of erythrocytes that fall outside (smaller or larger) the standard gated population of erythrocytes. An elevated RDW value reflects an abnormal divergence of erythrocyte size. The RDW begins to increase in cases of iron deficiency before any other change in erythrocyte indices or concentrations. The HDW is expressed in grams per deciliter (g/dL) and provides an index of divergence of hemoglobin concentration within erythrocytes. The RDW provides a numeric assessment of anisocytosis, and the HDW provides a numeric assessment of anisochromasia.

98.2.5 Reticulocyte Count

As the erythroid precursor cells clonally mature within the bone marrow their nucleus becomes pyknotic and is extruded (usually at the orthochromatic normoblast stage), and the cells are thereafter released into the blood. Cytoplasmic organelles, such as ribosomes, mitochondria, and the Golgi complex, generally persist for some time after the erythrocytes have reached the circulation. Supravital stains such as new methylene blue and brilliant cresyl blue stain the nucleic acid within these organelles (new methylene blue is a distinct chemical stain; regular methylene blue stains reticulocytes poorly). The circulating erythrocytes that contain organelles and thus have a reticulum of blue stain are termed reticulocytes [10]. Reticulocytes have generally been in the circulation for 24 hours or less and thereafter they lose the organelles and fail to stain as reticulocytes. The quantity of reticulum (i.e., nucleic acid) in an erythrocyte diminishes as it matures, thus in the youngest reticulocytes the reticulum is densely packed while in the oldest ones only a few scattered threads are found. Reticulocytes are on average about 20% larger than mature erythrocytes [11]. Scanning electron microscopy has shown that reticulocytes are not generally bilaterally indented disks like mature erythrocytes, but rather are irregularly shaped and polylobulated.

A neonatologist usually orders a reticulocyte count to assess the level of erythrocyte production, because high reticulocyte counts signify increased erythropoiesis and counts of 0 signify a low level of effective erythropoiesis. Reticulocytes can be reported in at least three different ways, which can sometimes be confusing; 1) as a percentage, 2) as an absolute number, or 3) as a corrected value. The immature reticulocyte fraction (IRF) is also gaining popularity among neonatologists [12].

A reticulocyte percentage is the percentage of erythrocytes that stain as reticulocytes. An obvious limitation of this method is that it fails to account for differences in the absolute number of erythrocytes. For example, each of two neonates may have a reticulocyte count of 5%. The neonatologist may be tempted to conclude that the two patients have similar levels of erythrocyte production. However, the first patient is anemic, with an erythrocyte count of $2 \times 10^6/\mu L$, and the other is not anemic, with an erythrocyte count of $4 \times 10^6/\mu L$. The anemic infant actually has only one-half the number of reticulocytes in the circulation (5% of 2×10^6, or 100,000 reticulocytes/μL of blood), as does the normal infant (5% of 4×10^6, or 200,000 reticulocytes/μL). Failure to recognize this pitfall can give the neonatologist the false impression that the anemic patient is mounting an appropriate increase in erythrocyte production. Reporting the reticulocyte count as an absolute number appears to be gaining popularity in neonatal intensive care units. In reporting the results of clinical trials of recombinant erythropoietin administration to preterm neonates this method has been more common for reporting a percentage because it gives a clearer comparison of effective erythropoiesis between groups, despite differences in hematocrit.

A third method of reporting reticulocytes is by using one or two corrections. One type of correction is for hematocrit. The reticulocyte percentage is adjusted to a standard hematocrit, usually 45% (0.45 L/L) and the correction is applied as follows:

$$\text{Corrected reticulocyte count} = \frac{\text{Patient's reticulocyte count (\%)} \times \text{Patient's hematocrit (L/L)}}{0.45\ \text{(L/L)}}$$

This correction is usually appropriate for neonatal patients and provides a better framework for assessing the level of effective erythropoiesis, because it normalizes all values to a standard hematocrit.

Another type of correction is sometimes made for shift reticulocytes. This correction accounts for the observation that whereas reticulocytes generally survive in the circulation for only about 1 day, during increased erythropoiesis even younger reticulocytes can be released from the marrow to the blood (i.e., shifted).

These shift reticulocytes, prematurely released from the marrow into the blood, survive longer than 1 day in the blood before losing their organelles, giving the false impression that the reticulocyte count is high. When reticulocytes survive in the circulation for 2 days, rather than 1 day, the correction for shift reticulocytes is made by reducing the percentage reported in half. To apply this correction, the degree of shift is assumed to be related to the intensity of stimulation of the marrow by erythropoietin. The examiner assumes that the maturation time of the reticulocyte in the circulation is 1 day when the hematocrit is normal, 1.5 days when the hematocrit is reduced moderately, and 2.0 days when tile hematocrit is reduced markedly. With a hematocrit of 20%, the physician assumes a marked erythropoietic effort, causing a shift in premature reticulocytes that survive 2 days in the circulation:

$$\text{Corrected reticulocyte count} = \frac{\text{Patient's reticulocyte count (\%)}}{2.0}$$

The shift reticulocyte count correction is rarely used by neonatologists. The correction for shift reticulocytes is only appropriate when the anemia is the result of hemorrhage or hemolysis, because it assumes that erythrocyte production has increased in response to the anemia. If the anemia is the result of hypoproduction of erythrocytes the reticulocyte count correction for shift reticulocytes would not be valid. Because relative hypoproduction of erythrocytes is thought to be a common component of anemia in preterm infants, the use of this correction might be misleading.

The immature reticulocyte fraction (IRF) is a measure of the proportion of reticulocytes with intense reticulum staining. A threshold is set, and the fraction of reticulocytes staining above that threshold reflects the "young" reticulocytes. Thus a high IRF is used as a parameter of brisk erythropoiesis. Thus, after erythropoietin treatment, the IRF might increase; otherwise an erythrocyte transfusion the IRF might fall.

On the day of birth, normal term infants have reticulocyte values of 4–7% and absolute reticulocyte counts of 200,000–400,000/μL [13]. Infants delivered prematurely have somewhat higher reticulocyte counts; values of 6–10% and absolute counts of 400,000–550,000/μL are common [14]. In healthy neonates, reticulocyte levels fall markedly over the first few days of life. By the fourth day the reticulocytes can be 0–1%, with an absolute count of 0–50,000/μL.

98.2.6 Erythrocyte Morphology

Using erythrocytes suspended in wet preparations, Zipursky enumerated the various morphologic forms of erythrocytes in term and preterm infants and in adults [15]. He observed considerable heterogeneity among erythrocytes of infants, particularly preterm infants. Whereas 78% of erythrocytes from adults were discocytes, only about 40% of the erythrocytes of neonates had this characteristic shape. Morphologic abnormalities of erythrocytes of neonates have also been reported using other methods. For instance, interference-contrast microscopy shows pits or craters on the surface of about 2.6% of erythrocytes of healthy adults. In contrast, about 25% of the erythrocytes of term infants and about one half of the erythrocytes of preterm infants have pits [16]. It is believed that these pits are cytoplasmic vacuoles and represent hypofunction of the spleen or reticuloendothelial system, but their significance is not clear.

98.2.7 Site of Sampling

The hematocrit, hemoglobin concentration, and erythrocyte concentration of newborn infants vary, somewhat predictably, according to the vascular source from which the sample is obtained (Table 98.2) [17–22]. In general, erythrocyte values are higher (i.e., more concentrated) when samples are obtained by lancing capillary beds than when drawn from an artery or a vein or obtained from an indwelling arterial or venous catheter. The specific anatomic site of the vein, artery, or capillary bed sampled appears not to affect the results. For instance, values obtained from a femoral vein are equivalent to those obtained from a scalp vein [21] and values from an umbilical artery are equivalent to those from a radial artery. Similarly, values from a capillary bed, such as from a heel, toe, or finger, are also equal if perfusion of those sites is similar [21].

As a general rule, capillary blood obtained from a neonate's poorly perfused extremity is a poor source on which to base clinical decisions. The erythrocyte values from such a source are about 15% (range of 5 to 25%) above those of simultaneously obtained venous or arterial blood. Capillary values obtained from a poorly perfused extremity can erroneously indicate the diagnosis of polycythemia and can erroneously exclude anemia. The amount that a capillary hematocrit is elevated above a venous or arterial hematocrit cannot be accurately predicted in individual cases, but in general, appears to vary with perfusion of the extremity.

When a CBC is obtained from a sick neonate with poor skin perfusion, the neonatologist interpreting the value should realize that a capillary hematocrit is less informative and less reproducible than a venous or an arterial hematocrit. Oh and Lind [20] and Lindercamp and colleagues [22] found that infants of the shortest gestation generally have the largest difference in capillary and venous hematocrits (Table 98.2).

Table 98.2 The effect of site of blood sampling on hematocrit or blood hemoglobin concentrations of neonates

Author	Year	Anatomic sites of comparison	Average difference
Valquist	1941	Capillary *vs* femoral vein	Capillary 10% higher
Oettinger & Mills	1949	Great toe *vs* internal jugular	Capillary 21% higher
Mollision	1951	Capillary *vs* venous	Capillary 5% higher
Oh & Lind	1966	Heel *vs* scalp or femoral vein	Capillary 15% higher*
Moe	1967	Patients with erythroblastosis fetalis; heel *vs* umbilical vessel	Capillary 25% higher
Linderkamp	1977	Capillary *vs* umbilical vessel	Capillary 10-21% higher
Rivera & Rudolph	1982	Heel *vs* antecubital vein	Capillary 12-20% higher
Thurlbeck & McIntosh**	1987	Heel *vs* UAC	Capillary 15% higher

UAC umbilical artery catheter.
* The capillary hematocrit was only 5% higher when the heel was warmed ** Preterm infants, 24 to 32 weeks' gestation, with respiratory distress.

Studies by Oh and Lind [20] and by Moe [21] indicate that warming the extremity before lancing the capillary bed can result in a better correlation between capillary and venous hematocrits. However, when a neonatologist feels it important to detect changes in serial hematocrit samples, it should likewise be important to keep a uniform site of sampling (i.e., all venous or all arterial). When comparing serial hematocrits of an ill neonate, it is useful to have the sample site documented.

98.2.8 Blood Sampling Relative to Delivery

About 100 mL of blood usually can be withdrawn from the placental vessels at term by using the technique of catheterizing the vessels and washing out the blood [23]. Direct venipuncture of the placental end of the umbilical vein after cord clamping generally yields somewhat less blood (50–60 mL). The blood within the umbilical cord and placenta constitute about one third of the entire circulating blood volume of the fetus.

Normally, after a term fetus is delivered, the umbilical arteries constrict in response to the increasing PO_2, retarding the flow of blood from the neonate into the placenta. The umbilical vein, however, fails to significantly constrict, permitting blood to flow in a direction partly controlled by gravity – from the placenta to the neonate or vice versa. In the time between delivery and clamping of the umbilical cord, the direction of the umbilical venous blood flow usually is from the placenta to the infant. However, if the neonate is held in a position significantly above the placenta, blood can flow through the umbilical vein from the neonate to the placenta [24, 25].

98.3 Leukocytes

The 1972 edition of *Holt's Pediatrics* stated, "the blood count is of relatively little help in the diagnosis of sepsis neonatorum" [26]. This was a prevalent teaching of the time, and when the first cases of group B streptococcal infection were reported, no mention was made of blood leukocyte counts or differential cells counts in these neonates. The notion that the CBC was not a useful test to perform on neonatal patients was based on the extreme variability of neutrophil counts in neonates, and the apparent lack of correlation between the blood neutrophil findings and the presence of infection.

Attitudes about the utility of CBCs of neonates began to change after publications of Xanthou [27], Zipursky et al [28], Akenzua et al [29], and Manroe et al [30]. These reports showed differences in blood neutrophil concentrations in groups of infected compared with noninfected neonates, and they pointed out that neutropenia, accompanied by a high ratio of immature neutrophils (bands and metamyelocytes) to total neutrophils (segmented neutrophils and band neutrophils and metamyelocytes) was particularly common in neonates with sepsis.

98.3.1 Site of Sampling

Neutrophil concentrations are lower in blood drawn from an umbilical artery catheter (or other arterial line) than in blood simultaneously drawn by venipuncture or capillary stick [31]. Arterial values are about 75% of the venous or capillary values. After moderate exercise in the form of chest physical therapy, the leukocyte counts increase to about 115% of baseline, but this is not accompanied by a change in the differential count. Lower neutrophil concentrations in arterial blood are observed in experimental animals [32]. The explanation appears to be related to the differences in blood flow of arterial compared with capillary or venous blood. The pulsatile flow of arterial blood appears to "push" the larger cells toward the periphery of the vessel, whereas the leukocytes and erythrocytes are more uniformly mixed in capillary and venous circulation.

98.3.2 Leukocyte Counts in Term Infants

In 1979, Manroe and associates from the University of Texas Southwestern Medical Center in Dallas published reference ranges for blood neutrophil concentrations in neonates and for the proportion of circulating neutrophils that were immature (nonsegmented) (Fig. 98.9). They reported values for

neonates of 26–44 weeks' gestation and with birth weights of 660–5000 g [30]. The data were obtained from 1974–1976, when the survival of very-low-birth-weight (VLBW) infants was 42% (compared with 79% a decade later). The number of VLBW infants represented in the Manroe study was limited. This publication constituted a landmark; for the first time, neonatologists could determine with some confidence whether their patient had a blood neutrophil count that was low, normal, or high [33].

Neonates at high altitude, such as those in the NICUs of Colorado [34], Utah [35], and New Mexico [36], have a higher range of neutrophil counts than do those reported from near sea level (Dallas) [30]. Fig. 98.10 shows the reference range of blood neutrophils among neonates at altitude and Fig. 98.11 shows the altitude and sea level ranges superimposed to directly compare the differences.

98.3.3 Leukocyte Counts in Preterm Infants

Several studies suggested that the normal values reported by Manroe might not be applicable to VLBW infants. One of the first of these was a report by Coulombel and coworkers of 132 neonates with CBCs obtained during their first 12 hours of life [37]. Blood was sometimes obtained from capillary samples and other times from umbilical venous or arterial catheters. All 132 infants had a clinical reason for obtaining a CBC, although this report excluded those with culture-positive evidence of bacterial infection. The researchers observed an inverse relationship between gestational age and blood neutrophil concentration.

In 1982, Lloyd and Oto reported serial leukocyte counts from 24 preterm infants, all less than 33 weeks' gestation [38]. They observed that the group's blood neutrophil concentrations were lower than those reported by Manroe (predominantly term infants). In 1994, Mouzinho and colleagues reported the results of 1799 blood leukocyte and differential counts obtained from 193 VLBW infants [33]. After excluding counts from neonates with perinatal and/or neonatal complications, values from normal VLBW neonates were displayed and compared with the Manroe reference ranges (Fig. 98.12). Infants of younger gestations had reference ranges for blood neutrophils that differed significantly from those of larger, older neonates. The VLBW infants had the same upper limit boundary for absolute neutrophil count of the larger, older infants, but their lower limit boundary was significantly less than the boundary of the older infants. Reference ranges for neonates 28–36 weeks gestation are shown in Fig. 98.13 and for neonates < 28 weeks gestation in Fig. 98.14.

98.3.4 Eosinophils

Eosinophilia is not a rare finding in the neonatal intensive care unit. In growing preterm infants a nonspecific low-grade eosinophilia is so common as to warrant the label "eosinophilia of prematurity" [39, 40]. Despite its relatively frequent occurrence, the causes and significance of this condition are uncertain. The concentration of eosinophils in the blood can increase to very high concentrations without a concomitant increase in the concentration of other leukocytes. This attests to a unique controlling mechanism. The mechanisms regulating eosinophil concentrations in blood are reviewed in Chapter 105 and the material given here relate only to reference ranges for eosinophils.

Defining the normal range of eosinophils in the blood of neonates has been attempted in relatively few studies. Medoff and Barber [41] reported that during the first 12 hours of life, absolute blood eosinophil concentrations range from 20 to 850/µL. On the basis of this report, eosinophilia on the first day of life would be defined as an absolute blood eosinophil count of more than 850/µL. Xanthou reported that, by the fifth day of life, eosinophil concentrations had a much greater range than on the first day, with values of 100–2500/µL [42]. By day 5, eosinophilia would be diagnosed if the count was more than 2500/µL. Our group recently complied reference ranges for neonates using electronic CBC records of over 80,000 neonates in a multihospital healthcare system [43]. As shown in Fig. 98.15, the blood concentration of eosinophils gradually increases over the interval of 22 to 42 weeks' gestation. As shown in Figure 98.16, the reference range over the first month following birth increases slightly, with the 95% value at birth being about 1200/µL, and at one month being 1500/µL.

According to the reports of Medoff and Xanthou, absolute eosinophil counts of less than 20/µL on the first day of life and

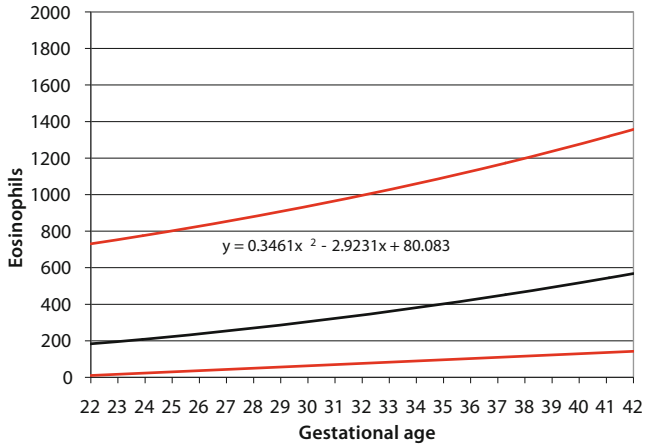

Fig. 98.15 Reference range for blood concentration of eosinophils on the day of birth from 22–42 weeks' gestation. The 5th percentile, mean, and 95th percentile values are shown. Reproduced from [43]

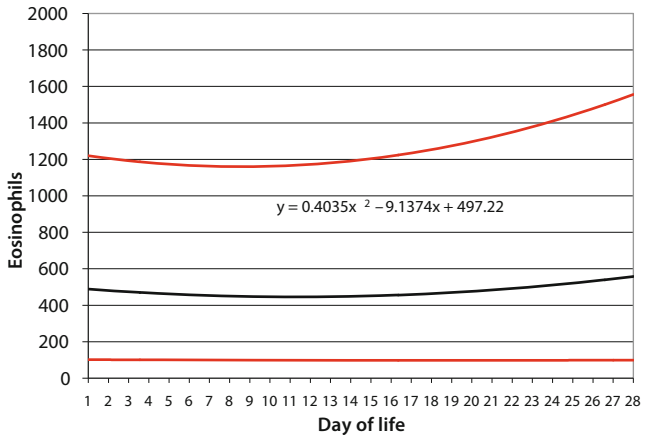

Fig. 98.16 Reference range for blood concentration of eosinophils during the first 28 days following birth. The 5th percentile, mean, and 95th percentile values are shown. Reproduced from [43]

less than 100/μL after the first 5 days should define eosinopenia. However, the diagnosis of eosinopenia in the neonatal intensive care unit is made rarely, because so many apparently normal infants have no eosinophils identified on individual differential cell counts. In contrast to this statement, Burell suggested that a complete lack of eosinophils in neonates should be considered an abnormality [44], our findings [43] are consistent with that conclusion. He found that a complete absence of eosinophils was common in infants who fared poorly and subsequently died. He reported that on the day of death there was generally a complete absence of blood eosinophils. Bass reported that blood eosinophil concentrations declined rapidly in the presence of bacterial infection [44].

By defining eosinophilia as blood concentration of more than 700/μL (a definition of eosinophilia sometimes used in adult medicine), Gibson and coworkers [45] found that about 75% of preterm infants develop eosinophilia. This may be because 700/μL is a value well within the reference range for neonates. They reported that eosinophilia in preterm infants generally occurs during a period in which an anabolic state is established. This anabolic state and the accompanying eosinophilia usually are seen in the second or third week of life, and the eosinophilia persists for many days and sometimes for weeks. Portuguez-Molavasi reported that at least one episode of eosinophilia (defined as an absolute eosinophil count of more than 1000/μL) occurred in 35% of all infants admitted to an intensive care nursery [46]. Craver reported that eosinophils can be seen in the cerebrospinal fluid weeks after intraventricular hemorrhage [47] but the significance of this finding is not clear and this finding did not correlate with blood eosinophil counts.

98.4 Platelets

98.4.1 Site of Sampling

Thurlbeck and McIntosh [48] reported no difference in the platelet counts drawn from umbilical arterial lines, venipunctures, or heel stick. Therefore, unlike the case for neutrophils and erythrocytes, it does not appear to matter what vascular source is used for drawing a platelet count. On that basis, it is common practice to obtain platelet counts of neonates from the most convenient sampling site, without concern of a potential sampling-site difference.

98.4.2 Reference Ranges for Platelet Counts and Mean Platelet Volume on the Day of Birth

In adults, the reference range for platelet count is > 150,000/μL and < 450,000/μL [49]. This same range has been used to define thrombocytopenia and thrombocytosis in neonates. However, the data suggest a more complex situation. The reference range for platelet count at birth, between 22 and 42 weeks' gestation, is shown in Fig. 98.17 [50]. Platelet counts as low as 100,000/μL can be normal for neonates > 29 weeks' gestation and counts above 35,000/μL are high for neonates > 29 weeks. While the blood concentration of platelets increases gradually between 22 and 42 weeks, the mean platelet volume (MPV) does not. The MPV averages 8 fL, with a range of about 7 to 9.5 fL.

Following birth platelet count gradually increases. As shown in the upper panel of Fig. 98.18, the reference range over the first 90 days after birth has the appearance of a sign-wave. The first wave could be the result of thrombopoietin (and perhaps other megakaryopoietic stimulators) surging after birth. The explanation for the second and third wave of peak platelet counts is not clear. Accompanying the increase

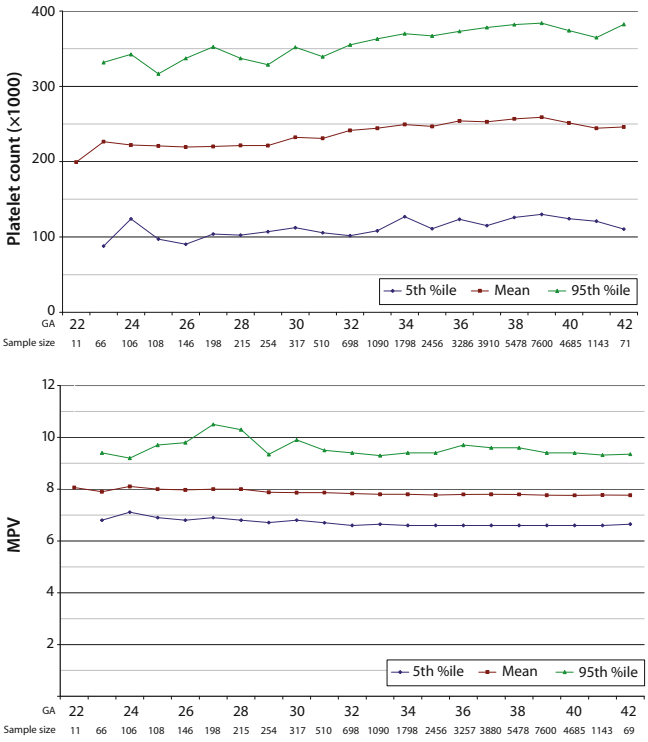

Fig. 98.17 Reference range for platelet count (*upper panel*) and mean platelet volume (*lower panel*) on the day of birth, for neonates delivered at 2242 weeks gestation. Values are shown for the 5th percentile, mean, and 95th percentile. Reproduced from [51]

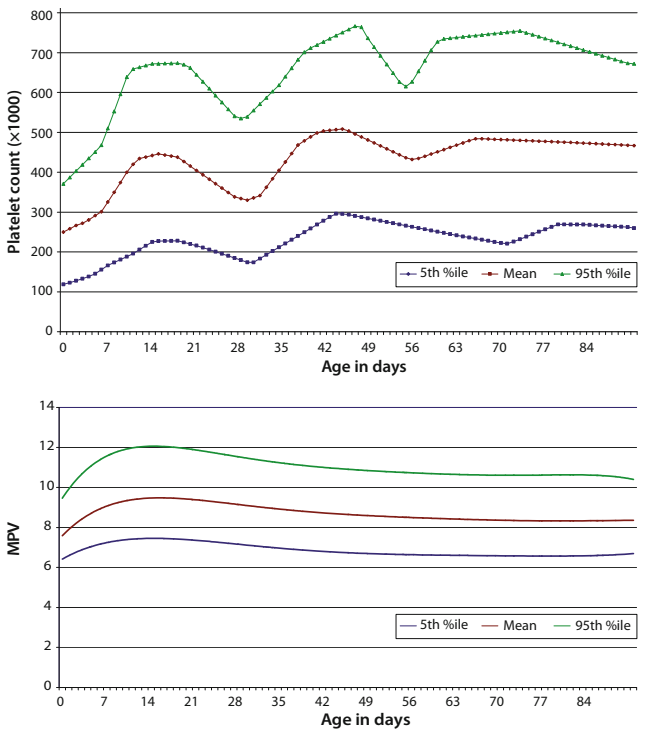

Fig. 98.18 Reference range for platelet count (*upper panel*) and mean platelet volume (*lower panel*) during the first 90 days following birth. Values are shown for the 5th percentile, mean, and 95th percentile. Reproduced from [51]

in platelet count after birth is an increase in MPV (shown in the lower panel of Fig. 98.17). At two weeks after birth, the reference range for platelet count is about 7.5–12 fL, but platelet size gradually falls to that at birth at a month or two.

98.4.3 Reticulated Platelets, Platelet Distribution Width, Platelet 'Crit and Immature Platelet Fraction

Additional information on platelet characteristics can sometimes be useful in managing a thrombocytopenic neonate. Relatively new tests include the reticulated platelets count, which requires flow cytometric capability, and the platelet distribution width and platelet 'crit, which can be performed on routine hematology analyzers (Beckman-Coulter), and the immature platelet fraction, which can be performed on other hematology analyzers (Sysmex Inc.).

Newly synthesized platelets generally have a higher content of ribonucleic acid than platelets that have been circulating for several days. These newly produced platelets can be recognized by flow cytometric analysis after RNA staining with thiazole orange. Such platelets have been called reticulated platelets to reflect their similarity to reticulocytes [52]. Between 3 and 5% of the circulating platelets of healthy term neonates and LBW infants are recognized as reticulated platelets. Peterec and colleagues [52] reported that infants of less than 30 weeks gestation had reticulated platelet percentages about twice those of term infants, although with a very large variation (8.8% ± 5.1%). Joseph and associates [53] observed that adults (n = 18) had a slightly but significantly higher percentage of reticulated platelets than did healthy term neonates (n = 42). They observed no difference in reticulated platelet count between infants depending on mode of delivery.

The platelet distribution width, like the erythrocyte distribution width, is a measure of the distribution of various sized platelets in the circulation [54].

98.5 Bone Marrow

A bone marrow aspirate or biopsy occasionally is useful in providing information not otherwise available. In cases of a persistent cytopenia, a neonatologist might want information relating to the state of production. For example, a persistent thrombocytopenia could be the result of decreased platelet production or of increased platelet destruction or use. A marrow examination can sometimes help differentiate these conditions because in cases of decreased platelet production, the marrow contains few megakaryocytes, but in cases of increased platelet use, the proportion of megakaryocytes should be increased.

Table 98.3 Differential cell counts of nucleated cells aspirated from the bone marrow of normal infants at term and from healthy adult men

Cell Types	Term Neonates (% [mean ± SD])	Health Adults (% [mean, 95% CI])
Nucleated erythroid		
Proerythroblast	0.1 ± 0.1	0.6; 0.1–1.1
Basophilic erythroblast	0.2 ± 0.2	1.4; 0.4–2.4
Polychromatic erythroblast	13.1 ± 6.8	21.6; 13.1–30.1
Orthochromic erythroblast	0.7 ± 0.7	2.0; 0.3–3.7
Neutrophil		
Promyelocytes	0.8 ± 0.9	3.3; 1.9–4.7
Myelocytes	3.9 ± 2.9	12.7; 8.5–16.9
Metamyelocytes	19.4 ±4.8	15.9; 7.1–24.7
Band neutrophils	28.9 ± 7.6	12.4; 9.4–15.4
Segmented neutrophils	7.4 ± 4.6	7.4; 3.8–11.0
Myeloid: erythroid ratio	4.3 : 1	3.1:1; 1.1–5.2:1
Eosinophils	2.7 ± 1.3	3.1; 1.1–5.2
Basophils	0.1 ± 0.2	0.1
Monocytes	0.9 ± 0.9	0.3; 0.0–0.6
Lymphocytes	14.4 ± 5.5	16.2; 8.6–23.8
Megakaryocytes	0.1 ± 0.1	0.1
Plasma cells	0.0 ± 0.1	1.3; 0.0–3.5
Undifferentiated blasts	0.3 ±0.3	0.9:0.1–1.7
Unknown of damaged cells	6.0 ± 3.2	

Data for term neonates: from Rosse C et al (1977) Bone marrow cell populations of normal infants: the predominance of lymphocytes. J Lab Clin Med 89:1225–1240; and from Shapiro LM, Bassen FA (1941) Sternal marrow changes during first week of life. Am J Med Sci 202:341–354.

Unfortunately, bone marrow aspirates of neonates are often diluted with peripheral blood, which can lead to misinterpretations about the state of production. This limitation can be minimized by taking care to withdraw the smallest possible marrow sample, thereby not overdiluting the specimen with blood. The limitation can be further minimized by using a biopsy technique [55].

Marrow is accessible from essentially any bone in the neonate. We have found that the flat part of the proximal tibia is a simple and reliable site from which to obtain a marrow sample, because this site is easy to stabilize, the landmarks are obvious, and the amount of tissue between the skin and the bone is small. The (right-handed) operator holds the tibia firmly in a gloved left hand, while the right hand is used to prepare and sterilely drape the area and then to inject 1% lidocaine as a local anesthetic. Lidocaine (typically 0.1 mL without epinephrine) is injected subcutaneously, holding the needle in place for several seconds, after the needle is advanced to the bone and another 0.1 mL is injected into the periosteum. A few minutes later, the operator holds the 19-gauge, 1/2-inch needle (Osgood marrow needle fitted with a trocar) in the right hand and twists it carefully through the anesthetized periosteum with the mid-tibia clearly marked directly between the left thumb and forefinger. The needle is directed toward the middle of the tibial shaft to enter the middle of the marrow cavity. The needle is correctly positioned when it is solidly in place and when, on aspiration, marrow enters the aspirating syringe [55].

If only a microscopic analysis of the bone marrow cells is to be accomplished, only a few drops of marrow should be aspirated. If flow cytometry, a karyotype analysis, or a hematopoietic progenitor cell culture is needed, more cells are needed, and up to 0.25 mL of marrow can sometimes be aspirated. Volumes exceeding this amount, particularly in very small preterm infants, essentially always draw significant amounts of peripheral blood through the marrow and result in a dilute specimen, which may be difficult to interpret.

Little information is available on bone marrow biopsies in neonates. Although the issue of cellularity is much more accurately assessed with a biopsy specimen than with an aspirate, neonatologists have been reluctant to perform this somewhat more invasive procedure, particularly on very small and ill neonates. We have found success in obtaining marrow needle biopsies, even in the smallest preterm infants in our neonatal intensive care unit, by using a modification of the aspiration method [55].

After the operator feels the Osgood needle penetrating the cortex of the tibia, the stylet (trocar) is withdrawn. The hollow needle is then advanced into the marrow space an additional 3–5 mm. Advancing the needle without a stylet cores a small segment of marrow into the needle. A syringe is then attached to the needle hub, and minimal suction is applied for about 1 second. This process helps secure the smallcore marrow biopsy specimen within the needle. The syringe and the attached needle are then withdrawn, and the core of marrow is pushed out of the needle by reintroducing the stylet. The core can be placed into fixative and subsequently sectioned and stained, or it can be smeared on coverglasses.

Anticipated results of bone marrow differential counts are shown in Table 98.3. Studies in 1941 and 1952 used marrow aspirates obtained from normal neonates, but this practice is no longer permitted. The normal values for marrow nucleated cell concentrations in neonates are available, but normal values for laboratory tests that were devised since 1952 (e.g., concentrations of hematopoietic progenitor cells) are not available [55]. In modern practice, bone marrow aspirates are only performed on neonates if a clinical reason exists to do so or the patient is enrolled in a study that requires a bone marrow study. These subjects therefore are not strictly normal subjects, and the results should not be considered normal values.

Pathophysiology of Coagulation and Deficiencies of Coagulation Factors in the Newborn

Rodney P.A. Rivers

99.1 Introduction

The main points of difference between neonatal and adult hemostasis are as follows:

- Platelets show significant differences in function
- Bleeding times are shorter through increased activity of von Willebrand factor (VWF)
- Increased tissue factor (TF) availability from monocytes and microparticles
- Many procoagulant and inhibitor levels are gestationally dependent
- Thrombin generation equivalent to adult
- Reduced procoagulant and inhibitor reserve
- Relatively impaired fibrinolysis
- In both, normal screening test results do not equate with normal hemostasis.

The principal function of the components making up the hemostatic system is to limit hemorrhage at sites of vascular injury. Subendothelial fibroblasts demonstrate strong TF protein staining and TF mRNA hybridization, as do pericytes surrounding capillaries. These sources of TF act as a "hemastatic envelope", triggering coagulation when exposed to blood.

Activated endothelial receptor expression and VWF secretion are essential for normal platelet participation in hemostasis. VWF is secreted as ultralarge multimers (ULVWFM). They are readily cleaved to shorter, less reactive multimers by the enzyme ADAMTS-13. In plasma, VWF has a half-life of approximately 12 hours and binds to FVIII, protecting it from activated protein C (APC).

Platelet adhesion, aggregation, granule release, surface phospholipid expression and contraction make critical contributions to hemostasis.

The plasma-based clotting factors form membrane-bound complexes of proteases and cofactors which achieve rapid amplification of the coagulation process. The phases of thrombin generation (TG) have been labelled as the initiation, amplification or propagation and termination phases (Figs. 99.1, 99.2, 99.3). Clot-bound thrombin activation of

FVIII results in continued FXa and thrombin formation, important for stable clot formation. This re-supply via FVIII is missing in hemophilia A.

The physiologic inhibitor of the TF-VIIa complex is TF pathway inhibitor (TFPI). Once this pathway of FX activation is blocked, the FIXa –VIIIa complex or intrinsic pathway becomes the principal pathway of FX activation. In the termination phase, free thrombin loses its procoagulant and platelet activating activity on binding to thrombomodulin (TM) and to the abundant antithrombin (AT).

99.2 Vitamin K-Dependent Proteins

During carboxylation of their precursor molecules in hepatocytes, vitamin K (VK) is oxidized to epoxide and is recycled via an oxidation-reduction pathway for reuse in its reduced, hydroquinone form, in the γ-carboxylation reaction (Fig. 99.4).

In hemostasis, two classes of VK-dependent proteins are identifiable, one of procoagulants: Factors II, VII, IX and X,

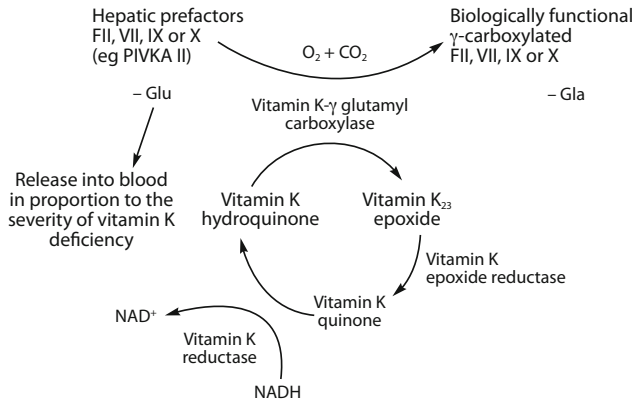

Fig. 99.4 Vitamin K - Metabolism and dependent factors. *PIVKA* protein induced by vitamin K absence or inhibition

and one of inhibitors: protein C (PC), protein S (PS) and protein Z (PZ). The serine protease domain of Factors II, VII, IX, X and of PC becomes functional after cleavage of specific peptide bonds. Neither PS nor PZ are serine proteases. All depend on γ-carboxylation of glutamic acid residues for their biologic activity. Reduced carboxylation in the absence of sufficient VK is associated with reduced activity. Precursor molecules in liver microsomes serve as immediately available substrates for the γ-carboxylase enzyme once VK becomes available. Precursors are released into the circulation as proteins induced by vitamin K absence (PIVKAs). With a 70 hour half life for PIVKA-II, its measurement can be used to diagnose previous VK deficiency even after VK has been administered.

99.3 Inhibitors in Plasma

Once the initiation phase is shut down by TFPI, the generation and activities of thrombin become regulated by AT and by α_2-macroglobulin (α_2-M) inhibition of the procoagulant serine proteases and by PC. The α_2-M is an anticoagulant when AT levels are low but it inhibits PS/APC complex formation and so can act as a procoagulant. Once bound to TM, thrombin activates PC on an adjacent endothelial protein C receptor (EPCR); PC is then released as APC. The EPCR is also a receptor for FVII/VIIa, facilitating FVIIa endothelial endocytosis. Soluble EPCR is found in plasma; it reduces PC availability for the membrane EPCR and inhibits APC inactivation of FVa thereby acting as a procoagulant (Fig. 99.5). PC has a half-time of some 6–8 hours in plasma, APC a half-time of only 15–30 minutes. APC proteolytic inactivation of FVa downregulates thrombin generation; inactivation of factor VIIIa diminishes the amplification phase. Rates of inactivation are enhanced by protein S. PS also acts as a cofactor in TFPI inhibition of FXa (Fig. 99.6). The heparin cofactor II (HCII) proteinase only inhibits thrombin; activity is enhanced by dermatan sulphate. Protein Z forms a complex with the protein Z-dependent protease inhibitor (ZPI) enhancing ZPI inhibition of FXa on phospholipid surfaces.

Fibrinolysis of cross-linked fibrin is initiated by tissue plasminogen activator (tPA) released from endothelial cells which, like urokinase plasminogen activator (uPA), activates plasminogen to plasmin, a process that is tightly controlled. On the clot surface, tPA and plasmin are relatively inaccessible to plasminogen activator inhibitor-1 (PAI-1)

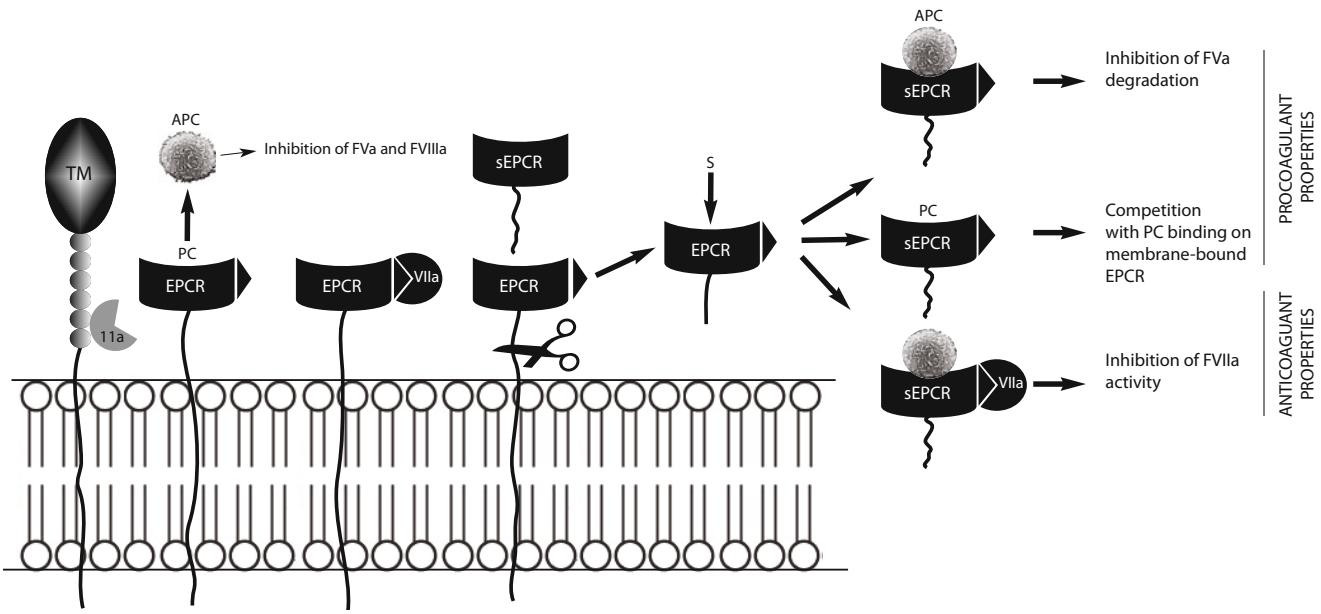

Fig. 99.5 EPCR and TM in coagulation/endothelium. Roles of thromboglobulin, of endothelially bound protein C receptor and of released plasma EPCR in downregulation of thrombin generation. *TM* thrombomodulin, *APC* activated protein C, *EPCR* endothelial protein C receptor, s*EPCR* soluble endothelial protein C receptor, *PC* protein C

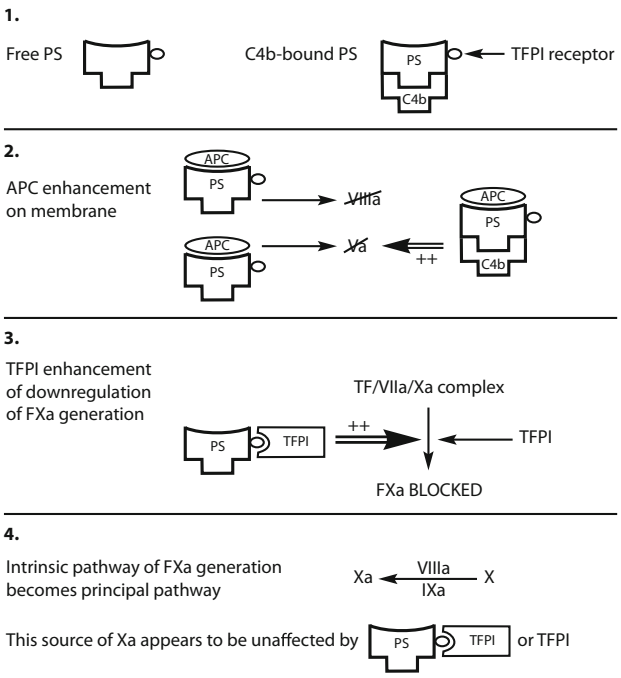

Fig. 99.6 Mechanisms of protein S enhancement of thrombin generation inhibition. Protease digestion of FVa and FVIIIa by protein C is enhanced by protein S. PS is active whether free or bound to C4b-binding. Enhancement of TFPI inhibition of the TF/VIIa/Xa complex is independent of protein C, but FXa generated by the intrinsic pathway is not inhibited. *PS* protein S, *TFPI* tissue factor pathway inhibitor, *APC* activated protein C

and α_2-antiplasmin (α_2-AP). In plasma, both are rapidly neutralised. Excessive activation, or a failure of inhibition, results in fibrinogen degradation (Fig. 99.7).

99.4 Hemostasis in the Neonate

Bleeding disorders may be life-threatening and rapid evaluation is essential. A detailed family history is required and consideration of clinical circumstances is needed. Is the baby apparently well or is the bleeding possibly a secondary phenomenon?

99.4.1 Investigations

Not all components of hemostasis are evaluated by routine screening tests and so "normal" test results for gestation and postnatal age do not equate with the presence of normal hemostasis. In 1991, the International Society for Thrombosis and Haemostasis Scientific and Standardisation Subcommittee on Neonatal Haemostasis published its recommendations for establishing normal ranges for neonates [1]. Data from cord blood studies may not equate with results obtained neonatally where difficult sampling may lead to TF contamination and slow withdrawal from catheters may lead to activation with soluble fibrin (SF) formation *in vitro*.

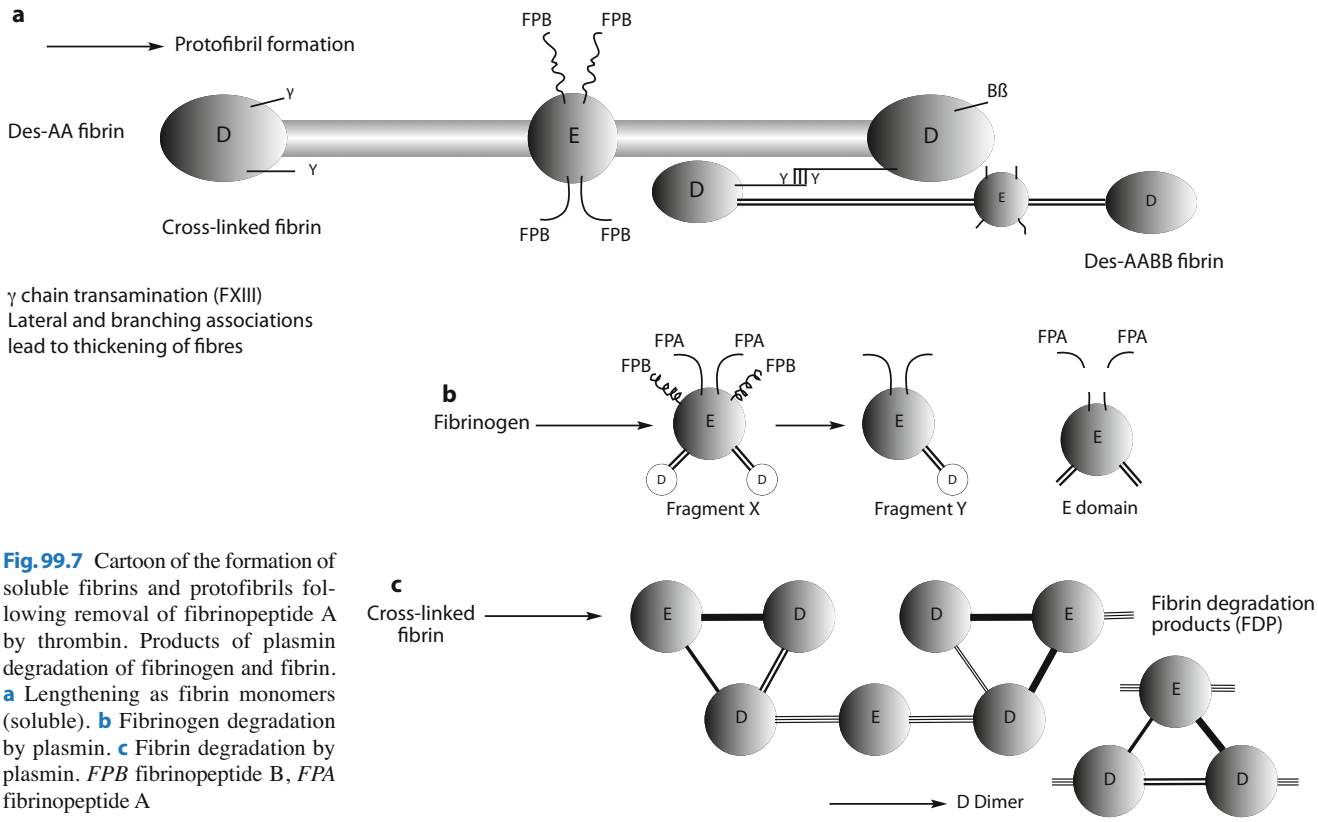

Fig. 99.7 Cartoon of the formation of soluble fibrins and protofibrils following removal of fibrinopeptide A by thrombin. Products of plasmin degradation of fibrinogen and fibrin. **a** Lengthening as fibrin monomers (soluble). **b** Fibrinogen degradation by plasmin. **c** Fibrin degradation by plasmin. *FPB* fibrinopeptide B, *FPA* fibrinopeptide A

Many problems may affect the validity of screening tests. These include incomplete anticoagulant mixing with clotting in the sample, hemolysis and lipemia which interfere with optical end point determinations, and contamination by heparin or the presence of an inhibitor as suggested by prolongation of an activated partial thromboplastin time (APTT) test on a 1:1 mixture of control and test plasmas. Heparinase degrades unfractionated or low-molecular weight heparin and, if added to a final concentration of 25 mg/mL, neutralises up to 2 U/mL, allowing accurate performance of the screening tests and of specific factor assays. Excessive dilution by anticoagulant (the normal 1 in 10 dilution assumes a hematocrit of 45%) may result in exaggeratedly prolonged times as neither the prothrombin time (PT) nor the APTT are linearly related to factor activities. The Clinical and Laboratory Standards Institute (CLSI) recommends adjustment of the ratio anticoagulant to sample volume according to the formula: volume of anticoagulant = (100 – PCV)/(595 – PCV) where PCV (packed cell volume) is expressed as a percentage. This should apply to hematocrits over 55% [1]. The high level of proteolytic activity after birth can result in *in vitro* formation of fibrinogen degradation products (FDP) and degradation of FV and FVIII by the plasmin present; proteases from activated granulocytes degrade FXIII, FIX, FX, FVII and FII. Incorporating ε-aminocaproic acid (AB Kabi, Stockholm) in the anticoagulant inhibits these effects. Sample cooling below 18°C induces FVII activation and loss of VWF.

Spontaneous aggregation of platelets due to leakage of adenosine diphosphate (ADP) from erythrocytes is described and a relationship to the hematocrit documented. Reported low platelet counts should always be checked microscopically.

The evolution of hemostasis development has been discernable from studies on fetal [2] and newborn plasmas at differing gestational and postnatal ages [3–5]. Problems in the diagnosis of congenital factor deficiencies arise from the normally low levels of several of the proteins involved. Most are measurable by 10 weeks' gestation; some display functional changes relating to differences in molecular composition.

FV, FVIII, fibrinogen and platelet count are present at close to adult values by 24 weeks' gestation whereas other components including high molecular weight kininogen (HMWK), the VK-dependent factors II, VII, IX and X, FXII and plasminogen approximate to 20% of adult levels by 28 weeks' gestation rising to around 50% at term.

Factor XIII shows no clear gestational dependence, remaining at 50–75% of adult from 30 weeks' gestation to term, but reaching adult values by 3 weeks' postnatal age.

At birth, FVIII levels are skewed towards the higher levels and fibrinogen levels continue to rise afterwards. The prolonged thrombin time (TT) obtained even when measures to prevent *in vitro* fibrinogenolysis are taken, results from the "fetal" form of fibrinogen. Removal of the increased sialic acid content of this fetal form leads to a correction of the prolonged TT as does adding calcium ions to the thrombin in the test.

Levels of VWF are increased at birth; the VWF is present in larger sized multimers than normal and displays increased activity in promoting platelet adhesion. The raised level persists for the first 3 months of life. Limited studies on ADAMTS-13 in the newborn have given discrepant results with both adult equivalent and reduced levels being reported.

99.4.2 Inhibitors of Coagulation

Protein C is present in a fetal form but function does not appear to be affected; it is present at around 50% of the adult value, increasing slowly after birth but not achieving adult values until the early teens.

Alpha$_2$-M, which is elevated above adult levels in neonates, has been shown to inhibit APC in a dose-dependent fashion therefore acting as a procoagulant.

Protein S exists in its free form in the newborn since the C4b-binding protein is virtually absent but the level is reduced. Its interaction with protein C may be affected by the level of α_2-M [6]. The free TFPI level is also reduced to some 50–65% of adult values. The PZ level has been reported as being low in neonates, particularly in preterms or in those born to mothers with pre-eclampsia; deficiencies in adults have not been reproducibly associated with pathological outcomes.

Antithrombin is at only some 30% of adult at under 30 weeks of gestation rising to 50% at term. α_1-antitrypsin (α_1-AT) and α_2-AP are somewhat reduced in proportion to gestation, but may exceed adult levels at term. A relative inhibition of fibrinolysis predominates throughout gestation.

99.4.3 Postnatal Changes

In the postnatal period, factor levels rise at differing rates; in term neonates, Factors VII and XIII attain adult levels by 3 weeks' postnatal age. Factors II, IX, XI, prekallikrein, AT and PC levels rise more slowly and in both term and preterm infants born at 30–36 weeks' gestation, adult levels are not attained until 3–6 months of age. In a separate study, the levels of Factors V and VII in infants born at gestations of 24–27 weeks increased to higher levels at 6 months postnatal age than those in infants born at greater gestational ages.

TM plasma concentrations are increased in the newborn with preterm neonates having higher levels than those born at term, the highest levels being found in those ventilated for severe respiratory distress possibly reflecting pulmonary endothelial damage.

Thrombin inhibition has been thought to be principally effected by the adult level of α_2-M since AT levels are low. With the demonstrated increased binding of thrombin to HCII, the overall inhibitory capacity in plasma appeared similar to the adult although thrombin inhibition was slower. Some inhibition may also be provided by a placental anticoagulant in cord

blood with similarities to dermatan sulphate. It catalyses thrombin inhibition by HCII. AT survival times, measured following exchange transfusion, are shorter than in adults possibly because exchange transfusions activate coagulation [7].

In studies of TG and on the time course of prothrombin fragment 1 and 2 formation, α_2-M inhibition was not evident. Changes made in α_2-M concentrations failed to result in changes in free TG or in prothrombin activation in neonatal plasmas. It was suggested that thrombin inhibition by α_2-M may be too slow to prevent feedback activation by the generated thrombin.

Clot strength has been assessed using thrombelastometry to provide information on maximum clot firmness (MCF) and on fibrin polymerization. MCF was significantly lower in cord versus adult whole blood reflecting "fetal" fibrinogen's impaired polymerization.

99.4.4 Fibrinolysis

In the neonate, all major fibrinolytic proteins demonstrate age-dependent concentration variations [8]. Marked changes in the components occur following birth. TPA and PAI-1 are below adult levels in cord blood whereas in both term and preterm neonates, tPA, uPA and PAI-1 are transiently increased above the adult value on day 1.

Plasminogen levels are some 20% of adult at 28 weeks and 50% at term, rising to the normal adult range by 6 months with α_2-AP levels being at 80% of adult at term. Fetal plasminogen exists in two major glycoforms with increased mannose and sialic acid content displaying slower activation kinetics than adult forms. Functionally they bind less well to cellular receptors and the plasmin formed from it has less enzymatic activity. Mean α_2-AP levels are around 80% of adult at term. The inhibition of the two fetal plasmin isoforms by α_2-AP (plasmin-antiplasmin [PAP] complexes) is slower than that of the adult plasmin variants. The other principal plasmin inhibitors, are α_2-M and α_1-antitrypsin. Although elevated levels of PAP complexes in healthy newborns derive from increased production of plasminogen activators at birth, inhibition of fibrinolysis predominates in the plasma of the newborn beyond day one.

The changes associated with advancing gestation were initially reported in the 1970s and have become known as developmental hemostasis, a term coined by Andrew [9]. Published reference ranges are available from data derived in the 1980s and early 1990s by Andrew, colleagues [8] and by others [10]. The preterm infants studied were all equal to or more than 30 weeks of gestation.

99.4.5 Clot Translucency and Strength

Over the years very different techniques have been utilised to record the end point of clot formation and published reference data may not be applicable to reported results from a neonate under investigation now. Differing reagents and machines used by laboratories reduce the utility of past published reference ranges. Comparisons with more recently acquired data have revealed important differences [11] (Table 99.1). When screening throws up an abnormal result, it is essential to have access to appropriate reference ranges; not only may further investigation be indicated but planned procedures may be delayed causing anxiety to parents and staff. Variation in the prothrombin time has been minimized by reporting the PT as an international normalized ratio. No such standardization exists for the activators and phospholipids in the APTT.

Table 99.1 Analyser comparisons. Comparison between prothrombin time results obtained using A, an ACL analyser and Thromorel, Behring [9] with B, those obtained using an STA Compact analyser with Neoplastine Cl reagent [11], and between a FVIII assay A using an ACL one stage factor assay and an in-house deficient plasma [9] with results B using an STA Compact analyser one stage assay with STA deficient plasma [11]

	Day 1 neonates	
	A	B
PT (sec)	15.16 (14.4-16.4)	13.10 (11.6-14.4)
INR	1.26	1.0
APTT (sec)	38.7 (34.3-44.8)	42.9 (31.3-54.5)
FVIII%	182	100

PT prothrombin time, *INR* international normalized ratio, *APTT* activated partial thromboplastin time.

Because of their relative rarity and because of the disorders so frequently encountered by them, true normative data for preterm neonates below 30 weeks' gestation do not exist.

It is hoped that reference ranges will be produced from large centers so that other centers using similar apparatus and reagents may be able to consult them when faced with abnormal results. Factor assays and screening tests need to be interpreted using gestational age and postnatal age-adjusted ranges.

99.4.6 Neonatal Platelets

Reference ranges for platelet counts in term and preterm neonates show that counts differ from the accepted adult normal range of 150,000/μL to 450,000/μL. Below 30 weeks' gestation, the 5th centile is 104,200/μL and in the late preterm and term population, it is 123,100/μL. The mean platelet volume is quite similar to that in adults (7–9 fl) with a mean of 8 fl (range 7–9.5 fl) [12]. Increased numbers of circulating megakaryocyte progenitors and of mature megakaryocytes are found. Circulating precursors are proportional both to the numbers in marrow and to the blood platelet count. Newly synthesised platelets have an increased RNA content and can be identified by flow cytometry. In non-thrombocytopenic neonates, the proportion is similar to that in adults.

Thrombopoietin is detectable in the plasma of newborns of all gestations. Levels are similar to baseline adult levels in term infants (140 pg/mL), with a wide range. In the preterm, levels have been reported to be higher.

99.4.7 Functional Aspects

It can be difficult to avoid activation of platelets in cord blood samples; pre-activation during birth has not been found to be the cause of the hyporeactivity observed. Aspects of neonatal platelet function have been repeatedly reviewed [13, 14]. Platelet receptors for adhesive proteins, GP1a/II (collagen), GP1b/IX/V (VWF) and GPIIb/IIIa (fibrinogen, fibronectin, VWF) are present on fetal and cord blood platelets with receptor concentrations being similar to those on adult-derived platelets. The number of α_2-adrenergic receptors is approximately half that on adult platelets and this is not due to receptor occupancy by catecholamines in cord blood. By 2 months of age, levels are similar to those on adult platelets. The diminished response to thromboxane analogues is not a consequence of a reduction in receptors but is due to attenuated downstream signalling.

99.4.8 Bleeding Time

Templates constructed to create small skin incisions have been utilised to study neonates. Results obtained indicate that bleeding times are similar to or shorter than those in adults. Both the existence of the more active ULVWFM in the newborn and the higher hematocrit contribute.

99.4.9 The Platelet Function Analyser 100 (Dade Behring)

Citrated whole blood is aspirated through an aperture and the time to occlusion of the aperture (150 μm) in the membrane coated with fibrillar type 1 collagen in the presence of either 10 μg epinephrine bitartrate or 50 μg ADP is measured. This is referred to as the closure time. Closure times are shorter for newborn than adult blood.

99.4.10 Aggregometry

Generally, aggregation to a variety of agonists is decreased. The differences are magnified in platelets from preterm neonates. The relevance of such findings to *in vivo* hemostasis has been thrown into question by a report claiming to use a more physiological set of stimuli in a whole blood experiment. Using a combination of collagen and endogenous thrombin as stimulants, maximal aggregation and lag time to the start of aggregation were similar in neonatal and adult samples [15]. This result was attributed to the faster generation of thrombin in neonatal blood and possibly offers an explanation for the "abnormally" short bleeding time of neonates. An increased response to ristocetin reflects the increased level and enhanced function of neonatal VWF. Studied using the cone/plate analyzer, a correlation between demonstrated platelet function and gestation has been reported.

99.4.11 Flow Cytometry

Requiring only small volumes with minimal manipulation, platelet responsiveness can now be followed postnatally. Platelets from both term and <30 weeks' gestational age preterm infants have reduced levels of activation markers following stimulation. In normal infants, adult responsiveness is seen by day 10. P-selectin expression following stimulation is further reduced in preterm newborns in proportion to their gestation. Agonist-induced secretion of granule components is reduced in both term and preterm platelets due to reduced function of receptor-mediated transduction pathways (Fig. 99.8).

99.4.12 Procoagulant Activity

The percentage of platelet-derived microparticles (MPs) is higher in preterm than in term newborn blood. MP generation and membrane flipping leading to phosphatidyl serine (PhS)

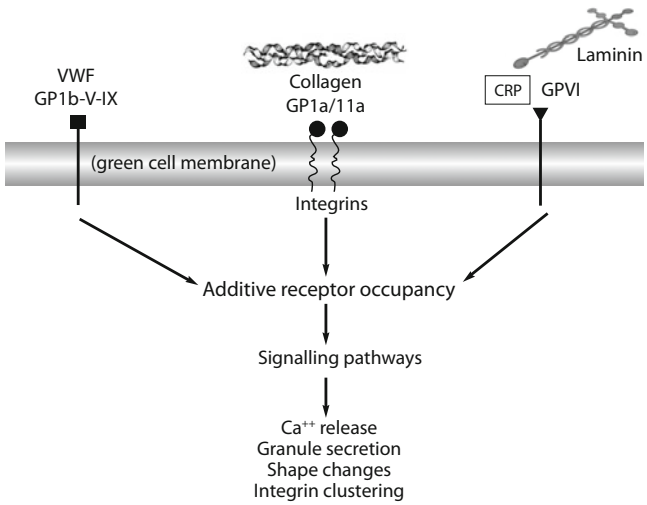

Fig. 99.8 Platelet adhesion receptors and signalling. A summation of platelet receptor occupancy is required for full platelet activation and granule secretion. *CRP* collagen-related peptide, *GP* glycoprotein

expression are both increased in term and in preterm platelets compared to adult platelets. Functionally, thrombin generation is supported [16].

99.4.13 Effects of Drug Exposure

A wide range of drugs including anti-inflammatory agents, antimicrobials, anti-depressants, β blockers and alcohol may cross the placenta and affect fetal and neonatal platelet function and may cause bleeding; in a few instances, drugs including indomethacin and nitric oxide used in neonatal management affect platelet function.

99.4.14 Evaluation of Hemostasis

Conventional tests utilising the strong activators as in the PT and APTT tests only reveal deficiencies in the procoagulant pathways; they provide no information on how the balance between procoagulant and inhibitor concentrations might affect TG in the neonate.

In the early studies of TG using strong activation, TG in neonatal plasma had been found to be some 30–50% of the peak value generated in adult, the poor response being attributed to the low levels of FII encountered in the newborn.

By manipulating the levels of inhibitors including TFPI, AT and PC and by activating the PC with soluble thrombomodulin, the effects on TG using low concentrations of lipidated TF for activation have been studied. TG in cord-derived plasma was found to start earlier due to faster FX activation and to be comparable with that generated in adult plasma, the free thrombin generated being approximately 90% of the adult value. APC was found to have a greater effect on prolonging the clotting time than did increases to AT [6, 17]. Along with evidence from thrombelastography, where clotting is often accelerated, one is led to conclude that the newborn may not be as hemostatically compromised as originally thought. That may be why well neonates exposed to surgery or trauma appear hemostaticly competent. The high levels of tissue factor availability in the newborn may also be contributing to this observed hemostatic competency [18]. However, the neonatal hemostatic components have little in the way of reserves when challenged by excessive activation; bleeding and thrombosis may ensue. In sick neonates, the shortened half-lives and reduced production of procoagulants may rapidly result in the development of a hemorrhagic diathesis.

Presentations of unsuspected hemostatic failure may be revealed following trauma, surgery or may appear to be spontaneous. Major bleeds or continued oozing from the cord or from puncture sites may be the first signs of hemostatic compromise.

Pseudohemorrhage as swallowed maternal blood from the stomach or stools can be distinguished from fetal blood using the Apt test in which a pink colour in 1% sodium hydoxide is retained by fetal but not by adult hemoglobin.

99.4.15 Coagulation Investigation in the Neonatal Period

Acquisition of a detailed family history is imperative. When there is a positive family history, the potential risk should the neonate have acquired the defect along with knowledge as to whether the diagnosis can be made in the neonate have to be taken into account when planning investigations and in determining whether follow-up investigations beyond six months of age may be required. This may be especially needed for the detection of milder congenital defects. Babies born to mothers on warfarin, anti-convulsants or anti-tuberculous drugs should

Table 99.2 Results of laboratory investigations into neonatal coagulation disorders

be screened because of inhibitory effects on VK. Awareness of conditions associated with disseminated intravascular coagulation (DIC) is important.

Samples that have been particularly difficult to obtain or where the tubes are over or under filled should be rejected. Screening tests should include a prothrombin time, which can normally be prolonged by up to 3 seconds in term infants but is more prolonged the shorter the gestation. Adult values for the PT should be achieved by day 4 in all but the most preterm neonates. The international normalised ratio (INR) should be calculated. An activated partial thromboplastin and mixture time, a thrombin-calcium time, a fibrinogen level and full blood count and platelet count should also be performed.

In the very preterm infant the APTT is normally prolonged but the mixture time will reveal whether an inhibitor such as heparin or dermatan sulphate is present. Adult APTT values are achieved by 2–6 months postnatally. The thrombin calcium time is slightly prolonged in the newborn. The Reptilase time with calcium is slightly prolonged in the neonate but is abnormal in some dysfibrinogenemias. Evidence of *in vivo* thrombin generation can be gained by finding thrombin-antithrombin complexes or soluble fibrin monomers. A D-dimer assay or fibrin degradation product measurement may also be useful if DIC is suspected. The changes associated with various conditions are shown in Table 99.2.

Deficiencies of ADAMTS-13, FXIII and of α_2-antiplasmin are not detected in the routine investigations. FXIII should be evaluated by measurement of the transglutaminase activity following thrombin/calcium activation [19].

Measurements of individual components of the systems involved may be required but antigen levels do not necessarily equate with biological function. Platelet function can be assessed by the platelet function analyzer closure time or by a template bleeding time, the latter having the disadvantage of being operator dependent. Platelet glycoprotein (GP) expression is fully developed in term and preterm neonates; by using flow cytometry, deficiency states in receptor expression can be identified. Investigation of the parents' platelet function may be helpful.

In the disordered proteolysis of DIC, routine tests if done sequentially would be expected to reveal falls in FV and FVIII whereas in metabolic liver disease or VK deficiency they are conserved, unless DIC has been triggered by blood loss and shock.

99.5 Inherited Coagulation Disorders

Exposure to surgery poses a considerable threat to an infant when a hemorrhagic diathesis has not been previously suspected. The risks entail complicating or life-threatening hemorrhage and transfusion-transmitted infections from infused plasma-derived products. Immune stimulation leading to inhibitor formation is particularly to be feared.

99.5.1 The Hemophilias

A well term neonate with signs of bleeding and an isolated borderline or prolonged APTT may have a form of hemophilia. Along with von Willibrand's disease, the hemophilias account for over 95% of all inherited bleeding disorders. Hemophilia, as it involves the neonate, has been reviewed by Chalmers [20].

There are three types arising from separate factor deficiencies: hemophilia A (FVIII deficiency), B (FIX deficiency) and C (FXI deficiency). Hemophilia A and B are indistinguishable clinically, both giving rise to bleeding of variable severity.

Prenatal carrier testing can be performed utilising polymerase chain reaction techniques; the molecular genetic testing for hemophilia A has been reviewed by Goodeve [21].

The genes for FVIII and FIX are present on the X chromosome and that of FXI is on chromosome 4. A male infant with abnormal bleeding and normal screening tests except for a prolonged APTT should be screened for FVIII and FIX deficiencies. Both have been described in phenotypic girls.

FXI deficiency gives rise to less severe bleeding but should be considered in all well neonates with bleeding and an abnormal APTT; it is an autosomal recessive disorder.

Even in FVIII or FIX severe deficiency, bleeding in the first week of life is uncommon. In one retrospective review, puncture bleeding (16%) and bleeding post circumcision (30%) were the most common; hemorrhagic shock from liver hematomata in two neonates has been reported.

Intracranial hemorrhage (ICH) is rare and elective cesarean section is not recommended for its prevention. The subject has been reviewed by Ljung [22]. Vacuum extraction was found to be particularly associated with extracranial hemorrhages in the Swedish studies with 69% of 16 cranial hemorrhages occurring in relation to this procedure. Some 50% of those born with hemophilia are not suspected antenatally. Extracranial hemorrhage (ECH) in the form of cephalhematomas and subgaleal hemorrhages can involve massive blood loss and can be accompanied by an ICH which may be clinically unsuspected.

Prophylactic treatment of identified cases of hemophilia is not generally advocated. If an ICH is identified, treatment should continue for 2–3 weeks aiming at 100% concentration over the first 7 days and 50% over the latter part of the course.

As cesarean section does not eliminate the risk of cranial bleeding, normal vaginal delivery for known carriers is generally recommended. The management of carriers and of babies has been reviewed by Street et al [23].

In cases of known or suspected carriers where the fetal diagnosis is unknown, a cord blood sample should be obtained for diagnosis and intramuscular administration of vitamin K should be withheld. Oral vitamin K prophylaxis should be commenced and continued if the diagnosis is confirmed and a cranial ultrasound performed before discharge. Circumcision should be avoided.

Because of the association of a low FVIII level in type III von Willebrand disease (VWD), VWF antigen should be measured in all infants with FVIII activity below 10%.

The FIX level may be as low as 15 IU/dL in normal neonates. Severe and moderately severe deficiency states may be discernible but mild cases cannot be differentiated from those who are not affected and require further evaluation when the child is older unless a genetic diagnosis is possible.

99.5.1.1 Why is Bleeding Uncommon?

Studies have demonstrated that the peak height of TG in FVIII-depleted neonatal plasma is almost as high as that in normal neonatal plasma whereas when adult plasma is similarly depleted of FVIII, TG is only 50% of that observed in normal adult plasma and the time to peak height was 50% longer [24]. Raised TF availability along with the lower levels of TFPI and AT, combined with the PS inhibition by α_2-M, may explain why bleeding in neonates with hemophilia is rare.

99.5.1.2 Management of Bleeding

Management of bleeding has been reviewed by Kulkarni and Lusher [25] and by Ljung et al [22]. Therapy utilising a recombinant product is the preferred option. Alternatively, a monoclonally purified, viral inactivated plasma-derived product may be used. Plasma should only be used when concentrates are unavailable.

Limited pharmacokinetic data in the newborn indicate a shortened half- life for FVIII. In adults the half-life of rFVIII is 11–17 hours but in the neonate it may be as short as 6 hours. The volume of distribution in adults is limited to the plasma volume so that each 1 IU/kg infused raises the plasma concentration by 2%. The volume of distribution in the newborn is increased. On this basis, it has been calculated that an initial infusion of 50–60 IU/kg followed by 8–12 hourly infusions of 25–30 IU/kg should raise the FVIII to adult levels.

Proposals for the use of prophylaxis in order to reduce any bleeding consequences of birth trauma are controversial and there is a lack of evidence-based guidelines. Prophylaxis in preterm infants, two with FVIII deficiency and one with FIX deficiency have been reported. The FVIII was given at 50 IU/kg daily increasing to twice daily with septic episodes.

In the neonate receiving rFIX, the half- life was estimated to be 5.8 hours. Because of a reported very large volume of distribution and this rapid elimination, up to 30 IU/kg each hour may be required to maintain 100% FIX activity. Experience with recombinant FIX in the USA has led to a dose recommendation of a 120 IU/kg bolus followed by 60 IU/kg 12 hourly as the maintenance dose.

Antibody (inhibitor) formation in neonates is rare. The genetic and non-genetic risk factors involved have been reviewed [26]. Although the risk of inhibitor development has been a concern, some evidence points to a reduced risk of inhibitor development with early prophylactic treatment.

99.5.2 Von Willebrand Disease

This bleeding disorder affects males and females and is caused by a quantitative or qualitative deficiency of VWF. It is the commonest inherited bleeding disorder with an estimated prevalence of 0.8–1.3%; in most instances it is inherited in an autosomally dominant fashion. Evidence-based guidelines for diagnosis and management have recently been published under the aegis of the National Heart, Lung and Blood Institute Expert Panel (USA) [27].

There are three major types of VWD: type I, in which there is a partial quantitative deficiency, is the most common. In type II, there is a qualitative VWF defect and in type III there is virtually a complete lack of VWF. The bleeding tendency is usually mild and since levels in the neonate are elevated with the high molecular weight multimers (HMWM) forms, bleeding in the neonatal period is unusual. Type III disease may however present with superficial mucosal bleeding; ICH in this form of VWD is described. Where VWD is associated with thrombocytopenia as in the type 2b subgroup or in the more severe form of type III disease, bleeding is more likely to occur.

Diagnosis of type III VWD is made by finding low levels of both FVIII and VWF antigen and of ristocetin cofactor activity. VWF multimers will also be missing. In the presence of thrombocytopenia, type IIb should be excluded. Because of the normally raised levels in the neonate, other forms of VWD can only be diagnosed by molecular techniques.

99.5.2.1 Management

Recombinant VWF is the treatment of choice although plasma-derived concentrates are licenced for use in the USA. VWF is also contained in viricidally treated FVIII concentrate. The recommended loading dose is 30–60 U/kg with maintenance doses of 20–40 U/kg every 12–48 hours. A trough level of > 50 IU/dL should be maintained for 3–5 days according to perceived risks of re-bleeding.

Desmopressin is contraindicated in the neonate because of the danger of inducing hyponatremia. Platelet replacement may be required in bleeding associated with type IIb disease.

99.6 Rare Inherited Bleeding Disorders

These disorders have been the subject of a recent reviews by Peyvandi [28, 29] and guidelines on diagnosis and management have been produced [30].

They are generally inherited as autosomal recessive traits and severe bleeding is encountered in individuals with either homozygous or compound heterozygous mutations.

99.6.1 Disorders of Fibrinogen

Quantitative and qualitative defects including afibrinogenemia and hypofibrinogenemia (autosomal recessive) and the dysfibrinogenemias (autosomal dominant) have been reviewed [31] and may be identified in the neonatal age group. Afibrinogenemia and the more severe forms of hypofibrinogenemia present most often as bleeding from the umbilical cord; however mucosal bleeding is encountered and ICH in afibrinogenemia has been reported. Significant bleeding would not be anticipated with levels above 0.5 g/L.

The dysfibrinogenemias may be detected following investigation of an abnormal coagulation test result or when screening is carried out against a background of a family history. They are associated both with bleeding and thrombotic disorders but are unlikely to present in the neonate.

99.6.1.1 Diagnosis

Fibrinogen levels are within the normal adult range at birth. In afibrinogenemia, the PT, APTT and TCaT are all markedly prolonged and fibrinogen levels in functional and antigenic assays are undetectable. In hypofibrinogenemia, the level of fibrinogen ranges from 0.20–0.80 g/L and determines the degree of prolongation of the above tests. The TCaT and Reptilase time are the tests most likely to reveal a dysfibrinogenemia, the antigenic levels being higher than levels suggested in functional assays.

99.6.1.2 Management

Virally inactivated fibrinogen concentrates are the treatment of choice in bleeding from afibrinogenemia or hypofibrinogenemia. A minimum level of 0.5 g/L is considered necessary for hemostasis although raising the level to 1 g/L is recommended in a bleeding neonate [30]. The half-life of 3–5 days permits infrequent dosing and prophylaxis from an early age given every 7–14 days has been used to maintain a level above 0.5 g/L. In the absence of concentrate, cryoprecipitate or fresh frozen plasma (FFP) can provide fibrinogen but the risks of viral transmission and of volume overload are greater. Use of fibrin glue and antifibrinolytic agents may need to be considered.

Primary prophylaxis is not generally recommended in afibrinogenemia. Following a severe bleed such as an ICH, secondary prophylaxis aimed at keeping a level of above 0.5 g/L is considered reasonable [30].

99.6.2 FII, FV, FVII, FX, FXI, FXIII and Combined FV/FVIII Deficiencies

Each of these deficiencies leads to a life-long bleeding disorder; the congenital disorders of the VK-dependent factors have been the subject of a review [32]. All the above are associated with a neonatal hemorrhagic diathesis. In a large Iranian series ICH was most commonly associated with FVII and FX deficiencies. The deficiencies of Factor II [33], FV [34], FVII [35], FX [36], FXI [37], and FXIII [19] have each been the subjects of recent reviews.

99.6.2.1 Diagnosis

As presented above, the levels of FII, FVII, FX and FXI are reduced compared with adult values both at term and in a gestationally determined manner. Although severe deficiency states are diagnosable in the newborn, those infants with higher levels may need follow-up re-testing to establish an heterozygote diagnosis. Undetectable FII is not compatible with life and has never been reported in a liveborn baby.

In FV deficiency, the severity of the bleeding tendency is variable and has been attributed to the co-existent finding of a reduced level of TFPI. As FV is at normal adult values at birth, both homozygous and heterozygous deficiency states are usually diagnosable in the neonatal period.

FXI severe deficiency is associated with a spectrum of bleeding severity with some homozygous states being almost asymptomatic.

FXII deficiency, although causing a prolonged APTT, does not give rise to clinical bleeding.

It should be noted that a normal APTT for gestation and age does not necessarily rule out an intrinsic factor deficiency since the high FVIII level can normalise the APTT in the presence of other deficiencies.

99.6.2.2 Management

As recommended above, specific factor concentrates (e.g., FVII, FXI) should be used when available; alternatively, prothrombin complex concentrate (e.g., FII and FX) may be considered. FVII deficiency can be rectified using plasma-derived FVII concentrate at 10–30 IU/kg twice weekly or by rFVIIa in doses of 15–25 μg/kg every 3–6 hours. FV replacement requires the use of virally inactivated FFP raising the level to 15 IU/dL with 15–20 mL/kg followed by 5 mL/kg 12 hourly. The level should be maintained at 25% after a severe bleed. FX deficiency is treated with FFP or prothrombin complex concentrates containing FX, although the high levels of FII, FVII and FIX in these concentrates pose a thromboembolic risk; a freeze-dried concentrate of human FIX and FX (FX P Behring, Germany) has become available which may prove useful in managing this disorder.

99.6.2.3 FXIII Deficiency

Although often presenting with umbilical cord bleeding from 1–19 days after birth when levels are below 5 IU/dL, with levels below 1 IU/dL, up to 80% of cases present in this way. The most feared complication is ICH which is common in severe deficiency. Making the diagnosis is therefore particularly important because monthly infusions of FXIII concentrate or of cryoprecipitate can prevent this complication (see below), the half-life of FXIII being around 30 days.

FXIII is not involved in any of the screening coagulation tests and must be analysed specifically utilising a functional assay.

Neonates diagnosed with FXIII levels below 3 IU/dL should be commenced on a prophylactic replacement regimen of viricidally treated, plasma-derived FXIII concentrate. FXIII distribution is limited to the plasma volume. Each 1 IU/kg infused raises the plasma concentration by 2%. The aim is to keep the pre-treatment trough at > 3 IU/dL. This requires 10 IU/kg every 4 weeks initially with subsequent monitoring. FXIII is also present in cryoprecipitate and in FFP.

99.6.2.4 Hereditary Combined VK Deficiency Factor Disease

This is a very rare autosomal recessive condition arising from mutations affecting either the γ-glutamyl carboxylase enzyme or the VK epoxide enzyme complex. In the severely compromised, bleeding may occur in the neonate with umbilical and intracranial hemorrhages reported.

The PT and APTT are variably prolonged depending on the degree of functional deficit. The condition may be difficult to distinguish from VK deficiency since some response may follow VK administration. Molecular studies may be required.

VK should be administered and ongoing prophylaxis with VK may be required. In those unresponsive to VK, both FFP and factor concentrates have been used.

99.7 Fibrinolytic Deficiency States

Inherited deficiencies of PAI-1 and of α_2-AP (autosomal recessive) are very rare; they can give rise to serious bleeding. They can be screened for using the euglobulin clot lysis time.

99.7.1 PAI-1 Deficiency

The uncontrollable fibrinolysis associated with PAI-1 deficiency can give rise to ICH. Infants have a very short euglobulin clot lysis time in the face of normal screening tests. Relative insensitivity of available assays to activity measurements and in antigen detection makes diagnosis of deficiency difficult. Replacement is by using FFP in combination with ε-amino-caproic acid (EACA) as a fibrinolytic inhibitor. Doses of EACA of 50–100 mg/kg every 6 hours orally can maintain clot stability after replacement therapy.

Alpha-1-AT deficiency can only be replaced with FFP and EACA may be of use in controlling excessive lysis.

99.8 Acquired Factor Deficiencies: Liver Dysfunction and Liver Failure

Liver disease can affect the synthesis of a number of coagulation proteins. Levels of procoagulants and anticoagulants can become reduced resulting both in hemorrhagic and prothrombotic tendencies. Comparisons between FV and FVIII levels are helpful in evaluating the liver dysfunction because both should be present at adult levels and FV is the only one dependent on liver synthesis. Abnormal activation can reduce FVIII. Brief responses to platelet and fibrinogen infusions are indicative of consumption. Unless the cause of the liver failure can be reversed, the associated hemorrhagic diathesis is likely to be fatal.

99.8.1 Management

Correction of the PT for liver biopsy or surgery requires rFVIIa. A dose of 90 μg/kg has been found to be effective. Prolongation of clotting factor half times has been advocated using very low doses of heparin (5–10 U/kg an hour).

99.9 Vitamin K Deficiency Bleeding (VKDB)

In the first published series of 50 cases of what he named hemorrhagic disease of the newborn, Townsend identified four key features distinguishing affected babies from cases of hemophilia: early onset, usually on day 2–3 of life, a self-limited time course, a lack of a family history and the importance of adequate feeds in reversing the condition. The name change recommended in 1999 by the ISTH Pediatric/Perinatal Subcommittee to VKDB indicates the specific etiology and widens the inclusion to babies beyond the 4 week neonatal period [38]. Recognition of the particular dangers from the late onset form has resulted in the widespread introduction of various prophylactic regimens. In VK deficiency the glutamate residues of factors II, VII, IX and X are variably, incompletely γ-carboxylated.

Their measurement has been used to detect degrees of VK deficiency. Cord blood levels of PIVKA II vary through gestation, increasing near term and in pregnancies complicated by pre-eclampsia.

Table 99.3 Newborn and adult liver vitamin K_1 and K_2 values. Vitamin K concentrations and total values in livers from newborns and adults. Values in parentheses are median. Data from [39]

	Vit K_1 (ng/g)	Total Vit K_1 (μg)	Total Vit K_1 and K_2 (μg)
Adult	1.1–21.3 (5.4)	1.7–38.3 (7.8)	33–330
Term newborn	0.1–8.8 (0.1)	0.02–0.91 (0.09)	0.02–0.91
Preterm newborn	0.3–6.0 (1.4)	0.02–0.91 (0.09)	0.02–0.91

The differences between the adult and neonatal liver contents per gram of liver are striking [39] (Table 99.3). No VK_2 menaquinones were detectable in the neonatal autopsy material until approximately 14 days postnatal age; in the adult they make up 75–97% of the total liver VK. The newborn seems totally dependent on VK_1 for sufficiency. Fortification of cow's milk formulae was recommended by the American Academy of Pediatrics in 1971 and continues at around 55–60 μg/L. In breast milk, the principal form of VK is phylloquinone (PhQ) with menaquinone-4 being the next highest. The average concentration of PhQ in colostrum is about 2 μg/L and in mature human milk, about 1 μg/L. Even if taking 200 mL/kg a day, it has been estimated that a baby would receive less than 1 μg VK a day. In one report, ceasing to supplement breast fed babies with formula feeds in the first days of life resulted in an incidence VKDB of 1 in 1200 live births.

The effect of the differences in VK intake between breast and formula fed infants on PIVKA II detection is shown in Table 99.4. PIVKA II was only present in the breast fed groups. MK-4 appears to be synthesised in the mother from phylloquinone. The neonatal protective effects of 20 mg VK given daily for 14 days to mothers on anti-convulsants, where early neonatal bleeding had previously been a feature, were clear. Intramuscular VK_1 (0.5–1.0 mg) given at birth raises hepatic concentrations 1000–5000-fold at 24–48 hours and at 6 days was 1.4 μg/g; by 28 days, levels remained some 200-fold above the levels encountered at birth. There is no evidence that neonatal VK_1 provision enhances dependent factor protein synthesis, so in the preterm infant with gestationally determined low levels of the VK-dependent factors, postnatal VK administration will only prevent an emergence of inactive forms. Factor replacement is the only way to achieve improved hemostasis.

Table 99.4 PIVKA II measurements in breast and formula fed infants. Immunoassay on plasma samples from two groups of infants

		Age (months)		
		1	2	3
Breast fed	Number	62	44	32
Vit K: 2.1 μg/mL	PIVKA II + ve	3	4	2
Formula fed	Number	43	48	45
Vit K: 50 μg/mL	PIVKA II + ve	0	0	0

PIVKA protein induced by vit K absence or inhibition. Data from [50].

VKDB, delineated into three types as described by Lane and Hathaway in 1985 and accepted by the Pediatric/Perinatal Subcommittee of the International Society on Thrombosis and Haemostasis in 1999, includes the division into idiopathic and secondary forms [38]. Amongst the secondary causes are the frequently undiagnosed causes of fat malabsoption such as cholestasis, biliary atresia, α_1-antitrypsin deficiency and cystic fibrosis and a failure to be aware of the effects of drugs given to the mother or infant (warfarin, anticonvulsants and antituberculous agents).

Early VKDB is defined as bleeding due to VK deficiency in the first 24 hours of life; it is usually caused by drugs administered to the mother that interfere with VK metabolism but can arise from conditions causing maternal fat malabsorption.

Classical VKDB occurs between days 2 and 7 and is regarded as idiopathic but often has its origins in the failure to establish adequate early breast feeding [40].

Late onset VKDB extends the period of bleeding from day 8 to 6 months [38]. The peak incidence is between 3 and 8 weeks. It is almost always in exclusively breast fed infants. An impaired secretion of bile salts with mild abnormalities in liver function tests leading to VK malabsorption is often implicated. Although warning bleeds can be a feature, many cases present with intracranial bleeds. In one series, severe ICH was noted in 63% of cases. Of those followed up, some 40% had long-term neurological consequences. Factors contributing to the VKDB are the relatively low VK content of breast milk, the lack of gut microflora that synthesise vitamin K_2 and, in preterm infants, inadequately functional VK epoxide cycles (Fig. 99.4). Various chemicals in the breast milk of mothers living in industrialised countries may be acting as enzyme inducers, interfering with quinone metabolism.

Diagnostic criteria of VKDB are: a prothrombin time ≥ four times the control value plus at least one of:

a. a normal or raised platelet count, normal fibrinogen and absent FDP
b. PT returning to normal after vitamin K
c. PIVKA (usually of FII) level above normal control values

A probable case: PT and APTT prolonged for age plus one of the above.

Use of PIVKA measurements may be helpful in differentiating VKDB from cases of non-accidental injury since retinal bleeds, often considered as pathognomonic of NAI, have been described in VKDB.

99.9.1 Treatment of VKDB

A slow intravenous dose of 1–2 mg Konakion will fully correct deficiency in those less than six months of age. The subcutaneous route can be utilised in the absence of venous access. Higher doses may be indicated for the reversal of warfarin antagonists. Increases in factor levels are detectable within 20 minutes of the intravenous dose, values rising to close to normal for age by 2 hours.

Severe bleeding may require factor replacement as well as the VK until the diagnosis can be confirmed. FFP in a dose of 15 mL/kg or prothrombin complex concentrate, where the dose extrapolated from adult data is 50 units/kg body weight, may be used but these take time to arrive and VK administration should not be delayed. rFVIIa can also be effective in life-threatening hemorrhage at 90 μg/kg.

99.9.2 Prevention of VKDB

Surveys on the incidence of both classical and late onset VKDB have been evaluated in a Cochrane review [41] and have been reviewed by Shearer [42]. A UK survey documented that almost all late onset cases were breast fed babies who had received either no VK or just one oral dose. The authors commented that parental refusal of prophylaxis had become more problematic.

99.9.3 Efficacy of Vitamin K Prophylaxis

The single intramuscular injection of 0.5–1.0 mg of phylloquinone offers better protection than the single or most multiple oral dose regimens. A depot effect is not achieved by intravenous or oral delivery. The move towards oral regimens was triggered by publications in 1990 [43] and 1992 [44] linking childhood cancer to receipt of intramuscular VK with a possible doubling of the risk of leukaemia. Subsequently reviews of data from many surveys have concluded that there is no convincing evidence that vitamin K provided by any route influences cancer risk in children, but an influence cannot be totally ruled out [45, 46].

Many oral regimens were found not to prevent all cases of late onset VKDB. However a Danish regimen used when the Konakion Cremophor preparation was available, of a 2 mg dose at birth followed by a 1 mg dose given weekly for 3 months resulted in no cases being reported over a 7.5 year survey period. In a randomized study in the USA with 67 infants in two groups, 2 mg Konakion MM given orally at birth, at 7 days and at 30 days was at least as effective as a single dose of 1mg intramuscularly at birth. Konakion MM given orally is not predictably absorbed in infants with cholestasis. Concerns remain over bioavailability and over compliance with oral dosing regimens. In the USA, a single intramuscular injection of 0.5–1.0 mg PQ remains the recommended prophylaxis. Low dose oral regimens should be continued for 3 months.

In preterm infants, the reduced activity of the VK epoxide reductase is associated with evidence of hepatic overload at previously prescribed parenteral VK dosages. In a recent trial in which differing dosage regimens in babies < 32 weeks' gestational age were compared, 0.2 mg intravenously or 0.5 mg intramuscularly led to VK_1 2,3-epoxide accumulation whereas 0.2 mg intramuscularly did not. The protection lasted almost 3 weeks following which additional supplementation was needed [47]. A prolonged PT in a preterm infant in the first month of life who has received intramuscular VK at birth is unlikely to be due to VK deficiency.

All infants with late-onset bleeding require testing for associated disorders. The importance of VKDB is reflected in the number of continuing reviews of the subject [48, 49].

Coagulation Disorders: Risk of Thrombosis in the Newborn

Angelo C. Molinari and Paola Saracco

100.1 Introduction

Newborns comprise the largest group of children developing thromboembolism (TE), due to the peculiarities of their developmental hemostatic systems.

The hemostatic system of the healthy neonate, although immature, is generally in balance; on the other hand, in the sick newborn, especially preterm ones, numerous acquired perinatal and iatrogenic conditions might result in a disturbance between coagulation and fibrinolysis, leading to thrombus formation. Nevertheless, the contribution of acquired prothrombotic disorders in the pathogenesis of thromboembolic disease in newborns remains poorly defined.

Little data is currently available regarding the influence of maternal or fetal genes on thrombotic risk in the fetus and neonate.

Due to the unique peculiarities of their developmental coagulation system, newborns are at highest risk of developing TEs among pediatric patients [1–3].

Recently, several studies based on national and international registries [4–7] have evaluated the role of risk factors for thrombosis both in children and newborns, emphasizing the differences between different pediatric and adult ages.

Nevertheless, at present there is no definitive consensus about recommendations on screening for thrombophilia in newborns with TEs.

The present chapter provides an overview of the current knowledge about the role of inherited, acquired perinatal and maternal prothrombotic risk factors as well as clinical and laboratory investigations in neonatal systemic arterial and venous thrombosis.

For neonatal central nervous system (CNS) thrombotic events, see Chapters 139 and 142.

100.2 Relevance of Laboratory Investigation of Coagulation in Newborns

Given the significant differences between the plasma factor concentrations in different age groups, a detailed knowledge on the development of hemostasis is critical for the neonatologist/intensivist in order to adapt pharmacological approaches and interpret results from laboratory tests in the neonate with TE [8]. Recently, in the first large scale study since Andrew et al [9–11], determining the age associated numerical changes in coagulation proteins, results clearly demonstrated that the absolute values of reference ranges for coagulation assays in neonates and children vary with analyzer and reagent systems. In this study the authors also present for the first time age related ranges for tissue factor (TF) pathway inhibitor (TFPI), D-Dimer and ETP [8].

Thus, coagulation laboratories should develop age-related reference ranges specific to their own testing systems. Without this, accurate diagnosis and management of neonates and children with suspected bleeding or clotting disorders is not possible.

Additional risk factors, as congenital thrombophilia or critical illness, have to be considered separately from the immaturity of neonatal hemostasis

100.3 Inherited Thrombophilia

The term thrombophilia is used to describe an extensive range of inherited defects in the coagulation system, in the fibrinolytic system, in the endothelial cells and in platelets, which are likely to predispose to thrombosis. Over the last decade the number of identified prothrombotic abnormalities has increased dramatically.

Genetic prothrombotic polymorphisms FV G1691A, also reported as R506Q and commonly called FV Leiden (FVL), Factor II G20210A (PRT G20210A) mutation and

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

the homozygous TT genotype of the methylentetrahydrofolate reeducates (MTHFR) C677T polymorphism, are established inherited thrombophilic condtions [12]. The FVL mutation is the most common genetic prothrombotic risk factor, with a prevalence of 4–6%; the presence of the PRT G20210A mutation (1–2% of Caucasians) has the potential to increase circulating concentrations of FII by 15–30%; homozygous mutations of MTHFR C677T (9–19% of Caucasians) produce a defect in the remethylation of homocysteine into methionine, with the end result being hyperhomocysteinemia. Currently, prospective clinical trials employing vitamin therapy are ongoing to determine whether hyperhomocysteinemia is a risk factor for atherothrombosis. Thus, the association between the MTHFR C677T gene mutation and the risk of pediatric thrombosis remains controversial [13]. The prevalence of mutations in protein C (PC), protein S (PS) and antithrombin (AT) is 0.023, 0.037 and 0.019, respectively; despite the low prevalence, the congenital deficiencies of these natural anticoagulants are the most important inherited thrombophilic conditions. Newborns with severe deficiency of PC, PS, or AT (due to homozygous or compound heterozygous conditions) usually present with purpura fulminans or extensive multiple TEs. More recently, some studies indicated that increased lipoprotein(a) [Lp(a)] concentrations play an important role in childhood and neonatal thrombosis in the German population [14–16]; however it is unclear whether this can be applied to all populations. Other very rare disorders, such as dysfibrinogenemia, dys/hypoplasminogenemia and homozygous homocystinuria have been associated with an increased risk of thrombosis but their role in favoring thrombotic events in newborns is unclear.

The evaluation of a neonate with a significant TE event for a genetic prothrombotic disorder is a debatable subject. There is some evidence that an infant with multiple trait thrombophilia and symptomatic thrombosis is at increased risk of thrombus recurrence, although those recurrent events usually occur in the setting of other comorbidities, such as infection, surgery, or trauma. In addition, there are no recommendations on secondary prevention of thromboses in infants with thrombophilia. However, many experts believe that screening for thrombophilia is warranted in a neonate with a symptomatic TE, regardless of other acquired risk factors [17, 18].

100.4 Maternal Thrombophilia and Gestational Risk Factors

Few data are currently available regarding the influence of maternal thrombophilia (prothrombotic polymorphisms, dislipidemia, antiphospholipid antibodies) and prenatal gestational risks (gestational diabetes, pregnancy-induced hypertension-preeclampsia, intrauterine growth restriction) on thrombotic risk in the fetus and neonate.

During gestation, the maternal and fetal circulation systems coexist and interact with the placenta. Association between thrombosis and infarction in the placenta and peri- and neonatal infarction, the most commonly presumed mechanism being embolization to the fetus, has been reported in literature [19–21].

Pregnancy itself is a prothrombotic state as shift toward prothrombotic reactions is seen in women as gestation progresses through the second and third trimesters and just after gestation (increased levels of vitamin K-dependent FII, FVII and FX; increased levels of thrombin anti-thrombin (TAT), increased endothelial activation with elevated levels of circulating von Willebrand factor (VWF) and soluble thrombomodulin; increased triglyceride and Lp(a) levels; reduced levels of free and total PS and reduced activated PC sensitivity ratio) [22]. However, maternal thrombosis during and just after pregnancy often occurs in the presence of additional risk factors (i.e., advanced maternal age, cesarean section, hypertension, gestational diabetes, infections, pre-eclampsia/eclampsia, antiphospholipid syndrome, and inherited thrombophilia). Some of these maternal factors may also predispose to placental infarction with subsequent cerebral infarction in the fetus.

Pre-eclampsia may lead to endothelial activation of coagulation. Gestational diabetes leads to maternal vascular damage, which can predispose to placental thrombosis and infarction. In case of chorioamnionitis, inflamed vessels of the placenta lead to localized thrombosis, vasospasm and infarction and maternal sepsis during gestation may lead to disseminated intravascular coagulation (DIC) resulting in placental thrombosis and infarction, too. Maternal smoking may lead to vasospasm and/or endothelial activation with resulting placental injury and growth restriction and maternal cocaine use may predispose to vasoconstriction with resulting placental infarction. Moreover, thrombocytosis has been observed in neonates of mothers with history of polydrug use. At the time of delivery, placental-fetal transfusion may lead to polycythemia [23]. Antiphospholipid syndrome (APLS) in pregnancy is characterized by the presence of auto antibodies in association with recurrent fetal loss and severe complications such as pre-eclampsia, fetal growth restriction, or placental insufficiency [24].

In a review of the literature until 2007 of infants born to mothers with antiphospholipid antibodies (aPL), 16 infants with perinatal thrombosis were reported. Thromboses were arterial (13/16), mostly strokes (8/16). Hydrops fetalis with left renal vein thrombosis was associated with a lupus anticoagulant (LA) present only in the child. Additional risk factors to aPL, either prenatal (pre-eclampsia and/or intrauterine growth restriction) or perinatal (asphyxia, sepsis, arterial or venous catheter and congenital thrombophilia) were present (one to four of them) in nine out of the 14 evaluable babies. aPL were the only risk factor found in five full term babies who suffered from stroke in four cases and from renal thrombosis in another. Eleven of these infants with aPL in their serum presented a neonatal APS with the same antibody (LA or aCL IgG) found

in neonates and their mothers, while the other infants had thrombosis with aPL only in their mother's blood.

100.5 Environmental and Iatrogenic Modifications

Endothelial, coagulation, and fibrinolytic systems are activated in newborns; this might occur during birth due to the mechanical stress, the adaptation of circulation, and the short-term hypoxic state [25].

Generation and inhibition of thrombin was compared with healthy neonates. Fifty neonates with respiratory failure requiring mechanical ventilation and 40 healthy neonates were studied on day 1 of life. Eight plasma pools from 40 healthy neonates of GA 30 LA or aCL 38 wk were compared with six plasma pools from 30 sick neonates of GA 30-38 wk. An additional four plasma pools prepared from 20 sick neonates of GA less than 30 wk were studied. Thrombin generation was similar for both healthy and sick neonates of GA 30-38 wk. However, the inhibition of thrombin was impaired in plasma from sick neonates of GA 30-38 wk compared with plasma from healthy neonates of GA 30-38 wk (4.37 ± 0.22 versus 5.21 ± 0.21 nmol; p less than 0.05) [26].

A combined hemostatic defect consisting of a reduction in certain procoagulant, anticoagulants (AT, PC) and components of the fibrinolytic system (PLG) was demonstrated in very-low-birth-weight infants (VLBW <1,500 g) with gestational age (GA) 26–32 weeks. Sixteen of them were healthy, 28 were suffering from RDS and 24 from septicemia. The hemostatic defect was more profound in the RDS group, nevertheless increased TAT and/or PAP values were a more frequent finding in the septicemic group of infants (91.8 *vs* 17.9%). Increased D-Dimers were demonstrated in 34.8 and 28.6% of the infants, respectively [27].

The modality of delivery (spontaneous vaginal delivery *vs* elective caesarian section) has been demonstrated to be able to modify the levels of PS, PC and AT; plasma collected from cord blood of 41 consecutive healthy newborns, 18 delivered vaginally (mean GA 39.7 ± 0.8) and 23 by elective caesarian section (mean GA 38.5 ± 0.7) were tested for AT activity, PC antigen and activity, total and free PS antigen, F1 concentration and PLG activity; among factors studied in cord blood of infants born after vaginal delivery, PC antigen levels and AT activity were statistically higher (41.3 ± 9.4 *vs* 33.9 ± 7.2 and 58.5 ± 10.0 *vs* 48.4 ± 12.7, respectively; $P < 0.01$), while free PS was significantly lower (36.8 ± 11.6 *vs* 46.4 ± 12.5; $P < 0.05$) than in newborns delivered by caesarian section. Cord blood PLG and F1 were elevated in vaginally delivered neonates in comparison to those delivered by caesarian section, but the difference was not statistically significant [28].

In a small group of newborns with CVL, increased platelet activation and VWF binding to platelets has been significatively recorded [29].

100.6 Neonatal Non-CNS Thrombotic Events

100.6.1 Epidemiology and Thrombus Location

Neonatal symptomatic thrombosis (excluding stroke) is reported to occur in 2.4/1,000 admissions to neonatal intensive care units according to an international Registry from Canada, USA, and Europe; 64 among 97 (66%) registered events are venous thrombosis [6]. In a German prospective nation-wide two-year registry, incidence of clinically apparent neonatal TEs (including cerebral events) is 5.1/100,000 live births; 76% are venous events [5].

Both arterial and venous non-CNS thrombosis in the newborn may be located in several anatomic sites (i.e., venous events: deep vein thrombosis of the limbs, intrathoracic vessels, pulmonary embolism, renal veins, hepatic veins, superior and inferior caval veins, portal vein, right intracardiac thrombosis, mesenteric veins, retinal vein; arterial events: aorta, left intracardiac thrombosis, renal artery, mesenteric artery and limb artery).

100.6.1.1 Venous Systemic Thrombosis

Neonatal renal vein thrombosis (RVT) is the most common non-catheter-related thrombosis in infancy. It has been reported to occur in 0.5/1,000 admissions in neonatal intensive care units; according to the German Registry the incidence is 2.2/100,000 live births [30]. It usually presents within 3 days after birth in neonates born at term; in 7% of neonates it presents in uterus and a male predominance has been reported [31, 32].

Central venous line (CVL) related venous thromboses (VT) are commonly associated with indwelling central venous catheters. Compared to adults, newborns presents a higher incidence of thrombosis of the superior limbs, due to the strong association with CVL placement in the upper venous system [33].

Portal vein thrombosis (PVT) is described in the neonate secondary to umbilical venous catheter insertion. A retrospective analysis reported 133 infants (all but 5 of whom were neonates) with portal vein thrombosis, with an incidence of 3.6/1,000 admissions; an umbilical vein catheter had been inserted in 73% of the infants and was not in an appropriate position in half of them [34].

The frequency of pulmonary embolism (PE) during the newborn period is unknown but likely underestimated because the clinical features are often subtle or masked by the presence of underlying lung disease. In a retrospective autopsy series an incidence of 14% has been reported [35].

100.6.1.2 Arterial Systemic Thrombosis

Arterial thromboses (ArT) represent almost 50% of all neonatal TEs and are mainly iatrogenic complications, associated

with catheterization of the femoral artery as well as peripheral arteries and umbilical artery.

The reported incidence of umbilical artery catheter-related TE is considerably influenced by the diagnostic test chosen. Studies considering only symptomatic TEs report an incidence of 1–3%, while studies using ultrasound and angiography report an incidence of 14–35% and 64%, respectively. In autopsy series an incidence of 9–28% has been reported [36]. Spontaneous, non catheter related ArT are uncommon in the newborn period and most frequently involve the aorta. Mortality rate has been reported in around 33% of pediatric thrombotic disease [37].

100.6.1.3 Intracardiac Thrombosis

Venous intracardiac thrombosis involving the right atrium frequently occurs in newborns with central venous lines (CVL), but no incidence data are reported in the literature. Thrombosis involving the right ventriculum is uncommon. Left intracardiac thrombi (atrium and ventriculum) are rare events usually occurring in children with underlying risk factors such as congenital heart disease, cardiovascular surgery or arrhythmia [38–40].

100.7 Risk Factors

100.7.1 Inherited Thrombophilia

At present, the role of thrombophilic proteins in both arterial and venous systemic thrombotic events in the neonate remains poorly defined; on the other hand, the presence of an indwelling line is clearly identified as the most important risk factor.

Manco-Johnson et al [41] did not find any association between thrombophilia and catheter related events in newborns, in contrast with previously published data by Nowak Gottl et al [42] who detected an high incidence of inherited prothrombotic factors in a cohort of infants and children, ranging from neonates to 18 years, with catheter related events.

In the registry from Netherlands, a higher incidence of thrombophilia in older children (21%, 95% CI 8–34%) than in neonates (6%, 95% CI 0–16%) was detected [7], while in the study by Revel-Vilk et al [43] the overall frequency of inherited prothrombotic proteins was similar in newborns and older children (13%). Kosch et al [44] investigated the prevalence of prothrombotic risk factors in renal vein thrombosis: the study evidenced a significant association with genetic risks, especially FVL and Lp(a).

Registry data and case studies have demonstrated that the majority of symptomatic neonatal TEs, especially spontaneous events (i.e., not catheter-related) are associated with multiple hemostatic prothrombotic defects or with the combination of prothrombotic defects and environmental or clinical conditions. As a result, the Perinatal/Pediatric Hemostasis Subcommittee of the International Society on Thrombosis and Hemostasis has recommended that pediatric patients with thrombosis (regardless of risk factors) should be tested for a full panel of genetic prothrombotic traits [17].

100.7.2 Acquired Risk Factors

The presence of an indwelling line has been identified as the most important acquired risk factor for the development of both arterial and venous systemic events, spontaneous non catheter-related events being relatively uncommon. Neonates in the neonatal intensive care unit may have umbilical artery (UAC) and vein (UVC) catheters as well as additional intravenous lines. These can cause damage of the endothelium wall and activation of the coagulation cascade. In a large prospective study, 148 neonates with both umbilical arterial and/or venous catheters were serially screened for thrombosis in abdominal aorta and inferior vena cava by 2-D ultrasonography. Abdominal aortic thrombi were detected in 32.3% of infants with UAC and small thrombi were detected in the inferior vena cava of 4.1% of infants with UVC. The only significant risk factors associated with abdominal aortic thrombosis was the presence of UAC compared with UVC and longer duration of UAC in situ [45]. Excluding renal vein thrombosis, catheter-related events accounted for 89% and 94% of TEs in the Canadian and Netherlands' Registry, respectively [6;7].

Central line placement is a recognized risk factor also for thrombosis involving the right atrium. Other identified risks for intracardiac events are congenital heart diseases (i.e., aortic coarctation), cardiac surgery, and ECMO [39, 40, 46].

Perinatal asphyxia, prematurity, dehydratation and maternal diabetes are established risk factors for renal vein thrombosis. However, in a recent review by Lau et al [32], pertaining to all the available literature about venal rein thrombosis, among 271 patients less than one third had a history of perinatal asphyxia, and dehydratation and maternal diabetes were even less common. One third (28%) of patients were before 36 weeks of gestation.

Numerous clinical and environmental conditions such as the use of central lines, cardiac diseases and polycythemia, renal diseases such as congenital nephrotic syndrome and neonatal hemolytic uremic syndrome, peripartum asphyxia, infants of diabetic mothers, dehydration, septicemia, necrotizing enterocolitis, acute respiratory distress syndrome, and extracorporeal membrane oxygenation lead to elevated thrombin generation and subsequent thrombus formation [47].

100.8 Clinical Investigation

The clinical picture of vascular incidents in neonates is extremely variable and largely dependent on the location and

the size of the thrombus or embolus. Presentation may vary from discrete symptoms or asymptomatic events to life or limb threatening acute events; as several right-to-left (i.e., venoarterial) shunts remain patent for a considerable time in the neonate, a paradoxical embolus cannot be ruled out even in the absence of congenital heart disease.

100.8.1 Arterial Thrombosis

Arterial vascular events are almost always directly related to arterial vascular catheterization of central or peripheral arteries. This underscores the need for meticulous clinical observation in children with arterial access in place. Obvious signs include ischemia of limbs or trunk, pale or cold extremities distal to the catheterization site, weak or absent palpability of the pulse (pulse oximeters will also show this) and decreased or immeasurable blood pressure. Signs of necrotizing enterocolitis such as feed intolerance, bilious gastric aspirates, blood-stained stools, and bowel wall pneumatosis in an infant with an umbilical arterial catheter should raise the suspicion of mesenteric infarction. Diagnostic work-up for renal failure in children with UAC should include a Doppler flow study of the renal arteries to avoid missing out on the diagnosis of renal artery thrombosis. Elevated blood pressure might also hint at decreased renal perfusion.

There are some reports of aortic thrombosis in the neonate mimicking coarctation of the aorta with significant blood pressure differences in upper and lower body blood pressure readings; thus, the simple investigation of upper and lower body blood pressure measurements should be performed in any infant with hypertension diagnosed by measurements obtained from the upper body [48].

100.8.2 Venous Thrombosis

Limb swelling, pain, and cyanotic or hyperemic color should raise the suspicion of venous thrombosis.

100.8.2.1 Renal Vein Thrombosis

RVT may present with an abdominal mass and hematuria or proteinuria; hence, these symptoms should ring a bell especially in neonates with risk factors such as prematurity, asphyxia, critical illness, femoral CVL, and male sex [30, 31].

100.8.2.2 Portal Vein Thrombosis

Signs of impaired liver function, hepatomegaly and splenomegaly should raise the suspicion of PVT; however, only about 10% of children with PVT develop acute clinical symptoms [34]. Thrombosis of the inferior vena cava can present with signs resembling obstruction of the renal vein (hematuria, retroperitoneal mass); however, these will occur bilaterally when the inferior vena cava is affected. In addition, the lower limbs may be edematous and, if blood flow is substantially impaired, the child may be in respiratory distress and may have high blood pressure.

100.8.3 Pulmonary Embolism

PE is a rare event in the neonatal period. Clinical signs of massive ventilation/perfusion mismatch, difficult oxygenation, and signs of right heart failure should raise the suspicion of PE, especially in babies with congenital heart disease. In the few cases reported in the literature, diagnosis of PE was confirmed by lung perfusion scans or angiography [49–51].

For further information on central nervous system thrombotic events, see Chapters 139 and 142.

100.8.4 Laboratory Investigation in Newborns with Thrombosis

Initial laboratory work-up in a neonate in whom thrombosis is suspected should include a full blood count as well as a coagulation screening with determination of prothrombin time, thrombin time and activated partial thromboplastin time.

100.8.4.1 D-Dimers

D-Dimers, which are elevated as an acute phase reaction in all patients with infection or a systemic inflammatory response syndrome, are a positive finding in almost all critically ill neonates. Conversely, negative D-Dimers might be relatively accurate in ruling out thrombosis in most patients, including neonates.

100.8.4.2 Platelets

In almost all neonates, platelets number decreases after birth. However, a sudden and severe drop in platelet counts should alert the intensivist. Although the differential diagnosis for thrombocytopenia in the neonate is broad, including auto- and allo-antibodies as well as effects of medications and consumption, thrombocytopenia remains one of the most sensitive indicators for micro- (in the setting of sepsis) or macro-circulatory thrombosis.

100.8.4.3 Thrombophilia Testing

Current evidence does not resolve the issue of thrombophilia testing, but a stepwise thrombophilia investigation in any

Table 100.1 Thrombophilia testing

Initial Laboratory Testing
Antiphospholipid antibody panel
Anticardiolipin antibodies and lupus anticoagulant (IgG, IgM)
Fibrinogen

Heparin cofactor II activity

neonate with a significant TE event is reasonable. A limitation to this approach is the amount of blood required. This is especially important in the premature or anemic infant, for whom excessive blood loss is not tolerable. Therefore, the evaluation should always take place at an experienced tertiary care center that has either a reference laboratory or a reliable referral center. The physiological reduction of some coagulation factors and anticoagulant proteins may lead to a difficult interpretation of laboratory investigations and therefore deficiencies need to be confirmed by repeat testing later in infancy (i.e., beyond 6 months or afterward in premature infants) [18]. As screening all newborns with TEs for a wide range of prothrombotic disorders may be prohibitively expensive, targeted screening may be more effective.

In case of a clinically significant spontaneous TE or ischemic skin lesions, it is mandatory to look for homozygous deficiency of PC and PS, as a specific treatment option is available. In remaining cases a stepwise approach starting with most common risk factors may be reasonable. Testing of natural anticoagulants for detecting a heterozygous defect should be performed after 6 months of age. The protein-based assays are affected by the TE event and must be repeated at 3–6 months of life, before a definitive diagnosis can be made. If anticoagulation is being administered, then the protein-based assays should be obtained 14–30 days after discontinuing the anticoagulant.

DNA-based assays are neither influenced by the acute thrombotic event nor by the treatment; Lp(a) concentrations tend to increase during the first year of life and should be repeated at 8–12 months if the original values are low, especially in white individuals.

In case of positive result for genetic thrombophilia in the newborn, testing of both parents (FVL and PRT G20210A mutations, Lp(a), natural anticoagulants) may be offered; in case of negative screening, testing of mother has been suggested for the newborn with perinatal stroke [52]. All these tests should be performed in the non acute setting as they are not useful to support management decisions but only for counseling about possible risks to parents theirselves and of other or future children. However, in those countries where the health system is mainly managed by insurance companies, family members should be carefully informed about the possible consequences of this screening (i.e., potential insurance issues) without potential specific benefit to the individual being screened.

Coagulation Disorders: Inflammation and Thrombosis

Jennifer L. Armstrong-Wells and Marilyn J. Manco-Johnson

101.1 Introduction

With a fifteen-fold increase in rate compared with infants and children, thrombosis is an important problem in the neonate. Most neonatal thromboses are diagnosed in the intensive care nursery in association with myriad underlying disorders, many of which are inflammatory. Clinically, most cases of neonatal thrombosis occur in two discrete populations: spontaneous perinatal events (primarily stroke and renal vein thrombosis) or catheter-related thrombosis related to neonatal intensive supportive care. The relationship of inflammation to these two categories of thrombosis is currently unknown.

A bidirectional cross-talk between inflammation and thrombosis has been elucidated in recent years [1]. Inflammatory cytokines activate coagulation via stimulation of tissue factor expression on endothelial and monocyte cell surfaces, decrease natural anticoagulant mechanisms and impair fibrinolysis [1]. The procoagulant enzyme thrombin activates the acute inflammatory response via intracellular signal transduction initiated through protease activated receptors (PARs) of endothelial cells [2]. The link between inflammation and arterial thrombosis and atherosclerosis has been clearly established in adults [3]. Data implicating inflammation and venous thrombosis has been less clear [4]. While the inflammatory marker C-reactive protein (CRP) performs similarly to D-dimer as a predictor in the diagnosis of venous thromboembolism (VTE) in adults, the use of CRP as a biomarker predicting the development of new VTE was not significant after correcting for the effect of body mass index (BMI); however, this risk factor is not clinically relevant in the newborn infant [4]. This chapter will explore evidence for the association of inflammation and thrombosis in perinatal arterial and venous events.

101.2 Etiology and Pathogenesis

101.2.1 Placental Inflammation, Thrombi and Infarcts

A role for inflammation, coagulation activation and thrombosis in diverse fetal and perinatal pathologies was suggested by the finding of placental thromboses and infarcts in cases of fetal growth restriction or demise. Histologic evidence of chronic inflammation of the distal placental villous tree is found in 76–136/1000 live births; evidence for an infectious etiology of this placental inflammation, known as villitis of unknown etiology (VUE) has been lacking [5]. At the more extreme end of this pathologic spectrum, a true fetal large vessel vasculitis develops with vessel wall damage, occlusion and, potentially, release of inflammatory cytokines into the fetal circulation [5]. Fetal thrombotic vasculopathy is significantly more frequent in the placentas of term infants with neurologic impairment [6]. A systematic review of inflammatory biomarkers in term infants with neonatal encephalopathy determined elevated levels of interleukin-6 (IL-6) in cord blood as positive predictors of adverse neurologic outcome [7]. Whether neurologic damage in fetal thrombotic vasculopathy is mediated by thrombotic ischemia or direct inflammatory damage to neurons is currently unresolved.

101.2.2 Mutations in Genes Involved in Inflammation

Reports of vascular impairments in infants found to carry genetic mutations affecting proteins involved in inflammation have shed rare clues into the physiologic gestational and perinatal interactions between inflammation and coagulation. A polymorphism in the promoter region of the cyclooxygenase-2 gene (-765 G>C), conveying 30% reduction

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

in the expression of COX-2 levels with GC or CC polymorphisms compared to GG, was associated with a three-fold reduction in histopathological evidence of placental ischemia and malperfusion and a four-fold reduction in the rate of intrauterine growth restriction [8]. Reduced levels of COX-2 have been associated with decreased levels of CRP and thromboxane A2 and increased prostaglandin E2 [9–11]. Conversely, an autoinflammatory disease caused by a 175-kb homozygous deletion at chromosome 2q13, which encompasses several interleukin-1 (IL-1) family members including the IL-1-receptor antagonist, was associated with marked elevations in markers of inflammation including CRP and extensive systemic thrombosis during the neonatal period [12].

In a study of over 1000 very low birth weight infants, there was no increase in adverse outcomes, including sepsis, bronchopulmonary dysplasia, intraventricular hemorrhage or periventricular leukomalacia in carriers of the thrombophilia mutations, factor V Leiden or Prothrombin 20210 [13]. Interestingly, the factor XIII-Val34Leu mutation, which results in thinner fibrin fibrils that are more resistant to fibrinolysis, was associated with an increased risk of sepsis. Additionally, the factor VII-323del/ins (323 A1/A2) promoter polymorphism, which is associated with a 20% decrease in plasma factor VII activity, was associated with a reduced risk of bronchopulmonary dysplasia. The tissue factor/factor VII complex promotes inflammation through activation of PARs; lower levels of factor VII activity could result in decreased inflammatory signaling. In both of these examples, mutations in coagulation genes exerted effects on neonatal outcomes through interactions with inflammatory pathways, rather than by direct effects on hemostasis and thrombosis.

101.2.3 Maternal Inflammation and Predictors of Fetal/Neonatal Thrombosis

Most investigations of neonatal inflammation and thrombosis have been performed in the context of arterial ischemic stroke. Perinatal stroke can be seen in a variety of systemic disturbances, and manifests as perinatal arterial ischemic stroke (PAS), perinatal hemorrhagic stroke (PHS), or cerebral sinovenous thrombosis (CSVT). While birth trauma and delivery-related anoxia were previously thought to be major causes of perinatal stroke, new studies now invoke other pathogeneses, including inflammation. Maternal factors, such as infertility, diabetes, pre-eclampsia and chorioamnionitis, have been associated with PAS [14–16]. Chorioamnionitis has also been associated with neonatal CSVT [17]. Further, fetal distress and postmaturity are strong predictors for intracerebral hemorrhage in term and late preterm newborns [18]. Therefore, inflammatory risk factors for perinatal stroke are identifiable before birth, allowing the unique opportunity for early screening and intervention for those newborns identified at risk.

101.2.4 Antiphospholipid Antibodies in Pregnancy

Maternal inflammatory factors may also play a pivotal role in neonatal thrombosis, including stroke, as pregnant women with antiphospholipid antibodies (APA) have a higher rate of placental thrombosis [19]. APA can be acquired and transiently observed with infection, tissue injury, and certain drugs, or can be part of an autoimmune syndrome. The diagnosis of obstetric antiphospholipid syndrome (APS) requires at lease one clinical and one laboratory criterion. Clinical criteria include objectively confirmed vascular thrombosis or pregnancy morbidity. Qualifying obstetrical complications include: three or more unexplained consecutive spontaneous abortions before the tenth week of gestation; one or more unexplained deaths of a morphologically normal fetal beyond the tenth week of gestation, with morphology confirmed by direct examination or ultrasound; or one or more births of a morphologically normal premature infant of less than 34 weeks gestation due to eclampsia, severe preeclampsia or recognized features of placental insufficiency [20].

It has been speculated but not proven that the syndrome of hemolytic anemia, elevated liver enzymes and low platelets (HELLP) of pregnancy is induced or exacerbated by APS in pregnancy. Laboratory criteria required for the diagnosis of APS include medium to high-titer IgG and/or IgM ACA or anti-β_2GPI antibodies detected in an ELISA assay or the presence of the lupus anticoagulant (LA). The diagnosis of the LA requires prolongation of a phospholipid-based clotting assay, failure to correct the prolongation with addition of normal plasma and correction with addition of excess phospholipid.

The mechanisms of adverse pregnancy outcomes in obstetrical APS include: direct fetal resorption and placental insufficiency; abnormal development of spiral arteries of the placenta; damage to placental trophoblasts; interference with the activation of protein C; interference in fibrinolysis; alterations in the structure and function of annexin V; increase in proinflammatory cytokines; and increase in complement activation [20]. Obstetrical morbidity and fetal loss increase with the number of positive APA tests [21]. Transplacentally-derived maternal APA may be risk factors for perinatal stroke or thrombosis [16, 22, 23].

101.2.5 Cytokines

Cytokines are small, soluble polypeptides that bind to cell surface receptors, instigating myriad responses by changing the behavior of target cells. Cytokines both mediate inflammation and are elicited as part of an immune response [24]. Individual cytokines rarely work in isolation, but rather act with other cytokines, whether it be by inhibition, synergism, or other unpredictable effects; they may also induce release of other cytokines, the so-called cytokine cascade [24].

Cytokines have recently been recognized as integral in endothelial cell maintenance. Cytokines can promote expression of adhesion molecules, while activating the endothelium, leading to procoagulant activity. Specifically, IL-1 has been shown to cause endothelial cells to generate and express tissue factor on their cell surface, which allows binding of Factor VIIa, and therefore initiates the extrinsic clotting pathway. IL-1 and tumor necrosis factor (TNF-α) also inhibit anticoagulant APC by decreasing thrombomodulin expression. Both IL-1 and TNF-α also increase plasminogen activator inhibitor type 1 (PAI-1), which inhibits the intrinsic fibrinolytic system of the endothelial cell. Therefore, IL-1 and TNF-α are thought to work in an additive fashion as procoagulant cytokines. Further, they are also classified as inflammatory cytokines, with ultimate induction of leukocyte activation and adhesion by the cytokine cascade (IL-1) as well as direct endothelial action and lymphocytic inflammation (TNF-α). Other cytokines have also been classified as proinflammatory, including IL-2, IL-6, and IL-8. Additionally, IL-18 (formally known as IL-1γ because of its homology to IL-1β) has been implicated in ongoing inflammatory brain injury [25, 26].

Because of the similarity between endothelial damage caused by inflammatory cytokines and damage determined in preeclampsia, levels of circulating cytokines in preeclampic women have been studied. Increased levels of TNF-α and IL-6 have been found to be increased in women with preeclampsia [27, 28]. It has been shown that in infants with neonatal hypoxia, encephalopathy or subsequent cerebral palsy, elevated serum levels of IL-1β, IL-6 or IL-8, cerebrospinal fluid levels of IL-1β or neuron-specific enolase, or brain concentrations of IL-1β or TNF-α have been determined [29, 30]. These proinflammatory cytokines, triggered by infection or hypoxia, are involved in a final common pathway within a molecular cascade that may lead to perinatal brain damage [31, 32]. Consequently, this inflammatory reaction is suggested to arise from the fetus itself – the so-called fetal inflammatory response – and has been postulated as a mechanism for perinatal brain injury [31]. Studies conducted to date demonstrate that the fetal inflammatory response and cytokine activation – with possible underlying genetic susceptibility – is associated with cerebral palsy in the term/late preterm newborn, and therefore may be also be associated in the pathophysiology of perinatal stroke [29–31].

101.3 Inflammation and Systemic Neonatal Thrombosis

Less data exist regarding the relationship of inflammation to thrombosis in other syndromes of neonatal thrombosis. In one study of newborn infants undergoing palliative surgery for single ventricle congenital heart disease, pre-operative elevations in CRP predicted post-operative venous thrombosis [32]. Thornburg and colleagues reported a positive association between thromboses and infections in newborn infants who did not have lines removed for infection and described a subset of catheter-related thromboses in newborn infants characterized by onset late in the presence of catheter associated blood stream infection [33]. They hypothesized that catheter-related thrombosis in the newborn infant may be caused by inflammation induced by infection. Other systemic thrombi that occur in the perinatal period, particularly renal vein thrombosis, could be hypothesized to occur through similar mechanisms of placental inflammation with systemic emboli through the umbilical vein; however, there is currently no objective evidence to support this.

101.3.1 Clinical Aspects

To date, there is almost no clinical application of existing data on the contributions of inflammation to the prediction, prevention or management of thrombosis in the newborn infant. The one exception is obstetrical APS in which clinical testing and management of the newborn infant by a skilled perinatal team can be facilitated by known APA positivity in the mother. There are some intriguing data that neonatal inflammation may be predicted by maternal obstetrical conditions, and that adverse consequences of fetal and neonatal inflammation, primarily effects on perinatal brain development, may be ameliorated by interventions targeted to antagonize neonatal proinflammatory cytokines and promote anti-inflammatory cytokines [31].

101.3.2 Differential Diagnosis

There is no direct application of emerging knowledge regarding placental and fetal inflammation on differential diagnosis of neonatal thrombosis. However, neonatologists caring for infants born to mothers with the obstetrical conditions discussed above that are characterized by the inflammatory response, may be alerted to a potential increased risk for thrombosis in these infants, facilitating prompt recognition and diagnosis of clinical thrombosis.

101.3.3 Prognosis

There is evidence from preliminary research studies that serum and cerebrospinal fluid IL-1β, serum IL-6 and cerebrospinal fluid neuron-specific enolase predict poor neonatal outcomes [29]. However, none of the research in cytokine biomarkers has been developed to clinical usage. The prognosis of neonatal thrombosis related to maternal or fetal/neonatal inflammatory conditions, such as choramnionitis or obstetrical APS, is related to the site, extent and response to therapy of the thrombus itself.

101.3.4 Therapy and Treatments

Currently, the only neonatal antithrombotic therapy specifically influenced by inflammation is neonatal thrombosis in an infant with APA. In addition to standard anticoagulant and thrombolytic agents, some affected infants have been treated with isovolemic exchange transfusion and low dose aspirin [23].

Recommendations for antithrombotic therapy in the newborn infant with thrombosis (excluding PAS) are given in Table 101.1 [34]. The risk of thrombus progression and recurrence in the newborn infant appears to be low. This may be because most perinatal inflammation promoting thrombosis appears to derive from placental and maternal inflammatory conditions that are resolved once the infant is born. For this reason, antithrombotic therapy in PAS is generally not indicated. Peripheral arterial thrombi may be treated until blood flow is restored and additionally for a brief period (e.g., 48 hours) thereafter; the entire course is often 10–14 days. The Chest guidelines for antithrombotic therapy suggest a standard duration of anticoagulation of three months for the neonate, equal to that recommended for older children and adults [35]. However, resolution of venous thrombi in the newborn infant is often rapid and thrombus recurrence risk is low. If the underlying trigger for thromboembolism is reversed, extracranial venous thrombi may be treated until thrombus resolution, which often occurs within 10–30 days. Neonatal renal vein thrombosis has been a particularly challenging lesion with no therapeutic regimen particularly effective and the majority of affected infants suffering sequelae of partial or complete renal infarction or hypertension [36, 37]. Although some advocate for the use of heparin-based therapy in neonatal CSVT, most clinicians agree that treatment is determined on a case-by-case basis; treatment may be withheld unless the thrombus is progressive.

Tissue plasminogen activator (TPA), interventional thrombolysis and/or mechanical thrombectomy is useful in selected cases of extracranial thrombosis, provided contra-indications are strictly followed as outlined in Table 101.2. Thrombolysis is indicated chiefly when life-or limb-threatening ischemia is present, and should be considered for completely occlusive thrombi of the aorta, superior or inferior vena cava, abdominal thrombi, and arterial occlusions of the limb. There is no role at this time for TPA, interventional thrombolysis or mechanical thrombectomy for cerebral thrombosis (PAS or CSVT) in the neonate.

Table 101.1 Dosing for antithrombotic therapy in children

	Unfractionated Heparin Continuous IV	Enoxaparin Every 12 hours subcutaneous	Tissue Plasminogen Activator Continuous IV
Loading dose	Newborn < 37 weeks: 50 U/kg Newborn ≥ 37 weeks: 100 U/kg	None	None
Initial maintenance dose	Newborn < 37 weeks: 20–25 U/kg/hr Newborn ≥ 37 weeks: 28 U/kg/hr (may need up to 50 U/kg/hr hr to achieve therapeutic anti-Xa level)	1.5 mg/kg/dose 1.5 mg/kg/dose (may require up to 2.0 mg/kg/dose)	0.06–0.12 mg/kg/hr 0.06–0.12 mg/kg/hr
Monitoring	Anti-Xa activity following 4–6 hours of infusion; Target range 0.3–0.7 U/mL	Anti-Xa activity 4 hours following 1st or 2nd dose; Target range 0.5–1.0 U/mL	

Table 101.2 Contraindications to specific antithrombotic therapies in newborn infants and children

Unfractionated heparin	Low molecular weight heparin	Systemic TPA	Thrombolysis by interventional radiology
Known allergy	Known allergy	Known allergy	Known allergy
History of HIT(T)s	Invasive procedure < 24 hours	Active bleeding	In cases where needed, inability to place a Greenfield filter
		CNS ischemia/Surgery ≤ 10 days (includes birth asphyxia)	Limitations: Size of involved vessels and experience of interventionalists
		Surgery ≤ 7 days	
		Invasive procedure ≤ 3 days	
		Seizures ≤ 48 hours	
Fibrinogen < 100 mg/dL * Platelet count < 50,000/μL *	Fibrinogen < 100 mg/dL * Platelet count < 50,000/μL *	Fibrinogen < 100 mg/dL * Platelet count < 50,000/μL * INR > 2 *	Fibrinogen < 100 mg/dL * Platelet count < 50,000/μL * INR > 2 *

* With transfusion support, if necessary.

101.4 Conclusions

Evidence for inflammation as a cause of neonatal thrombosis exists mainly in studies of placental pathology and perinatal arterial ischemic stroke, but data relating catheter thrombosis to infection and inflammation is intriguing. Future research directed at determination of biomarkers for maternal inflammation may allow us to predict and prevent thrombosis in the developing fetus and newborn infant. The application of anti-inflammatory therapies, directed at activations of cytokines, complement proteins and inflammatory cells, applied to decrease cellular dysfunction and tissue infarction consequent to inflammation and thrombosis are in early stages. Anti-inflammatory therapies offer the hope of substantial advancement of therapy, particularly for perinatal arterial ischemic stroke.

Coagulation Disorders: Clinical Aspects of Platelet Disorders

Antonio Del Vecchio

102.1 Introduction

Platelets contribute to primary hemostasis and their function is affected by their number and condition. Platelets arise from the fragmentation of megakaryocytes in the bone marrow, and circulate in the blood as disk-shaped non-nucleated particles, with a lifespan of 7–10 days. Their average diameter is about 1.5 μm, 20% of the diameter of erythrocytes. Once released from the bone marrow, young platelets enter the circulation, where a large proportion pool in the spleen. It has been suggested that this splenic sequestration of young platelets is the result of a longer transit time of large platelets through the splenic cords. The spleen serves as a reservoir for platelets, containing about one-third, which are then able to enter the circulation after exercise or epinephrine administration. In addition to the spleen, the lungs also contain a small pool of platelets, perhaps 10–15% of the total number, and these are also able to enter the circulation after exercise or epinephrine administration [1].

Blood platelets adhere to sites of vascular injury, generate biological mediators, secrete their granule contents, form multicellular aggregates and serve as a nucleus for plasma coagulation reactions. When endothelial continuity is disrupted, platelets adhere to the exposed basement membrane collagen and change their shape from smooth disks to spiny spheres, interacting with subendothelium-bound von Willebrand factor (vWf) via the membrane glycoprotein Ib (GPIb) complex (platelet adhesion). Subsequently, they secrete and release proaggregatory substances, such as adenosine 5'-diphosphate (ADP) and they synthesize thromboxane A2 from arachidonic acid. Additional platelets are recruited and form aggregates on those platelets that are adherent to the vessel wall to consolidate the initial hemostatic plug. A platelet glycoprotein IIb/IIIa (GPIIb-IIIa) complex mediates platelet-to-platelet interactions (platelet aggregation), a primary hemostatic plug is formed and bleeding is stopped (primary hemostasis).

Platelets also provide an extensive phospholipid surface for the interaction and activation of clotting factors in the coagulation cascade. Enzymes and cofactors of the coagulation system, and a fibrin mesh further stabilise the initial hemostatic plug (secondary hemostasis). Collectively, they help to maintain the integrity of the vascular system [2].

Disorders of platelets produce defects in primary hemostasis and result in signs and symptoms which differ from those of coagulation factor deficiencies. The usual clinical presentation of a primary hemostatic disorder is that of mucosal bleeding, epistaxis, petechiae, and purpura. By contrast, defects in secondary hemostasis show delayed deep tissue bleeding into muscles and joints.

102.2 Platelet Function in Neonates

The hemostatic system of neonates matures during the early weeks and months of life. It has been well characterised with regard to plasma coagulation factors. However, because of the difficulty of obtaining adequate volumes of blood for aggregation tests, few data are available about the function of neonatal platelets. GPIb appears on platelets early during fetal life and is present in fetuses of 18–26 weeks' gestation in greater amounts than those found in adults. The plasma of neonates contains higher concentrations of vWf than adult plasma, with an increased proportion of functional high-molecular-weight forms, which result in enhanced platelet adhesion. In the immediate newborn period, this enhanced platelet adhesion may compensate for the decreased intrinsic platelet activation in healthy neonates, but may leave sick neonates at increased risk of bleeding.

Platelets also express GPIIb-IIIa early in gestation, and at 27 weeks' gestation fibrinogen is found in concentrations similar to those in adults with normal binding to newborn platelets. Studies of platelet adhesion and platelet aggregation

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

evaluating the responses to agonists are not easily performed in newborn infants, and frequently generate conflicting results. There is diminished platelet function in neonates, as measured by aggregation in response to a number of physiological agonists [1, 3]. Recent studies, using flow cytometry of cord blood and peripheral blood of neonates, demonstrated that platelets from term and preterm neonates display generalized hyporeactivity to thrombin, collagen, ADP, and U46619 (a stable thromboxane A2 analog) during the first few days of life. Platelet responses reach normal adult levels between the fifth and the ninth days of life. Persistence of platelet hyporeactivity in neonates after the tenth day of life may therefore suggest a platelet disorder.

The mechanism for the decreased reactivity of neonatal platelets has not been adequately explained. Platelet hyporeactivity was formerly considered to be the result of platelet activation and degranulation during labor and delivery, but more recent studies of platelet activation markers have not supported this theory [4]. Decreased activation is due to relative deficiencies of phospholipid metabolism, calcium mobilization, granule secretion, and aggregation. Although the hyporesponsiveness of neonatal platelets depends on gestational age, and is indicative of the maturation of the hemostatic system, this transient dysfunction may be a developmental phenomenon to protect the neonate from the possible harmful effects of birth stress on the coagulation system [1].

102.3 Clinical Aspects

Compared with adults or older children, the hemostatic system of neonates is naturally immature with a low functional reserve capacity. In spite of this, neonatal hemostasis is generally in equilibrium, and there is a relatively low incidence of inappropriate bleeding in term infants [1–3]. However, in the presence of additional risk factors such as prematurity, asphyxia or infection, the neonatal hemostatic system is easily overwhelmed and bleeding can be rapid and dramatic.

Abnormalities of platelet function or of platelet-vessel wall interactions should be considered, particularly in infants who have platelet-type bleeding (e.g., petechiae, purpura, mucous membrane bleeding) with a normal platelet count [1]. A precise understanding of the type of platelet dysfunction and identification of the individual disorder allows for appropriate therapy.

102.4 Quantitative Disorders of Platelets

102.4.1 Thrombocytosis

A moderately elevated platelet count in the range of 450,000/μL to 600,000/μL is not an uncommon finding in the neonatal population, although a platelet count peak above 600,000/μL is rare. No adverse outcomes related to thrombocytosis have been described. In many preterm infants, a moderately increased platelet count has been observed at around 4–6 weeks of age, at the same time as the nadir of anemia of prematurity [5, 6].

Initial studies on the administration of recombinant erythropoietin (rEPO) to preterm infants reported an increase in hematocrit and reticulocyte numbers, followed by a period of iron deficiency. This iron deficiency and decreased ferritin levels was accompanied by a significant thrombocytosis. Iron deficiency is known to cause thrombocytosis in older children [7], but this relationship was not noticed in NICU patients before the introduction of rEPO treatment.

A secondary reactive thrombocytosis has been described in very young infants, particularly during infection. Antimicrobial therapy can also cause thrombocytosis in neonates treated with ceftriaxone, aztreonam, imipenem-cilastatin, ceftizoxime, and ceftazidime for suspected infection. No morbidity is generally associated with the elevated platelet count, and no treatment is necessary [6].

Early elevation of serum thrombopoietin levels is also related to subsequent thrombocytosis in low-birth-weight preterm infants [8]. Infants with Down syndrome occasionally have a slightly raised platelet count between 6 weeks to around 1 year of age, and thrombocytosis may occur in infants with congenital adrenal hyperplasia (CAH) [9]. The latter may have a normal hemoglobin, hematocrit and red blood cell counts while having significantly elevated white blood cell and platelet counts, possibly due to a stress-related response by marrow precursors as may occur in the course of sepsis. Usually, thrombocytosis resolves with the successful treatment of CAH [10]. Thrombocytosis is also seen occasionally in neonates with gastroesophageal reflux disease and following maternal use of methadone, but the causes and significance of these varieties of thrombocytosis are unclear.

102.4.2 Thrombocytopenia

Thrombocytopenia is one of the commonest hematological problems in neonates, affecting 22–35% of infants admitted to the neonatal intensive care unit, and almost 50% of all sick preterm neonates. The incidence of neonatal thrombocytopenia varies greatly, depending on the patient population and on the definition of thrombocytopenia. The platelet count in healthy neonates is similar to the range observed in older children and adults (150,000/μL to 450,000/μL), even though various centers, mostly in Europe, consider 100,000/μL as the lowest limit. Premature infants may have slightly lower values than term infants, since fetal platelet counts increase linearly with gestation. Recent data suggest a lower normal limit of 120,000/μL for preterm neonates during the first days following birth [11]. Thrombocytopenia is defined as mild when platelet count is

between 100,000/μL and 150,000/μL, moderate between 50,000/μL and 100,000/μL, and severe < 50,000/μL.

One classification of thrombocytopenia is based on the timing of onset: early (≤ 72 hours of life) *vs* late (> 72 hours). Early thrombocytopenia is commonly associated with feto-maternal conditions, reduced platelet production being secondary to placental insufficiency and fetal hypoxia, intrauterine growth restriction or maternal hypertension. The resulting neonatal thrombocytopenia is usually mild to moderate, resolves spontaneously and does not generally warrant treatment. The most frequent causes of thrombocytopenia occurring after the first 72 hours of life, both in preterm and term infants, are sepsis and necrotising enterocolitis and the associated thrombocytopenia can be severe and protracted, often requiring therapy [12].

Variation from this pattern of thrombocytopenia suggests an immune thrombocytopenia with an increased risk of hemorrhage, since in this case the thrombocytopenia is usually severe (platelets <50,000/μL). Thrombocytopenia in the neonate can be asymptomatic or can present with a variety of symptoms, including petechiae, melena, hematuria, blood-stained endotracheal secretions, and bleeding from previous puncture sites. Other clinical signs of thrombocytopenia are intraventricular hemorrhage (IVH) or pulmonary hemorrhage [13].

An infant with clinical signs of thrombocytopenia but without coagulation abnormalities should prompt examination for hepatosplenomegaly, congenital anomalies, and/or signs of sepsis.

In the mother, the platelet count, appearance of the blood smear, drug history, and evidence of transmissible infection should be investigated. Parental consanguinity and/or hematologic disease in family members should also be excluded [14]. Neonatal thrombocytopenia is broadly due to the following mechanisms: decreased platelet production, increased platelet destruction, or platelet sequestration [15].

102.4.2.1 Thrombocytopenia Due to Decreased Platelet Production

Overlap exists between the varieties of thrombocytopenia among neonates with intrauterine growth restriction (IUGR) and those with pregnancy-induced hypertension (PIH). Placental insufficiency and/or fetal hypoxia are likely involved in the reduced production of platelets [16]. Plasma concentrations of thrombopoietin are generally elevated in these patients, who have low to normal platelet counts (150,000/μL to 200,000/μL) or mild thrombocytopenia (100,000/μL to 150,000/μL) in the first day after delivery. Thereafter the platelet count usually falls, with a nadir on days 4–5, generally recovering to above 150,000/μL by days 7–10. If not complicated, the nadir is rarely below 50,000/μL, and the risk of hemorrhage is not significant. These patients usually do not need platelet transfusions or other treatments for thrombocytopenia [13].

Most cases of decreased platelet production are the consequence of reduced megakaryocytes or impaired platelet production by megakaryocytes. Congenital amegakaryocytic thrombocytopenia (CAMT) is a rare disorder with absence or near absence of megakaryocytes in the bone marrow, and a risk of developing aplastic anemia. Compound heterozygosity for two-chain termination point mutations in the Mpl gene (thrombopoietinreceptor) has been identified. Consequently, plasma thrombopoietin levels in these patients are significantly elevated. Both X-linked and autosomal recessive patterns of inheritance have been reported. Bone marrow transplant is currently the only treatment [17, 18].

Thromobcytopenia with absent radii syndrome (TAR) is an autosomal recessive disorder with hypomegakaryocytic thrombocytopenia and bilateral absence of the radii, with the presence of functional thumbs. Bone marrow samples show decreased, absent, or immature megakaryocytes. No thrombopoietin gene mutations have been found. TAR may be associated with congenital heart disease, renal problems, defects of the lower limbs, and other hematological abnormalities, including aleukemoid reaction, eosinophilia and anemia. There is symptomatic thrombocytopenia within the first 4 months of life in 90% of patients, often resulting in gastrointestinal or intracranial bleeding. The elevated level of thrombopoietin despite normal Mpl suggests that the imperfect thrombocytopoiesis in TAR is probably due to a lack of response to thrombopoietin in the signal transduction pathway [17].

Fanconi anemia is an autosomal recessive disorder associated with skeletal and genitourinary abnormalities. These patients can become pancytopenic. It is important to note that 25% of affected patients are structurally normal and the diagnosis should be considered in presence of thrombocytopenia, anemia, leukopenia, in the absence of dysmorphic features.

Thrombocytopenia associated with a myeloproliferative disorder or with a wide variety of hemostatic abnormalities has been reported in Noonan syndrome, a rare autosomal dominant disorder with facial anomalies, congenital heart disease, skeletal abnormalities, and genital malformations [19]. Alport's syndrome, a genetic disorder associated with nephritis and nerve deafness, may present with thrombocytopenia and macrothrombocytes. Wiskott-Aldrich syndrome is a rare, sex-linked recessive disorder with thrombocytopenia, eczema, a tendency to severe bleeding and an increased incidence of recurrent infections because of an impairment of cellular and humoral immunity. There is also an increased incidence of malignancy, such as lymphoma. The platelets are small, with one-half normal volume and decreased platelet-mass, and their aggregation and life span also is diminished. The general prognosis is poor, and marrow transplantation is considered the treatment of choice [14].

Thrombocytopenia is also present in other chromosomal abnormalities. For instance, thrombocytopenia is found in 87% of infants with trisomy 18, in 54% of those with trisomy 13, in 31% of those with Turner's syndrome, and in 28% of those with trisomy 21 [1].

102.4.2.2 Thrombocytopenia Resulting from Increased Platelet Destruction

Immune Thrombocytopenias

Autoantibodies, alloantibodies, or drug-dependent antibodies may combine with platelet membranes and produce platelet impairment, resulting in platelet removal by phagocytes of the reticuloendothelial system. Immune destruction of platelets may be prompted by antibodies against a platelet membrane antigen, or antibodies as part of an immune complex that binds Fc receptors on platelets. These immunologic mechanisms are responsible for various clinical syndromes, including neonatal alloimmune thrombocytopenia (NAIT), autoimmune thrombocytopenia and post-transfusion purpura.

NAIT is the platelet counterpart of hemolytic disease of the neonate. It is secondary to placental transfer of maternal alloantibodies directed against paternally inherited antigens present on the fetal platelets, but absent on maternal platelets. When this type of incompatibility between parental platelet exists, the mother may develop an immune response to antigens expressed on the fetal platelets inherited from the father. Homozygosity of the father for a specific platelet antigen results in the expression of that antigen on the fetal platelets; however, heterozygosity of the father for that antigen results in approximately 50% incidence of neonatal alloimmune thrombocytopenia [20].

Antigens appear on fetal platelets early in the gestation and maternal antibodies are able to cross the placenta early in the second trimester, thereby reacting with antigens on fetal platelets and inducing severe fetal thrombocytopenia. Mothers do not generally have a history of abnormal bleeding and have a normal platelet count. Neonatal alloimmune thrombocytopenia is usually a consequence of antibodies against the antigen HPA-1a, but there are also other antigens [21].

The severity of thrombocytopenia is unpredictable. Nevertheless certain clinical features are characteristic of neonatal alloimmune thrombocytopenia, such as severe thrombocytopenia (20,000/μL–50,000/μL) at birth with a platelet count that continues to fall over the first days of life and then increases over the next 1–4 weeks. Intracranial hemorrhage occurs in approximately 10–15% of cases; at least one half of these occur in utero, with death occurring in 10% of affected infants and neurological sequelae in 20%. Although controversial, prenatal treatment with percutaneous umbilical cord blood sampling and administration of IVIG to the mother may influence the natural history of the disease. Neonatal alloimmune thrombocytopenia causes more intracranial hemorrhage than any other hemostatic disorder in the newborn period. The usual presentation of an infant born to healthy mother is with purpura and/or petechiae within a few hours of birth, and severe thrombocytopenia without other signs of disseminated intravascular coagulopathy (DIC) or sepsis. The full blood count is usually normal in the affected neonates apart from the severe thrombocytopenia [20].

In addition to a low platelet count, usually due to platelet consumption and rarely associated with reduced production, an infant's platelets may also have defective function [22]. The treatment of choice for rapidly raising the platelet count in neonates with severe neonatal alloimmune thrombocytopenia is transfusion with maternal or HPA-matched platelets because random donor platelet transfusions usually do not improve, or only briefly improve, the platelet count. Maternal platelets are usually washed to remove plasma, which may contain antiplatelet antibodies. IVIG can be used in the neonate to augment the platelet count, even though first improvement in platelet count may not be evident for 24–72 hours [20].

Autoimmune thrombocytopenia occurs in neonates born to mothers with idiopathic thrombocytopenic purpura (ITP), systemic lupus erythematosus (SLE), lymphoproliferative disorders, or hyperthyroidism. Maternal autoantibodies bind to the maternal and the fetal platelets and result in platelet destruction [22]. Thrombocytopenia occurs in approximately 10% of cases in which the mother has ITP or SLE, and intracranial hemorrhage occurs in approximately 1% of these. The mother is usually healthy without a history of ITP or other autoimmune disorder, but with a slightly decreased platelet count that resolves after delivery. Autoimmune thrombocytopenic purpura in pregnant women can induce moderate or severe thrombocytopenia in the fetus or the newborn, but the severity of the maternal disease and maternal platelet count usually predicts the neonatal platelet count [23].

The neonate born to a mother with autoimmune disease should have platelet counts monitored for at least the first week. The usual clinical picture includes mild to moderate thrombocytopenia, petechiae or bruising in an otherwise healthy neonate. Intracranial hemorrhage is very rare. Thrombocytopenia usually persists 1–2 months in the infant, with spontaneous resolution.

The severity of thrombocytopenia in the first infant delivered to a woman with active ITP usually predicts the degree of thrombocytopenia of the next sibling. Monitoring the course of thrombocytopenia in breastfed neonates of mothers with ITP is recommended, since IgG antibodies are transferred via breast milk, and Bussel has reported one neonate in whom severe neonatal thrombocytopenia resolved only after stopping breastfeeding [20, 24].

Treatment of infants affected by maternal ITP may include intravenous immunoglobulin (IVIG) or steroids, or a combination of IVIG and steroids, platelet transfusion, or exchange transfusion [1].

Infections

Thrombocytopenia frequently accompanies systemic neonatal infection, even in the absence of disseminated intravascular coagulation (DIC). The reported incidence of thrombocytopenia associated with sepsis in neonates is extremely variable,

depending on the definition of thrombocytopenia; 80% of neonates if thrombocytopenia is diagnosed as a platelet count of less than 150,000/μL, 55–65% if thrombocytopenia is diagnosed as a platelet count of less than 100,000/μL.

The usual mechanism responsible for thrombocytopenia in infected neonates is accelerated platelet destruction, which may be caused directly by the organism or its products, immune-mediated destruction, and adhesion of the platelets to the subendothelial layer of injured blood vessels [25].

Twenty-five percent of neonates with a bacterial infection are thrombocytopenic at the time sepsis is diagnosed. Thrombocytopenia may develop after 36–48 hours but bleeding is rare because this variety of thrombocytopenia is usually moderate. However, monitoring the platelet count is recommended, since these patients may require platelet transfusions. Recovery occurs over 5–7 days as the sepsis improves [26].

Fungal sepsis, which is a particularly common problem among extremely-low-birth-weight neonates is frequently associated with thrombocytopenia. In contrast to the thrombocytopenia that may complicate bacterial infection, it is generally severe with platelet counts falling below 50,000/μL. Antifungal treatment is recommended while awaiting culture results in a clinically septic extremely low-birth-weight infant with thrombocytopenia [27].

Thrombocytopenia is common with congenital viral infections. All the viruses that cause TORCH infections, coxsackie virus B, Epstein Barr virus, adenovirus, and echovirus can cause thrombocytopenia. The mechanism is most likely a combination of accelerated destruction, diminished production and accelerated removal of platelets from the circulation because of the reticuloendothelial hyperactivity and splenomegaly that often accompany congenital viral infections. Vacuolization of megakaryocytes has also been reported [28].

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is a disorder of hemostasis, with an inappropriate systemic activation of normal clotting mechanisms after endothelial injury, which is secondary to the underlying disease, which may include infection, shock, anoxia, renal vein thrombosis, necrotising enterocolitis and meconium aspiration. All these disease processes are complicated by endothelial disruption and result in release of tissue factors and cytokines, and excessive activation of coagulation and fibrinolysis, and, ultimately, a consumptive coagulopathy [29].

Infants with DIC have low platelet counts and fibrinogen levels, prolonged prothrombin time (PT) and partial thromboplastin time (PTT), and elevated fibrin degradation products. They often present with gastrointestinal bleeding, bleeding from venipuncture sites, or pulmonary hemorrhage. Successful treatment of neonatal DIC depends on a correct diagnosis, treatment of the underlying disorders, and maintaining platelet counts greater than 50,000/μL, fibrinogen concentrations greater than 1 g/L and PT values within the physiological range.

Necrotizing Enterocolitis

Thrombocytopenia is common in neonates with necrotising enterocolitis (NEC). Platelet counts frequently fall to the range of 30,000–60.000/μL, and platelet transfusions do not usually maintain a normal blood platelet concentration for more than 1 or 2 days, suggesting that platelet destruction is the chief mechanism [1].

Asphyxia

Placental insufficiency can be associated with early-onset thrombocytopenia in preterm neonates, and perinatal hypoxia has been associated with severe and prolonged thrombocytopenia. Some of these infants have a decreased platelet count without DIC or persisting beyond the resolution of DIC. The decreased platelet count is probably due to the direct harmful effects of hypoxia on the megakaryocyte progenitors [30].

Thrombosis

Thrombocytopenia sometimes occurs in neonates who have a localized thrombus in the renal vein, or attached to an indwelling catheter, or in the ECMO circuit. It is unclear whether the thrombocytopenia is caused by platelet adhesion and aggregation to a developing thrombus, or by platelet consumption at the vascular surfaces where the thrombus has begun.

Some sick neonates develop thrombocytopenia without any other coagulation defect, associated with platelet thrombi on the cardiac valves. In some neonates, platelets which have aggregated in the pulmonary capillaries release substances causing vasoconstriction with consequent pulmonary hypertension [29].

Kasabach-Merritt Syndrome

Consumption of platelets in giant hemangiomata can cause thrombocytopenia. These vascular tumors are usually solitary and may involve internal organs, head or neck, the trunk, or the extremities. Platelets are trapped by abnormal endothelium within the hemangioma, and the platelet counts often fall to less than 50,000/μL. In some patients there is laboratory evidence of DIC but thrombocytopenia may also occur in the absence of DIC. Proposed treatments have included steroids, alpha interferon, total or partial surgical excision of the hemangioma, or embolisation or irradiation of the hemangioma [31].

Drugs Producing Thrombocytopenia in Mother and Fetus

Thrombocytopenia as a result of maternal-fetal drug interaction is thought to be caused by immune reactions in which antibody is formed against a drug-haptene complex that cross-reacts with a platelet antigen. This has been reported with the maternal use of quinine, carbamazepine, phenytoin and valproic acid [14]. Thrombocytopenia induced by the maternal use of thiazide diuretics has also been reported and may be due to impaired fetal platelet production with reduced megakaryocytes in the marrow but without inducing thrombocytopenia in the mother. *In vitro* studies have described thrombocytopenia with the maternal use of ampicillin and furosemide [1].

102.5 Qualitative Disorders of Platelets

Qualitative disorders of platelets form a large group of rare diseases in which the infant has a normal platelet count but excessive mucocutaneous bleeding. The qualitative platelet disorders are classified as either hereditary or acquired.

102.5.1 Hereditary Disorders

Most hereditary disorders of platelet function do not cause problems during the neonatal period but present later in life. Glanzmann's thrombasthenia is one type of hereditary platelet dysfunction that may present during the neonatal period. A deficiency of the glycoprotein IIb/IIIa complex, which is inherited in an autosomal recessive pattern, results in platelets that do not aggregate in response to normal stimuli, except to ristocetin. The microscopic appearance of the platelets and the platelet count are normal [32]. Although platelet transfusions are effective, they should be used only for serious hemorrhage or if there is a need for surgery because these patients often develop alloantibodies. Recombinant factor VIIa may provide a therapeutic alternative to platelet transfusion for some patients [33].

Bernard-Soulier syndrome is an autosomal recessive disorder resulting from a deficiency of platelet glycoprotein protein Ib, which mediates the initial interaction of platelets with subendothelial components via the von Willebrand protein. This syndrome can result in a severe bleeding disorder. Platelets do not aggregate in response to ristocetin. The platelet count is low, but the platelets are usually large, often the size of red blood cells. As in Glanzmann's thrombasthenia, platelet transfusions may cause antibody formation to the absent glycoprotein, and the administration of recombinant factor VIIa for acute bleeding episodes should be considered as an alternative treatment.

May-Hegglin anomaly is a benign condition characterised by giant platelets. Giant platelets are also found in variants of Alport's syndrome. Platelet function disorders relating to platelet secretion cause mild to moderate bleeding. Included in this subset of disorders are Gray Platelet syndrome, Dense Granule deficiency, Chediak-Higashi syndrome, and Hermansky-Pudlak syndrome [1].

102.5.2 Acquired Disorders

Acquired disorders of platelet function are common. A primary hemostatic defect can occur as a result of medications given to the mother or neonate. Aspirin, given to the mother, crosses the placenta and may produce irreversible inhibition of the cyclooxygenase enzyme, increasing the bleeding time for the life of affected platelets. Gastrointestinal bleeding, melena, or cephalohematoma may affect neonates whose mothers received aspirin during pregnancy within 5 days of delivery [1].

Indomethacin and ibuprofen, commonly used for the closure of patent ductus arteriosus, can interfere with cyclooxygenase function. The influence of these drugs on platelet function is transitory, generally lasting about 24 hours. Ibuprofen, administered to neonates with a PDA, has little adverse effect on platelet plug formation, and prolongs the bleeding time less than indomethacin [34, 35]. Nitric oxide (NO) also has the potential to reduce platelet function, probably because of increased cGMP. In premature infants, inhaled NO may prolong bleeding time, decrease platelet aggregation, and inhibit platelet adhesion to endothelial cells, increasing the risk of intraventricular hemorrhage [36].

Extracorporeal membrane oxygenation (ECMO) is used in neonates for the treatment of persistent pulmonary hypertension, meconium aspiration, and congenital diaphragmatic hernia. Impaired platelet function and thrombocytopenia have been described in patients on ECMO. During ECMO, platelet dysfunction persists despite platelet transfusions, and platelet function returns to normal 8 hours after thediscontinuation of ECMO [1].

Other circumstances where platelet dysfunction has been described include hyperbilirubinemia and phototherapy, although bleeding has not been reported in otherwise healthy infants in these situations [1].

Uremia and/or renal failure can also cause neonatal platelet dysfunction. Gastrointestinal tract bleeding is the most frequent symptom, and bleeding time is often very prolonged in these patients. Excessive production of nitric oxide by endothelial cells inhibits platelet function, and may be responsible for bleeding in uremic patients. Because the prolonged bleeding time and the hemostatic abnormalities may be partly corrected by red blood cell transfusion or erythropoietin therapy, the failure of hemoglobin to turn off excess

nitric oxide synthesis has been suggested as a cause of the platelet dysfunction. Another suggestion is that platelets arrive on exposed vascular subendothelium, being propelled there mainly by erythrocytes, which release ADP to activate the platelets following vessel injury. Consequently, a low hematocrit may result in a prolonged bleeding time [37].

102.6 Evaluating Platelet Function in a Neonate

The main goal of platelet function testing is to determine the cause of abnormal bleeding. However, a thorough assessment of platelet function in the neonate is difficult because of difficulties in obtaining sufficient blood for these types of studies [16]. This is particularly true for aggregometry and flow cytometric evaluation of platelet activation, but various other studies, such as those listed below, can be helpful.

102.6.1 Laboratory Studies

102.6.1.1 Peripheral Smear

Examination of the peripheral smear is useful for evaluating platelet clumping or platelets adhering to neutrophils (platelet satellitism), or Bernard-Soulier syndrome with giant platelets.

102.6.1.2 Platelet-Associated Immunoglobulin G

Assays have been developed to assess the presence of IgG on platelets. In the thrombocytopenic neonate this may indicate platelet destruction and reduced platelet survival. The detection of increased platelet-associated immunoglobulin is observed in a variety of conditions associated with thrombocytopenia, which limits the value of this test for the diagnosis of specific disorders, such as ITP.

102.6.1.3 Bleeding Time

The bleeding time measures the time required for a platelet plug, which occurs through the interaction of platelets with the subendothelial structures of a damaged vessel, to arrest bleeding from a standardised superficial skin incision [38, 39].

102.6.1.4 Platelet Function Analyzer 100

The platelet function analyzer 100 (PFA-100) is an *in vitro* method for the assessment of primary hemostasis under shear stress, where primary hemostasis is simulated by an *in vitro* quantitative measurement of platelet adhesion, activation and aggregation in whole blood. The PFA-100 uses a disposable test cartridge that contains a membrane coated with collagen and either ADP (Col/ADP membrane) or epinephrine (Col/Epi membrane), thus mimicking exposed subendothelium. A blood sample of 0.8 mL of citrated blood is placed in a cup and is aspirated through the aperture. The shear stress and the agonists in the membrane activate platelets lead to platelet aggregation. The end point, expressed as closure time, is when blood flow stops because of occlusion of the aperture by platelet aggregates, giving a measure of platelet dependent hemostasis [40]. The closure times, similar to bleeding times, are significantly shorter in neonates than in adults and healthy children. The advantages of this instrument include simplicity and reproducibility.

102.6.1.5 Mean Platelet Volume

The mean platelet volume (MPV) is a measure of the average size of circulating platelets. Since the average platelet size is larger when the marrow produces increased numbers of platelets, high MPV in thrombocytopenic neonates can be an indirect measure of increased platelet production in bone marrow.

102.6.1.6 Reticulated Platelet Count

Reticulated platelets, similar to reticulated erythrocytes, lose their RNA content in the process of aging and senescence. Because reticulated platelets are detectable in the circulation for only 24 hours, they are an excellent measure of platelet production and turnover. These new platelets can be recognized by flow cytometry, and in term neonates they represent 3–5% of circulating platelets. Increased production of platelets is expected to increase the percentage of reticulated platelet [41].

102.6.1.7 Bone Marrow Biopsy

In most cases of platelet disorders, bone marrow biopsy is not necessary. It provides important information about the state of platelet production that is not otherwise available. It is particularly useful in evaluating neonates with thrombocytopenia when an estimate of the marrow megakaryocyte mass is needed. Unlike a direct aspiration of cells from a neonate's bone marrow, which can result in a sample that is so diluted with peripheral blood that interpretation is limited, the marrow biopsy preserves the basic architecture of the marrow. Bone marrow biopsy uses a 19 gauge, half-inch Osgood needle to obtain bone marrow clots from the tibia of a baby, enabling the assessment of marrow cellularity and architecture [42].

102.7 Treatments

102.7.1 Platelet Transfusion

Platelet transfusions represent the only specific therapy currently available for most thrombocytopenic neonates. There is great variability worldwide in neonatal platelet transfusion practice, due to the lack of concrete evidence to guide transfusion decisions [43–46]. In approximately 75% of neonates with thrombocytopenia, the condition is mild and transient and needs no treatment. However, in 20–25% of cases, one or more platelet transfusions are given in an attempt to treat or decrease the risk of hemorrhage. Among critically ill patients, most platelet transfusions are given to prevent, rather than to treat, bleeding, with a transfusion trigger of 40,000 – 50,000/μL. It is not clear how many platelet transfusions in the NICU are actually unnecessary, or provide more risk than benefit [43, 47].

Baer and coworkers reported that the number of platelet transfusions administered in the NICU predicts the mortality rate, suggesting that multiple platelet transfusions may be harmful. Since platelet transfusions carry risks, eliminating unnecessary platelet transfusions would be useful [48]. Improving transfusion practice requires the definition of a safe lower limit for platelet counts in stable neonates, platelet transfusion strategies for critically ill neonates, and improved treatments for conditions that are associated with severe thrombocytopenia. To avoid unnecessary transfusions, Christensen et al proposed transfusion guidelines based on platelet mass (platelet count times mean platelet volume). In a pilot study, the use of these guidelines was associated with fewer platelet transfusions without any increase in problems due to hemorrhage [49, 50].

While there is no scientific evidence to guide platelet transfusion practices in neonates, individual NICUs should adopt guidelines appropriate to their practice, and adhere to them closely [50]. As a general rule, platelets should be given to non-bleeding thrombocytopenic neonates as prophylactic transfusions to maintain platelet count > 20,000/μL for clinically stable neonates, and > 50,000/μL for clinically unstable neonates. Platelet counts should be maintained > 50,000/μL to 100,000/μL when there is significant bleeding and > 50,000/μL for invasive procedures [51].

102.7.2 Thrombopoietic Factors

Inadequate megakaryocyopoiesis and platelet production are major contributors to most episodes of neonatal thrombocytopenia. As alternatives to platelet transfusion, the administration of thrombopoietic growth factors, such as recombinant thrombopoietin (rTPO) and interleukin 11 (IL-11) may be useful. rTpo and IL-11 are promising agents for older patients, but both have potential toxicities that are likely to preclude their use for sick preterm infants.

102.7.3 Other Therapies

Recombinant activated factor VII has been used successfully off-label in controlling life-threatening bleeding during infancy, but the clinical situations in which benefits are likely, and potential toxicities, particularly thrombosis, remain unknown. The administration of intravenous immunoglobulin (IVIG) is useful for the treatment of immune thrombocytopenia. Corticosteroids were classically used for alloimmune and autoimmune neonatal thrombocytopenia, often in combination with IVIG, but are now unusual. Dosing schedules for IVIG include 400 mg/kg/d for 3–5 consecutive days or a single dose of 1000 mg/kg on day 1.

Anemia in the Neonatal Period

Robert D. Christensen and Robin K. Ohls

103.1 Introduction

The term anemia refers to a pathological reduction in the hematocrit, blood hemoglobin concentration, and circulating erythrocyte count [1, 2]. These three laboratory measures are somewhat similar to one another, in that each quantifies the same biological variable involving the capacity of blood to deliver oxygen to tissues. However, none of the three measurements actually assesses whether oxygen demands of tissues are being adequately met. In fact, limitations in delivery of oxygen to a neonate's tissues are frequently not the result of anemia at all, but instead are due to abnormalities in oxygen intake from pulmonary pathology. This chapter reviews the various pathologies that give rise to anemia during the neonatal period, and provides practical approaches for dealing with these clinical issues.

103.2 Erythropoietin – Biological Considerations in the Fetus and Neonate

During early fetal and neonatal development, erythropoietin is more than an erythropoietic growth factor. Erythropoietin (Epo) is a constituent of amniotic fluid in concentrations of 25–40 mU/mL. A normal human fetus swallows 200–300 mL of amniotic fluid/kg/day and thus swallows 10–15 U of Epo/kg/day [3, 4]. In humans, Epo does not cross the placenta, and the source of the Epo in amniotic fluid is not the maternal circulation. In the second and third trimesters, amniotic fluid is largely derived from fetal urine, with minor constituents from fetal tracheal effluent and the placenta and fetal membranes. However, Epo in amniotic fluid does not come from fetal urine. The fetal kidney makes little Epo before delivery, and the first-voided urine of neonates generally has no detectable Epo [3]. Studies using in situ hybridization and immunohistochemistry indicate that the source of Epo in amniotic fluid is largely maternal: from mesenchymal and endothelial cells in the deciduae and from the amnion [4].

Epo is also present in colostrum and breast milk in concentrations of 10–20 mU/mL [3, 5, 6]. Epo levels in milk do not correlate with Epo levels in the mother's blood [5, 6]. In fact, over the first weeks of lactation, mother's serum Epo concentrations fall, while her milk Epo concentrations increase, reaching the highest concentrations in women breastfeeding for a year or more. The source of Epo in breast milk appears to be mammary gland epithelium [4–6].

Epo in human amniotic fluid, colostrum, and breast milk is relatively protected from proteolytic digestion in the fetal and neonatal gastrointestinal tract. Rather than being absorbed from the gastrointestinal track into the blood, the Epo swallowed by the fetus and neonate binds to Epo receptors on the luminal surface of villous enterocytes, where it serves as a growth and development factor. Experimental animals artificially fed formulas devoid of Epo have retarded villous development, a condition that can be remedied by enteral recombinant Epo and blocked by antiEpo antibody [4].

Epo is produced by cells in the developing central nervous system and is present in relatively high concentrations in fetal cerebrospinal fluid (CSF) [7–12]. The highest concentrations of Epo in the CSF are in the most premature neonates, and by several years of age CSF Epo concentrations are generally below 1 mU/mL [12]. Epo receptors are expressed on human fetal neurons [13–15], and at least small quantities of recombinant Epo administered intravenously cross the blood brain barrier and appear in the CSF [16]. Epo is a neuroprotectant [8–10]. Its production increases rapidly in the brain during hypoxia, and when Epo binds to receptors on neurons, antiapoptotic activity is induced. The clinical utility of recombinant Epo as a neuroprotectant is a topic of current studies.

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

The liver is the primary site of fetal Epo production. The kidney produces only about 5% of the total Epo during midgestation. The mechanisms regulating the switch in Epo production from the liver to the kidney are not completely known but may involve developmental expression of transcription activators such as hypoxia inducible factor and hepatic nuclear factor 4 [18, 19], or developmental methylation of promoter and enhancer regions. Alternatively, the switch might involve the GATA transcription factors, particularly GATA-2 and GATA-3, which are negative regulators of Epo gene transcription.

103.3 Normal Erythrocyte Values During Human Fetal Development

"Reference ranges" are generally used in Neonatology in place of "normal ranges" commonly used in adult medicine. The difference is, reference ranges are constructed from clinically-obtained laboratory tests, not from tests performed on healthy volunteers. In order to more closely approximate a normal range, the laboratory tests included in a reference range include only patients with minimal pathology or with pathology not known to be related to the test under consideration. For instance, reference ranges for the hematocrit of neonates excludes data from neonates with clinical issues known to affect the hematocrit, such as PRBC transfusion recipients, those with hemolytic disease, or those with a reduction transfusion. Reference ranges for hematocrit and hemoglobin on the day of birth [1] are shown in Fig. 103.1.

Circulating erythrocytes in the fetus have features reminiscent of "stress erythropoiesis" in adults. These features include marked anisocytosis, pokilocytosis, macrocytosis, and the presence of nucleated erythrocytes. Marrow cellularity in the fetus is relatively high. Erythroid precursors account for 30–65% and myeloid cells 45–75% of nucleated marrow cells at birth [20]. The myeloid to erythroid ratio at birth is approximately 1.5:1. Marrow cellularity decreases after birth, attaining a density that is normal for adults by 1–3 months. Initially, this decrease in cellularity results from a rapid decline in red cell production. At 1 week of age, erythroid elements account for only 8–12% of nucleated cells, and the myeloid to erythroid ratio exceeds 6:1. The normal adult proportion of myeloid to erythroid precursors is not established until the

Table 103.1 Characteristics of neonatal erythrocytes

A. Characteristics explained by large and young erythrocytes
   1. Increased levels of ATP
   2. Increased consumption of glucose and galactose
   3. Increased enzymatic activity

third month. Both the percentage and absolute number of lymphocytes increase during the first 2 months, so that by 3 months of age, they constitute nearly 50% of nucleated marrow cells. Differential counts of bone marrow aspirates from preterm infants are similar to those of term infants [21].

In newborn infants, the hemoglobin (Hb) concentration and hematocrit of capillary blood are 5–10% higher than those of venous blood [1]. The difference between capillary and venous values is greatest at birth but disappears by 3 months of age. The discrepancy is greatest in preterm infants and in those with hypotension, hypovolemia, and acidosis [22–24].

Reticulocytes at birth are approximately 5% of erythrocytes, with a range of 4–7% [22, 25]. Reticulocytes remain elevated for the first 1–3 days, dropping abruptly to 0–1% by day 7. Nucleated red blood cells (NRBC) are seen regularly on blood smears during the first day of life constituting about 0.1% of the red cell population (500 normoblasts/mm3) [22]. The absolute count of NRBC decreases with advancing gestational age. It has been observed that the mean value of NRBC varies from 5643.3 (SD 7228.2) in newborns of 26.6 weeks of gestation to 441.6 (SD 807.3) in newborns of 38.6 weeks [26]. The finding of higher than normal content of NRBC in cord blood, in relation to the gestational age, strongly suggests that the fetus had severe hypoxia several hours before the birth. The increased NRBC production by the hypoxic fetus reflects a higher erythropoietin production as an answer to low tissue oxygen availability [27]. NRBC are not common in the circulation after the first 3 days unless intermittent or chronic hypoxemia is present.

Red cell morphology is characterized by macrocytosis and poikilocytosis. Target cells and stomatocytes are particularly prominent. Similarly a high proportion of siderocytes (3.2% versus normal adult mean of 0.1%) are seen [28, 29].

Measuring the circulating red blood cell volume in a fetus or neonate is difficult. Mock et al used a nonradioactive method, based on *in vivo* dilution of biotinylated RBC enumerated by flow cytometry, to estimate the correlation between hematocrit and circulating RBC volume in infants below 1300 grams and found that venous hematocrit values correlated highly with the circulating erythrocyte volume ($r = 0.907$; $p < 0.0001$) [30, 31].

Neonates have a shorter red cell survival than do children and adults. The life span of red cells from term infants is estimated to be 60–80 days, using the 51Cr method [32] and 45–70 days using methods involving 59Fe [33]. Fetal studies using [14C] cyanate-labeled red cells in sheep revealed an average red cell life span of 64 ± 6 days [34]. The mean red cell life span increased linearly from 35–107 days as the fetal age increased from 97 days (midgestation) to 136 days (term).

Neonatal red cells transfused into adults have a short survival [33], indicating that factors intrinsic to the newborn red cell are responsible. This conclusion of factors intrinsic to the newborn red cells gains further support by the demonstration that adult red cells survive normally in newborn recipients [34]. The life span frequency function is not parametrically distributed, in that most cells are destroyed before the mean survival is reached. Shortened red cell survival corresponds with erythropoietic rates at birth that are three to five times greater than those of normal adults.

The abrupt transition from the relative hypoxia of the uterus to an oxygen-rich environment triggers responses that have profound effects on erythropoiesis (Fig. 103.2). During the first 2 months of life, the infant experiences both the highest and lowest Hb concentrations occurring at any time in development. Epo levels at birth are usually well above the normal adult range and fall in the immediate postnatal period [35]. By 24 hours, the Epo value is below the normal adult range where it remains throughout the first month of life. The decrease in Epo is followed by a decline in the number of bone marrow precursors [36] and a fall in the reticulocyte count.

The combination of shortened cell survival, decreased production, and growth related expansion of the blood volume is responsible for a progressive fall of the Hb concentration to a mean of approximately 11 g/dL at 2 months of age [1]. The lower range of normal for infants of this age is approximately 9 g/dL. This nadir is called physiologic anemia, in that it is not associated with apparent distress and is not prevented with nutritional supplements. Stabilization of the Hb concentration is heralded by an increase in reticulocytes at 4–8 weeks. Thereafter, the Hb concentration rises to a mean level of 12.5 g/dL, where it remains throughout infancy and early childhood [21, 22].

At term, the placenta and umbilical cord contain 75–125 mL of blood (30–40 mL/kg), or approximately 1/4–1/3 of the fetal blood volume. Umbilical arteries constrict shortly after birth, but the umbilical vein remains dilated, and blood flows in the direction of gravity. Infants held below the level of the placenta can receive half of the placental blood volume (30–50 mL, or 10–15 mL/kg) in 1 minute. Conversely, infants held above the placenta can lose 20–30 mL of blood back into the placenta per minute [37, 38]. The blood volume of infants with early cord clamping averages 72 mL/kg, whereas the volume of infants with delayed cord clamping averages 93 mL/kg.

Linderkamp et al compared postnatal alterations in blood viscosity, hematocrit, plasma viscosity, red cell aggregation, and red cell deformability in the first 5 days of postnatal life in full-term neonates with early (less than 10 seconds) and late (3 minutes) cord clamping [37, 38]. The residual placental blood volume decreased from 52 ± 8 mL/kg of neonatal body weight after early cord clamping to 15 ± 4 mL/kg after clamping. The neonatal blood volume was 50% higher in the late cord-clamped infants. Intrauterine asphyxia appears to have little effect on blood volume, whereas intrapartum asphyxia and nuchal cords are associated with a reduced blood volume [39, 40].

Placental transfer of blood to preterm infants occurs by delayed clamping of the umbilical cord. Transfer of about 10 mL/kg body weight can be expected by delaying clamping for 30–60 seconds and has been claimed to reduce intraventricular hemorrhage and late-onset sepsis [39–41]. However,

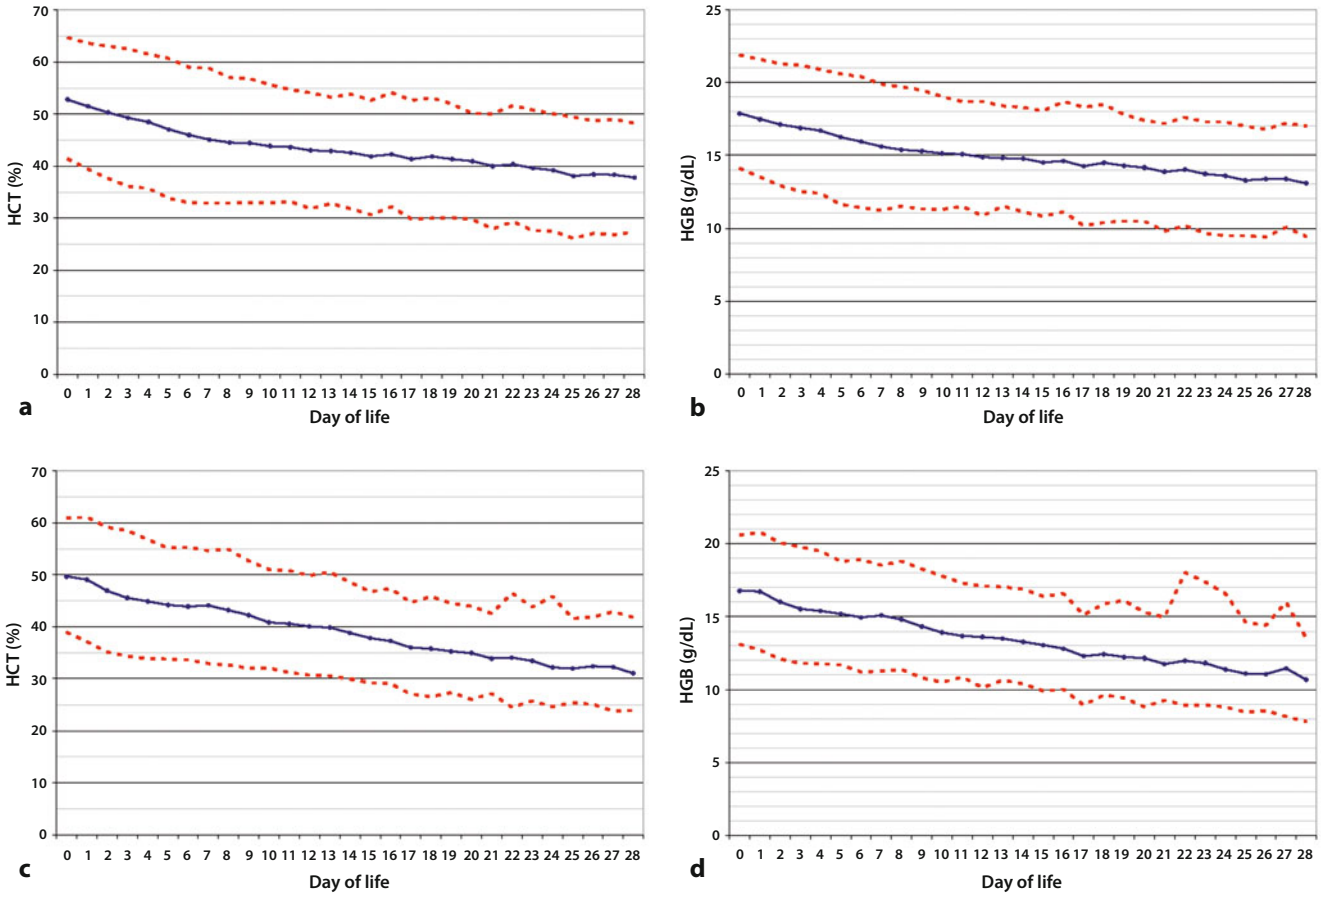

Fig. 103.2 Reference ranges for hematocrit and blood hemoglobin concentration during the first month after birth. **a** Hematocrit from late preterm and term neonates. **b** Hemoglobin from late preterm and term neonates. **c** Hematocrit from preterm neonates. **d** Hemoglobin from preterm infants. *HCT* Hematocrit, *HGB* Hemoglobin. in actual practice, preterm deliveries often have rapid cord clamping in order the pass the neonate to the neonatal team for resuscitation.

103.4 Fetal and Neonatal Anemia Due to Abnormalities in the Erythrocyte Membrane or Cellular Metabolism

Neonates have erythrocyte membranes that differ slightly from those of adults [42]. The percentage of spectrin dimers is the same as in adult cells but neonatal cells have more immunoreactive myosin [43]. The quantity and distribution of lipids in neonatal red cells differ in several respects from adult red cells. Total lipids, phospholipid, and cholesterol are increased out of proportion to the surface area of newborn red cells [44].

Antigen expression in neonatal cells differs from that of adult cells. The A, B, S, and Lutheran antigens are present in lower amounts, membrane receptors for digoxin are 2.5 times that in adult red cells, and an increase in insulin receptors is also seen, possibly explainable by their larger surface area [45]. Red cell deformability and viscoelastic properties are normal [57], but the passage of newborn red cells through small pore filters is impaired. This is probably the result of larger size. Osmotic fragility of erythrocytes from preterm neonates is similar to or less than erythrocytes of term neonates. However, preterm neonates may have a small subpopulation of cells more susceptible to hemolysis, giving them a greater tendency to develop hemolytic jaundice [45, 46].

Red cells of neonates have distinctive metabolic characteristics [47–49]. To some extent these differences are explained by the young age and increased size of the red cells. The increase in activity of many of the glycolytic enzymes is comparable in magnitude to that observed in high-reticulocyte adult blood. Increased glycolytic enzyme activity is responsible for increased consumption of glucose and galactose and increased levels of adenosine triphosphate (ATP).

The concentration of 2,3-DPG falls rapidly during short periods of incubation [49], apparently because of accelerated breakdown. Preterm infants have lower 2,3-DPG concentrations than term infants. These concentrations gradually increase with gestation. Concentrations can be increased with the use of Epo, thereby shifting the oxygen dissociation curve to the right [50].

The activities of two key enzymes of the pentose phosphate pathway, glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase, are increased due to the young mean red cell age. The response of the pentose phosphate pathway to oxidant stimuli is normal, and the level of reduced glutathione is equal to or greater than that found in adults [51]. However newborn cells have glutathione instability, increased Heinz body formation, and a propensity to increased methemoglobin generation, all indicative of greater susceptibility to oxidant-induced injury. This characteristic, which has been known for a long time [52], has been better explained by recent investigations. It has been demonstrated that red cells of newborns and particularly of premature infants have high intraerythrocyte release of non-protein bound iron and evident binding of autologous IgG to band 3 dimers [53]. These markers of oxidative stress demonstrated that red cell injury is enhanced by hypoxia and acidosis [54]. Therefore, the demonstration of increased oxidative cell injury of red cells during hypoxia strongly suggests a role of hypoxia induced cell damage in the reduced life span of the fetal and neonatal erythrocytes. The high susceptibility of neonatal erythrocytes to oxidative stress does not appear to only depend upon low levels of glutathione peroxidase and glutathione synthetase, no apparent relationships have been clearly demonstrated to exist between these deficiencies and clinical evidence of red cell vulnerability.

Although elevated at birth, the red cell ATP level falls rapidly during short periods of incubation. The uptake of labeled orthophosphate by cord blood cells is slower than that by adult cells, resulting in delayed incorporation of phosphate into ATP and 2,3-DPG [50, 55].

Cord blood contains three types of Hb: HbF (α_2, γ_2), HbA (α_2, β_2), and HbA2 (α_2, δ_2). HbF constitutes the major fraction (50–85%). Because of this, hemoglobinopathies involving β-chain synthesis, such as sickle cell disease and β-thalassemia, are not problematic during the neonatal period. The G-γ to A-γ ratio at birth is approximately 3:1, in contrast to a ratio of 2:3 in adults [55, 56]. HbA accounts for 15–40% of the Hb at birth. HbA2 is only present in trace amounts (mean, 0.3%) at birth, but it increases slowly after birth, reaching the normal adult level (2–3%) by 5 months of age. Relative to values in adults, free erythrocyte protoporphyrin is high at birth and remains elevated through the first six months.

The level of HbF at birth is influenced by a number of variables, the most significant of which is gestational age. Premature infants have more HbF and postmature infants less [55]. Neonates who have survived chronic intrauterine hypoxia have higher levels of HbF. Hemolytic disease is associated with lower levels of HbF. This association does not result from a difference in the synthetic ratios of β- and δ-globin chains, but rather relates to a younger population of red cells produced late in fetal life. The switch from γ-chain synthesis to β-chain synthesis is insensitive to environmental variables and appears to be developmentally programmed. Neither intrauterine transfusion nor neonatal exchange transfusion affects the synthetic rates of β- and δ-chains. Studies quantifying the specific globin mRNAs report that (G)gamma globin mRNA to total gamma globin mRNAs remains around 66% until the 44th week of post-conceptional age, when a change in the (G)gamma and (A)gamma globin mRNA proportions occurrs. Immature red cells of adults have a range of (G)gamma globin mRNA to total gamma globin mRNAs varying from 20–74%.

HbF has a higher affinity for oxygen than does HbA [55]. The oxygen tension at which the Hb of cord blood is 50% saturated is 19–21 mmHg, 6–8 mmHg lower than that of normal adult blood. This shift to the left of the Hb-oxygen dissociation curve results from poor binding of 2,3-DPG by HbF. The position of the oxygen dissociation curve is determined by both the percentage of HbA and the red cell content of 2,3-DPG. As the relative proportion of HbA increases, the oxygen dissociation curve shifts by approximately 4–6 months of age to the adult position. The increased oxygen affinity of HbF confers a physiologic advantage to the fetus in facilitating the transfer of oxygen from mother to fetus.

HbF is resistant to acid elution. This property forms the basis for its chemical quantitation. Unlike HbA, HbF is not eluted from fixed blood smears immersed in an acid buffer [55]. This property permits the differential staining of HbF and HbA, a technique widely used to study the distribution of HbF in red cells and to detect fetal cells in the maternal circulation, termed a Kleihauer Behke stain.

When a neonate has Coombs negative hemolytic jaundice, considerations include an inherited disorder of erythrocyte membrane structure or erythrocyte metabolism. In neonates of Northern European ancestry with hemolytic jaundice in the first days of life and a negative Coombs test, Hereditary Spherocytosis (HS) or Hereditary Elliptocytosis (HE) should be considered. HS has a prevalence estimate of about one case per 2000 births and HE about one case per 3000 births. Neonates with HS tend to have a large MCHC, as shown in Fig. 103.3 [57]. When a neonate of Southeastern Asia has Coombs negative jaundice a variety of HE called Southeastern Asian Ovalocytosis should be considered. These disorders can be identified by peripheral smear, noting the distinctive abnormalities of erythrocyte shape [57–61]. All involve genetic mutations of the erythrocyte cytotoskeletal components, as noted in Table 103.2 and illustrated in Fig. 103.4.

Programs to mass-screen neonates for hemoglobinopathies appear to be successful. For instance, during a 10-year evaluation in Brussels over 100,000 neonates underwent screening for hemoglobinopathies. Sickle cell was identified in 64, six had beta-thalassemia major, four had an Hb C disease, and three had an Hb H disease [62].

Table 103.2 The more common varieties of Coombs negative neonatal hemolytic disease with abnormal erythrocyte shapes

Defect	Disorder	Proportion with this variety	Inheritance	Severity
Ankyrin	Spherocytosis	40–65%	Dominant	Mild to moderate
Band 3	Spherocytosis Southeast Asian Ovalocytosis	20–35%	Dominant	Mild to moderate
β-spectrin	Spherocytosis	15–30%	Dominant	Mild to moderate
α-spectrin	Spherocytosis	<5%	Recessive	SEVERE
Protein 4.2	Spherocytosis	<5% (Japan)	Recessive	Mild to moderate
Protein 4.1	Elliptocytosis		Dominant	Mild to moderate

103.5 Fetal and Neonatal Anemia Due to Immune-Mediated Hemolytic Disease

Various causes of fetal and neonatal hemolytic disease are noted in Table 103.3. Fetal bilirubin is cleared by the placenta and metabolized by the maternal liver [63]. As a result fetal hemolytic disease essentially never presents as severe jaundice at birth. However, after birth the products of heme catabolism must be processed by the neonate's liver, which is limited in its ability to metabolize bilirubin efficiently. This limitation is due in part to a deficiency of the cytoplasmic acceptor protein ligandin, and in part because of decreased activity of uridine diphosphoglucuronyl transferase [63, 64].

Worldwide, isoimmunization caused by maternal-fetal blood group incompatibility is the most common cause of newborn hemolytic jaundice. Antigens in the Rh, ABO, MN, Kell, Duffy, and Vel systems are well developed on fetal red cells

Table 103.3 Causes of neonatal hemolytic disease

A. Immune mediated
   1. Rh (anti-D) incompatibility
   2. ABO incompatibility
   3. Other blood group incompatibility- Duffy, Kell, Jka, MNS, Vw
   4. Maternal autoimmune hemolytic anemia

B. Erythrocytes enzyme mutations

during early intrauterine life [65]. They are present in the fifth to seventh gestational week and remain through the remainder of intrauterine development. Other antigens, such as the Lutheran and XgA systems, develop more slowly but are present at birth, unlike Lewis antigens, which develop after birth. By 2 years of age the red cell antigens have developed a pattern that is seen throughout the remainder of life [66]. Although A and B antigens are present early in utero, A and B isoagglutinin production occurs later during the second and third trimester [66]. By 30–34 weeks' gestation, about one-half of all fetuses have measurable anti-A or anti-B antibodies.

Alloimunization to Kell can present with unique neonatal findings. A low reticulocyte count can be seen along with a low Hb and elevated bilirubin [67]. This is because anti-Kell antibodies can bind to erythroid progenitors and reduce red cell production [68].

Extremely high titers of anti-C antibody have been associated with neonatal hemolytic disease [69]. However, routine screening of anti-C titers during pregnancy is not warranted because antibody titers do not accurately reflect the severity of hemolytic disease [70, 71].

103.6 Fetal and Neonatal Anemia due to Hemorrhage

Causes of hemorrhage that can result in fetal or neonatal anemia are noted in Table 103.4 and are divided into prenatal, perinatal, and postnatal varieties.

Table 103.4 Causes of hemorrhage in the fetus and neonate

A. Prenatal
1. Twin-twin transfusion
2. Fetal maternal hemorrhage
3. Trauma with bleeding into cord, placenta, amniotic fluid

B. Perinatal
1. Placenta previa
2. Placental abruption
3. Vasa previa
4. Velementous insertion of the umbilical cord
5. Nuchal cord
6. Trauma or incision of the cord or placenta during cesarean section
7. Rupture of the umbilical cord at delivery

C. Postnatal
1. Subgaleal hemorrhage
2. Cephalohematoma
3. Organ trauma after birth
4. Pulmonary hemorrhage
5. Intrcranial hemorrhage
6. Iatrogenic blood loss

103.6.1 Prenatal Hemorrhage

Approximately 1 pregnancy in 400 is associated with fetal to maternal hemorrhage (FMH) of 30 mL or more, and 1 pregnancy in 2000 is associated with FMH of 100 mL or more (72). FMH consisting of small volumes of blood is very common. Perhaps as many as 75% of pregnancies can be shown to have 0.01–0.1 mL of fetal blood transferred into the maternal circulation. Transfer of fetal blood cells into the mother occurs during abortions as well. This has been reported in approximately 2% of spontaneous abortions and in 4–5% of induced abortions [73]. The Kleihauer Betke stain of maternal blood evaluates the acid elution of Hb from red cells [74]. HbF resists acid elution to a greater degree than adult Hb. Therefore maternal cells appear clear (termed ghost cells), whereas any erythrocytes of fetal origin will appear pink. False positive results occur when mothers have an increase in HbF (i.e., sickle cell disease, thalassemia, and hereditary persistence of HbF). Diagnosing FMH can also be difficult to detect when the mother is blood group O and the infant is A, B, or AB, because fetal cells are rapidly cleared from the maternal circulation by maternal anti-A or anti-B antibodies and therefore they do not appear on the Kleihauer Betke stain.

Severe FMH can be suspected before delivery by decreased fetal movements and a fetal sinusoidal heart rate pattern [75, 76]. Giacoia reviewed these variables to determine if they correlated with the severity of FMH [73]. Fetal movements for a period ranging between 24 hours and 7 days were absent in 17 of 134 cases evaluated. In this group, six infants survived, five were stillborn, and five died in the neonatal period. A sinusoidal heart rate pattern was reported in 21 cases, and was associated with decreased fetal movement in 40% of the cases. No significant difference was found between the cases with a hemorrhage of less than 200 mL and those less than 200 mL. Significant FMH has been described following maternal trauma [76].

Neonates delivered after a significant FMH can be very pale, tachycardic, and tachypnec, but they generally do not have marked respiratory distress or a requirement for supplemental oxygen. Their Hb concentration can be as low as 4–6 g/dL and a significant metabolic acidosis is often present in association with poor perfusion. Other causes of pallor can be ruled out once the infant is stable. Infants with asphyxia or chronic anemia due to hemolysis can also present with pallor. These diagnoses can be distinguished from acute hemorrhage based on differences in clinical signs and symptoms. With chronic blood loss the signs of shock are usually absent. Asphyxiated infants are pale, floppy, and may have poor peripheral circulation. The Hb will be stable, but may decrease if disseminated intravascular coagulation (DIC) and internal bleeding occur.

Twin-twin transfusion is a complication of monochorionic twin gestations, occurring in 5–30% of these pregnancies [75, 76]. It involves placental anastomoses that permit transfer of blood from one twin to the other. The perinatal mortality rate can be 70% or more. About 70% of monozygous twin pregnancies have monochorionic placentas. Although vascular anastomoses are present in almost all such, not all develop

twin-twin transfusion. Acute twin-twin transfusion generally results in twins of similar size but with Hb concentrations that vary by more than 5 g/dL [75, 76]. In chronic twin-twin transfusion, the donor twin becomes progressively anemic and growth retarded, whereas the recipient twin becomes polycythemic, macrosomic, and sometimes hypertensive. Both can develop hydrops fetalis; the donor twin becomes hydropic from profound anemia, and the recipient twin from congestive heart failure and hypervolemia. The donor twin often has low amniotic fluid volumes, whereas the recipient twin has increased amniotic fluid, due to significant differences in blood volume, renal blood flow, and urine output.

Chronic twin-twin transfusion can be diagnosed by serial prenatal ultrasound measuring cardiomegaly, discordant amniotic fluid production, and fetal growth discrepancy of >20%. Percutaneous umbilical blood sampling can determine if Hb concentration differences of greater than 5 gm/dL exist. After birth, the donor twin may require transfusions and can have neutropenia, hydrops from severe anemia, growth retardation, congestive heart failure, and hypoglycemia. The recipient twin is often the sicker of the two, with problems including hypertrophic cardiomyopathy, congestive heart failure, polycythemia, hyperviscosity, respiratory difficulties, hypocalcemia, and hypoglycemia. Neurologic evaluation and imaging are imperative because the risk of antenatally acquired neurologic cerebral lesions is 20–30% in both twins. The incidence of neurologic morbidity following the intrauterine death of one of the fetuses averages 20–25%. Morbidities include multiple cerebral infarctions, hypoperfusion syndromes from hypotension, and periventricular leukomalacia. Long-term neurologic follow-up is indicated for all survivors of twin-twin transfusion [75, 76].

Prenatal treatment for twin-twin transfusion consists of close monitoring and reduction amniocenteses to decrease uterine stretch and prolong the pregnancy. Selective feticide of the hydropic twin has been advocated by some and has resulted in the survival of the healthier twin in some studies [77]. Treatment in utero has occurred during some pregnancies using laser ablation of bridging vessels, resulting in improved survival rates up to around 50%, with approximately 70% of the pregnancies having at least one survivor [78–80]. However, the survival rate without morbidity in the surviving twin is approximately 50%. Supski et al performed a meta analysis of 140 cases to correlate types of treatment with outcome [81]. They found no differences in outcome between amnioreduction, fetoscopy, septostomy, or close observation.

103.6.2 Perinatal Hemorrhage

Perinatal blood loss to the fetus can occur with various obstetric complications, such as placenta previa, placental abruption, incision or tearing of the placenta during cesarean section, and cord evulsion. When a fetus undergoes significant blood loss back into the placenta the term fetoplacental hemorrhage is used. Placental anomalies such as a multilobed placenta and placental chorioangiomas can be a source of perinatal bleeding [82].

Placental abruption occurs in 3–6 per 1000 live births. Risk factors of placental abruption include prolonged rupture of the membranes, severe fetal growth restriction, chorioamnionitis, hypertension, maternal diabetes, cigarette smoking, and advanced maternal age [83]. The incidence of abruption increases with lower gestational age. Neonatal mortality rates from abruption range from 0.8–2.0 per thousand births, or 15–20% of the deliveries in which significant abruption occurs.

Women with a history of a previous cesarean birth and increased parity are at increased risk of placenta previa [84], a condition where part or all of the placenta overlies the cervical os. Cigarette smoking is associated with a 2.6- to 4.4-fold increased risk of placenta previa [85]. Prenatal diagnosis of vasa previa (anomalous vessels overlying the internal os of the cervix) can be made with transvaginal color Doppler, and should be suspected in cases of antepartum or intrapartum hemorrhage. Although uncommon (1 in 3000 deliveries), the perinatal death rate is high, ranging from 33–100% when this condition is undetected before delivery [86].

Neonates delivered after placental abruption or after placenta previa can be anemic but they can also have signs of hypoxia and ischemia. The majority of blood lost in an abruption or previa is maternal blood, but the neonate can have some degree of anemia as well. Therefore, when perinatal blood loss is recognized or suspected, the neonate's Hb should be measured at birth and again 12 hours or so later. A Kleihauer Betke stain can be performed on maternal blood to determine if fetal hemorrhage can be documented. Monitoring bleeding mothers with ultrasound might detect placental abnormalities.

Cord rupture due to traction on a shortened or abnormal umbilical cord usually occurs on the fetal side. Cord aneurysms, varices, and cysts can all lead to a weakened cord. Cord infections (funisitis) can also weaken the cord and increase the risk of rupture. Infants born precipitously may be at increased risk for hemorrhage due to a ruptured cord.

Cord hematomas occur infrequently (1 in 5000–6000 deliveries) and can be a cause of fetal blood loss and perinatal mortality. Intrauterine death can occur due to compression of the umbilical vessels by a cord hematoma. Cord hematomas can result from trauma from percutaneous umbilical blood sampling. Hematomas of the cord can be diagnosed in utero by ultrasound [86, 87].

Subamniotic hematomas can occur when chorionic vessels rupture near the cord insertion. Most subamniotic hematomas are the result of traction on a normal or shortened umbilical cord and are not noted until after delivery.

Velamentous insertion of the umbilical cord occurs when the umbilical cord enters the membranes distant from the placenta. This is present in 0.5–2.0% of pregnancies [88]. Blood vessels left unprotected by Wharton jelly are more likely to tear. Rupture of anomalous vessels in the absence of traction or trauma can occur even if the cord itself attaches

centrally or paracentrally. Fetal mortality remains very high in this condition, often because detection by routine ultrasound is rare [89].

103.6.3 Postnatal Hemorrhage

Loss of fetal blood into the placenta can occur during delivery. In fact, a net shift of blood from the fetus into the placenta is a rather common cause of low-grade neonatal anemia. At term, the fetal-placental-umbilical cord unit contains about 120 mL of blood per kg body weight. After delivery, but before the umbilical cord is severed, blood in this unit can flow predominantly toward or away from the neonate. A fetoplacental hemorrhage can occur when the neonate is held significantly higher than the placenta after birth. Also, neonates can lose up to 20% of their blood volume when born with a tight nuchal cord, which allows blood to be pumped through umbilical arteries toward the placenta, while constricting flow back from the placenta to the baby, through the umbilical vein, which is more easily constricted due to its thin wall.

As shown in Fig. 103.5, blood loss can occur into the subgaleal space before or after birth. This is seen most commonly with difficult deliveries requiring vacuum or forceps assistance. Subgaleal hemorrhages are potentially life-threatening and must be recognized as early as possible to prevent significant morbidity or mortality. The hemorrhage occurs when bridging veins are torn, allowing blood to accumulate in the large potential space between the galea aponeurotica and the periosteum of the skull. The subgaleal space extends from the orbital ridge to the base of the skull and can accommodate a volume equivalent to a neonate's entire blood volume [90, 91].

Subgaleal hematomas can form because of risk factors such as coagulopathy or asphyxia, but vacuum extraction itself is a risk factor for their development. The diagnosis should be considered in the presence of a ballotable fluid collection in dependent regions of the infant's head, coupled with signs of hypovolemia [92]. Treatment requires restoration of blood volume and control of bleeding. Exsanguination due to subgaleal hemorrhage has been reported. A suggested way to estimate the volume of blood lost is by following head circumference; 40 mL of blood has been lost for every 1 cm increase in head circumference that occurs [93]. The duration of vacuum application is thought to be the best predictor of scalp injury, followed by duration of second stage of labor and paramedian cup placement. Of those with reported subgaleal hemorrhages, 80–90% had some history of vacuum or instrument-assisted delivery [92, 93]. Limiting the frequency and duration of vacuum assistance in high-risk infants might decrease the incidence of subgaleal hematomas.

Anemia appearing after the first 24 hours of life in a nonjaundiced infant can be a sign of hemorrhage. Hemorrhages

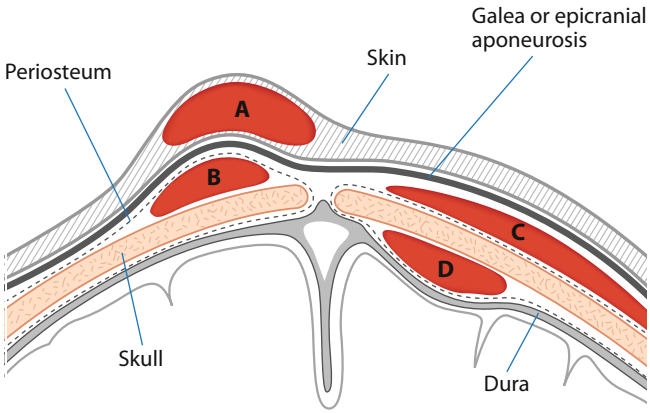

Fig. 103.5 A schematic drawing of the scalp and skull of a newborn infant, illustrating four distinct anatomic spaces where fluid or blood might collect during or after delivery. **A** caput hemorrhage, **B** cephalhematoma, **C** subgaleal hemorrhage, **D** extradural hemorrhage

can be visible, such as a cephalohematoma, or occult. Breech deliveries can be associated with renal, adrenal, or splenic hemorrhage into the retroperitoneal space. Delivery of macrosomic infants, such as infants born to diabetic mothers, can result in hemorrhage. Infants with overwhelming sepsis can bleed into soft tissue and organs.

In addition to causing anemia, adrenal hemorrhage can result in circulatory collapse due to the loss of organ function. The incidence of adrenal hemorrhage is 1.7 per 1000 births [94]. Adrenal hemorrhage can also affect surrounding organs. Intestinal obstruction and kidney dysfunction have been reported in infants with adrenal hemorrhage [95]. The diagnosis can be made using ultrasonography, during which calcifications or cystic masses are noted. Adrenal hemorrhage can be distinguished from renal vein thrombosis (RVT) by ultrasound, in that RVT generally results in a solid mass. Occasionally, both entities coexist in the same patient.

The liver of a neonate is prone to iatrogenic rupture, resulting in high morbidity and mortality [96]. Neonates with this problem can appear asymptomatic until the liver ruptures and hemoperitoneum occurs. This problem can occur in both term and preterm infants [97] and has been associated with chest compressions during cardiopulmonary resuscitation. Surgical intervention has been reported to save some infants but the mortality is very high [97].

Splenic rupture can result from birth trauma or as a result of distention caused by extramedullary hematopoiesis, such as that seen in erythroblastosis fetalis. Abdominal distension and discoloration, scrotal swelling, and pallor are clinical signs of splenic rupture; these can also be seen with adrenal or hepatic hemorrhage [96–98].

More rare causes of hemorrhage in the newborn period include hemangiomas of the gastrointestinal tract [99], vascular malformations of the skin, and hemorrhage into soft tumors, such as giant sacrococcygeal teratomas. Occult intraabdominal hemorrhage can occur with fetal ovarian cysts, which are

usually benign and resolve spontaneously. One case of fetal anemia was diagnosed by a spontaneous hemorrhage into a fetal ovarian cyst and was managed by intrauterine blood transfusions [100].

103.7 Fetal and Neonatal Anemia Due to Congenital Infection

Neonatal bacterial sepsis can cause anemia on the basis of hemolysis, DIC, and hemorrhage. Some microorganisms responsible for neonatal sepsis produce hemolytic endotoxins that result in accelerated erythrocyte destruction, often associated with a microangiopathic process [101].

Congenital viral infections can also cause hemolytic anemia. Congenital syphilis can present with hemolytic anemia. Initial maternal screening for syphilis can be negative despite overwhelming infection, a condition termed the prozone effect [101], which occurs when a higher than optimal amount of antibody in the tested sera prevents the flocculation reaction seen in positive reagin test. In cases of nonimmune hydrops, nontreponemal testing should be repeated using serum dilutions to prevent a missed diagnosis of syphilis in women with negative syphilis serologic results.

Fetal and neonatal infection with parvovirus B19 can cause severe anemia, hydrops, and fetal demise [102]. This is generally a hypoplastic anemia, but hemolysis can occur as well. The virus replicates in erythroid progenitor cells and results in red cell aplasia. In utero transfusions for hydropic fetuses can be successful. Intrauterine fetal infusion of B19 IgG-rich high titer gamma globulin has been reported to be successful [103].

Other fetal infections associated with neonatal anemia include malaria and HIV. Congenital malaria is seen rarely in the USA, generally in large cities where imported cases of malaria are increasing. In certain African countries, congenital malaria has been reported in up to 20% of neonates [104]. Congenital HIV infection in a neonate is generally asymptomatic. However infants born to mothers on zidovudine can have a hypoplastic anemia due to suppressive effects of the drug on fetal erythropoiesis [105].

103.8 Anemia of Prematurity and Other Hypoproliferative Disorders

Impaired erythrocyte production can occur in a fetus or neonate for a variety of reasons. Lack of an appropriate or sufficient marrow environment (as seen in osteopetrosis), lack of specific substrates or their carriers (e.g., iron, folate, vitamin B12, or transcobalamin II deficiency) and lack of specific growth factors (e.g., decreased Epo production or abnormalities in Epo receptors) can be causative.

103.8.1 Anemia of Prematurity

Infants delivered before 32 completed weeks gestation typically develop a transient and unique anemia knows as the anemia of prematurity. During the first week or two after birth, while in an intensive care unit, anemia secondary to phlebotomy loss is common. However, after this period has passed, a second anemia is sometimes seen; characterized as a normocytic, normochromic, hyporegenerative anemia, with serum Epo concentrations significantly below those found in adults with similar degrees of anemia [106]. This anemia is not responsive to the administration of iron, folate, or vitamin E. Some infants with the anemia of prematurity are asymptomatic, whereas others have clear signs of anemia that are alleviated by erythrocyte transfusion. These signs include tachycardia, rapid tiring with nipple feedings, poor weight gain, increased requirements for supplemental oxygen, episodes of apnea and bradycardia, and elevated serum lactate concentrations.

The reason preterm infants do not significantly increase serum Epo concentration during this anemia is not known. Indeed, it is unclear whether production of Epo does in fact increase, yet the serum concentration does not. Certainly their erythroid progenitors are sensitive to Epo [107, 108], and concentrations of other erythropoietic growth factors appear to be normal [109].

The molecular and cellular mechanisms responsible for the anemia of prematurity remain undefined. Some explanations include the transition from fetal to adult Hb, shortened erythrocyte survival, and hemodilution associated with a rapidly increasing body mass [110]. It is unknown whether preterm infants rely on Epo produced by the liver (the source of Epo in utero), or that produced by the kidney, or a combination of the two. Regardless of the mechanism responsible for the anemia of prematurity, exogenous Epo administered to preterm infants accelerates effective erythropoiesis [111]. A meta-analysis of studies evaluating the use of "late" Epo administration to prevent and treat the anemia of prematurity reveals a positive effect on decreasing transfusion requirements in preterm infants [112]. In addition, beneficial neurodevelopmental effects of recombinant Epo administration have been reported in preterm infants [113–116].

Pharmacokinetic studies of darbepoetin, the long-acting erythropoietic stimulator, have been conducted among neonates with the anemia of prematurity, with the speculation that less frequent dosing and cost savings might render Darbepoetin a more attractive alternative than recombinant Epo

Table 103.5 Terminal half-life of darbepoetin among adults, children, and neonates after subcutaneous or intravenous dosing

	After subcutaneous dosing	After intravenous dosing
Adults	49 hours	25 hours
Children	43 hours	22 hours
Neonates	22 hours	10 hours

for treating the anemia of prematurity [117–119]. Following subcutaneous and intravenous dosing, Darbepoetin has a considerably shorter terminal half-life in neonates than in adults (Table 103.5). Intravenous dosing appears to be as effective as subcutaneous dosing.

103.8.2 Other Hypoproliferative Anemias and Associated Syndromes

During the neonatal period hypoproliferative anemias are rare, with the exception of the anemia of prematurity, which is common (Table 103.6). Diamond-Blackfan syndrome can be diagnosed at birth but usually is not recognized until after 2–3 months of age. At least 10–25% of infants with Diamond-Blackfan syndrome have anemia at birth [120, 121], and severe anemia with hydrops has been reported. Aase syndrome, another congenital hypoplastic anemia syndrome involving skeletal anomalies [122], is sometimes classified as a variant of Diamond-Blackfan syndrome. Congenital dyserythropoietic anemia is a rare disorder marked by ineffective erythropoiesis, megaloblastic anemia, and characteristic abnormalities of the nuclear membrane and cytoplasm seen on electron microscopy. Fanconi anemia almost never manifests during the neonatal period. This autosomal-recessive disorder is characterized by marrow failure and congenital anomalies, including abnormalities in skin pigmentation, gastrointestinal anomalies, renal anomalies, and upper limb anomalies [123].

Osteopetrosis involves osteoclast dysfunction, resulting in a decreased marrow space [124, 125]. Developmental delay, ocular involvement, and neurodegenerative findings occur in these patients in association with hypoplastic anemia. Patients are generally treated with stem cell transplantation, but they are particularly susceptible to post-transplantation complications after myeloablation, and reduced-intensity conditioning programs may be helpful.

Pearson syndrome is a congenital hyporegenerative anemia that can progress to pancytopenia, and additionally affects the exocrine pancreas, liver, and kidneys [126]. These patients can present during the neonatal period, but typically do so later in infancy. Features include failure to thrive and cytopenia. The marrow examination shows characteristic vacuoles within erythroid and myeloid precursors, hemosiderosis, and ringed sideroblasts. The syndrome is caused by a loss of large segments of mitochondrial DNA [127, 128].

Table 103.6 Syndromes associated with congenital anemia

Syndrome	Phenotypic features	Genotypic features
Adenosine deaminase deficiency	Autoimmune hemolytic anemia, reduced erythrocyte adenosine deaminase activity	AR, 20q13.11
Congenital dyserythropoietic anemias	Type I (rare): megaloblastoid erythroid hyperplasia and nuclear chromatin bridges between nuclei; type II (most common): "hereditary erythroblastic multinuclearity, positive acidified serum (HEMPAS) test, increased lysis to anti-i; type III: erythroblastic multinuclearity ("gigantoblasts"), macrocytosis	Type I: 15q15.1-q15.3; type II: 20q11.2; type III: 15q21
Diamond-Blackfan syndrome	Steroid-responsive hypoplastic anemia, often macrocytic after 5 months of age	AR; sporadic mutations and AD inheritance described; 19q13.2, 8p23.3-p22
Dyskeratosis congenita	Hypoproliferative anemia usually presenting between 5–15 yr of age	X-linked recessive, locus on Xq28; some cases with AD inheritance
Fanconi pancytopenia	Steroid-responsive hypoplastic anemia, reticulocytopenia, some macrocytic RBCs, shortened RBC lifespan. Cells are hypersensitive to DNA cross-linking agents	AR, multiple genes: complementation; group A: 16q24.3; B:; C: 9q22.3; D2: 3p25.3; E: 6p22-p21; F: 11p15; G: 9p13
Osler hemorrhagic telangiectasia syndrome	Hemorrhagic anemia	AD, 9q34.1
Osteopetrosis	Hypoplastic anemia from marrow compression; extramedullary erythropoiesis.	AR: 16p13, 11q13.4-q13.5; AD: 1p21; lethal: reduced osteoclasts
Pearson syndrome	Hypoplastic sideroblastic anemia, marrow cell vacuolization	Pleioplasmatic rearrangement of mitochondrial DNA; X-linked or AR
Peutz-Jeghers syndrome	Iron deficiency anemia from chronic blood loss	AD, 19p13.3
X-linked α-thalassemia/ mental retardation (ATR-X and ATR-16) syndromes	ATR-X: hypochromic, microcytic anemia; mild form of hemoglobin H disease ATR-16: more significant hemoglobin H disease and anemia are present	ATR-X: X-linked recessive, Xq13.3; ATR-16: 16p13.3, deletions of α-globin locus

AD autosomal dominant, *AR* autosomal recessive, *RBC* red blood cell.

103.9 Considerations Regarding Erythrocyte Transfusion in the Neonatal Period

Best practices in neonatal transfusion medicine are largely undefined. A very basic issue that remains unsettled is at what level to keep the Hb concentration during the NICU stay. Specifically, it is not clear whether to keep a NICU patient's Hb as high as it would be in utero (often requiring multiple transfusions to do so) or whether to permit the Hb to fall to considerably lower values, attempting to avoid or minimize transfusions. Attempts have been made to define the best Hb range for NICU patients, but study findings are discordant.

In a single-centered study, Bell et al randomized 100 neonates with birth weights <1300 g (average birth weight 956 grams) to maintain a hematocrit in a higher range versus a lower range. Those kept in the lower range received fewer transfusions (average of 2 additional transfusions per patient), but were more likely to have intraparenchymal brain hemorrhage or periventircular leukomalacia [129]. In contrast, the PINT study (Premature Infants in Need of Transfusion), a larger multicentered study involving 451 extremely low birth weight neonates (average birth weight 770 grams), concluded that neonates randomized to the lower hematocrit range had fewer transfusions but similar neurodevelopmental outcomes [130].

Various neonatal transfusion guidelines have been used over the last 2 decades, and research is ongoing to determine the optimal strategy for administering red cell transfusions to preterm and term neonates. One strategy developed by the Canadian Paediatric Society in 2002 is shown in Table 103.7. When considering a transfusion in a preterm infant with a low hematocrit which is not due to acute hemorrhage, it should be determined if the infant needs an immediate increase in oxygen to tissues. If so, then treatment consists of a transfusion of packed red cells. If there is no evidence that an immediate increase in oxygen delivery is necessary, then treatment with red cell growth factors and appropriate substrates might be considered. As the process of stimulating erythropoiesis requires at least a week to significantly impact the reticulocyte count, and may not appreciably increase the hemoglobin concentration during that time, the infant should continue to be observed for signs consistent with anemia.

A method of reducing erythrocyte transfusions, among a subset of preterm neonatal patients, is to begin the administration of recombinant Epo to those with low hematocrits after the first three weeks of life [110–113]. Recombinant Epo certainly stimulates erythropoiesis in such patients, although its combination with additional folate, iron, vitamin E, and vitamin B12 may be superior to recombinant Epo alone [132].

Haiden and colleagues achieved significantly greater success in preterm infants <800 grams (38% of infants not transfused) when vitamin B12 at a dose of 21 mg/kg/week SC was added to a regimen of Epo, iron, vitamin E and folate [132]. When combined with limited phlebotomy losses, this therapy shows great promise in ELBW infants.

Another method of reducing erythrocyte transfusions to ill neonates is to delay clamping the umbilical cord. Even a delay of 30 seconds can result in improved iron status [133], fewer transfusions [130], and perhaps superior neurodevelopmental outcomes [134-137].

Yet another method of reducing or postponing early erythrocyte transfusions among extremely low birth weight neonates is to draw the blood for the initial laboratory tests from the placenta not from the neonate. The initial phlebotomy of an extremely low birth weight neonate, on admission to the NICU, can include a blood culture, CBC, type and cross-match, metabolic screen, blood gas, electrolytes, and glucose. Sometimes other studies such as coagulation tests are also drawn at or shortly following NICU admission. The total blood volume needed for these base-line NICU laboratory studies can be 4–5 mL or more. In a 400–500 gram neonate this can exceed 10% of the total blood volume. Early transfusions in the NICU can also be reduced by careful attention to phlebotomy volumes during the first days following delivery. Transfusions given during the first week or two are principally to replace phlebotomy losses for laboratory tests. Employing laboratory methods that minimize blood loss will reduce early transfusions. Such methods include point of care monitors, point of care analyzers, and a concerted effort to use the smallest amount of blood possible for the needed laboratory studies [137–138].

Table 103.7 Canadian Paediatric Society recommendations for RBC transfusions in newborn infants

- Acute blood loss resulting in hypovolemic shock
- Hemoglobin between 10 and 12 g/dL or hematocrit between 30 and 35% in extreme illness conditions for which RBC transfusion may improve oxygen delivery to vital organs
- Hemoglobin between 6 and 10 g/dL or hematocrit between 20% and 30%, in severely ill neonates and/or on mechanical ventilation with compromised oxygen delivery
- Hemoglobin below 6 g/dL or hematocrit below 20% with absolute reticulocyte count 100–150 × 10^3/μL or less, suggesting low plasma concentration of erythropoietin, with the presence of the following clinical signs: poor weight gain, heart rate >180 beats/minute, respiratory distress and increased oxygen needs, and lethargy

Modified from [131].

Fetal and Neonatal Hydrops

Gennaro Vetrano and Mario De Curtis

104.1 Introduction

Hydrops fetalis (i.e., fetal hydrops) (HF) is a serious condition defined as an abnormal accumulation of fluid in two or more fetal compartments. It presents as ascites, pleural effusion, pericardial effusion and skin edema. In some patients, it may also be associated with polyhydramnios and placental edema. In 1943, Potter was the first to distinguish non-immune hydrops fetalis (NIHF) from immune hydrops [1].

104.2 Epidemiology

Previously, hemolytic disease due to Rh incompatibility was the main cause of both fetal and neonatal immune hydrops. These days approximately 90% of cases of hydrops fetalis are due to non-immune disease, with the number of liveborn ranging from 1:1500 to 1:3800 [2, 3]. Hydrops fetalis is much more common in Southeast Asia; in Thailand the expected frequency of non-immune hydrops fetalis due to homozygous alpha-thalassemia or Bart hydrops ranges from one every 500 to one every 1500 pregnancies [4, 5]. Although the availability of ultrasound technology has greatly improved antenatal diagnosis of HF, perinatal mortality (PNM) remains high.

104.3 Pathogenesis

The basic mechanism for the formation of HF is an imbalance between interstitial fluid production and lymphatic return. Fluid accumulation in the fetus can be due to (a) heart failure, (b) anemia, (c) obstructed lymphatic flow, or (d) decreased plasma osmotic pressure. The fetus is particularly susceptible to interstitial fluid accumulation because of its greater capillary permeability, compliant interstitial compartments, and liability for raised venous pressure because of impaired lymphatic return [5, 6]. Clinical and animal studies have shown that elevation of central venous pressure (CVP) has a pivotal role in the development of fetal hydrops [7]. Increased CVP causes edema and effusions by increasing capillary hydrostatic pressure and decreasing lymphatic return [8]. Albumin is the main oncotically active plasma protein and when its hepatic synthesis is impaired, transcapillary fluid movements increase [5, 6]. Hypoproteinemia and hypoalbuminemia are common in human hydrops. However, studies in humans and animals have shown that hypoalbuminemia is unlikely to trigger this condition [9].

104.4 Etiology

The possible etiologies of HF are still being unrevealed, as previously unknown causes are reported. However, despite extensive pre- and postnatal investigations, no definite cause can be determined in 33% of cases [10]. HF is an end-stage process and a non-specific finding that is associated with a range of abnormalities. Its causes can be divided into 6 broad categories: hematological disorders, cardiovascular and infectious conditions, genetic abnormalities, tumors, and idiopathic.

Table 104.1 summarizes the causes of fetal hydrops.

104.5 Diagnosis

A pregnant woman with polydramnios, severe anemia, toxemia or isoimmune disease should undergo further investigation.

The antenatal diagnosis of HF is made by the ultrasound finding of fluid accumulation in the fetus or placenta. Specifically, excess serous fluid should be identified in at least one

Table 104.1 Causes of hydrops fetalis

Hematological
- Isoimmunization (immune hydrops) (hemolytic disease of the newborn, erythroblastosis)
  - Rh (most commonly D; also C, c, E, e)
  - Kell
  - ABO
  - Others
- Other hemolytic disorders
  - Glucose phosphate isomerase deficiency
  - Pyruvate kinase deficiency
  - G-6-PD deficiency
- Disorders of red cell production
  - Diamond-Blackfan syndrome
  - Leukemia (usually associated with Down or Noonan syndrome)
  - Alpha-thalassemia (Bart hemoglobinopathy)
  - Parvovirus B19
  - Others
- Fetal hemorrhage
  - Placental subchorial tumors
  - Feto-maternal hemorrhage
  - Twin-to-twin transfusion
  - Isoimmune fetal thrombocytopenia
  - Others

Cardiovascular
- Structural anomalies
  - Abnormalities of left ventricular outflow
  - Abnormalities of right ventricular outflow
  - Other vascular malformations
- Non-structural anomalies
  - Obstruction of venous return
  - Supraventricular tachycardia
  - Congenital heart block
  - Prenatal closure of the foramen ovale or ductus arteriosus
  - Myocarditis
  - Idiopathic arterial calcification or hypercalcemia

Infectious
- Parvovirus B19
- Cytomegalovirus (CMV)
- Syphilis
- Herpes simplex
- Toxoplasmosis
- Hepatitis B
- Adenovirus
- Ureaplasma urealyticum
- Coxsackie virus type B
- Listeria monocytogenes

Genetic
- Inborn errors of metabolism
  - Glycogen-storage disease, type IV
  - Lysosomal storage diseases
  - Hypothyroidism and hyperthyroidism

  - Meconium peritonitis
  - Intracranial teratoma
  - Sacrococcygeal teratoma

Idiopathic

space (ascites, pleural effusion, or pericardial effusion), accompanied by skin edema (> 5 mm thick), or fluid in two potential spaces without edema [11, 12]. Ascites can be detected when a minimum of 50 mL is present in the fetal abdomen [13]. Polyhydramnios and placental thickening (> 6 cm thick) may be present, but oligohydramnios is a particularly ominous finding when it develops in non-immune hydrops fetalis [14].

The subsequent workup of the hydropic fetus should focus on detecting the underlying cause. In general, the first step is to collect detailed information about the mother's medical history, specifically in relation to hereditary or metabolic diseases, diabetes, anemia, exposure to infectious agents, and use of medication. The second step includes a detailed ultrasound examination of the fetus and maternal investigations. The third step, after obtaining maternal results, is a systematic approach to the fetus, including invasive testing, such as villocentesis, amniocentesis, cordocentesis and sampling of any effusions. Invasive investigations of the fetus are necessary when maternal bloods and ultrasound examination fail to provide a definitive cause of HF. The recommended workup of a fetus with HF is shown in Table 104.2.

If the etiology of HF is not identified before birth, postnatal investigations should be done. Blood samples for laboratory analysis are similar to those taken antenatally: blood group including Rh status, direct Coombs antibody screen, full blood cell count, karyotype, metabolic and chemistry studies, hemoglobin electrophoresis, if indicated. Structural defects should be evaluated using skeletal radiographs and ultrasound. A genetic consultation may also be helpful, particularly to determine risk of recurrence. In case of intrauterine or neonatal death, an autopsy is mandatory.

104.6 Treatment

The management of hydrops fetalis is a great challenge for fetal medicine specialists and neonatologists.

A woman with a hydropic fetus should be hospitalized in a level 3 perinatal centre if antenatal non-stress testing (NST)

Table 104.2 Antenatal evaluation of hydrops fetalis

Maternal history
- Age, parity, gestation
- Hereditary or metabolic diseases, anemia
- Recent infections or contacts
- Medication use

Maternal laboratory evaluation
- Complete blood cell count
- Blood type, Rh, indirect Coombs antibody screen
- Kleihauer-Betke stain
- Syphilis, TORCH and parvovirus B19 titers
- Culture for group B streptococcus, Listeria
- Maternal triple screen
- Oral glucose tolerance test
- Optional, as indicated:
  - Metabolic studies
  - Hemoglobin electrophoresis
  - G6PD, pyruvate kinase
  - Autoimmune screen (SLE, anti-Ro and -La)

Ultrasonography
- Identify anatomic abnormalities
- Evaluate extent of edema and effusions
- Exclude twin pregnancy
- Doppler blood flow studies

Fetal echocardiography
- Look for cardiac malformation, arrhythmia

Amniocentesis
- Karyotype
- Culture or PCR for TORCH, parvovirus
- Amniotic fluid alpha-fetoprotein
- Restriction endonucleases (thalassemias)
- Lecithin-sphingomyelin ratio, phosphatidyl glycerol to evaluate lung maturity

Fetal blood sampling
- Karyotype
- Complete blood cell count
- Blood type; hemoglobin electrophoresis
- Blood chemistry, albumin, gases
- Culture or PCR for TORCH, parvovirus
- Metabolic testing (Tay-Sacks, Gaucher, GM_1 gangliosidosis)

Fetal effusion sampling
- Culture or PCR for TORCH, parvovirus
- Protein content
- Cell count and cytology

G6PD glucose-6-phosphate dehydrogenase, *PCR* polymerase chain reaction, *SLE* systemic lupus erythematosus, *TORCH* toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex. Modified from [10].

Table 104.3 Conservative management in hospital

- Hospitalize the patient in the presence of
  - Fetal skin thickening
  - Pericardial effusion
  - Nonreactive NST
  - Biophysical profile (BPP) ≤ 6
  - Subjective decreased fetal movement
  - Gestational age below 32–34 weeks
- Treat the underlying cause, if possible
- Administer antenatal corticosteroids
- Monitor serial growth and effusion volumes
- NST and BPP every 2–3 days

NST non-stress test.

[15] and biophysical profile (BPP) [16] are not reassuring (Table 104.3). At the same time, efforts should be continued to determine the underlying etiology of HF. Delivery is indicated after 34 weeks' gestation, or earlier if there is evidence of a mature fetal lung profile at amniocentesis or if the fetal condition deteriorates. Delivery is also necessary in cases of compromised maternal conditions due to the mirror syndrome (maternal hydrops) [17], a pre-eclampsia-like disease in mothers of hydropic fetuses.

The appropriate treatment of the fetus with hydrops, which carries a high mortality, can only be undertaken after a precise and detailed diagnosis. Full parental involvement is essential because the associated abnormalities may be severely debilitating or even lethal. In addition, invasive fetal treatment and elective preterm delivery remain controversial. Therefore obstetricians, fetal medicine specialists and neonatologists should consult about the optimal timing of delivery also involving pediatric surgeons, cardiologists, and cardiothoracic surgeons. Various anecdotal approaches are found in the literature, but no properly designed clinical trials have been done to provide the clinician with an evidence-base for management. Furthermore, the hydropic process may resolve spontaneously. Thus, management schemes aim to correct the underlying pathophysiology, including fetal transfusion to correct anemia (regardless of the cause), drug treatments for cardiac arrhythmias, correction or reduction of space-occupying lesions that impede cardiac venous or lymphatic return, and procedures intended to stop fetal blood loss (regardless of cause) [18–20].

Fetal transfusion with packed red blood cells (RBCs) given intraperitoneally has become accepted as standard care for the fetus with severe anemia. It carries low risk, even if there is no definitive evidence from randomized clinical trials. This approach has been used successfully in the treatment of severely anemic fetuses of isoimmunized pregnancies and to correct anemia due to various other causes. More recently, other routes (percutaneous umbilical vein, intrahepatic umbilical vein, umbilical artery, intracardiac transfusions) for the administration of blood products to the fetus have been reported. Other approaches have been aimed at the mother, fetus and newborn baby. Maternal plasmapheresis, promethazine or corticosteroids have been used for the mother. Fetal therapies have included partial packed-cell exchange transfusion, fetal intravenous IgG, platelet transfusion, and the administration of human granulocyte-stimulating factor. Neonatal stem cell transplantation has been used for α-thalassemia [21]. However, these newer therapeutic techniques have a greater risk to the fetus than the intraperitoneal route and should therefore be used cautiously.

Highly vascular tumor masses and acute, massive twin-to-twin hemorrhages are life-threatening diseases that may justify life-threatening treatment. Techniques such as tumor debulking surgery, surgery for active bleeding, photocoagulation

and radiofrequency thermal ablation may all be helpful in the treatment of fetal conditions such as sacrococcygeal tumors, highly vascularised fetal intraabdominal, thoracic, or placental masses, and when there is massive arteriovenous shunting [22–23].

The management of the twin-to-twin transfusion syndrome is currently an unresolved problem: treating an anemic fetus with transfusions has shown no evidence of benefit; volume reduction for the transfusion recipient or a combination of transfusion and fetal reduction has rarely been used or may not correct the ongoing pathophysiology. Furthermore, feticide of the affected twin is often followed by the development of hydrops in the previously normal surviving twin [24].

Treatments of fetal arrhythmias include doing nothing, drugs, and immediate delivery. In the presence of fetal maturity, the simplest and most direct approach is delivery of the affected fetus and treatment of the arrhythmia directly after birth. If this is not possible, drugs have been used. Drugs have been administered to mother, or fetus, or both. Medications have included digitalis, furosemide, flecainide, verapamil, amiodarone, propranolol, procainamide, quinidine, adenosine, sotalol, terbutaline, corticosteroids, and immunoglobulins. Various drug combinations have also been used. However, the choice of the drug remains empirical and arbitrary, until definitive evidence from clinical trials becomes available [25, 26].

The management of space-occupying masses varies depending on the type of lesion and from centre to centre. If immediate delivery is not practicable, the mass is either reduced or removed. Pleural and pericardial effusions and ascites have been treated with single or serial drainage. Fetal surgery with definitive correction of the underlying anomaly has also been used. Successes and failures have been reported with all methods; there is no evidence suggesting that one approach is better than another [27].

Postnatal management of HF poses a unique set of problems for the neonatologist. Treatment of the infant after delivery is helped by knowing the cause. In addition to appropriate equipment and supplies for resuscitation, a skilled team of health care professionals (neonatologists, nurses, respiratory therapists, radiograph and ultrasonography technicians) should be present in the delivery room [28, 29]. Fluid in the pleural, pericardial and abdominal cavities may require aspiration in the delivery room to allow adequate ventilation and circulation. Umbilical arterial and venous catheters are sited to monitor and treat arterial pressure, blood gases, venous pressure, hematocrit and the metabolic state of the infant. Packed red cells or whole blood cross matched with the mother should be available for the correction of severe anemia by partial exchange transfusion, even when due to non-immune causes. Surfactant therapy and mechanical ventilation are used to manage surfactant deficiency and pulmonary hypoplasia, which may be associated with hydrops. Fluid intake is based on an estimate of the infant's "dry weight" (e.g., 50th percentile for gestational age) and kept to a minimum (e.g., 40–60 mL/kg/day) until the edema is resolved. Inotropic support (e.g., dopamine) may be required to improve cardiac output [30, 31].

104.7 Prognosis

Estimates of mortality vary widely. The condition has a mortality rate of virtually 100% when structural defects are present or the cause of HF is unknown. Most case series report 60–90% mortality, although notable improvements have been described in more recent reports [5]. In cases of tachyarrhythmias, the prognosis has been improved by antenatal antiarrhythmic treatment. Cases presenting before 24 weeks have a worse prognosis [32], whereas those that present later may benefit from delivery and intensive neonatal care. The risk of recurrent hydrops in a subsequent pregnancy is low, although one series reported a 10% risk of recurrence [18]. In conclusion, despite the fetus with hydrops having profoundly compromised perfusion and impaired function of multiple organ systems, the limited follow-up data that is currently available provides an optimistic outlook for babies who survive fetal hydrops [33].

Physiology and Abnormalities of Leukocytes

Kurt R. Schibler

105.1 Physiology of Leukocytes in the Fetus and Neonate

105.1.1 Introduction

The circulating pool of neutrophils reflect a dynamic equilibrium between neutrophil precursors and mature neutrophils in the bone marrow, circulating neutrophils and activated neutrophils that have migrated into the tissues. The bone marrow is the predominant hematopoietic organ after birth. Within the bone marrow, pluripotential hematopoietic stem and progenitor cells give rise to lineage committed neutrophil precursors. These precursors mature under the influence of growth factors such as granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony stimulating factor (GM-CSF). The bone marrow thus contains pools of immature neutrophils and of stored mature neutrophils. After leaving the bone marrow, neutrophils are transiently in the circulation for a brief period of hours after which they translocate into the tissues.

The peripheral blood neutrophil pool is estimated to contain approximately 5% of the total neutrophil pool. Approximately 1.5 billion neutrophils per kilogram body weight are produced daily. The neutrophil life span consists of about 9 days in the bone marrow, 3–6 hours in the blood, and 1–4 days in the tissues.

Myeloblasts, promyelocytes, and myelocytes are collectively referred to as the neutrophil proliferative pool (NPP) because these cells retain the capacity for cell division. As committed neutrophil precursors mature, their capacity to undergo cell division is lost. This population of postmitotic cells includes metamyelocytes, band neutrophils and mature segmented neutrophils, and is called the neutrophil storage pool (NSP). Neutrophils are released from the NSP to maintain the circulating and marginated neutrophil pools in equilibrium. About 0.3×10^9 neutrophils per kilogram body weight are present in the circulating pool of healthy adults [1].

Adults have a large NSP and can increase circulating neutrophils rapidly in response to infection [2]. By contrast, newborn infants have a relatively small NSP [2]. These differences in the available pool of postmitotic neutrophils limit the ability of newborn infants to respond to the challenges of infections. The circulating neutrophil concentration in humans is relatively low during gestation, but progressively rises until term. Postnatally, the circulating neutrophil count is much higher. Manroe and colleagues described neutrophil ranges in normal term infants during the first 28 days of life [3]. They demonstrated a rise in neutrophil count with a peak between 12 and 24 hours and neutrophil concentrations at that time between 7800 and 14,500 cells per microliter. The neutrophil count subsequently decreased and stabilized after 72 hours with a lower value of 1750 cells per microliter. Mouzihno and coworkers established a reference range for blood neutrophil concentrations in very low birth weight infants [4]. The upper range for normal neutrophil concentration was similar to that of term infants. The lower levels, defining neutropenia, were about 2000 cells per microliter at 12 hours and stabilized at 1000 cells per microliter by 48 hours of life.

The normal circulating monocyte count in the healthy human adult is estimated to be between 300 and 450 monocytes/mm^3. Peripheral blood monocyte counts have been observed to vary in a cyclic fashion over a 3–6 day period [5, 6].

The promonocyte cell cycle rate varies between 30 and 48 hours. These rapidly dividing cells achieve a production rate between 7×10^5 and 7×10^6 monocytes/kg of body weight per hour. After 60 hours of maturation in the bone marrow, mature monocytes move into the intravascular space, where they circulate for approximately 3 days [7]. Van Furth and coworkers [8] calculated that 1.66×10^{10} circulating monocytes leave the intravascular space/hour.

Tissue macrophages are derived from bone marrow precursors. The first evidence for the bone marrow origin of

G. Buonocore et al. (eds.), *Neonatology. A Practical Approach to Neonatal Diseases*.

macrophages was obtained in mouse chimeras [9] and rat parabiosis experiments [10, 11]. Studies in patients undergoing bone marrow transplantation, isolation and characterization of lung [12] and liver macrophages [13], provided evidence that these cells contained the karyotype of the bone marrow donor. Thus, terminally differentiated macrophages must have been derived from transplanted bone marrow. Furthermore, by following the disappearance of the Y body–containing macrophages from male patients who have received female donor marrow, the half-life of the alveolar macrophage was estimated to be 81 days.

The size of the tissue macrophage compartment is considerable. According to some estimates, the number of tissue macrophages is 500–1000 times greater than the bone marrow compartment. Some organs, such as the lung and liver, may have particularly large macrophage populations that may account for between 20 and 30% of the total cell number. These cells are long lived and have been estimated to survive for several months [12–14].

105.1.2 Leukocyte Functional Differences Associated with Prematurity

After neutrophils have emigrated from the circulation, cell movement may occur either by random movement or by directed movement toward a chemoattractant. Random movement not related to a stimulus occurs in any direction with equal probability. The ability to undergo directed migration depends upon sensory mechanisms capable of detecting differences in concentration of chemotactic molecules and linking this information to the locomotory apparatus in the cell.

Random movement by neonatal neutrophils is normal compared to that observed in adult cells [15]. However, a number of studies indicate that directed movement of neutrophils from preterm and term neonates to defined chemotactic stimuli is impaired [16–18].

Mononuclear phagocytes exhibit both random and directed movement. Random or nondirected movement occurs in the absence of attracting substances. Directed movement along a concentration gradient of chemical attractants is essential for the effective localization of mononuclear phagocytes to sites of infection and inflammation. This directional movement, called chemotaxis, is governed by chemoattractant molecules that bind to receptors on the cell surface. Chemotactic substances are produced through activation of the complement, fibrinolytic and kinin systems or are directly produced by microorganisms. These chemoattractants may also accentuate random migration of mononuclear phagocytes in the absence of a concentration gradient. An entire family of proinflammatory molecules called chemokines has been identified and many of its members have been characterized [18]. Several members of this family serve as potent chemoattractants for mononuclear phagocytes. Monocyte chemotactic protein 1, macrophage inflammatory protein 1, and RANTES (regulation upon activation, normal T-cell expressed and secreted) are key regulators of monocyte migration. Monocyte-derived dendritic cells migrate to lymphoid organs in response to secondary lymphoid chemokine [19, 20].
